The COVID-19 pandemic was associated with an increased incidence of several diseases. The stress on health care systems, disruptions to health care services, and changes in lifestyle and behavior due to lockdown measures contributed to these effects. Some diseases that showed an increased incidence included mental health disorders, cardiovascular diseases, and respiratory diseases. The COVID-19 pandemic negatively affected all components of systems of care related to OHCA, disrupting the chain of survival. A recent review demonstrated an increase of approximately 120% in the incidence of OHCA and a 65% decrease in OHCA-related survival to hospital discharge during the pandemic, compared to the prepandemic period [2].

In addition, previous studies have reported significant changes in the incidence and epidemiological characteristics of OHCA and the prognosis of patients with OHCA during the pandemic compared to the pre–COVID-19 period. These reports have indicated a decrease in bystander cardiopulmonary resuscitation (CPR) and public-access defibrillator (PAD) use. In contrast, the emergency medical service (EMS) reaction time, frequency of arrests at home, and use of supraglottic airways have increased. Treatment-induced return of spontaneous circulation, survival to admission (STA), survival to discharge, 30-day survival, and favorable neurological outcomes all showed decreased incidence during the pandemic compared with the prepandemic period [2-5]. Despite the end of the COVID-19 pandemic, comprehensive analyses of the entire period are scarce. This lack of evaluation of the effects of COVID-19 on OHCA during each wave of the outbreak may skew the results.

While many studies have explored the effect of COVID-19 on OHCA during the pandemic, 2 research gaps need to be filled. First, a significant limitation is that no studies have comprehensively monitored changes in the prevalence of OHCA in the population during the prepandemic period and during the entire duration of the COVID-19 pandemic. The lack of continuous monitoring data hinders our ability to fully comprehend the impact of the progression of the COVID-19 pandemic on OHCA. Second, there is a notable deficiency in data concerning the epidemiology of OHCA and the corresponding survival rates within the Hong Kong (HK) population. HK, a highly developed region of China, exhibits a lower survival rate for patients with OHCA compared to other industrialized countries [1]. A previous study reported a local survival rate of 15.3% upon admission and a discharge rate of 2.3% for patients with OHCA [6]. The lack of comprehensive data on OHCA in HK during the pandemic hampers our ability to fully understand the scope of the problem and develop effective strategies to improve survival rates for patients with OHCA. It is crucial to conduct extensive research to gather detailed epidemiological data on OHCA in the HK population. This would provide valuable insights into the impact of COVID-19 on OHCA and inform the development of targeted interventions to improve patient outcomes [1,6]. Therefore, we aimed to conduct a large-scale regional registry study to systematically explore the incidence and outcomes of OHCA during the prepandemic and pandemic periods in HK.

Methods

Study Design and Participants

We established our database by matching OHCA data, based on electronic records provided by the Hong Kong Fire Service Department (HKFSD), with confirmed COVID-19 case records from open-source data [7] provided by the Hong Kong Centre for Health Protection (CHP). The HKFSD is the official sector that provides publicly funded paramedic emergency ambulance services to more than 7.4 million HK residents, operating from 41 ambulance depots. It maintains the electronic records of victims of OHCA who call for ambulance services. These electronic records include call triage and dispatch information, EMS response times, demographics, first aid provided, and short-term clinical outcomes. From January 2020, the CHP began to report the official number of confirmed cases of infection with SARS-CoV-2 variants in HK. Information on the number of cases and daily deaths due to COVID-19 in HK at the peak of the pandemic was obtained from the Hong Kong University information hub [8].

Data and Procedures

The HKFSD provided general data on OHCA cases through its internal record system. The research team collaborated with a superintendent from the HKFSD. This superintendent, who is in charge of quality assurance and ambulance services training, was appointed by the chief director of the HKFSD to provide the necessary data. The data elicitation method followed the method used in a previous study aimed at exploring the prevalence of OHCA in HK [6]. The senior author of that paper (YC Siu) is a member of our research team. A list of variables of interest developed based on internal discussion and a literature review was provided to the superintendent for internal discussion. The research team, superintendent, and senior medical officers from the HKFSD held 3 rounds of meetings to revise and confirm the data analysis protocol and the variable list. This study included patients of all ages. Victims of OHCA who were directly transferred to the public mortuary from the scene by EMS personnel and patients who did not use a ground ambulance were excluded from this study.
We collected data from December 1, 2017, to May 31, 2023. These data included the date of the incident, the response time (from the time of the call to the arrival of an ambulance or EMS personnel), the location of the OHCA (home, en route to hospital, nursing home, public place, or street), and the presence of an OHCA witness (yes or no). Clinical data consisted of the initial rhythm (pulseless electrical activity, ventricular fibrillation or ventricular tachycardia, asystole, or other), bystander CPR (yes or no), the number of times a PAD was used, resuscitation in the accident and emergency (A&E) department (yes or no), and STA (yes or no). Sociodemographic data included sex, age, and area of residence.

Although cases of COVID-19 were first reported in late December 2019 in Wuhan, the HK CHP started recording such cases in HK in January 2020. Therefore, we defined the prepandemic period as December 1, 2017, to December 31, 2019, and the pandemic period as January 1, 2020, to May 31, 2023, despite the World Health Organization announcing the end of the pandemic on May 5, 2023. We compared patient characteristics, the setting of OHCA occurrences, and OHCA outcomes between the prepandemic and pandemic periods.

Statistical Analysis
Descriptive analyses were primarily used to present our findings. Continuous data are presented as means with SDs, while categorical data are presented as frequencies (n) and proportions (%). The differences between continuous variables were examined using analysis of variance, the Mann-Whitney test, or the Kruskal-Wallis test, as appropriate. Differences between categorical variables were examined using the χ² test.

The total incidence of OHCA (‰) in HK and the incidence stratified by 3 districts (Hong Kong Island, Kowloon, and the New Territories) are presented as the number of OHCA cases divided by the mid-year population and survival to A&E department admission (%) from 2018 to 2022, respectively. Figures were created to visually represent the changing incidence of OHCA across different years and its relationship with the outbreak and progression of the COVID-19 pandemic. Additionally, we present the change in the prevalence of OHCA at different key cutoff points (eg, different waves of an outbreak) of the COVID-19 pandemic in HK.

Multivariate logistic regression analysis was used to assess the association between survival and A&E department admission, as well as the use of CPR and PAD during the prepandemic and pandemic periods. The analysis was adjusted for factors including sex, age, the cause of OHCA, the initial rhythm, the response time, whether the OHCA was witnessed, the location of the OHCA, and the area of residence of the patient. Adjusted odds ratios (aORs) and their 95% CIs were calculated. Furthermore, we collected additional data and described the prevalence of OHCA and COVID-19 during the peak of the pandemic (11 weeks from February 7, 2022, to April 24, 2022). Differences with P values less than .05 were considered statistically significant. All statistical analyses were performed using Stata (version 16; StataCorp LLC).

Ethical Considerations
The Institutional Review Board of Hong Kong Polytechnic University approved this study protocol (HSEARS 20211004004). The requirement for informed consent was waived.

Results
Participants’ Background Characteristics
From December 1, 2017, to May 31, 2023, HK reported 43,882 cases of OHCA (Table 1). Of these, 13,946 cases were recorded during the prepandemic period (2017-2019), and the remaining 29,936 cases were reported during the pandemic period (2020-2023). During the prepandemic period, 56.6% (7896/13,946) of the patients were men, with an average age of 75.81 (SD 17.12) years. The majority of OHCAs (n=7566 cases, 54.3%) occurred at home. During the pandemic period, the proportion of female patients increased to 44.1% (13,215/29,936), and the average age increased slightly to 76.5 (SD 18.5) years. The majority of OHCAs (n=18,143, 61.1% cases) occurred at home. A witness was present in 45.9% (n=10,723) of the cases, and CPR was initiated in 44.6% (n=13,318) of the cases. The average response time increased to 13.6 (SD 13.3) minutes, and only 8.3% (n=2464 cases) of the patients were alive when admitted to an A&E department, which is half the rate observed in the prepandemic period.

<sup>a</sup>OHCA: out-of-hospital cardiac arrest.
<sup>b</sup>VF/VT: ventricular fibrillation or ventricular tachycardia.
Prevalence of OHCA During the COVID-19 Pandemic

Figure 1 presents a comparative analysis of the prevalence of OHCA during this study’s period. The prevalence of OHCA was lower in 2018-2019 than in 2020-2023. During the pandemic, each wave of the COVID-19 outbreak in HK aligned with a significant increase in the prevalence of OHCA. Notably, the peak in OHCA incidents coincided with the onset of the Chinese New Year holiday in 2022, a surge that lasted for approximately 11 weeks. This period marked the highest recorded number of COVID-19 cases throughout the pandemic. We also found a significant increase in the prevalence of OHCA following the discontinuation of zero-tolerance measures in mainland China. However, the removal of mandatory mask-wearing regulations by the HK government in March 2023 did not result in a significant increase in the prevalence of OHCA.

OHCA Incidence Stratified by Year and Region

Table 2 demonstrates the increased incidence of OHCA from 2018 (6438/7,451,500, 0.85‰) to 2022 (10,618/7,345,000, 1.45‰). However, the STA rate significantly decreased from 16.9% (1090/6438) to 5.6% (584/10,424) during this period. When stratified by region, the incidence of OHCA was higher in Kowloon and Hong Kong Island than in the New Territories. During the prepandemic period, the STA rate was approximately 4% higher in the New Territories than in the other 2 districts. However, during the pandemic period, the gap in STA rates narrowed, with the STA rate in the New Territories becoming slightly lower than the STA rates in Kowloon in 2021 (245/3407, 7.2%, vs 212/2805, 7.6%) and 2022 (277/4837, 5.7%, vs 215/3636, 5.9%). Figure 2 provides additional information on the incidence of OHCA in all 18 districts. Generally, the incidence of OHCA was lower in districts in the north (New Territories) than in the other districts. Kwun Tong District (Kowloon, mid-part of HK) reported the highest incidence of OHCA during both the prepandemic and pandemic periods. The OCHA incidents, STA rate, and use of CPR among different demographic groups in the 3 regions over this study’s period are detailed in Multimedia Appendix 1.

Relationship Between STA and Patients’ Characteristics

Table 3 presents the results of the multivariate logistic regression analysis of the associations between the STA rate and various factors during the prepandemic and pandemic periods. The key findings included higher odds of OHCA among men during the pandemic period and higher odds of certain initial electrocardiogram rhythms during the same period. There were also higher odds of nontrauma causes of OHCA during both periods. There were other factors, such as the response time, whether the OHCA was witnessed, the location of the OHCA, and the region exhibited varying aORs between the 2 periods. Notably, we found that bystander CPR administration (aOR 1.48, 95% CI 1.17-1.86) and PAD use (aOR 1.16, 95% CI 1.05-1.28) were significantly associated with a high STA rate during the pandemic period.

Correlation Between OHCA and COVID-19 Cases During the Pandemic

Figure 3 graphically presents the correlation between OHCA incidents and the progression of COVID-19 during the pandemic period in HK. Overall, there was a consistent relationship between these 2 variables, with a higher SARS-CoV-2 infection rate leading to an increased prevalence of OHCA. This correlation was particularly evident in 2022, which had the highest prevalence of COVID-19 and corresponded with the highest prevalence of OHCA. Table 4 provides a detailed overview of the OHCA and COVID-19 statistics from February 7, 2022, to April 24, 2022. This period marked the peak of COVID-19 cases, which coincided with a sharp increase in the number of OHCA incidents. During these 11 weeks, the number of OHCA cases increased dramatically, reaching a peak of approximately 114 cases per day in the fourth week. Concurrently, the number of COVID-19 cases increased, reaching a daily average of 67,583 cases during the same week. However, the highest daily death toll from COVID-19 was recorded in the fifth week. In contrast, the STA rate in cases of OHCA demonstrated a slightly different trend, with marginally higher numbers recorded during the most severe 5 weeks (weeks 3-7) of the COVID-19 outbreak.

Figure 3. Correlation of prevalence between OHCA and COVID-19 during pandemic (January 2020 to May 2023). OHCA: out-of-hospital cardiac arrests.

During the pandemic, a significant shift in OHCA location was occurring in public places, likely due to the implementation of lockdowns and social distancing measures, which resulted in fewer people being out in public. This finding aligns with those of most previous studies [11-13], but a different trend has been reported in some Asian populations. For instance, Riyapan et al [14] reported no significant change in the occurrence of OHCA in public places in Thailand before and during the pandemic. Watanabe et al [15] also reported no decrease in the occurrence of OHCA in public places. However, the decrease observed in the number of OHCAs in public places does not necessarily indicate a reduction in the overall number of OHCAs. Instead, this may suggest a shift in the location of these incidents, with a potential increase in the number of OHCAs occurring at home.

There was a significant decrease in the number of OHCAs reported in nursing homes during the pandemic. This trend is surprising given the vulnerability of the older population to OHCA. The findings for this outcome in previous studies have been mixed. For example, a study in Portugal reported no difference between the number of OHCAs in nursing homes before and during the pandemic [13]. Another study in the United States found that the percentage of patients experiencing an OHCA in a nursing home was higher in 2020 than in 2019 [16]. A study in HK revealed that 96% of COVID-19–related deaths were among individuals aged 60 years and older, with 53% being nursing home residents [17]. Our findings suggest that, although the number of OHCAs in nursing homes decreased during the pandemic, this does not necessarily mean fewer older individuals experienced an OHCA. Many older individuals may have died from COVID-19, and their deaths were not classified as OHCA-related. This may result in an underestimation of the devastating impact of OHCA on the older population, particularly for those in nursing homes, during this public health emergency. The government should update and standardize mortality calculations during future public health emergencies [18].

Another reason for the decrease in the number of OHCAs in nursing homes during the pandemic may be the effectiveness of nonpharmaceutical interventions in reducing the number of COVID-19 cases and fatalities within long-term care facilities.
and nursing homes. Previous studies have shown an association between a decrease in the number of COVID-19 cases and the rigor of various containment measures, notably school and workplace closures, and public information campaigns globally [19,20]. In HK, border restrictions, quarantine and isolation, social distancing, and behavioral changes in the population were significantly linked to the control of the COVID-19 pandemic [21]. This may underscore the crucial role that nonpharmaceutical interventions can play in safeguarding vulnerable populations during pandemics.

Our study revealed an increase in the bystander CPR rate during both the prepandemic and pandemic periods, albeit at a slower rate during the pandemic. During the prepandemic period, the bystander CPR rate increased by approximately 10% from 2018 to 2019. However, this trend plateaued with the onset of the COVID-19 pandemic, resulting in a negligible difference in the CPR rate between 2019 and 2020. A Korean study reported a similar finding [22], but studies in some Western countries have reported notable decreases in CPR rates. For example, in France, the CPR rate dramatically fell from 63.9% to 47.8% between March and April 2020 [12]. A study in Spain also found a decrease in CPR rates from 51.1% to 42.6% between 2017/2018 and 2020 [23]. These decreases in CPR rates highlight the profound effects of the pandemic on critical medical procedures across different nations. Nevertheless, we found that, as the pandemic progressed, the CPR rate showed another increase, stabilizing between 44% and 48%. Data on bystander CPR rates during the pandemic are mixed. A systematic review of studies conducted in 2020 suggested a decline in the incidence of bystander CPR at the onset of the pandemic, with 1 study noting that this decline was observed only in patients diagnosed with COVID-19 [24]. Another review, including studies published in 2020 and 2021, indicated a change in the community response to OHCA, with fewer occurrences of bystander CPR [25]. However, a recent review of studies published in 2022 found no significant difference in bystander CPR rates between the COVID-19 pandemic and prepandemic periods [4]. It is important to note that the pandemic also affected other aspects of the CPR response and outcomes, such as EMS availability. A review of the relationship between OHCA and EMS indicated that difficulties encountered by the first responder system during the COVID-19 pandemic, such as dispatcher overload, increased response times, and adherence to personal protective equipment requirements, were superimposed on shortages in the supply of personal protection equipment [26]. Our findings highlight the complex impact of the pandemic on OHCA outcomes.

Although the frequency of witnesses of OHCA and bystander CPR significantly increased, we observed a drastic reduction in the rate of STA en route to the A&E department during the pandemic, which is consistent with the findings of previous studies [4,24,25]. During the prepandemic period, the overall STA rate in 2018 was approximately 16.9%, and this increased slightly to 18.5% in 2019. However, during the first year of the pandemic, the STA rate decreased by more than 25% and further decreased to approximately 5.6% at the peak of the pandemic in 2022. By the end of this study’s period, the STA rate had slightly increased to 6.7% in the first 5 months of 2023 but remained approximately 65% lower than the rate observed in the final year of the prepandemic period (2019). The STA rate was lower in HK than in other countries or regions during the pandemic [12,27,28]. Several factors may have accounted for this discrepancy. An overburdened health care system can lead to delayed recognition of and intervention in unstable patients. For instance, following the 2022 Chinese New Year holiday, public hospitals in HK were dealing with more than 1800 COVID-19 cases requiring EMS per day. Emergency medical systems, especially emergency departments, which serve as the frontline of the health care system, experienced severe overload and challenging working conditions. This was a global issue [29]. Moreover, there were fewer cardiac arrests in public places during the pandemic, which may have influenced the survival rate of patients with OHCA. Additionally, the lack of sufficient CPR training in HK [30,31] and the fear of COVID-19 may have affected the willingness of witnesses to perform CPR. Given that CPR is considered an aerosol-generating procedure with a significant risk of viral transmission, witnesses may have hesitated to perform it, potentially affecting the STA rate [32].

A strong correlation was observed between outbreaks of COVID-19 and surges in OHCA cases in HK over the past 4 years. In particular, the fifth wave of the pandemic, which coincided with the Chinese New Year holiday, resulted in a significant surge in OHCA cases. The older population, the most vulnerable group to both COVID-19 and OHCA, bore the brunt of the pandemic. The average age of our sample was over 75 years (SD 17.1 years), highlighting the insufficient protection provided by the government for this demographic during the pandemic. A previous review demonstrated a gradual age-associated increase in the COVID-19 mortality rate [33]. For example, 1 study showed a 10.5% fatality rate for older patients compared to 0.43% for younger patients [34]. As of April 2022, less than one-third of HK residents aged older than 80 years had been fully vaccinated. The vaccination rate was even lower among residents of care homes when the Omicron variant arrived in HK, at less than 20%. This is not surprising, given that vaccine hesitancy to both the first vaccine dose and the booster was widespread [35]. Another study underscored the urgency of vaccination for older people, revealing that approximately one-quarter of countries reported lower vaccination coverage among older adults compared to the overall population [36]. Additionally, as reported in a previous study [37], lockdown measures and no-visit policies resulted in older adults being unable to meet their families for extended periods, leading to heightened levels of anxiety and depression among this population, thereby increasing the risk of OHCA. It is crucial to develop comprehensive policies and strategies to mitigate the direct and indirect effects of public health emergencies on health outcomes in the older population.

In 2019, the HK Legislative Council suggested promoting bystander intervention to improve the survival rates for patients with OHCA. The suggestions included adopting technologies to reduce rescue time, providing education and training to enhance the skills of the public, and urging the government to develop laws and regulations to protect bystanders legally and limit their liability [38]. Thus, the outcomes of our regression analysis revealed that, during the pandemic, bystander CPR and PAD use significantly improved the STA rate for individuals...
with OHCA compared to the prepandemic period, during which the associations between STA rate and bystander interventions were insignificant. Furthermore, our regression analysis revealed a significant relationship between the response time and STA rate. To handle emergencies during the pandemic, the HKFSD adopted a target-oriented approach to devise various emergency response strategies and measures. In the meantime, the Director’s Command Post also established an artificial intelligence–powered social media service platform capable of providing automated inquiries and instant replies 24 h/d, 7 d/wk [39]. The importance of reform and collaboration in multiple social sectors is paramount to improving the STA rate of patients with OHCA during public health emergencies.

Limitations
Our study is among the first to delineate the relationship between COVID-19 and the prevalence of OHCA at the population level during both the prepandemic and pandemic periods. However, this study has certain limitations that need to be acknowledged. First, although we observed a decrease in the STA rate during the pandemic, we lacked information about patient survival rates upon discharge and their short- and long-term health outcomes, because patient data in A&E departments and hospital settings are managed by the Hospital Authority rather than the HKFSD. Matching OHCA patient data with medical records would provide a more comprehensive understanding of the impact of COVID-19 on OHCA in HK. Second, the HKFSD did not collect information about whether patients with OHCA had COVID-19 during the provision of services. Consequently, we lack knowledge about the prevalence of COVID-19 among patients with OHCA, which may have led to an inaccurate estimation of the impact of COVID-19 on the survival rate of patients with OHCA in HK.

Conclusions
In our study of the prevalence of OHCA from 2017 to 2023, we observed a significant increase in OHCA incidence and a considerable decrease in survival rates of patients with OHCA during the COVID-19 pandemic compared to the period before the pandemic. Moreover, we found that the spikes in the number of OHCA cases closely matched the increase in the number of confirmed COVID-19 cases in HK. Components of both the social sector, such as the Home Office, and the health care sector, such as EMS systems, should prepare for potential increases in the number of OHCA cases during future public health crises. It is necessary to reform these sectors to make them more resilient, efficient, and effective at meeting the needs of individuals with OHCA. Developing an effective multidisciplinary mechanism for leveraging resources, sharing knowledge and expertise, and coordinating efforts are key factors for improving the survival rates of patients with OHCA during future pandemics.

Abstract

Background: Male-to-male sexual transmission continues to account for the greatest proportion of new HIV diagnoses in the United States. However, calculating population-specific surveillance metrics for HIV and other sexually transmitted infections requires regularly updated estimates of the number and proportion of men who have sex with men (MSM) in the United States, which are not collected by census surveys.

Objective: The purpose of this analysis was to estimate the number and percentage of MSM in the United States from population-based surveys.

Methods: We used data from 5 population-based surveys to calculate weighted estimates of the proportion of MSM in the United States and pooled these estimates using meta-analytic procedures. We estimated the proportion of MSM using sexual behavior–based questions (encompassing anal or oral sex) for 3 recall periods—past 12 months, past 5 years, and lifetime. In addition, we estimated the proportion of MSM using self-reported identity and attraction survey responses. The total number of MSM and non-MSM in the United States were calculated from estimates of the percentage of MSM who reported sex with another man in the past 12 months.

Results: The percentage of MSM varied by recall period: 3.3% (95% CI 1.7%-4.9%) indicated sex with another male in the past 12 months, 4.7% (95% CI 0.0%-33.8%) in the past 5 years, and 6.2% (95% CI 2.9%-9.5%) in their lifetime. There were comparable percentages of men who identified as gay or bisexual (3.4%, 95% CI 2.2%-4.6%) or who indicated that they are attracted to other men (4.9%, 95% CI 3.1%-6.7%) based on pooled estimates. Our estimate of the total number of MSM in the United States is 4,230,000 (95% CI 2,179,000-6,281,000) based on the history of recent sexual behavior (sex with another man in the past 12 months).

Conclusions: We calculated the pooled percentage and number of MSM in the United States from a meta-analysis of population-based surveys collected from 2017 to 2021. These estimates update and expand upon those derived from the Centers for Disease Control and Prevention in 2012 by including estimates of the percentage of MSM based on sexual identity and sexual attraction. The percentage and number of MSM in the United States is an important indicator for calculating population-specific disease rates and eligibility for preventive interventions such as pre-exposure prophylaxis.

KEYWORDS
sexual behavior; sexual identity; sexual attraction; men who have sex with men; population estimates; MSM; men who have sex with other men; national surveys; census; United States

Introduction
Men have been the epicenter of HIV infections in the United States since the beginning of the epidemic, accounting for the largest proportion of new cases each year [1]. Most new HIV infections are among gay, bisexual, and other men who have sex with men (MSM) [1]. In 2021, 67% of new HIV infections in the United States were among MSM [2]. To better understand national rates of HIV infections, medication adherence, and preventative measures among MSM, it is imperative to have accurate estimates of the proportion and number of MSM in the United States [3]. However, the most recent published national estimates for MSM populations were published over a decade ago [4].

There is currently no census-based question on same-sex behavior that yields data to estimate a national proportion or count of MSM in the United States, although there is 1 question about being part of a same-sex household [5]. However, these data exclude MSM who are not domiciled with a male partner or who decline to report that their housemate is a partner. Therefore, previous estimations of MSM in the United States have focused on periodically conducted representative surveys, such as the General Social Survey (GSS) [6] or National Health and Nutrition Examination Survey (NHANES) [7]. In 2012, Centers for Disease Control and Prevention scientists used meta-analysis [4] to determine the population size of MSM in the United States and calculate disease rates and rate ratios for HIV and primary and secondary syphilis [4]. Subsequent analyses by Grey et al [8] extended national estimates of MSM to smaller area estimates such as states and counties.

These past analyses focused on sexual behaviors to determine MSM status. Because some national surveys ask about sexual orientation or attraction, it also is possible to examine prevalence using orientation or attraction and consider the concordance between self-reported sexual behavior and self-reported sexual identity or attraction. Currently, the GSS, NHANES, and the National Survey of Family Growth (NSFG) [9] contain both sexual behavior and sexual identity or attraction questions. These 2 measures are not always concordant, and the concordance can vary by age and race [10,11]. It has been argued that for some public health uses of estimates such as estimating populations of MSM in need of HIV prevention services or testing, behavior might be a better indication of need than identity [8]. However, willingness to report a same-sex orientation may affect willingness to seek prevention services.

It has been over a decade since Purcell et al [4] published their national estimates of MSM, and in that time, it has been cited over 200 times [12]. However, there have also been major policy decisions, such as the 2015 Supreme Court decision affirming the right for same-sex couples to marry in Obergefell v. Hodges that may affect our understanding of the proportion of the population who are MSM. Since the landmark 2015 decision, public support for marriage equality has grown consistently year-over-year, indicating larger acceptance of lesbian, gay, bisexual, transgender, queer or questioning, intersex, and asexual persons [13]. Therefore, we sought to update national behavior prevalence estimates of MSM and explore whether there are enough data to provide estimates of MSM based on orientation or attraction. Following the methods of Purcell et al [4], we used population-based surveys and meta-analysis to estimate separate estimates of each survey and year combination and then aggregate estimates into single, nationally representative proportions of MSM in the United States.

Methods

Study Selection
To determine which population-based surveys to include in our analysis, we started with the selection methods used by Purcell et al [4]. We examined the sources used in the previous estimates to identify whether the data collection was ongoing. We then completed a literature search using PubMed (National Institutes of Health) and Google Scholar to identify additional sources that include questions about sexual behavior, sexual identity, or attraction. We searched using key terms for measurement (prevalence and estimation), male-to-male sexual behavior or identity (MSM, male-to-male sexual contact, gay, and bisexual), geography (United States), and survey (population-based survey). Abstracts were screened by the lead author (BWB) in consultation with the coauthors for data sources that used population-based surveys for estimation.

Studies eligible for inclusion were population-based surveys with available complex survey methodology documentation to allow weighting to obtain estimated population proportions of MSM and 95% CIs. Surveys that recruited predominantly at sites that are likely to have a high proportion of MSM (ie, surveys among HIV-infected persons and surveys at sexually transmitted infection clinics) were excluded to minimize overestimation. We identified 4 ongoing population-based surveys from Purcell et al [4] that currently include questions about sexual behavior, sexual identity, or attraction: the GSS [6], NHANES [7], NSFG [9], and National Survey on Drug Use and Health [14]. In addition to this, we also identified the National Health Interview Survey [15] as another eligible study (Table 1). Gallup [16] and the US Census Pulse Household Survey [17] also estimate the proportion of men who identify as gay or bisexual; however, we were unable to gain access to CIs for reported point estimates and, therefore, excluded these data from our analysis.
To determine the study-level prevalence of MSM by sexual behavior, we considered questions about anal or oral sex with another male for 3 time periods: lifetime, in the past 5 years, and past 12 months. Survey-specific questions are outlined in Table S1 in Multimedia Appendix 1. For sexual identity, we categorized men who indicated that they are “gay,” “homosexual,” or “bisexual” best described them to be MSM. For sexual attraction, we considered men who indicated that they are “equally attracted to males and females,” “mostly attracted to the same sex,” or “only attracted to the same sex” to be MSM. Data were analyzed accounting for the complex sample design [18]; proportions of MSM and variances were estimated for each behavioral domain, for attraction and for orientation.

### Meta-Analysis

We applied Rao et al’s [19] meta-analytic method to pool survey-specific results into a single estimate with confidence bounds. First, for each recall period (eg, lifetime sex, past 5 years, and past 12 months) and for each identity or attraction category, we multiplied the population-level prevalence by the inverse of its variance. Then, we summed these weighted prevalence estimates across studies and then divided by the sum of the weights. Because surveys included in our analysis were conducted over several years and with differing sample designs and age ranges, we included a corresponding between-studies variance term [20] before deriving the overall prevalence estimates.

We examined heterogeneity of prevalence estimates across surveys using the Q-statistic [19] and Higgins I index [21]. Pooled estimates for the overall prevalence of MSM were based on random-effects models, which provide a more conservative estimate of the variance, generating potentially more accurate
inferences about a population of studies beyond what we present in this analysis [4]. All meta-analytic calculations were completed in R (R Foundation for Statistical Computing) using the “meta” package [22].

Calculation of Count of MSM and Other Men in the United States

To calculate the total number of MSM and non-MSM, aged 18 years and older, in the United States, we took our recently derived past 12-month estimate of the proportion of MSM and its 95% CI and multiplied it by the 2022 population estimate of men aged 18 years and older in the United States from the US Census Bureau [23]. The number of MSM was then subtracted from the total estimated number of men aged 18 years and older in the United States to compute the population size of other men.

Ethical Considerations

This project did not require review by an internal review board because it did not include human subjects, nor was it a clinical investigation as defined by federal regulations [24].

Results

MSM Estimates Based on Sexual Behavior

The estimated proportions of men who have sex with other men, by recall period, for each of the included population-based surveys that contained sexual behavior–based questions and the pooled estimates obtained from the meta-analysis are presented in Table 2. The pooled estimates were 3.3% (95% CI 1.7%-4.9%) in the last 12 months, 4.7% (95% CI 0.0%-33.8%) in the last 5 years, and 6.2% (95% CI 2.9%-9.5%) in their lifetime. The tests for heterogeneity were significant for both the “past 5 years” and “lifetime sex” recall periods but not for the past 12 months recall period.

Table 2. Estimated proportion of men who have sex with men for individual studies and combined meta-analysis by behavior, NSFG, NHANES, and GSS surveys, United States, 2017-2021.

| Study name | Time period | Sample size | Estimated prevalence (%; 95% CI) | Q statistic | P value | I² (%)
|------------|-------------|-------------|---------------------------------|-------------|---------|-------
| Past 12 months | | | | | | |
| GSS | 2018 | 502 | 3.3 (1.7-4.9) | 6.8 | .08 | 55.6 |
| GSS | 2021 | 809 | 2.9 (1.4-4.4) | | | |
| NSFG | 2017-2019 | 5206 | 3.1 (2.4-3.8) | | | |
| NHANES | 2017-2020 | 3338 | 2.7 (1.9-3.4) | | | |
| Past 5 years | | | | | | |
| GSS | 2018 | 559 | 4.7 (0.0-33.8) | 14.4 | <.001 | 93.1 |
| GSS | 2021 | 904 | 2.5 (1.2-3.8) | | | |
| Lifetime sex | | | | | | |
| GSS | 2018 | 500 | 6.2 (2.9-9.5) | 25.9 | <.001 | 88.4 |
| GSS | 2021 | 807 | 3.1 (1.6-4.6) | | | |
| NSFG | 2017-2019 | 5163 | 7.0 (6.9-7.0) | | | |
| NHANES | 2017-2020 | 3338 | 6.9 (5.6-8.2) | | | |

bNHANES: National Health and Nutrition Examination Survey.
cGSS: General Social Survey.
dQ-statistic follows a chi-square distribution to determine the presence or absence of heterogeneity in a set of studies in a meta-analysis.
eI² quantifies the degree of heterogeneity in a meta-analysis.

MSM Estimates Based on Sexual Identity and Sexual Attraction

Table 3 contains the estimated prevalence and 95% CIs, along with the pooled aggregate results, by self-reported sexual identity and attraction. The pooled estimated prevalence of gay and bisexual men by sexual identity was 3.4% (95% CI 2.2%-4.6%), which comes from 8 collection cycles across 5 different surveys. Both tests for heterogeneity (Q-statistic and I²) indicated heterogeneity across surveys (I²=95.4%; Q=152.4; P<.001). The pooled estimated prevalence of gay and bisexual men by sexual attraction was 4.9% (95% CI 3.1%-6.7%), with significant heterogeneity across the 3 collection periods from 2 surveys (I²=79.2; Q=9.6; P=.008). We calculated pooled estimates of the proportion of gay and bisexual men by including a broader definition that includes men who responded that they are “mostly attracted to women.” This broader definition resulted in a proportion of MSM of 9.3%, which is substantially higher than any other proportion calculated from this analysis. Therefore, for the purpose of this paper, we used the stricter definition of MSM based on attraction (ie, men who indicated...
that they are “equally attracted to males and females,” “mostly attracted to the same sex,” or “only attracted to the same sex.”

Our data indicate limited fluidity in respondents’ identification and attraction. For the GSS, which has both sexual identity or attraction questions and sexual behavior questions, approximately 0.6% of straight-identifying men in 2018 sample and 2.6% in the 2021 sample also reported anal or oral sex with another man in the past 5 years. Similarly, for the 2017-2019 NSFG, of men who identified as straight, 4.4%-5.9% also reported anal or oral sex with another man in their lifetime and 0.9%-2.2% reported anal or oral sex in the past 12 months.

Table 4 shows the estimated number of MSM and non-MSM men aged 18 years and older in the United States. These totals were derived by multiplying the proportion of MSM from the pooled estimate for sexual behavior in the past 12 months (95% CI 1.7-4.9) by the total number of men aged 18 years and older in the United States [25]. We estimated that there were 4,230,000 MSM (95% CI 2,179,000-6,281,000) aged ≥18 years in the United States.

Table 3. Estimated proportion of men who identify as gay or bisexual for individual studies and combined meta-analysis by identity and attraction (GSS\textsuperscript{a}, NSDUH\textsuperscript{b}, NSFG\textsuperscript{c}, NHANES\textsuperscript{d}, and NHIS\textsuperscript{e} surveys, United States, 2017-2021).

\textsuperscript{a}MSM: men who have sex with men.

Discussion

Principal Findings

Our meta-analysis of data from 5 population-based surveys indicated that 3.3% of the US male population report recent sex with men, and 3.4%-4.9% of the US male population report identifying as gay, bisexual, or being sexual attracted to men. We found substantial overlap between estimates based on behavioral measures and measures based on orientation or attraction. Our behavioral estimates are all within 1 percentage point of the Centers for Disease Control and Prevention’s 3 behavior estimates from over a decade ago [4]. Additionally, compared to this analysis, they include more national surveys that asked about sexual behavior or identification [4]. Although there is growing interest in understanding the experiences and risks of MSM, there is a smaller number of ongoing population-based studies that examine these issues.
Previous estimates by Purcell et al [4] have also been used extensively in calculating the rates of disease among MSM. We hope that these updated percentages of MSM will be used in future analyses to calculate the rates of health states and conditions among MSM. For example, time periods for syphilis diagnoses can be matched to time periods for the estimated MSM population size. Then, the count of syphilis diagnoses among MSM can be divided by the estimated population size of MSM for that same recall period and transformed into rates per 100,000 population.

For our calculation of the total number of MSM in the United States, we chose to use the prevalence of male-male sex during the past 12 months. This differs from the previous paper by Purcell et al [4], which used the estimated prevalence from self-reported sex with a man in the past 5 years. Our decision was both practical and methodical. \( Q \)-statistics and \( P \) for the pooled “past 5 years” estimates indicated heterogeneity across surveys (\( Q=14.4, P=.001; I^2=93.1\% \)). In addition, our “past 5 years” estimates also had very wide 95% CIs (0.0-33.8), indicating a substantial amount of instability in the estimate. Out of the behavior-based estimates in our analysis, self-reported sex in the past 12 months had the lowest heterogeneity. In addition to considering current risk for sexually transmitted infections, using an estimate based upon recent sexual activity may allow us to enumerate those MSM who are currently most at risk for disease acquisition or most appropriate for prevention services.

Estimates from “past 5 years” or “lifetime” behavioral data might be used in other circumstances. For example, Purcell et al [4] use of the “past 5 years” measure to estimate number of MSM in the United States in 2012 was designed to include a broader section of MSM, including those who were not recently sexually active. Such denominators might be relevant for characterizing the impact of MSM on other types of diseases, depending on the timelines for exposure and pathogenesis. Having separate behavioral measurements with different recall periods allow users to determine which estimate makes the most sense for their public health purposes.

We expanded on previous work by calculating the prevalence of self-reported sexual identity and attraction to update and to understand the percentage of MSM in the United States. Identity and attraction are neither mutually exclusive nor perfectly concordant, and they do not necessarily overlap with behavior. The term MSM specifically refers to sexual behavior, but identity and attraction refer to how men classify themselves—an important distinction for epidemiologists and sexual health researchers who seek to avert disease transmission associated with male-male sex. Identity and attraction are not risk factors for sexually transmitted infections but may be proxies for current or future risks and for prevention service needs. However, as our data show, identity and attraction are not necessarily specific or sensitive [26]: a person who identifies as straight may still engage in anal or oral sex with another man, a man identifying as gay or bisexual may have anal or vaginal sex with a female. Providing additional prevalence estimates for orientation and attraction gives users more choices to fit their needs when trying to estimate these proportion of men who identify as gay or bisexual or are attracted to men, based on their programmatic goal or research question. Furthermore, including this new estimate of sexual identity and attraction aligns with new reports form the US Census Bureau, which began collecting data on sexual orientation in 2021. According to these data, 6.5% of cisgendered US men reported identifying as gay or bisexual [27].

Here, we calculated the 3 updated prevalence estimates for MSM, a new estimate for gay or bisexual men, and a new estimate for men who are attracted to other men. Going forward, we plan to update these estimates at regular intervals and to share public use data sets through AIDSVu [28]. We propose to update these estimates every 5 years, given the pace at which the national population-based surveys are implemented and published. We do not anticipate a substantial change in the estimates in the coming 5 years. Comparing the newly calculated “past 12 months” estimate to the “past 12 months” estimate from Purcell et al [4], we found a relatively small change over a decade of time (3.3% vs 2.9%, respectively). However, the visibility of sexual behavior and identity in our culture has shifted rapidly over the past few decades, and regular updated analyses will allow us to identify any unexpected shifts should they emerge and to provide estimates that always include the most recently collected data.

Limitations

This analysis has important limitations. First, meta-analyses rely on the strengths of the underlying studies. The surveys that we used are minimally biased in terms of sampling—5 population-based surveys—but they have varying sample sizes of MSM (which comprise a small subpopulation of the sampled population). Thus, the individual survey estimates that feed into our pooled estimates have varying confidence limits around their point estimates. Furthermore, these surveys have varying age ranges for inclusion in the survey and thus may not be exactly transferrable across surveys. Similar to Purcell et al [4], we were unable to directly calculate stratified estimates of the proportion of MSM by race, ethnicity, or age because of small sample sizes within stratifications.

There is also the potential for misclassification of a respondent’s true sexual behavior, identity, or attraction, leading to an underestimation of the count and percentage of MSM in the United States from our calculation. A recent analysis in Canada found that 13.5% of the gay and bisexual male population (based upon sexual behavior) reported being unlikely to disclose their sexual identity on government surveys [29]. However, it is unclear whether these estimates of misclassification are transferrable to the US population. Additionally, although we provide estimated percentages of MSM by sexual attraction and sexual identity, our final estimation of the total MSM population for the United States was solely based on sexual behavior (anal or oral sex) in the past 12 months rather than identity or attraction alone or a combination of identity or attraction and behavior.

Finally, we did not adjust for differing age ranges between individual surveys. This may have implications for our outcomes; however, only 1 survey, the NSFG, included men younger than 18 years in their estimate, and the number of
respondents younger than 18 years old who answered that they had ever had sex with another man was <0.5% of the total respondents for NSFG and is, therefore, unlikely to have a significant impact on the results. Only the NSFG included data from men aged younger than 18 years; all other estimates for sexual behavior or identity or attraction used men older than 18 years of age.

Conclusions
The National HIV or AIDS strategy and the Ending the HIV Epidemic Initiative in the United States each highlight the prevention of HIV among MSM as key to meeting the goal of decreasing new HIV infections by 90% by 2030 [30]. Developing updated, accurate estimates of this population at risk is critical to better understanding the disproportionate burden of HIV and risk for HIV among MSM. Updated estimates of the MSM population sizes can help to guide resource allocation and programmatic efforts and support key benchmarks for progress as we seek to end the HIV epidemic and other health concerns that disproportionately impact MSM. Providing public, updated estimates of behaviors across different time periods and data on orientation and attraction can offer choices to researchers and health departments seeking to serve these populations.

Acknowledgments
This work was supported by the Center for AIDS Research at Emory University (P30 AI050409). The authors acknowledge receipt of financial support for this project from Gilead Sciences. The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the Centers for Disease Control and Prevention.

Data Availability
Data from General Social Survey, National Survey of Family Growth, National Health Interview Survey, and National Household Survey on Drug Use and Health are publicly available at their respective survey websites [4,6,14,15]. The 2017 to 2020 National Health and Nutrition Examination Survey sexual behavior data are not publicly available due to being “limited access data,” containing sensitive private information, but they can be accessed at a National Center for Health Statistics Research Data Center [7].

Related Article:
Correction of: https://publichealth.jmir.org/2024/1/e54769
doi:10.2196/64080

Shortly after the publication of the article titled “COVID-19 Vaccine Hesitancy: Umbrella Review of Systematic Reviews and Meta-Analysis” in JMIR Public Health and Surveillance [1], the editors discovered processing errors that occurred during the peer review process. Specifically, Roy Rillera Marzo, MD, acted as guest editor for the theme issue titled “Preventive Strategies: Scaling Up Effective Public Health Interventions for Long-Term Population Health Benefits” and made a decision for this paper where they are also a coauthor, which is against the Committee on Publication Ethics (COPE) [2] and JMIR Publications’ Conflict of Interest policies [3].

As a result, the paper underwent additional post-publication editorial review to address the question whether the published version should be retracted or can stand. During the post-publication review process, the editor in chief of JMIR Public Health and Surveillance, Travis Sanchez, DVM, MPH, reviewed the manuscript drafts, peer review comments, and author responses. He noted that the paper adheres to standards for systematic reviews. There were two reviews on record, including one peer review that identified methodological issues that the authors addressed in a subsequent revision.

After the first round of reviews, guest editor Marzo did not adhere to JMIR Publications’ best practices and decision-making guidelines for editors by issuing a “B” decision (ie, minor revisions, no further peer review required) instead of a “C” decision (ie, revise and re-review), which would have presented the revised manuscript to the peer reviewers for re-review [4]. Upon editorial review of the revised manuscript and the authors’ point-by-point responses to the peer reviewers’ comments, it was noted that there could have been additional clarifications in the author responses, including more explicit comments on impacts of the changes made on the results. However, on examination of the edits that the authors made in the final draft of the manuscript by the editor in chief, it appears that the authors appropriately addressed the most substantive methodology concerns noted by the peer reviewers. Although minor revisions or refinements could have been made, the validity of the study appears to be sound and would not be impacted by minor revisions. No further revisions, corrections, or addenda are required at this time.

As a result of our investigations and a de novo evaluation of the acceptability of the paper by the editor in chief Travis Sanchez, the determination is that the editor of record for this manuscript has been corrected to Travis Sanchez. The editor information in the published paper will be changed from:

Edited by R Marzo

to:

Edited by T Sanchez

At the time of this manuscript publication, Marzo had not made other decisions for this theme issue. Henceforward, Marzo and other guest editors will only make future decisions for this theme issue together with editor in chief Sanchez.

JMIR Publications adheres to COPE guidance, including the 2023 published guidance on “Best practices for guest edited collections” [2]. JMIR Publications also routinely reviews and updates its Conflict of Interest disclosure policies as part of a larger effort to promote integrity of the published scientific record [3]. JMIR Publications has adhered to all key points from the COPE guidance on guest edited collections, and processes have been further optimized to mitigate risks and prevent further similar occurrences.
The correction of the editor’s name will appear in the online version of the paper on the JMIR Publications website on July 10, 2024, together with the publication of this correction notice. Because this correction was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

KEYWORDS
benefit-risk assessment; discrete choice experiment; hemophilia A; patient preference; prophylactic treatment

We read with great interest the paper “Quantifying benefit-risk trade-offs toward prophylactic treatment among adult patients with hemophilia A in China: discrete choice experiment study” by Wang et al [1]. The results were unsurprising and aligned with clinical practice and provided valuable insights into the preferences of patients for prophylaxis in hemophilia A treatment. The authors designated the annual bleeding rate as an important item in the questionnaire used. This is rational as most clinical studies on hemophilia consider it a primary clinical outcome. However, there is a need for greater specificity in the annual bleeding rate, particularly with regard to joint bleeding and spontaneous bleeding.

As the standard treatment for patients with hemophilia A, prophylaxis with coagulation factor VIII (FVIII) was proposed to maintain a steady trough FVIII level mainly to prevent spontaneous and breakthrough bleeds [2]. In the study, the annual bleeding rate was calculated using all types of bleeds, including injury-caused, spontaneous, joint, and subcutaneous bleeds. However, a great difference exists across these bleeding types. For example, compared with subcutaneous bleeds, joint bleeds typically result in more serious consequences and require greater attention and more effective management. The definition of “target joint” only needs 3 spontaneous bleeds to occur in a single joint [2]. However, patients with target joints will need a substantially higher FVIII level to ensure their safety [3]. On the other hand, it is common for patients with active lifestyles to report more mild injury-caused bleeds (e.g., bleeding resulting from a sports-related injury) but a good quality of life and normal joint structure or function [4]. As reported before, the primary aim of prophylaxis is to prevent spontaneous bleeds, which could be completely different from injury-caused bleeds [2]. All individuals can bleed if an injury occurs while taking part in sports; thus, sports-related bleeds are not equivalent to spontaneous bleeds [5]. For example, there are substantial differences in treatment or clinical outcome between patients with 6 instances of spontaneous joint bleeds and those with 6 instances of injury-caused bleeds in 1 year. Thus, Wang et al [1] could consider distinguishing bleed types, at least for spontaneous, injury-caused, joint, and other mild bleeds. With reference to the attributes of efficacy factor among the authors’ citations, 3 studies (references 22, 23, and 25) picked reduction of bleeds and 2 studies (references 25 and 26) selected breakthrough bleeds instead of annual bleeding rate. In 2 studies that did not involve specific bleed types, one (reference 28) added joint evaluation to make the results clearer.

In conclusion, although the annual bleeding rate is a commonly used indicator for clinical outcomes among patients with hemophilia, it is better to distinguish different kinds of bleeds or simply choose a more detailed and suitable one for analysis in a discrete choice experiment. This will eliminate potential
confusion during the interpretation of results and make study findings and conclusions more detailed and valid, thus enhancing their clinical application.

KEYWORDS
benefit-risk assessment; discrete choice experiment; hemophilia A; patient preference; prophylactic treatment

We appreciate Huang’s [1] thoughtful consideration of our article [2]. Their suggestion to refine the attribute of “annual bleeding rate” in our discrete choice experiment (DCE) by distinguishing between spontaneous versus injury-induced bleeding, and further categorizing bleeds as joint or mild, is acknowledged with appreciation. In the formulation of our DCE questionnaire, considerable attention was devoted to addressing this aspect. However, the integration of a comprehensive spectrum of bleed types into the DCE was met with challenges, particularly within the context of the current hemophilia A scenario in China and the specific focus of our investigation.

Our study focused on adult patients with hemophilia. With the notable increase in the adoption of low-dose prophylactic treatment and advancements in diagnostic and therapeutic capabilities, there has been a significant rise in pediatric patients benefiting from prophylaxis with coagulation factor [3]. However, it is important to highlight that the current percentage of adult patients undergoing prophylaxis with coagulation factor remains relatively low [4]. In our DCE, the number of annual bleeds attribute was operationalized as spontaneous bleeding events. The decision not to delve into further details of bleeding types in the DCE was primarily influenced by the reasons listed below.

First, patients have limited ability to assess their own bleeding, and misrecording or missing records often occur [5]. Unlike during a clinical trial, it is challenging for them to obtain detailed descriptions of all types of bleeds per year via questionnaire. Second, while adult patients with hemophilia in developed countries engage in physical activities at rates comparable to the general population, the situation in China is markedly different [6]. With age, patients often exhibit varying degrees of joint damage or deformities, particularly in the knees, ankles,
and elbows, resulting in a generally reduced activity level [7]. Consequently, the incidence of activity- or injury-induced bleeding is relatively low. Moreover, a significant portion of adult patients in China may already be experiencing joint deformities or at a stage requiring joint replacement [4], rendering the notion of “target joints” less relevant.

In the DCE context, it is crucial that the chosen attribute and levels align with practical conditions, ensuring ease of investigation and data collection from the participants. Therefore, for this study, we selected the number of annual bleeds (spontaneous bleeding) as the attribute. Our DCE design, particularly in determining attributes and levels, entailed multiple rounds of consultations and interviews with clinical experts, including hemophilia specialists from the Shandong Hemophilia Treatment Center (the core center of the Hemophilia Treatment Center Collaborative Network of China and the World Federation of Hemophilia). These consultations were instrumental in providing valuable professional guidance.

We believe that these additional details provide a comprehensive background of our DCE design. Furthermore, our aspiration is to enhance access to prophylaxis with coagulation factor for adult patients in China, accompanied by a commitment to maintain precise bleeding records. This commitment would not only benefit our study but also pave the way for future research to refine the measurement of annual bleeding frequency by incorporating additional indicators like bleeding types.

Abstract

Background: Contextual variables that capture the characteristics of delimited geographic or jurisdictional areas are vital for health and social research. However, obtaining data sets with contextual-level data can be challenging in the absence of monitoring systems or public census data.

Objective: We describe and implement an 8-step method that combines web scraping, text mining, and spatial overlay analysis (WeTMS) to transform extensive text data from government websites into analyzable data sets containing contextual data for jurisdictional areas.

Methods: This tutorial describes the method and provides resources for its application by health and social researchers. We used this method to create data sets of health assets aimed at enhancing older adults’ social connections (eg, activities and resources such as walking groups and senior clubs) across the 374 health jurisdictions in Catalonia from 2015 to 2022. These assets are registered on a web-based government platform by local stakeholders from various health and nonhealth organizations as part of a national public health program. Steps 1 to 3 involved defining the variables of interest, identifying data sources, and using Python to extract information from 50,000 websites linked to the platform. Steps 4 to 6 comprised preprocessing the scraped text, defining new variables to classify health assets based on social connection constructs, analyzing word frequencies in titles and descriptions of the assets, creating topic-specific dictionaries, implementing a rule-based classifier in R, and verifying the results. Steps 7 and 8 integrate the spatial overlay analysis to determine the geographic location of each asset. We conducted a descriptive analysis of the data sets to report the characteristics of the assets identified and the patterns of asset registrations across areas.

Results: We identified and extracted data from 17,305 websites describing health assets. The titles and descriptions of the activities and resources contained 12,560 and 7301 unique words, respectively. After applying our classifier and spatial analysis algorithm, we generated 2 data sets containing 9546 health assets (5022 activities and 4524 resources) with the potential to enhance social connections among older adults. Stakeholders from 318 health jurisdictions registered identified assets on the platform.
between July 2015 and December 2022. The agreement rate between the classification algorithm and verified data sets ranged from 62.02% to 99.47% across variables. Leisure and skill development activities were the most prevalent (1844/5022, 36.72%). Leisure and cultural associations, such as social clubs for older adults, were the most common resources (878/4524, 19.41%). Health asset registration varied across areas, ranging between 0 and 263 activities and 0 and 265 resources.

**Conclusions:** The sequential use of WeTMS offers a robust method for generating data sets containing contextual-level variables from internet text data. This study can guide health and social researchers in efficiently generating ready-to-analyze data sets containing contextual variables.

**Introduction**

**Background**

Contextual variables refer to the social or physical attributes of geographic or jurisdictional areas (eg, country, city, neighborhood, and administrative health area) that are not derived from the characteristics of their members [1]. Common examples include social cohesion [2], social capital [3], and presence of green spaces [4]. Contextual variables have multiple applications in health and social research. As people living in the same community or context are likely to be exposed to a similar environment, contextual variables can be used in multilevel models to explain variability in health outcomes [5].

Although information on some contextual variables, such as census data, is widely available, accessing context-level data in emerging research fields can pose significant challenges. For example, monitoring systems may not exist yet to fully capture the social determinants of health (SDOH) across delimited areas. In addition, there may not be data available on the exposure and implementation of large-scale interventions targeting SDOH, making program and implementation evaluation studies challenging or impossible [6]. This could be the case for regional or state public policies and public health programs, such as provincial public health programs to promote local intersectoral collaborations to tackle SDOH [7] or national legislation to promote healthy nutrition to prevent obesity [8]. As these policies and programs can be implemented without an evaluation plan, and data might be complex or unavailable, they often remain unevaluated [9].

When structured databases or primary data gathering are not feasible, the internet can be a valuable resource for compiling information to define contextual variables. However, this presents several challenges: internet data are often cluttered, fragmented, and spread over multiple websites [10]. Moreover, the content of most websites is not designed for use by health researchers nor is it grouped by relevant contextual areas. To overcome these challenges, we developed a novel 8-step method, which we have termed web scraping, text mining, and spatial overlay analysis (WeTMS) to collect large amounts of internet data from websites, transforming it into meaningful data sets containing research-relevant variables, and classifying them based on delimited geographical or jurisdictional areas.

This method combines the techniques used in web scraping, text processing and mining, and spatial analysis. Web scraping, also known as web data mining, involves the creation of programs that can automatically download, parse, organize, and store information collected from the web in structured data sets [11]. This process is more efficient and less prone to errors compared with the traditional and laborious process of manually copying and pasting internet information into a spreadsheet [11]. Web scraping has been gaining traction in health research, fueling the rise of infodemiology, which analyzes the spread and impact of web-based information to inform public health and policy [12]. As of January 2023, a search of the keyword “web scraping” in Medline yielded 105 records, 95 of which were published starting from 2019. Articles using web scraping in health and social research mostly used information from social media [13,14] (eg, Twitter, Instagram, and TikTok), forums [15,16], business and review websites [17], and news web pages [18]. Similarly, text mining has been increasingly applied in health and social research [19]. Text mining is the process of extracting meaningful information from large volumes of unstructured text data using techniques such as text classification, sentiment analysis, and pattern recognition [19]. Examples include using sentiment analysis on social media posts to identify health and mental well-being issues [20] and characterizing mental health problems [21]. In addition, topic modeling has been used to understand public perceptions of the COVID-19 pandemic on Twitter [22] and to uncover health-related topics on social media [23].

Spatial overlay analysis is a group of methodologies used in geographic information systems to simultaneously display multiple layers of spatial information and assess the relationships between different geographic features and attributes [24]. Spatial overlay analysis can be used to examine the relationships between multiple layers of geospatial data to locate spatial points (eg, coordinates) in delimited geographic or jurisdictional areas. Geographic information system methods have been used in health geography and environmental epidemiology to study the geographic incidence or distribution of diseases [25]. When census data or data sets containing contextual variables are unavailable, researchers may have to engage in laborious manual extraction of web-based data, which can be time-consuming and susceptible to inaccuracies [11]. Currently,
there is a gap in the literature regarding methods that enable researchers to automatically convert large volumes of internet text information into meaningful, ready-to-analyze data sets containing contextual data. We propose that by combining techniques used in WeTMS, researchers can efficiently extract, process, and geolocate vast amounts of internet text data to produce structured data sets that encompass variables reflecting the contextual characteristics of specific geographic or jurisdictional areas.

**Objectives**

The aims of this study are 2-fold. First, we outline the implementation of the WeTMS method through a research case, creating data sets with contextual variables on health assets that could improve social connections for older adults across various health jurisdictions in Catalonia, Spain. Second, we analyze these data sets to describe the characteristics and registration trends of these health assets by local stakeholders.

In this tutorial, we first introduce the WeTMS method and describe its application to a research case for compiling data sets of health assets that could enhance social connections among older adults in the health jurisdictions of Catalonia. These assets include activities and resources in the community that can facilitate social interaction, such as social activities, walking groups for retirees, libraries, and senior community centers [26].

Next, we use these new data sets to extract assets with the potential to foster older adults’ social connections and conduct a descriptive analysis to explore their characteristics and asset registration trends across jurisdictions. This analysis demonstrates the potential application of this method in program evaluation. In addition, we discuss the challenges that health and social researchers may face during the WeTMS process and provide resources and programming codes to facilitate its application in other areas of research.

**Methods**

**Context and Data Sources**

In 2015, the government of Catalonia launched the Assets and Health platform as a component of 2 provincial public health programs that aimed to promote intersectoral collaborations among health and nonhealth organizations to tackle complex public health issues, including older adults’ lack of social connections [7]. The Assets and Health platform (created by the Asturias Health Observatory and shared through the Spanish Community Health Alliance) is a search engine and repository where stakeholders from multiple local organizations can register community health assets [27]. Health assets are activities and resources within the community that contribute to maintaining the health and well-being of individuals and groups [28].

Health assets were registered as “activities” (time-bound initiatives and structured interventions, like arts and crafts or supervised walking outings) and “resources” (permanent community fixtures such as associations, parks, and civic centers). Once registered, each health asset is stored on an individual website detailing characteristics, such as its title, description, location, and target population. These individual websites are linked to a search engine, enabling stakeholders to locate assets available in their basic health areas (BHAs), which can be used in collaborative interventions to address public health problems. Each BHA in Catalonia is a local health jurisdiction that functions as an administrative unit within the Catalan healthcare system [29]. In urban settings, BHAs typically cover specific neighborhoods or districts, whereas in rural areas, they may span one or more municipalities, as determined by demographic, epidemiological, and accessibility considerations.

**Overview of the WeTMS Method**

The 8 steps of the proposed method are summarized in Figure 1. The first 3 steps involve identifying and extracting website data through web scraping, and then storing the information in structured data sets to facilitate their analysis. Steps 4-6 describe the application of text processing and mining techniques to analyze the scraped data, identify patterns in the text content, and classify the data into new variables and categories. Steps 7 and 8 elaborate on the use of spatial overlay analysis to locate data within delimited geographic or jurisdictional areas.
Steps 1 to 3: Using Web Scraping for Data Extraction

**Step 1: Defining Variables of Interest**

The target information, including the type of data and the desired outputs for web scraping, was first outlined to avoid extracting irrelevant information. We aimed to generate context-level variables capturing the attributes and registration dates of community health assets to enhance social connections among older adults in Catalonia's BHAs. The data to be extracted from each website detailing a health asset included text elements such as title, description, target population, location, asset registration date, cost, duration, and activity topics. Other data types that could be targeted for extraction include images, links, and metadata, while outputs might be structured data sets such as CSV files, which contain prespecified variables.

**Step 2: Identifying and Exploring the Data Sources**

The second step involves identifying the URLs or web addresses containing the target information and understanding how their content is structured. Identifying URLs can present challenges such as information being dispersed across multiple websites or URLs being hidden or changing [30]. Consequently, sites may be missed because the web scraping “crawler” (the portion of code responsible for finding each URL) requires exact web addresses [30].

In our initial exploration of the Assets and Health search engine, only the last 100 registered health assets were displayed, and those URLs were hidden. A pattern in the URLs for websites describing each health asset, comprising a fixed segment and variable reference number, was identified using Chrome DevTools for network inspection.

The source code of the target websites, usually HTML, was examined to discern their organization and structure. The attributes of HTML elements containing target data (eg, asset titles and descriptions) were identified and used to program the web scraper. Additional information and resources required to implement step 2 are available in Multimedia Appendix 1 [11,31-36].

**Step 3: Extracting and Parsing URL Source Data**

After identifying the relevant URLs and HTML elements, a web scraper comprising a crawler, parser, and data handler was developed using Python 3.10 [37] on the PyCharm 2022.2.2 environment, and the libraries “requests” [38], “beautifulsoup4” [39], and “pandas” [40]. The web scraper also incorporated error-handling mechanisms to manage potential issues, such as connection failures when URLs were nonexistent. The code is explained in detail in Multimedia Appendix 2 and is publicly accessible on GitHub [41].

The web crawler requested 50,000 URLs from websites linked to the Assets and Health platform, comprising 25,000 activities and 25,000 resources, to capture reference numbers from the onset of the program, from July 2015 to December 23, 2022, which was the day when the data were scraped. The program “parser” then analyzed the HTML code of each existing URL and extracted the desired elements, stripping the text, which was automatically stored in 2 CSV data sets for activities and resources. The encoding of the data sets was revised to avoid mismatches between the character set used to represent the text data and that of the scraped text, as this can result in certain characters being displayed as symbols. An initial review of scrapped health assets was conducted to exclude irrelevant observations. We filtered out assets registered outside Catalonia or targeted solely at children and youth before proceeding with the text processing and mining steps.
Steps 4 to 6: Text Processing and Mining to Generate Meaningful Contextual Variables

Step 4: Cleaning and Preprocessing
Cluttered and inconsistent text data obtained from web scraping were preprocessed for analysis [31]. We used RStudio (version 2022.12.0), with the “tm” [42] and “qdap” [43] libraries. The “tm” library provides functions for cleaning, preprocessing, and analyzing text data. The “qdap” library allows text categorization, word frequency calculation, tokenization, and clustering.

The first author manually examined a set of activities and resources from scraped text to assess the quality and structure of the text data. This step was crucial for identifying inconsistencies, such as assigning different age ranges (e.g., 60 and 65 years) to older adults simultaneously.

To preprocess the text data, the columns containing free text, namely titles and descriptions of the health assets, were merged and converted to “corpus” objects—a data structure for text data in R. Columns with text derived from fixed responses were not preprocessed. Irrelevant stop words were then removed, text data were segmented into individual units that could be transformed into numerical variables (tokenization), and words were normalized to their root form (stemming) [44]. The 2 data sets, containing health assets registered as activities and resources, were processed independently. The code with explanations for this step can be accessed through GitHub [45].

Step 5: Defining Dictionaries and Categorizing Text
We used text mining techniques to develop a classification system to filter and categorize health assets for older adults to enhance social connections from all other registered activities and resources on the platform. Text classification is pivotal for the generation of new variables of interest from unstructured data, because it can categorize text into predefined classes or labels.

First, to classify health assets, we predefined new variables and categories created through a deductive approach, based on the literature on social connections [46,47]. We also used inductive processes to create new variables and categories based on patterns identified during the text analysis and discussion among the research team. Table 1 lists the new variables, categories, type of creation process, and literature sources. Detailed definitions of the new variables and categories are provided in Multimedia Appendix 3 [46,48-51].

Second, we created document-term matrixes from the corpus of preprocessed text data containing health asset titles and descriptions. A document-term matrix is a mathematical matrix that describes the frequency of terms in a collection of textual data [31]. The frequency of each word was calculated and sorted based on their frequency values, representing the number of times a term appeared in the title and description of health assets.

Third, over the course of 3 meetings, 2 researchers (PG-H and CM) identified and selected high-frequency words that were repeated 15 times or more in the scraped data, grouped them into topic-specific dictionaries, and refined the list. Eligibility criteria, informed by the definitions of each new variable category, were developed to determine which words to include in each dictionary.

Finally, a classification system was developed using a rule-based classifier. A rule-based classifier categorizes data into predefined classes by applying a set of human-defined rules and conditions based on the features and attributes of the data [52]. We opted for a rule-based system over more complex machine learning classifiers, as this approach is better suited for scenarios with a limited number of specific labels and smaller data sets and ensures efficiency and interpretability without the need for extensive training data [52,53]. Topic-specific dictionaries consist of lists of words related to the definitions of the predefined variable categories as conditions to classify the text data [54]. Finally, an R function was developed to automatically generate a new column for each new variable, search for dictionary words in the scraped data, and assign a new category value if a word was found. The classifier system, including topic-specific dictionaries, is accessible on GitHub [45].

**Step 6: Manual Verification**

The categories assigned to the new variables for each health asset were reviewed for inconsistencies by 2 researchers with expertise in the topic (PG-H and Angeli Chaculiaz). Manual verification refers to a one-by-one examination of the classified data by human reviewers to ensure the accuracy of the new variables created [55]. Verification involved an independent review of 200 health assets by 2 researchers to assess new variable categories based on eligibility criteria. Discrepancies were resolved through web meetings with manual reclassification if necessary. The data sets were then divided into groups of 500 health assets for independent review. Agreement rates between the verified and automatically generated variables were computed using the Excel software.

**Step 7: Identifying the Layers of Spatial Data**

We used a spatial overlay analysis to generate a new variable that identified the BHA in which each health asset was located. The analysis was conducted in RStudio (version 2022.12.0) because of its many packages specifically designed for spatial overlay analysis, such as “sp,” [56] “sf,” [57] “rgdal,” [58] “rgeos,” [59] and “ggplot2” [60]. In this step, 2 spatial layers were identified. The first layer consisted of polygonal data depicting 374 BHAs in Catalonia. The data were obtained from the open database of the General Directorate of Health Planning and Research in Catalonia. Polygonal data can represent geographic or jurisdictional regions by defining their boundaries [61]. The second layer comprises a vector of geographic point data for each health asset. Point data consisted of longitude and latitude coordinates obtained from the addresses scraped for each activity and resource using Excel add-on GeoCode, a map tool that uses Google services to automatically retrieve longitudes and latitudes from addresses.

**Step 8: Matching Coordinate Reference System and Finding Intersection Points**

Step 8 involves transforming the spatial data layers into a common coordinate reference system (CRS) and identifying the intersecting points. The CRS of a spatial object determines its location on the Earth’s surface. Thus, analyzing 2 or more spatial layers with different CRS can produce misleading outcomes [61]. To identify areas of overlap between health asset coordinates and BHAs, the following steps were taken: (1) coordinates were transformed to a simple feature object format, (2) simple feature objects were converted into single points using the “st_point” function, and (3) both spatial data layers were converted to a common CRS.
Finally, a spatial overlay analysis was performed using the “st_intersects” function to determine the BHA polygons with which each health asset point data intersected. The function was applied in a loop to each row of the activity and resource data sets. The resulting outputs are stored in new columns named “Code_BHA” and “Name_BHA.” The code, along with explanations for steps 7 and 8, is available in GitHub [45].

Data Set Filtering and Descriptive Analysis

The new data sets were filtered using the new variables and categories to select health assets with the potential to foster social connections among older adults from all scrapped assets. Eligible health assets registered as activities and resources were included if (1) the target population included older adults, (2) the format was either group activities or individual activities fostering social connections (eg, befriending), and (3) they were located in Catalonia.

A descriptive analysis was conducted in RStudio (version 2022.12.0), to understand the characteristics and asset registration trends of stakeholders across BHAs. Frequencies and proportions were calculated for each category of the new variables (activity type, format, focus, age, sex, and vulnerable populations). Temporal registration trends of activities and resources were analyzed using time-series graphs with local polynomial regression fitting lines, a nonparametric method used to describe the deterministic variation in data [62]. We also computed the average weekly registration of activities and resources in each BHA, assuming a Poisson distribution, where \( \lambda \) represents the weekly health asset registrations per area. Finally, visualization techniques were used to analyze the temporal evolution of the registration of activities and resources on the Assets and Health websites across BHAs, as well as their geographic distribution.

Ethical Considerations

The data collected in this study were publicly accessible and did not contain any personal or sensitive information. Thus, ethical approval and participant consent were not required for this study. In addition, before data collection, we verified that the websites of interest did not have any explicit prohibitions against automatic web scraping, such as a “robots.txt” file or similar declarations.

Results

Results From WeTMS

Web Scraping

Of the 50,000 URLs inspected, 17,305 contained websites describing health assets (9558 activities and 7747 resources) registered with local stakeholders from July 2015 to December 2022. The number of observations obtained through web scraping matched the total number of assets reported on the Assets and Health platform, thus demonstrating the efficacy of the web scraper. No missing values were detected for the main variables (eg, title, description, location, and date of asset registration). In the activity data set, 9.56% (480/5022) of observations did not disclose the activity cost, and 49.04% (2463/5022) did not report the activity duration. An example of an activity and resource, as they appear in the scraped data sets, is provided in Textbox 1.

Text Mining

From the text processing of the corpus of titles and descriptions, a total of 12,560 tokens (or raw words) were identified for activities and 7301 for resources, of which 996 (7.9%) and 594 (8.1%) words had a frequency >15. Using words with a frequency of >15, we constructed 73 topic-specific dictionaries corresponding to each category of the new variables. For instance, for the physical activity category under the activity type variable, the topic-specific dictionary included words such as “physical,” “exercise,” “gym,” “yoga,” and “sport.” Figure 2 presents popular dictionary words for each category within the activity type variable.

Figure 2. Categories within the “activity type” variable showcasing popular words derived from topic-specific dictionaries (English translation).

After applying the rule-based classifier using topic-specific dictionaries, manual verification of the output yielded variable levels of agreement ranging from 62.02% (3417/5509) to 99.47% (4886/4912) across variables. For instance, variables with lower classification accuracy had a larger number of possible categories, a more evenly distributed number of observations across categories, or words repeated fewer than 15 times within the title and description corpus. The agreement rates between the verified and automatically generated databases are presented in Table 2.

<sup>a</sup>Automatic classification of the categories for variables activity type, format, and focus was performed only for activities targeting older adults (n=5509).

Spatial Overlay Analysis

Coordinates for the locations of 0.36% (18/5055) of activities and 2.41% (109/4530) of resources were not identified. Manual searches on Google Maps using addresses allowed us to locate the coordinates for all but 7 activities and 2 resources. Through spatial overlay analysis, intersections between spatial points and BHAs were not identified for 26 activities or 4 resources. The newly generated columns for the variables Code_BHA and Name_BHA encompassed values for 318 distinct BHAs, representing 85% of the 374 BHAs.

Results From Data Set Filtering and Descriptive Analysis

Filtering Health Assets With Potential to Enhance Older Adults’ Social Connections

Using the newly generated contextual variables, we filtered the data sets of activities and resources to identify those with the potential to foster social connections among older adults. From the initial 17,305 health assets identified, we obtained 9546 eligible health assets, comprising 5022 activities and 4524 resources. The reasons for exclusion and the stages in which health assets were discarded are shown in Figure 3.
Figure 3. Flowchart for the filtering of health asset data sets by contextual variables related to social connection constructs generated using the web scraping, text mining, and spatial overlay (WeTMS) method. BHA: basic health area.

Characteristics of Eligible Health Assets

Of the health assets registered as activities, 24.59% (1235/5022) specifically targeted older adults, whereas 75.41% (3787/5022) targeted broader age ranges, including the older population. Most resources targeted the general population and included older adults, with only 4.12% (207/5022) being exclusively for older adults, such as civic centers for retirees. Only 2.49% (238/9546) of the health assets had a sex-specific target; these were predominantly women (n=212). Among all health assets, 13.5% (678/5022) of activities and 7.98% (361/4524) of resources were tailored for specific vulnerable groups, with physical or mental illness being the primary focus.

Group-oriented activities promoting social interactions accounted for 99.56% (5000/5022) of the eligible activities. However, only 4.36% (219/5022) explicitly used concepts related to social connections (eg, loneliness and social isolation) in titles and descriptions. Over 57% (2862/5022) of the activities were cost-free, and the most common activity duration was 1 to 3 months (975/5022, 19.41%). Data on format, duration, and cost are not available for resources.

The analysis of the new variable *activity type* showed that leisure and skill development activities were most common (1844/5022, 36.72%). This included group handcrafts, dance, painting, theater, cooking, choir courses, and conversation groups that focused on shared-interest topics. Group exercise activities (eg, walking groups) accounted for 31.08% (1561/5022) of the activities. Over 22% (1103/5022) of the activities involved group activities with health and social professionals outside the health care center, including psychological therapies and health and social care. Finally, 8.46% (425/5022) were social facilitation activities such as group meetings to share common interests (eg, film forums). Overall, more than half of these activities were registered between 2021 and 2022 (Figure 4).
Almost 61.49% (2782/4524) of the registered resources facilitated exchange of knowledge and interests among older adults. These resources included leisure and cultural associations; public libraries; civic centers; and cultural, sports, and educational institutions. Municipal natural and green spaces where adults can gather accounted for 17.28% (782/4524) of the resources. A total of 595 (13.1%) health institutions and 140 (3.1%) social welfare institutions were found, including primary care centers, health and social foundations, and advocacy institutions promoting social inclusion. Other resources linked to health and social welfare include patient advocacy groups, faith-based organizations, and charitable and voluntary organizations. In contrast, most resources were registered before 2019 (Figure 5). A detailed descriptive analysis of the type, target population, focus, cost, format, and duration of health assets is included in Multimedia Appendix 4.

Figure 4. Number of activities with the potential to enhance older adults’ social connections by type and year of registration (2015-2022).

Figure 5. Number of resources with potential to enhance older adults’ social connections, by type and year of registration (2015-2022).
Overview of Registration Trends of Eligible Health Assets Across BHAs

The first registry of a health asset on the Assets and Health websites occurred on July 23, 2015, and the last on December 23, 2022, the day when web scraping was conducted. Total registration of activities remained consistently low from the start of the program until early 2018, whereas for resources, a registration peak was observed in late 2016. Activity and resource registrations have increased from 2018 to mid-2020. A decline in registration was observed from early 2020 to mid-2021, coinciding with the outbreak of the COVID-19 pandemic. Local polynomial regression fitting lines showed a growing pattern in the registration of activities from 2021 onwards, whereas resource registration remained low (Figure 6).

On the basis of the observed trends, 4 implementation periods were defined to better understand registration trends: period 1, from July 2015 to January 2018; period 2, from February 2018 to February 2020; period 3, from March 2020 to May 2021; and period 4, from the end of June 2021 to December 2022. During the first two and a half years of the program, the average number of activities and resources registered per week across all BHAs was 0.37 and 3.47, respectively, increasing to 11.83 and 25.27 in period 2. During the COVID-19 pandemic in period 3, these figures decreased to an average of 3.19 activities and 20.64 resources per week. Period 4 had the highest registration rate for activities (38.52/wk).

To calculate the registration trends in individual BHAs, we divided the number of BHAs with one or more activities registered by the total number of BHAs (n=374) for each period. We did not consider the resource data set because of the observed patterns suggesting centralized registration, rather than local registration. For instance, in late 2016, resources in 237 BHAs were registered in a single day. At the end of period 1, 8% (30/374) of the BHAs had one or more registered activities, which increased to 85% (318/374) by the end of period 4 (Figure 7; Table 3). The number of health assets registered per BHA varied significantly, ranging from 0 to 263 activities and 0 to 265 resources. The median number of activities registered per BHA from 2015 to 2022 was 5 (IQR 13.75) and 9 (IQR 10) for resources. Figure 8 illustrates the geographic distribution of the activities and resources registered in each period.

Figure 6. Weekly registration trends of health assets from July 2015 to December 2022. The y-axis represents the number of registered activities and resources per week. The x-axis represents time, labeled by years for clarity.
Figure 7. Cumulative frequency of basic health areas (BHAs) with registered health assets aimed at enhancing older adults’ social connections from July 2015 to December 2022. Each point represents a BHA at the time of its first asset registration on the Assets and Health platform, cumulative.

Discussion

Innovation: Generating Area-Specific Contextual Variables From Unstructured Web-Based Data

We introduce a novel approach for generating area-specific contextual variables from unstructured website data using WeTMS. By combining the methods commonly used in computer and data science, we were able to efficiently gather and transform large amounts of website data into comprehensive data sets of theoretically informed variables. The resulting data sets enabled us to identify and characterize health assets with the potential to enhance social connections among older adults registered within health jurisdictional areas from 2015 to 2022. In addition, this approach allowed us to examine area-specific registration trends for health assets, showing the use of the Assets and Health platform developed as part of a public health strategy in Catalonia. We provided detailed explanations of concepts, steps, and the code used, and included supplementary information to facilitate the replication of the steps, attempting to familiarize novice readers with these techniques.

Applications of the WeTMS Method

Our method provides a tool for researchers interested in developing new contextual variables when data are scarce or difficult to obtain using traditional means. Researchers in fields such as public health, nursing, and social epidemiology who study the impact of emerging health and social phenomena on health outcomes and determinants of health can benefit from this method. A practical example of an emerging social determinant of health, such as precarious employment [63], can consist of applying the web-scraping steps to obtain website data from employment portals, text mining to analyze posts, identifying precarious job offers, and spatial overlay analysis to locate them into geographic areas and study the effect on population outcomes using multilevel modeling. Researchers and program evaluators in health services research and implementation science can use this method to obtain data to conduct descriptive analyses explaining policy adoption within jurisdictional or geographic areas, following the research case outlined in this study.

A key feature of this method is that its steps can be implemented in sequence or independently, depending on the research goals. For example, researchers interested in generating new variables from text data without locating them in specific geographic areas can follow steps 1 to 6, which involve web scraping, text processing, and mining. If a data set is already available and researchers want to group the data by geographic settings, they can follow steps 7 and 8, which involve overlay spatial analysis.

Challenges and Limitations

There are challenges with this method that can limit its feasibility and application. In our example, extracting comparable data from multiple URLs was feasible because the websites associated with the Assets and Health platforms had similar HTML structures. The consistent placement of targeted information across websites simplifies the complexity of the web-scraping program. Thus, the attached web scraper code is only suitable for single or multiple websites with a limited number of distinct HTML structures (eg, forums, social media, and employment portals). Studies in which the target data are spread over different websites with varied designs require more advanced programming [11].

A key step in the process—the creation of topic-specific dictionaries for the classification of observations—necessitates a deep understanding of the field and the terminology used in the data. Overall, the rule-based classifier demonstrated high
accuracy. However, some variables, such as activity type, showed a higher rate of errors, in part because the dictionaries used to classify them contained only high-frequency words found in the titles and descriptions. Thus, our experience suggests that manual verification of new variables and categories by researchers with a comprehensive understanding of the data and subject matter is essential to ensure data validity before statistical analysis. However, this can be unfeasible for large data sets. In such scenarios, the impracticality of manual verification may necessitate the use of complex machine learning classifiers, presenting a trade-off in the confidence of the data that potentially compromises the robustness of the resulting variables [52].

Spatial overlay analysis effectively localizes health assets to their respective health jurisdictions, facilitated by the acquisition of complete addresses during the web scraping phase and the availability of a high-quality polygon map for analysis. Geospatial maps can be obtained from government agencies, nonprofit organizations, and commercial providers. If maps are unavailable, they can be created using accessible satellite imagery [64]. However, the necessity for location-specific data (eg, addresses, postal codes, and cities) for each observation to generate contextual-level variables limits the range of suitable data sources available to researchers.

Ethical and data protection considerations are important. Web scraping is typically permitted when data are publicly accessible and not subject to international legislation concerning personal data, trademarks, copyrights, or private information [30]. Automatic extraction of internet data might be unfeasible if the data are not publicly available or if a website’s terms of service restrict automated collection and analysis [65]. Researchers may consult ethics bodies to ensure that the methodology adheres to ethical standards when dealing with sensitive topics and personal information, even when relying on publicly available sources.

In addition to these challenges, the method and data sets that it produces have limitations. The complexity of these steps requires introductory technical knowledge. Thus, we have provided detailed explanations and supplementary information that can support researchers, as they familiarize themselves with the steps. We anticipate that the compendium of concepts, code, software packages, and references gathered from trustworthy sources will serve as a resource for those interested in these techniques.

Another limitation is the bias associated with the classifier system. The development of classification systems inherently relies on the subjective judgment of researchers. This can result in misclassifications, particularly those related to assumptions about race, gender, or social exclusion factors, especially within machine learning classifiers [66]. It is advisable for researchers to engage in a reflexive process, carefully considering their assumptions in the definition and selection of dictionary words and to critically evaluate how these decisions may influence the investigation [67].

Finally, although the data sets generated are robust for descriptive analysis, researchers should proceed with clearly defined assumptions when using new context-level variables in statistical analyses, particularly in multilevel modeling or ecologic studies that aim to draw inferences. Although we successfully compiled 2 data sets of health assets from targeted websites, their comprehensiveness and accuracy in reflecting all identified assets across BHAs remain unknown. It is possible that some local organizations in BHAs were more or less likely to register assets on Assets and Health websites, influenced by context-specific factors such as management support and training on the platform [68]. If feasible and ethical, it would be advisable for researchers to triangulate data to validate the data sets, thus verifying web-scraped data with secondary sources or direct inputs from stakeholders [69].

Conclusions

The sequential use of WeTMS enabled the efficient creation of data sets of health assets registered with the Assets and Health websites in Catalonia, Spain, which aimed to enhance the social connections of older adults in local health jurisdictions. Our descriptive analysis demonstrated the usefulness of the data sets in exploring the characteristics of contextual variables, as well as in understanding temporal patterns and spatial distributions. Contextual-level variables generated via WeTMS may also be used in hierarchical analyses to evaluate the impact of contextual factors on health outcomes when more robust sources, such as census data, are not available. Adherence to data protection standards and ethical considerations should also guide this process. Although WeTMS has potential value for multiple research disciplines, it presents challenges and limitations, including the need for internet data sources to have comparable structures, a dependence on location data, the potential lack of representativeness in website content, the requirement for technical expertise, and a significant time investment for manual verification.

Acknowledgments

The authors thank Angeli Chacaliaza for his valuable contribution as a second reviewer in the manual verification stage and Ann Tourangeau, Martine Puts, and Tina Behrouzi for their comments and suggestions on the first draft. The authors also acknowledge Charles Anderson for his technical assistance. This study was not supported by any funding. The authors attest that there was no use of generative artificial intelligence technology in the generation of text, figures, or other informational content in this manuscript.

Data Availability

The data sets generated and analyzed during this study are available from the corresponding author upon reasonable request.
Authors' Contributions
PG-H and CM conceptualized the study; PG-H wrote the study protocol, developed the method, and drafted the manuscript; and AG-V, LG-P, and CM provided expert input and conducted manuscript review and editing. All the authors have read and agreed to the published version of the manuscript.

Abstract

Staff at public health departments have few training materials to learn how to design and fine-tune systems to quickly detect acute, localized, community-acquired outbreaks of infectious diseases. Since 2014, the Bureau of Communicable Disease at the New York City Department of Health and Mental Hygiene has analyzed reportable communicable diseases daily using SaTScan. SaTScan is a free software that analyzes data using scan statistics, which can detect increasing disease activity without a priori specification of temporal period, geographic location, or size. The Bureau of Communicable Disease’s systems have quickly detected outbreaks of salmonellosis, legionellosis, shigellosis, and COVID-19. This tutorial details system design considerations, including geographic and temporal data aggregation, study period length, inclusion criteria, whether to account for population size, network location file setup to account for natural boundaries, probability model (eg, space-time permutation), day-of-week effects, minimum and maximum spatial and temporal cluster sizes, secondary cluster reporting criteria, signaling criteria, and distinguishing new clusters versus ongoing clusters with additional events. We illustrate how to support health equity by minimizing analytic exclusions of patients with reportable diseases (eg, persons experiencing homelessness who are unsheltered) and accounting for purely spatial patterns, such as adjusting nonparametrically for areas with lower access to care and testing for reportable diseases. We describe how to fine-tune the system when the detected clusters are too large to be of interest or when signals of clusters are delayed, missed, too numerous, or false. We demonstrate low-code techniques for automating analyses and interpreting results through built-in features on the user interface (eg, patient line lists, temporal graphs, and dynamic maps), which became newly available with the July 2022 release of SaTScan version 10.1. This tutorial is the first comprehensive resource for health department staff to design and maintain a reportable communicable disease outbreak detection system using SaTScan to catalyze field investigations as well as develop intuition for interpreting results and fine-tuning the system. While our practical experience is limited to monitoring certain reportable diseases in a dense, urban area, we believe that most recommendations are generalizable to other jurisdictions in the United States and internationally. Additional analytic technical support for detecting outbreaks would benefit state, tribal, local, and territorial public health departments and the populations they serve.

Introduction

Background
The Bureau of Communicable Disease (BCD) at the New York City (NYC) Department of Health and Mental Hygiene monitors electronic reports daily of >70 reportable infectious diseases for an urban population of approximately 8.5 million residents [1]. Since 2014, to help prioritize resources for case and outbreak investigations and response activities, the BCD has automated daily analyses to prospectively detect and monitor spatiotemporal clusters of reportable communicable diseases using SaTScan [2,3]. SaTScan (an abbreviation of Space and Time Scan Statistics) is a free software that analyzes data using scan statistics [4], which can detect increased disease activity without a priori specification of temporal period, geographic location, or size. SaTScan has effectively detected clusters of enteric and respiratory diseases and of antimicrobial-resistant infections using varied data sources from settings worldwide [5-11]. The BCD has applied several prospective SaTScan analyses to address varied surveillance needs in NYC, with early detection and near–real-time monitoring of salmonellosis, legionellosis, shigellosis, and COVID-19 outbreaks [2,12-14].

For example, in 2015, SaTScan analyses provided the first signal for the second largest outbreak of community-acquired legionellosis in the United States [13]. Detecting serious outbreaks even a day or 2 earlier can potentially save lives.

In the absence of centralized training and technical support for designing and fine-tuning such systems, we have provided informal consultations for other health departments. While there are scientific papers describing the statistical methods [4,15-19] and the SaTScan user guide [20] explains input data requirements and various software features, this is the first such practical resource for health department staff.

Objectives
We aimed to share our recommendations for health departments to design and fine-tune a system to detect community-acquired reportable communicable disease outbreaks using SaTScan (Tables 1-3). This guide describes requirements and parameter settings for a variety of analytic aims and how to use built-in features to interpret results. Methods for detecting building-level outbreaks, hospital-associated outbreaks, purely temporal clusters such as seasonal increases, or early warning signs of diseases with pandemic potential are described elsewhere [21-24].
Table 1. Summary of input file and parameter setting recommendations for designing a system to detect reportable communicable disease outbreaks using SaTScan.

<table>
<thead>
<tr>
<th>Section and subtopic</th>
<th>Recommendations</th>
</tr>
</thead>
</table>
| **Input data**       | 1. The case file for each reportable disease should contain the census tract of the patient home address and the best approximation of illness onset date and can contain additional patient information such as gender and age.  
2. Include all reported events in the case file, whether subsequently confirmed or not.  
3. The coordinates file should include 1 row per census tract with its latitude and longitude.  
4. A network file can be used to avoid clusters that span hard-to-cross boundaries, such as lakes, rivers, and mountain ranges. |
| **Parameter settings** | 5. Use prospective space-time analysis.  
6. Use the space-time permutation probability model.  
7. If case ascertainment over both space and time is highly affected by testing variability, the Bernoulli or Poisson model may be used instead. This additionally requires a control file of negative tests or a population file of all tests.  
8. The space-time permutation model automatically adjusts for purely spatial variations and for purely temporal patterns.  
9. Adjust for day-of-week by space interaction.  
10. To quickly detect outbreaks before many events accrue, use the default minimum number of events of 2.  
11. To support resource allocation to areas with high and increasing disease transmission rather than prioritize case investigations, the minimum number of events can be increased.  
12. For most jurisdictions, allow the cluster to expand in size to include up to 50% of all events during the study period.  
13. For geographically large jurisdictions, either use 10% as the maximum cluster size or add another maximum cluster size (eg, 200 km).  
14. For most communicable diseases, scan for clusters with a minimum of 2 days and a maximum of 30 days.  
15. The study period should preferably be at least 3 times as long as the maximum temporal cluster size. A study period of 1 year is usually reasonable.  
16. The end of the study period should be set to previous day or the most recent day with sufficiently complete data.  
17. Aggregate to daily resolution.  
18. Run analyses daily.  
19. Use the default P value method with the maximum number of Monte Carlo replications set to 999.  
20. Use a signaling threshold of RI ≥ 100 days.  
21. Consider an RI of 100 to <365 days as a weak cluster, an RI of 365 days to <5 years as a moderate cluster, an RI of 5 to <100 years as a strong cluster, and an RI of ≥100 years as a very strong cluster.  
22. Enable the Most Likely Clusters, Hierarchically option and choose No Cluster Centers in Other Clusters. |

Providing context and examples to build intuition, we discuss system setup requirements, data quality assurance, input file preparation, parameter setting recommendations derived from public health and statistical principles, and new features in the 2022 SaTScan release that simplify routine analyses. Multimedia Appendix 1 [2,13,14,25-37] provides further details about parameter settings and advanced options, demonstrates cluster interpretation using artificial but realistic data, and offers strategies for fine-tuning analyses. In Multimedia Appendix 2, a video demonstrates how to set up a cluster detection system, and sample input and output files are provided.

*RI: recurrence interval.*
Analysis Design

Ethical Considerations
The BCD’s prospective cluster detection activity was deemed nonresearch, public health surveillance by the NYC Department of Health and Mental Hygiene Institutional Review Board. Figures in this tutorial are for illustrative purposes only and reveal no confidential patient information.

Requirements and System Setup
A strong informatics infrastructure and uninterrupted data streams are key for a successful prospective reportable disease outbreak detection system. Near–real-time electronic laboratory reporting with patient location data is required, as well as epidemiologists to interpret signals and resources to investigate outbreaks.

Local installation of SaTScan is needed, and confidential information is never transmitted elsewhere. Google Earth installation and mail server information are optional requirements for certain SaTScan features.

To ensure optimal system performance, we recommend proactive data quality assurance practices, including monitoring for data feed interruptions, deduplicating events reported more than once, and correcting patient information (eg, correcting typographical errors in addresses failing to geocode, correcting when laboratories misreport patients’ residential addresses, maintaining geocoding reference files to account for newly constructed buildings, and correcting implausible onset dates).

SAS or R can be used to prepare input data, run SaTScan in batch mode, create output summary files and visualizations, and send email alerts. Sample code for these systems is freely available [2,38-40], but the 2022 SaTScan release eliminates the need for much of this complicated, external code.

Defining the Aim
Most routine prospective SaTScan analyses of reportable communicable diseases are designed to quickly detect and monitor spatiotemporal outbreaks using patients’ home addresses [2]. We refer to this as our base analysis. In these disease-specific analyses, cluster summaries and patient line lists are routed to in-house disease experts for interpretation and potential action to stop transmission or to focus public health resources. We believe this system is relevant for all acute infectious diseases except for diseases of which a single case is a public health emergency, such as anthrax or botulism. For a few diseases, we modified the base analysis (Table S1, Figure S1, and the Analysis Design: Supplement section in Multimedia Appendix 1).

Input Data
Overview
SaTScan detects data aberrations, which can represent true clusters or data errors. Hence, input data require attention to detail. A case file contains all disease events with their epidemiologically relevant location (eg, census tract of home address) and date (eg, illness onset date), and a coordinates file includes all locations (eg, census tracts) together with the latitude and longitude of their center points. We refer throughout to events as all reported disease events and cases as the subset that meet the surveillance case definitions established by the US Centers for Disease Control and Prevention and the Council of State and Territorial Epidemiologists [41].

Case File
The case file must contain a location ID (eg, census tract number), a temporal element such as a date, and the number of events at that location and time. The case file may be aggregated by location and date. Alternatively, it can be formatted as having 1 row per event and may contain additional columns that are not used in the analysis but can be output in a line list or used to group events on a map (refer to the Built-In SaTScan Implementation and Output Interpretation Features section).

For our base analyses, the temporal element is the best approximation of the date when patients became ill, prioritizing symptom onset date, diagnosis date, or report date such that there is no missingness in the temporal data element. The spatial location is the census tract of patient residence. Some degree of spatial aggregation is necessary to scan along a network (refer to the Network File section), and geocoding to census tracts is sufficiently fine resolution. Even if the public health action occurs at a larger spatial unit, using smaller geographic units increases both the precision and statistical power to quickly detect emerging outbreaks, including those that are geographically small or that do not conform to the boundaries of larger administrative areas. Patients who have a missing, inaccurate, or undefined spatial location can either be purposely excluded from the analysis or included by assigning them a location (eg, assigning patients whose home address is a post office box to the census tract of the post office holding their mail and assigning unsheltered patients experiencing homelessness to a unique, artificial census tract).

For some analyses, we restrict the case input file. For amebiasis, cryptosporidiosis, giardiasis, and shigellosis, we analyze all ages combined as well as children aged <5 years separately to detect outbreaks that might affect patients attending childcare programs. For diseases for which household transmission is likely, for example, norovirus and shigellosis, we restrict the case input file to include only 1 event per household (refer to the Difficulty Detecting Outbreaks Affecting a Particular Age Group and Clusters Are Driven By Within-Household Transmission sections in Multimedia Appendix 1).

If there is a spatiotemporal outbreak in the baseline, it may become harder to prospectively detect a subsequent outbreak. If a purely spatial adjustment is applied, either explicitly or implicitly as in the space-time permutation model, then it will be harder to detect subsequent outbreaks around the same location. This problem can be resolved by removing historic outbreaks from the input files (refer to the Difficulty Detecting New Outbreaks in Areas With Prior Outbreaks section in Multimedia Appendix 1).

We include all reported events during the study period specified in the parameter settings regardless of whether they are subsequently confirmed according to Centers for Disease Control and Prevention and Council of State and Territorial
Epidemiologists surveillance case definitions [41] upon investigation. By analyzing all reported events, timeliness is preserved in that events can be analyzed as soon as they are reported rather than waiting until investigation and case classification processes are complete. Ensuring consistent event inclusion criteria across the study period supports a valid comparison of total reporting volume between current and historical periods [42].

Coordinates File

The coordinates file has 1 row per location with a location ID and its geographic coordinates. Most BCD analyses use the latitude and longitude of each census tract centroid per census 2010 definitions.

Alternatively, space need not be conceptualized as geographical coordinates. To identify temporal clusters of infections by particular Salmonella serotypes, we replace space with arbitrary coordinates for serotype and detect citywide clusters of particular serotypes that could not be explained by the overall seasonality of Salmonella infections [25].

Network File

Spatial scan statistics can be used with windows of different shapes, including circular, elliptical, and nonparametric [43-46]. SaTScan is typically used with a circular scanning window, which also has very good statistical power to detect clusters of other geographical shapes and sometimes better power to detect irregularly shaped clusters than flexibly shaped spatial scan statistics [47]. This is because flexibly shaped spatial scan statistics without some form of noncompactness penalty will often detect spindly, octopus-like clusters that cherry-pick areas with high rates and with long, thin connections between them [47].

An enhancement in SaTScan version 10.0 is the option to scan locations along a network, which may represent travel distance between locations or the amount of interaction between different communities. For example, census tracts or zip code tabulation areas may be geographically close but separated by lakes, rivers, or mountain ranges. We recommend constructing a network file connecting neighboring locations unless separated by those barriers so that clusters can form around rather than through them (Figure 1; refer to Figure S2 and the Network File: Supplement section in Multimedia Appendix 1).

Figure 1. Illustrative cluster detected using a circular scanning window (in yellow) versus scanning along a network (in red) using the same input data. Scanning along a network accounts for limited connectivity across water bodies, resulting in more precise spatial clusters, such as illustrative cluster 4 in the Rockaway peninsula in Queens, New York City.
Parameter Settings

Unlike machine learning methods, in which hyperparameters are tuned using real data during model development, SaTScan parameter settings are derived from underlying public health and statistical principles that should be generalizable across jurisdictions.

Type of Analysis and Probability Model

We use the prospective space-time permutation scan statistic for almost all routine SaTScan analyses conducted at the BCD, including the base analysis [2,17,25]. Prospective analyses detect currently active unusual clusters, evaluating only the subset of possible clusters that encompass the last day of the study period together with a flexible number of previous days. Cluster statistics are determined by the counts of observed and expected events within a cluster window, which is bounded by the user-specified minimum and maximum temporal cluster size. For the space-time permutation scan statistic, the expected number of events for any area is a function of the observed counts during the baseline period and the jurisdiction-wide trend during the temporal window [17]. For example, if a collection of 5 census tracts has 2.3% of cases during the baseline period and there are 100 total cases in the jurisdiction during the cluster period, then the expected number of cases during the cluster period in those 5 census tracts is 2.3.

SaTScan compares a statistical likelihood function calculated from the real data sets with likelihoods calculated from random data sets generated under the null hypothesis of no clustering. There is a cluster if a geographical area has a higher proportion of its events in the cluster period compared with the previous baseline period or, equivalently, if a period has a higher proportion of its events within versus outside the geographical cluster area. For example, if Manhattan’s Upper East Side has 10% of all NYC events during the last 7 days but only 3% of all events during the previous months, a prospective space-time permutation analysis will detect a cluster in the Upper East Side during the most recent week. Note that, while such a cluster is most likely due to an outbreak or increased testing in the Upper East Side, it can also be generated by a sudden decrease in disease occurrence or ascertainment in the rest of the city. The former is more likely for geographically small clusters, whereas larger clusters could have either explanation.

The permutation in the space-time permutation model refers to keeping all observed locations and dates fixed when simulating random data sets under the null hypothesis while randomly shuffling which observed event locations are connected to which observed dates. By conditioning on locations and dates with observed events, the space-time permutation model automatically adjusts nonparametrically for any purely temporal patterns, including seasonality, secular trends, and day-of-week effects, as well as any purely geographical variations in disease occurrence, diagnosis, and reporting, such as due to insurance coverage and access to care. An area’s larger population size, which also affects disease incidence, is accounted for by having more disease counts observed in the baseline period.

For count data such as disease events, Bernoulli and Poisson models are also available. However, the space-time permutation model is often preferred because it requires only event data and automatically adjusts nonparametrically for both purely temporal and spatial variations (refer to the Bernoulli and Poisson Probability Models section and Figure S1 in Multimedia Appendix 1).

Space and Time Adjustments

If there is an overall increasing temporal trend, SaTScan may identify an outbreak if there is no temporal adjustment. One may want to adjust for naturally occurring seasonal variation, for example, while still detecting local outbreaks not explained by jurisdiction-level seasonal trends. When applying a spatial adjustment, SaTScan will identify clusters in which case counts are increasing faster or decreasing slower than elsewhere in the jurisdiction even if the absolute level is lower than that in surrounding areas.

The space-time permutation model automatically adjusts for purely temporal patterns and purely spatial variations, unlike the Bernoulli and Poisson models, for which these adjustments must be explicitly requested. We additionally adjust for space by day-of-week interaction in our base analysis because the day-of-week pattern of health care-seeking behavior and diagnoses may vary geographically in NYC. With this adjustment, the dates in which events occurred are shuffled and assigned to the original event locations, restricting them to the same day of the week. This adjustment should only be applied when there are several weeks in the study period; with only a few weeks, the day-of-week–specific estimates become too unstable. We do not use covariate adjustment because this is unnecessary for prospective outbreak detection and doing so could adjust away emerging outbreaks affecting a particular demographic group.

Scanning for High or Low Rates

Most BCD analyses scan for areas with high rates as we are interested in detecting outbreaks of excess events. The one exception is data quality analyses, where we scan for low rates to quickly identify laboratories with unusually low reporting volume [26].

Minimum Number of Events

In the base analysis, we require only 2 events at minimum because we want to quickly detect outbreaks before many events accrue. For example, 2 salmonellosis events on the same day residing on the same block could be of great interest. For COVID-19, we set the minimum number of events in a cluster to 100 when volume was high because the purpose was to support resource allocation to areas with high and increasing disease transmission rather than to conduct case investigations and contact tracing to identify a common exposure source.

Maximum Spatial Cluster Size

The option that imposes the fewest assumptions is to allow the cluster to expand in size to include up to 50% of all events during the study period. This is reasonable for modestly sized areas such as NYC but might yield too large and uninformative clusters in national- or state-level jurisdictions. For geographically large study areas, we recommend either using 10% as the maximum geographical cluster size or adding another
maximum geographical cluster size. For example, a maximum of 50% may appropriately limit the cluster size around Anchorage, whereas Western Alaska may be better served with a 200-km maximum cluster radius. When using a network file and defining a geographical maximum spatial cluster size, a cluster will expand until reaching a network location at the specified distance from the cluster centroid, which allows for irregularly shaped clusters. We recommend erring on the side of searching for larger clusters, followed by using other principled approaches to interpret or prevent large clusters (refer to the System Fine-Tuning section in Multimedia Appendix 1).

The BCD has on occasion applied a maximum spatial cluster size of a 1-km radius. To search for clusters of locally acquired Zika virus infection, we assumed that a maximum 1-km radius was consistent with the typical flight distance of an *Aedes* mosquito [27] plus some additional distance to include residences of people moving around and coming into contact with the same infected mosquito. To search for clustering of legionellosis events around cooling towers to guide environmental sampling [13], we considered a 1-km radius to be consistent with the area of highest risk of exposure around a contaminated cooling tower.

Of note, setting the maximum spatial cluster size is different from applying a maximum reported spatial cluster size in the advanced output features, which limits the clusters reported in the output rather than limiting the clusters evaluated by the analysis. While it is OK to vary the maximum reported spatial cluster size, an analysis should never be repeated with a different maximum spatial cluster size as *P* values and recurrence intervals (RIs) are inaccurate if one manipulates and tries multiple such parameter settings [48].

**Minimum and Maximum Temporal Cluster Size**

The base analysis scans for clusters that are between 2 and 30 days long, which is enough to encompass the upslope of an epidemic curve for point-source outbreaks, typically spanning a few days or weeks depending on the pathogen. We extended the maximum temporal cluster size to 60 days for salmonellosis, Shiga toxin–producing *Escherichia coli*, paratyphoid fever, and typhoid fever and to 120 days for listeriosis to align with PulseNet USA definitions based on clustering in time and genetic relatedness [49]. Although campylobacteriosis, shigellosis, noncholera *Vibrio spp.* infection, and yersiniosis are also PulseNet organisms, we kept the maximum temporal cluster size at 30 days to slightly increase power to detect more focal clusters of these diseases. These diseases are higher volume and commonly detected using culture-independent diagnostic testing such that laboratory subtyping is not routinely available in NYC to support defining clusters. We similarly extended the maximum temporal cluster size to 60 days for hepatitis A because the incubation period can extend to 50 days [50] and to allow additional time for patient care seeking.

A maximum of 30 or 60 days may not be long enough for diseases with long incubation periods, extended propagated transmission, or intermittent common-source outbreaks. For example, exposure to point sources of listerioses can be intermittent when persistent environmental contamination, and the incubation period can be nearly 70 days [28], so for this disease, we scan for clusters between 7 and 365 days at weekly aggregation.

In the base analysis, we set the minimum temporal cluster size to 2 days because few true outbreaks of the diseases we monitor span only 1 day, and not evaluating clusters of only 1-day duration slightly improves power given less statistical adjustment for multiple comparisons. However, note that a 2-day cluster can have all cases on the same day. If there will be no public health action unless a cluster has persisted for some time, the minimum temporal cluster size can be lengthened. For COVID-19, for example, we scanned for clusters with a minimum temporal size of 14 days to support resource reallocation to areas with sustained high test positivity.

**Study Period**

It is important to balance the need for a period long enough to establish a stable local baseline for each spatial unit yet short enough to avoid variable secular trends due to, for example, geographical population shifts over time. As a rule of thumb, the study period should preferably be at least 3 times as long as the maximum temporal cluster size. This is analogous to a case-control study, which has diminishing returns in statistical power when the control-to-case ratio is increased beyond approximately 3 [51]. If there is a permanent change in surveillance so that recent and older data are no longer comparable, the study period should be shortened. For example, laboratories adopting a culture-independent diagnostic test can lead to increased case ascertainment, and temporarily shortening the study period to begin after the new test was adopted can restore consistency in the baseline [29] (refer to the Clusters Are Driven by the Changing Nature of Input Data section in Multimedia Appendix 1).

For timeliness, the end of the study period should be set to the previous day or the most recent day with sufficiently complete data. In the base analysis, the study period is 1 year with an end date set to the day before the analysis is run. Although 1 year is >3 times longer than the maximum temporal cluster size of 30 days, case ascertainment is generally consistent over a 1-year period for most diseases, and the longer study period provides a more stable baseline. For COVID-19, we shortened the study period to 63 days because volatility in testing access and outreach during the public health emergency made older data less comparable, and we set the end of the study period to 3 days before the run date because more recent testing data were largely missing [14].

**Time Aggregation**

With thousands of locations, long study periods, and multiple data streams, space-time SaTScan analyses can be computationally intensive. To reduce computing time, data may be aggregated into longer time intervals by, for example, aggregating daily data into weekly data. Another reason for aggregating to time intervals of 7 days is to remove day-of-week effects. For the base analysis, we use a time aggregation of 1 day to detect outbreaks as quickly as possible, increase the statistical power to detect outbreaks that do not conform to weekly or other prespecified time intervals, and obtain a more precise estimate of the cluster start date.
**Frequency of Analyses**

With near–real-time electronic laboratory reporting, we run analyses daily. If prospective analyses are conducted at a different frequency than the aggregated time units, such as weekly analyses with daily data, the analysis frequency must be specified. This may be needed if data are reported weekly but with daily resolution; if weekly analyses are sufficiently frequent given limited staffing capacity; or to support public health objectives other than acute outbreak investigations, such as guiding resource allocation. It is important to monitor for unusual clusters near continuously (eg, hourly analyses to detect early indications of a possible bioterrorist attack), consider inputting data using the generic time precision option.

**Secondary Clusters**

Any disease may have multiple active outbreaks at any moment, so secondary clusters should be reported by enabling the Most Likely Clusters, Hierarchically option. We use the No Cluster Centers in Other Clusters option rather than the default No Geographical Overlap. This allows for reports of slightly overlapping clusters so that clusters located close to each other can be detected and can also help define the extent of irregularly shaped outbreaks. At the same time, it avoids redundant clusters that are almost identical to each other as well as clusters almost completely driven by the primary cluster but with large outlying areas with no or modest excess risk. Epidemiological judgment must be used to determine whether events in overlapping clusters are attributable to a single or multiple outbreaks or whether the secondary cluster is of limited interest. It may not be worthwhile to investigate every event in a large secondary cluster with a much lower RI that has a large proportion of events that are also in the primary cluster.

**RIs and Inference**

Monte Carlo hypothesis testing compares the maximum likelihood value for the real data with the maximum likelihoods from each of the random replicas of the data set. For prospective analyses, SaTScan assigns an RI to each cluster. The RI is an alternative to the P value (RI=1/P value), and the greater the RI, the less likely the cluster is due to chance. If a cluster has an RI of 1 year, then under the null hypothesis and during any 1-year period, the expected number of false signals with the same and higher magnitude is 1. For rare diseases, this expected number is lower depending on cluster size restrictions. While P values are commonly used for determining statistical significance, the typical cutoff of P<.05 is not meaningful for prospective analyses. With daily analyses for 1 disease, applying a P<.05 threshold would generate 1 false signal every 20 days on average, or approximately 18 false signals per year, which is too frequent.

Increasing the number of Monte Carlo replications generating random data sets under the null hypothesis slightly increases the statistical power of the scan statistic but also increases the run time. Our base analysis uses 999 replications, with the default P value option to end early if the P value is large. The number of replications must be at least 999 to avoid unnecessary loss of power.

**Signaling Threshold**

In the base analysis, we set the signaling threshold to RI≥100 days. We think of a cluster with an RI of 100 to <365 days as a weak cluster, a cluster with an RI of 365 days to <5 years as a moderate cluster, a cluster with an RI of 5 to <100 years as a strong cluster, and a cluster with an RI of ≥100 years as a very strong cluster. P values or RI thresholds determine which clusters trigger an alert, but they should be considered alongside other factors to establish whether a cluster is of public health importance [52]. While we have suggested rules of thumb for RI interpretation, investigators should holistically interpret other cluster characteristics and apply epidemiological judgment considering the disease severity, relative risk, location, period, and patient characteristics in the line list (refer to the Cluster Investigation and Response section).

**Assessment of Analysis Design**

Our SaTScan parameter settings are derived from underlying public health and statistical principles. While we believe that our recommendations are generalizable, parameter settings may require adjustment for other diseases and jurisdictions. When using real-world rather than simulated data, there is generally no gold standard that can be used to evaluate results. For local proof of concept, one way to determine whether an analysis needs adjustments is to identify at least one known historical acute, localized, community-acquired outbreak and mimic prospective surveillance around that period to assess the speed and precision with which the outbreak would have been detected.

If an analysis consistently produces results that are unsatisfactory and data quality issues have been ruled out as a cause, then the input files or parameter settings may need fine-tuning. Issues we have encountered include missed or delayed outbreak detection, clusters too large to be useful, and too many signals to be actionable given available resources (refer to the System Fine-Tuning section in Multimedia Appendix 1).

**Built-In SaTScan Implementation and Output Interpretation Features**

SaTScan version 10.1 introduced several built-in features to simplify adopting and implementing routine prospective analyses and streamline output interpretation. These include a tool for automating multiple prospective analyses, temporal and geographical visualizations of clusters and events, line lists with information about cluster events, and a feature that allows users to send automated email alerts summarizing analysis results (refer to the Cluster Output Interpretation section in Multimedia Appendix 1 and video demonstration in Multimedia Appendix 2).

**Multiple Analyses**

When independently monitoring multiple diseases, running multiple analyses is necessary. This is easily managed using the multiple analyses feature. The only preanalysis coding required is to generate the input files in the appropriate format (refer to the video demonstration in Multimedia Appendix 2).
Temporal Graphs
Temporal graphs are useful for visualizing epidemic curves. SaTScan can produce temporal graphs that display observed and expected event counts inside and outside the geographical cluster area, marking the period before and during the cluster (Figure 2; refer to the Temporal Graphs: Supplement section in Multimedia Appendix 1).

Figure 2. SaTScan-generated temporal graph depicting the observed and expected event counts in the geographical area of the cluster during (band shaded in gray) and before the cluster temporal window.

Visualizing Clusters and Cases on a Map
SaTScan can produce maps for visualizing the spatial extent of clusters in HTML, KML, and shapefile formats. Locations of events during the study period can be added to the map and can be grouped by any variable (eg, case status, age group, and gender), distinguished using different icons. A legend that distinguishes events as being Inside Cluster, new entry; Inside Cluster, not new entry; or Outside Clusters exceeding the RI signaling threshold can be displayed. Events are also distinguished as Recent versus Prior to a date specified on the Recent Events time slider in the HTML file, by default the start date of the most likely cluster (Figure 3; refer to the Visualizing Clusters and Cases on a Map: Supplement section in Multimedia Appendix 1).

Figure 3. HTML visualization produced by SaTScan depicting 4 clusters exceeding the signaling threshold with (artificially generated) events mapped to their exact locations. Events are distinguished by disease status and whether they are newly identified in a cluster exceeding the signaling threshold. Disease status may be replaced with any categorical variable included in the case input file.

Drilldown Analysis
Geographically large clusters can be further investigated using the SaTScan drilldown tool to determine whether events are randomly distributed or clustered within a cluster (Figure 4; refer to the Drilldown Analysis: Supplement section in Multimedia Appendix 1).
**Line List of Cluster Events**

When a cluster is detected, SaTScan can produce a line list of all events in clusters exceeding the RI signaling threshold with information such as age, gender, and location of each event. This may help with determining whether an outbreak investigation is warranted, as well as with the investigation itself (refer to the Line List of Cluster Events: Supplement section in Multimedia Appendix 1).

Examining the line list is also an opportunity to check for data quality issues and other unintended drivers of signals, such as duplicate individuals, erroneous addresses, multiple events in the same household, events that do not ultimately meet the surveillance case definition, or events for which it can be determined that an available address is unrelated to an exposure site (eg, a person experiencing homelessness whose address is a hospital). Because the purpose of the system is to detect ongoing community clusters of disease, an analysis may be rerun excluding these events to determine whether the community cluster persists. At the BCD, we proactively check for and correct data quality issues (refer to the Requirements and System Setup section), but inspecting the line list can detect problems missed by other routine checks.

In addition, the line list may be useful for filtering detected clusters by the number of events with certain statuses, for example, requiring a minimum number of confirmed or probable cases to investigate. At the BCD, although we scan for clusters with as few as 2 events, we normally require ≥3 confirmed, probable, suspected, or pending events to warrant further investigation. Thus, producing a line list that includes a case status field can support cluster prioritization.

**Automated Email Alerts**

The email alert feature can be used to automatically notify up to 2 groups of recipients of analysis results. One email can notify that the analysis has been completed, irrespective of the results, and another email can notify the same or a different group of recipients when a cluster exceeds the RI signaling threshold (refer to the Email Alerts section in Multimedia Appendix 1).

**Cluster Investigation and Response**

A well-developed cluster detection system focuses staff attention on emerging outbreaks to catalyze field investigations [53]. At the BCD, disease experts interpret cluster output and determine whether to launch an investigation and response, which, depending on the disease, might involve prioritizing patient
interviews, conducting environmental investigations (eg, inspecting cooling towers or food service establishments), and conducting community outreach and education to rapidly identify outbreak sources and interrupt ongoing transmission.

**Discussion**

**Overview**

This tutorial is intended to support public health officials in understanding the details of the successful communicable disease outbreak detection system in NYC [2,12-14] and how to adapt and fine-tune a similar system for their own jurisdictions. For early outbreak detection, spatiotemporal methods are preferable to purely temporal methods (eg, the refined historical limits method [42] and other time-series analyses) because, if data are analyzed at one resolution (eg, by county and week) while an outbreak is emerging at a different resolution (eg, a collection of a few census tracts over a few days), the outbreak may be difficult to detect. Unlike other software for spatiotemporal cluster detection (eg, the ArcGIS Emerging Hot Spot Analysis tool [54]), SaTScan analyzes data using scan statistics to search flexibly over time and space rather than within arbitrary administrative boundaries while accounting for multiple comparisons. SaTScan also avoids the modifiable areal unit problem [55] when using input data at the finest geographic resolution available, allowing for more precise identification of areas with elevated rates, and has options for spatial adjustments and nonparametric temporal adjustments to account for jurisdiction-wide trends. SaTScan version 10.1 includes multiple enhancements allowing for increased customizability, automation, and output visualization, which have not previously been described in real-world applications. Assuming input data are timely, complete, and accurate, the primary limitation of the system is diminished power to detect spatiotemporal outbreaks involving very few patients or involving patients located in a long and narrow area, such as along a river [56].

**Health Equity**

Our cluster detection system supports the NYC Department of Health and Mental Hygiene’s mission to protect and promote the health of all New Yorkers. Many communicable diseases disproportionately affect residents of high-poverty areas [57]. The faster that public health officials can detect outbreaks anywhere, the sooner disease transmission can be interrupted to support health equity and harmful environmental exposures can be remediated. To minimize the number of patients excluded from spatiotemporal analyses, we maintain data quality by proactively correcting typographical errors in addresses failing to geocode and assigning persons who are unsheltered and without a geocodable address to a separate category. By selecting the space-time permutation probability model for our base analyses, we account for purely spatial patterns, such as areas with comparatively lower access to care and testing for reportable diseases. Nevertheless, if very few patients in an outbreak access care (eg, as a consequence of systemic racism), then outbreak detection may be delayed or missed entirely. Hence, better and wider access to health care will not only benefit those patients but also strengthen public health surveillance and response efforts that benefit all residents.

**Future Directions**

Going forward, we advocate for more centralized analytic technical support for outbreak detection for state, tribal, local, and territorial public health departments in keeping with the Data Modernization Initiative [58] and other public health system investments. We hope to provide video tutorials to orient new users and foster a community of users to share knowledge and best practices. While we believe our recommendations should be generalizable to other jurisdictions in the United States and internationally, our practical experience is limited to monitoring certain reportable communicable diseases in one dense, urban area. To better understand generalizability, additional jurisdictions will similarly need to add their voices to this conversation and contribute their experiences using this system. We are particularly interested in the experiences of jurisdictions covering larger geographic and rural areas; experiences using the network locations file with user-specified, non-Euclidean distances; and the adaptation of this system for additional jurisdictions will similarly need to add their voices to this conversation and contribute their experiences using this system. We are particularly interested in the experiences of jurisdictions covering larger geographic and rural areas; experiences using the network locations file with user-specified, non-Euclidean distances; and the adaptation of this system for other data streams for infectious diseases, including syndromic surveillance, social media, wastewater, antimicrobial susceptibility testing, and veterinary data.

**Acknowledgments**

ALR was supported by the Epidemiology and Laboratory Capacity for Prevention and Control of Emerging Infectious Diseases Cooperative Agreement (ELC) Coronavirus Aid, Relief, and Economic Security Act (CARES; grant NU50CK000517-01-09) funded by the US Centers for Disease Control and Prevention (CDC). ERP and SKG were supported by the Public Health Emergency Preparedness cooperative agreement (grant NU90TP922035-03-03) funded by the CDC. MK and SH were supported by the SaTScan Enhancements Project managed by the Fund for Public Health in New York City and funded by CDC ELC CARES, the CDC Foundation, and the Alfred P. Sloan Foundation. The authors thank the many colleagues at the New York City Department of Health and Mental Hygiene who have provided feedback and suggestions on the BCD’s communicable disease cluster detection system, particularly Julia Latash for reviewing this tutorial and Gretchen Culp for contributing with geographical expertise. The authors did not use generative artificial intelligence for any portion of manuscript writing.

**Authors’ Contributions**

ALR is a cluster detection analyst at the Bureau of Communicable Disease (BCD) and the lead analyst of the SaTScan Enhancements Project. MK provided statistical and analytical support. ERP developed disease-specific analytic customizations and features to support cluster interpretation and investigation at the BCD, including line lists and dynamic maps, which formed the basis for
outputs now directly produced by SaTScan as of version 10.1. MK and SH provided technical software support to the project. SG has overseen the BCD’s reportable disease spatiotemporal cluster detection analyses since 2012 and is principal investigator of the SaTScan Enhancements Project, which implemented several of the analytic enhancements described in this tutorial. ALR, MK, and SG drafted the tutorial. All authors critically reviewed and revised the tutorial for important intellectual content and gave final approval for the submitted version.

Abstract

Background: Mental health disparities have been documented among lesbian, gay, and bisexual (LGB) adults in the United States. Substance use disorders and suicidal ideation have been identified as important health concerns for this population. However, the interrelationships among these factors are not well understood.

Objective: This study aims to investigate the interrelationships among mental health, substance use disorders, and suicidal ideation among LGB adults in the United States using a population-based statewide survey.

Methods: Our study was an observational cross-sectional analysis, and the data for this study were collected from a sample of LGB adults who participated in the statewide survey. The survey collected information on mental health, substance use disorders, and suicidal ideation using validated measures. Descriptive statistics and inferential data analysis were conducted to explore the interrelationships among these factors.

Results: The results showed that LGB adults who reported higher levels of depression and drug abuse and dependence also reported higher levels of suicidal tendency and mental illness. Inferential data analysis using $\chi^2$ tests revealed significant differences in depression score ($\chi^2=458.241; P<.001$), drug abuse and dependence score ($\chi^2=226.946; P<.001$), suicidal tendency score ($\chi^2=67.795; P<.001$), and mental illness score ($\chi^2=363.722; P<.001$) among the 3 sexual identity groups. Inferential data analysis showed significant associations between sexual identity and mental health outcomes, with bisexual individuals reporting the highest levels of depression, drug abuse and dependence, suicidal tendency, and mental illness.

Conclusions: This study provides important insights into the interrelationships among mental health, substance use disorders, and suicidal ideation among LGB adults in the United States. The findings underscore the need for targeted interventions and research aimed at addressing the mental health needs of sexual minority populations. Future research should aim to better understand the underlying mechanisms driving these disparities and develop culturally sensitive and tailored interventions that
Introduction

Lesbian, gay, and bisexual (LGB) individuals encounter a multitude of health disparities stemming from their marginalized status and the strain of minority stress [1-3]. The focal points of concern encompass mental health, substance use disorders, and suicidal ideation within the LGB community [4-6]. Despite the recognition of these issues, there remains a discernible void in the comprehensive exploration of the intricate interplay among these concerns among LGB individuals within the United States.

Within the context of the LGB community, the nexus of mental health, substance use disorders, and suicidal ideation presents a complex landscape. Existing research underscores that LGB individuals are confronted with an elevated risk of grappling with mental health challenges—ranging from depression and anxiety to posttraumatic stress disorder—a consequence of societal stigma, discrimination, and violence [6-8]. The resultant minority stress often propels substance use disorders as a coping mechanism, manifesting in a higher prevalence of substance abuse and dependency among LGB individuals in contrast to the general population [9-11].

Furthermore, the vulnerability of LGB individuals to suicidal ideation and attempts surpasses that of the broader populace. The multifaceted risk factors underpinning suicidal ideation within this demographic encompass discrimination, victimization, familial or social rejection, internalized homophobia, and compromised mental health [12,13]. Remarkably, substance use disorders have been shown to further amplify the propensity for suicidal ideation and attempts among LGB individuals [5,14,15].

The intricate interlinking of mental health, substance use disorders, and suicidal ideation among LGB individuals is underscored by a nuanced interdependence [4]. For instance, compromised mental health may act as a precursor to substance use disorders, in turn fostering a milieu for the emergence of suicidal ideation. In a different trajectory, the direct influence of discrimination and victimization can accentuate both mental health adversities and heightened substance use [16-19]. In light of these multifaceted dynamics, a holistic approach to address mental health, substance use disorders, and suicidal ideation becomes imperative within the LGB community.

To this end, comprehensive interventions and policies targeting the underlying causative factors—discrimination and minority stress—are paramount to curtailting the prevalence of mental health issues, substance use disorders, and suicidal ideation among LGB individuals. Bridging this research gap, this study is dedicated to an in-depth exploration of the interrelationships among mental health, substance use disorders, and suicidal ideation among LGB adults within the United States. Leveraging a population-based statewide survey conducted in 2019 through an extensive web-based questionnaire, our study seeks to illuminate both the prevalence of these issues and the intricate associations binding them. Through these insights, we aspire to foster the development of efficacious interventions and policies designed to enhance the health and well-being of LGB individuals across the United States. The outcomes of this investigation are poised to advance the comprehension of the intricate interplay among mental health, substance use disorders, and suicidal ideation within the LGB community, thereby serving as a guiding compass for the implementation of evidence-based strategies to alleviate the burden of these issues within this population.

Methods

Setting

The study used data from the 2019 National Survey on Drug Use and Health (NSDUH), a nationally conducted population-based survey covering noninstitutionalized individuals across all 50 states within the United States.

Population

The focus was on adults aged 35 years and above, resulting in a final sample size of 59,864 individuals.

Sample

The sample consisted of individuals who participated in the 2019 NSDUH, a data set accessible through the web-based repository provided [20].

Sampling

The NSDUH used a multistage probability sampling approach for each state to ensure a representative sample of the diverse population [21].

Recruitment Process

Participants were selected through computer-assisted personal interviews and audio self-interviews, aiming to enhance the credibility of responses, especially on sensitive aspects of the survey. A remuneration was provided upon successful completion of the interview.

Data Collection

The study used a comprehensive analysis of the NSDUH data set, covering domains such as mental health, substance use, and suicidal ideation.

Data Analysis

The analysis involved the use of SPSS software (version 27.0; IBM). An observational cross-sectional analysis was conducted,
using 4 derived variables: depression score, drug abuse and dependence score, suicidal tendency score, and mental illness score. These variables were calculated from specific questions within the survey, allowing a nuanced exploration of mental health within the LGB community [22]. Descriptive statistics in this study illustrated the distribution of depression scores, drug abuse and dependence scores, suicidal tendency scores, and mental illness scores across different sexual identities. The chi-square test of independence demonstrated the association between sexual identity and socioeconomic and health characteristics, revealing significant differences in total family income, poverty level, and overall health across sexual identity groups. Inferential data analysis indicated significant differences in mean ranks of depression score, drug abuse and dependence score, suicidal tendency score, and mental illness score across heterosexual, lesbian or gay, and bisexual groups.

Variables
The meticulous assessment of mental health within the context of heterosexual, gay, and bisexual men in the United States engenders the use of 4 distinct derived variables [23].

Depression Score
Calculated through an intricate amalgamation of 8 questions sourced from the adult depression module of the survey. This module is broadly acknowledged in research circles for its efficacy in quantifying the severity of depressive symptoms and their reverberations upon an individual’s quality of life.

Drug Abuse and Dependence Score
This metric is derived through an intricate synthesis of 13 carefully curated questions, explicitly tailored to assess alcohol and drug abuse and dependence within the adult demographic. The strategic inclusion of this variable attests to the complex interrelationships between substance abuse and compromised mental health outcomes.

Suicidal Tendency Score
Forged from a set of 3 core questions, this variable delves into respondents’ perceptions and emotions surrounding suicide.

Mental Illness Score
Given the profound gravity of this issue within the realm of mental health, this variable emerges as a pivotal yardstick in evaluating the prevalence of suicidal tendencies within the study cohort.

Descriptive Analysis
The descriptive analysis results (Table 1) show the distribution of depression score, drug abuse and dependence score, suicidal tendency score, and mental illness score across different sexual identities. The sample consisted of 59,864 individuals, of which 96.2% (n=57,575) identified as heterosexual, 1.7% (n=1017) identified as lesbian or gay, and 2.1% (n=1272) identified as bisexual.

<td>0.5890 (0.40123)</td>
<td>1.3113 (1.68115)</td>
</tr>
<tr>
<td>Total</td>
<td>59,864 (100)</td>
<td>0.5594 (0.23192)</td>
<td>0.0071 (0.03458)</td>
<td>0.4792 (0.24839)</td>
<td>0.6144 (1.16840)</td>
</tr>
</tbody>
</table>

The mean depression score for heterosexual individuals was 0.5549 (SD 0.22978), while the mean depression score for lesbian or gay individuals was 0.6387 (SD 0.25316), and for bisexual individuals it was 0.6972 (SD 0.25646). The mean drug abuse and dependence score for heterosexual individuals was 0.0067 (SD 0.03306), while the mean score for lesbian or gay individuals was 0.0137 (SD 0.05186), and for bisexual individuals it was 0.0208 (SD 0.06673). The mean suicidal tendency score for heterosexual individuals was 0.4763 (SD 0.24216), while the mean score for lesbian or gay individuals was 0.5119 (SD 0.30884), and for bisexual individuals it was 0.5890 (SD 0.40123). The mean mental illness score for heterosexual individuals was 0.5932 (SD 1.14332), while the mean score for lesbian or gay individuals was 0.9518 (SD 1.44794), and for bisexual individuals it was 1.3113 (SD 1.68115).
The results indicate that individuals who identified as lesbian, gay, or bisexual reported higher scores on all 4 variables compared to those who identified as heterosexual. The percentage of the total number for each sexual identity group was consistent across all 4 variables. The minimum and maximum scores for depression, drug abuse and dependence, and suicidal tendencies were 0 and 1, while the maximum score for mental illness was 5. The SD for all 4 variables was highest for bisexual individuals, indicating greater variability in scores for this group. The mean and SD of all 4 variables are presented for the overall sample, which can serve as a reference for future comparisons with other populations.

**Chi-Square Test of Independence**

The chi-square test of independence was conducted to examine the association between sexual identity and 3 characteristics: total family income, poverty level, and overall health. The sample consisted of 59,864 individuals, of whom 96.2% (n=57,573) identified as heterosexual, 1.7% (n=1038) identified as lesbian or gay, and 2.1% (n=1253) identified as bisexual.

The results of the chi-square test of independence (Table 2) revealed that sexual identity was significantly associated with total family income ($\chi^2_{6}=97.704; P<.001$), poverty level ($\chi^2_{4}=117.163; P<.001$), and overall health ($\chi^2_{8}=32.945; P<.001$). Specifically, higher proportions of LGB individuals reported lower total family income and higher poverty levels compared to heterosexual individuals. For example, 13.2% (n=7892) of individuals reporting a total family income of less than US $20,000 were heterosexual, while 0.3% (n=180) of individuals reporting the same income level were lesbian or gay and 0.4% (n=263) were bisexual. Similarly, 11.3% (n=6767) of individuals reporting living in poverty were heterosexual, while 0.2% (n=141) were lesbian or gay and 0.4% (n=244) were bisexual (Table 2). The associations between sexual identity and total family income and poverty level were statistically significant at the $P<.001$ level.

Regarding overall health in Table 2, there were statistically significant differences in the percentage of individuals reporting excellent, very good, good, fair, and poor health across sexual identity groups. However, the differences were relatively small, and the associations were statistically significant at the $P<.05$ level. Overall, these findings suggest that sexual identity is associated with socioeconomic status and health, with LGB individuals experiencing greater social and economic disadvantage compared to heterosexual individuals.

These additional results provide more detailed information about the distribution of each characteristic within and across sexual identity groups, which may be useful for understanding patterns of inequality and designing interventions aimed at reducing disparities.
Table 2. Association between sexual identity and socioeconomic and health characteristics ($\chi^2$ test results; N=59,864). Percentages represent comparisons within different groups and sexual identity categories in the data.

Inferential Data Analysis

Inferential data analysis (Table 3) was conducted to determine whether there were significant differences in mean ranks of depression score, drug abuse and dependence score, suicidal tendency score, and mental illness score across 3 sexual identity groups: heterosexual, lesbian or gay, and bisexual. The sample consisted of 59,864 individuals, with 96.2% (n=57,599) identifying as heterosexual, 1.7% (n=1018) identifying as lesbian or gay, and 2.1% (n=1257) identifying as bisexual.

The results of the inferential data analysis revealed statistically significant differences in the mean ranks of all 4 variables across the 3 sexual identity groups. Specifically, heterosexual individuals had the lowest mean ranks for all 4 variables, while bisexual individuals had the highest mean ranks for all 4 variables. Lesbian or gay individuals had intermediate mean ranks for all 4 variables. The chi-square test of independence was used to determine the statistical significance of the differences in mean ranks. The results of the chi-square tests were statistically significant for all 4 variables (depression score: \( \chi^2 = 458.241; P < .001 \); drug abuse and dependence score: \( \chi^2 = 226.946; P < .001 \); suicidal tendency score: \( \chi^2 = 67.795; P < .001 \); and mental illness score: \( \chi^2 = 363.722; P < .001 \)). The results suggest that there are significant differences in the distribution of depression score, drug abuse and dependence score, suicidal tendency score, and mental illness score across sexual identity groups.

These findings suggest that sexual identity is an important factor to consider when examining depression, drug abuse and dependence, suicidal tendency, and mental illness. The findings also underscore the importance of addressing the specific mental health needs of sexual minority populations.

Discussion

Principal Results

In recent years, there has been growing recognition of the unique mental health needs of LGB individuals. Studies have consistently shown that sexual minority populations are at increased risk for mental health problems including depression, anxiety, substance use disorders, and suicidal ideation. These disparities have been attributed to a range of factors, including discrimination, stigma, and marginalization, as well as social and economic disadvantage [24-26].

The results of this study support these findings, demonstrating that sexual minority individuals in the United States are at greater risk for experiencing social and economic disadvantage, as well as mental health problems, compared with heterosexual individuals [27]. The descriptive statistics analysis revealed that LGB individuals were more likely to report lower total family income and higher poverty levels compared with heterosexual individuals. These differences were statistically significant, indicating a robust association between sexual identity and socioeconomic status. Furthermore, the chi-square test of independence demonstrated that a higher percentage of LGB individuals reported lower total family income and higher poverty levels compared with heterosexual individuals. These findings suggest that sexual minority populations experience greater social and economic disadvantage compared with heterosexual individuals, which may contribute to their increased risk for mental health problems.

Moreover, the inferential data analysis demonstrated that sexual minority individuals are at increased risk for mental health problems compared with heterosexual individuals. Bisexual individuals, in particular, had the highest mean ranks for depression score, drug abuse and dependence score, suicidal tendency score, and mental illness score. These findings underscore the need for targeted interventions to address the mental health needs of sexual minority populations, particularly those who identify as bisexual.

The mental health disparities experienced by sexual minority populations have important implications for health care providers, policy makers, and other stakeholders. These disparities must be recognized and addressed through the development of targeted interventions aimed at reducing stigma and discrimination, increasing access to mental health services, and addressing the social and economic factors that contribute to poor mental health outcomes among sexual minority individuals [13,28-30]. Health care providers can play a critical role in addressing the mental health needs of sexual minority populations by creating safe and supportive environments that are free from discrimination and stigma [31-34]. This may involve providing culturally sensitive care, offering support groups or counseling services that are specifically tailored to the needs of sexual minority individuals, and increasing access to mental health services through community-based organizations and other resources.

Policy makers can also play an important role in addressing the mental health needs of sexual minority populations. This may involve passing laws and policies that protect the rights of sexual minority individuals such as antidiscrimination laws and laws that ensure access to health care and other resources [35,36]. Additionally, policy makers can work to increase funding for research and intervention programs aimed at reducing mental health disparities among sexual minority populations [37]. The results of this study highlight the importance of addressing the unique mental health needs of sexual minority populations. The findings suggest that sexual minority individuals are at increased risk for experiencing social and economic disadvantage, as well as mental health problems, compared with heterosexual individuals [38]. Health care providers, policy makers, and other stakeholders must work together to develop targeted interventions aimed at reducing these disparities and ensuring that all individuals have access to the support and care they need to lead healthy and fulfilling lives.

Future Implications

The findings of this study have important implications for future research and intervention efforts aimed at addressing the mental health needs of sexual minority populations. The following section outlines several potential future directions for research and intervention in this area.

First, future research should aim to better understand the underlying mechanisms driving the mental health disparities experienced by sexual minority populations. This may involve investigating the role of discrimination, stigma, and marginalization in contributing to poor mental health outcomes among sexual minority individuals. Additionally, future research could explore the impact of other social and environmental factors, such as social support and access to health care, on mental health outcomes among sexual minority populations.

Second, future intervention efforts should aim to address the specific mental health needs of sexual minority populations. This may involve developing culturally sensitive and tailored interventions that are designed to meet the unique needs of LGB individuals. For example, interventions could include support groups or counseling services that are specifically tailored to the needs of sexual minority individuals, as well as community-based programs that provide access to mental health services and other resources.

Third, future interventions should also focus on reducing stigma and discrimination against sexual minority populations. This may involve working with health care providers and policy makers to develop and implement policies and programs that protect the rights of sexual minority individuals, increase access to health care and other resources, and reduce discrimination and stigma in health care settings.

Finally, future research and intervention efforts should also focus on the mental health needs of bisexual individuals. The results of this study suggest that bisexual individuals may be at particularly high risk for poor mental health outcomes, compared with other sexual minority populations. Therefore, interventions aimed at addressing mental health disparities among sexual minority populations should include a specific focus on the needs of bisexual individuals.
The findings of this study underscore the need for targeted interventions and research aimed at addressing the mental health needs of sexual minority populations. By developing culturally sensitive and tailored interventions, reducing stigma and discrimination, and addressing the specific needs of bisexual individuals, we can work to reduce mental health disparities and ensure that all individuals have access to the support and care they need to lead healthy and fulfilling lives.

Limitations

The primary focus of this study revolves around examining the intricate relationships between various variables within the context of mental health, substance use disorders, and suicidal ideation in LGB adults. However, it is important to acknowledge that our investigation does not extend to the assessment of specific interventions targeting these issues. Consequently, although we have successfully discerned associations between the examined variables, our study is unable to furnish insights into the effectiveness of interventions aimed at ameliorating mental health concerns, substance use disorders, or suicidal ideation among LGB adults.

This limitation not only emphasizes the scope of our study but also underscores the necessity for future research endeavors to venture into the domain of interventions. To comprehensively address the challenges faced by the LGB community in terms of mental health and well-being, further investigations should explore and evaluate the potential impact and efficacy of intervention strategies. By delving into this unexplored territory, future studies can contribute to a more comprehensive understanding of effective approaches for reducing mental health disparities, substance use issues, and suicidal tendencies within the LGB population.

Conclusion

This study highlights the need for future research and interventions that address the mental health needs of sexual minority populations. Future research should investigate the underlying mechanisms driving mental health disparities and explore the impact of social and environmental factors on mental health outcomes. Interventions should be developed that address the specific needs of minority populations including tailored support groups and community-based programs. Efforts to reduce stigma and discrimination against sexual minority individuals are also crucial. Finally, interventions should focus on the mental health needs of bisexual individuals, who may be at particularly high risk for poor mental health outcomes. By addressing these issues, we can work toward reducing mental health disparities and ensuring that all individuals have access to the support and care they need.

Data Availability

The data sets generated or analyzed during this study are available in the 2019 National Survey on Drug Use and Health (NSDUH) repository [20].

Authors’ Contributions

ASWC, HLT, and FKCW were primarily responsible for writing this manuscript. JMCH, PMKT, GW, and LML provided expert advice and recommendations throughout the discussion process. Abstract

Background: Increasingly, survey researchers rely on hybrid samples to improve coverage and increase the number of respondents by combining independent samples. For instance, it is possible to combine 2 probability samples with one relying on telephone and another on mail. More commonly, however, researchers are now supplementing probability samples with those from online panels that are less costly. Setting aside ad hoc approaches that are void of rigor, traditionally, the method of composite estimation has been used to blend results from different sample surveys. This means individual point estimates from different surveys are pooled together, 1 estimate at a time. Given that for a typical study many estimates must be produced, this piecemeal approach is computationally burdensome and subject to the inferential limitations of the individual surveys that are used in this process.

Objective: In this paper, we will provide a comprehensive review of the traditional method of composite estimation. Subsequently, the method of composite weighting is introduced, which is significantly more efficient, both computationally and inferentially when pooling data from multiple surveys. With the growing interest in hybrid sampling alternatives, we hope to offer an accessible methodology for improving the efficiency of inferences from such sample surveys without sacrificing rigor.

Methods: Specifically, we will illustrate why the many ad hoc procedures for blending survey data from multiple surveys are void of scientific integrity and subject to misleading inferences. Moreover, we will demonstrate how the traditional approach of composite estimation fails to offer a pragmatic and scalable solution in practice. By relying on theoretical and empirical justifications, in contrast, we will show how our proposed methodology of composite weighting is both scientifically sound and inferentially and computationally superior to the old method of composite estimation.

Results: Using data from 3 large surveys that have relied on hybrid samples composed of probability-based and supplemental sample components from online panels, we illustrate that our proposed method of composite weighting is superior to the traditional method of composite estimation in 2 distinct ways. Computationally, it is vastly less demanding and hence more accessible for practitioners. Inferentially, it produces more efficient estimates with higher levels of external validity when pooling data from multiple surveys.

Conclusions: The new realities of the digital age have brought about a number of resilient challenges for survey researchers, which in turn have exposed some of the inefficiencies associated with the traditional methods this community has relied upon for decades. The resilience of such challenges suggests that piecemeal approaches that may have limited applicability or restricted accessibility will prove to be inadequate and transient. It is from this perspective that our proposed method of composite weighting has aimed to introduce a durable and accessible solution for hybrid sample surveys.

Introduction
The survey sampling landscape is rapidly evolving. In an era of diminishing response rates and escalating costs, more effective survey sampling alternatives are no longer academic curiosities [1]. While the new realities suggest that departures from traditional methods are becoming inevitable, they also beckon an immediate question as survey researchers continue to experiment with hybrid sampling techniques. That is,

Are such sampling alternatives conducive to the inferential integrity of scientific surveys by reaching a representative subset of the target population in a pragmatic and cost-effective manner?

In addition to adopting multiple modes of data collection [2] it has become a customary practice to use less expensive samples selected from online panels to supplement costly alternatives from address or telephone frames [3]. The so-called opt-in panels are compiled using a potpourri of recruitment techniques, mostly relying on social media to fish for individuals willing to partake in surveys—hence the term river sampling [4]. The resulting convenience of these recruitment methods, however, is often achieved at the expense of compromising the organic representation that has been a natural byproduct of probability-based samples. This trade-off becomes of elevated concern since with samples obtained from opt-in panels, typical geodemographic weighting adjustments may no longer be adequate for ensuring their representativity [5].

It has been suggested that with such samples more granular weighting and calibration adjustments become necessary to ameliorate their compromised representations [6]. Specifically, calibration adjustments result in behavioral and attitudinal benchmarks that go beyond geographic corrections might be needed to improve the representation of survey respondents from less representative samples [7,8]. Moreover, when mixing samples secured from different sampling frames, special procedures must be used to combine the various sample components in an optimal fashion [9]. If conducted effectively, the resulting hybrid samples may address both cost and coverage challenges of traditional single-frame sample surveys—especially when surveying rare or hard-to-get cohorts.

While the literature on how to improve the external validity of survey estimates from nonprobability samples is maturing, existing studies have focused solely on surveys of adults [10-12]. Moreover, proposed methods are often theoretical in nature or certain to ad hoc techniques with limited scalability. Given the increasing inefficiencies of traditional survey sampling methodologies on the one hand, and the growing possibilities of emerging alternatives on the other, it is incumbent upon data scientists to explore innovative options that can address the evolving challenges facing the survey research community. This includes being able to produce useful inferences even when working with less-than-perfect data [13].

In this paper, we present practical weighting and calibration techniques that can be used to address the unique nuances of hybrid samples with varying representational properties, including those for the surveys of hard-to-get cohorts such as young adults. We will start with a review of the classical statistical technique known as composite estimation for combining survey estimates from 2 samples [14,15]. Next, as an extension of the methodology developed by Fahimi [16], we will introduce the method of composite weighting that is significantly more efficient, both computationally and inferentially, when pooling data from multiple surveys. For empirical illustrations, we will demonstrate results using data from 3 surveys with hybrid samples composed of probability-based components from the United States Postal Service address database and supplemental samples from online panels.

Methods

Ethical Considerations
All study procedures were conducted in accordance with the Declaration of Helsinki and its amendments. All study participants provided informed consent prior to being included in the study, which was approved by Advarra Institutional Review Board (IRB protocol numbers: Pro00010120 and Pro00009087).

Mathematics of Survey Data Integration
As mentioned earlier, there is a growing interest in hybrid methodologies that combine 2 or more independent samples with varying representational properties to reduce cost. This includes combining probability samples that could be based on random digit dialing or address-based sampling, as well as the many instances where probability and nonprobability samples are combined. Integrating survey data from independent samples provides a larger analytical database with enhanced inferential possibilities.

Data pooling is also relevant to regional surveys that are conducted independently of their national counterparts, but in which both surveys collect similar data from a common cohort. In these situations, one might be interested in combining data from a regional survey with those obtained from the corresponding subset of the national survey. For example, the National Health Interview Survey [17] and the Behavioral Risk Factor Surveillance System [18] both have national as well as local components that can be combined to produce more robust estimates at overlapping domains.

While the various algebraic building blocks of composite estimation methodology have been referenced in different textbooks and papers, to the best of our knowledge, the entire inferential machinery underpinning this cumbersome process has never been furnished in full detail in 1 place. As such, in the following section, we will provide a comprehensive
description of the mathematics of this classical methodology under varying scenarios.

**Composite Estimation Methodology**

Traditionally, the method of composite estimation has been used to blend results from different surveys to improve the robustness of the resulting estimates [19]. That is, individual point estimates from different surveys are produced and then blended together into 1 estimate at a time. In this section, we will furnish the mathematical foundation for this arduous approach before a more efficient alternative is introduced that can produce more stable estimates while significantly reducing the computational burden.

Consider a population of $N$ units from which 2 independent samples of size $n_1$ and $n_2$ have been selected. Under the conventional composition methodology, individual estimates from the 2 samples are produced separately and then combined to produce composite estimates that might be more robust. When the parameter of interest is, say population mean $\mu$, the general composite estimator will have the following form [20]:

$$\hat{\mu} = \alpha \hat{\mu}_1 + (1-\alpha) \hat{\mu}_2$$

(1)

In the above equation, $\hat{\mu}_1$ and $\hat{\mu}_2$ represent independent estimates of $\mu$ from the first and second samples, respectively. Using this decomposition, the optimal value for the blending or composition factor $\alpha$ can be obtained by minimizing the mean square error of $\hat{\mu}$, which is a function of the variance and bias of this composite estimate [21]:

$$\text{MSE}(\hat{\mu}) = \text{Var}(\hat{\mu}) + \text{Bias}(\hat{\mu})^2$$

(2)

Under this general scenario when neither of the 2 estimates can be considered unbiased, the optimal value of $\alpha$ can be obtained by [22]:

$$\alpha^* = \frac{n_1}{n_1 + n_2}$$

(3)

As mentioned earlier, a growing number of surveys complement their main probability samples with less expensive supplements secured from online panels from which the resulting estimates may not be unbiased. When probability and nonprobability samples are to be combined whereby only 1 of the 2 samples can provide unbiased estimates, say when $\hat{\mu}_1$ the optimal value of $\alpha$ becomes:

$$\alpha^* = 1$$

(4)

However, when the 2 independent estimates $\hat{\mu}_1$ and $\hat{\mu}_2$ could be assumed to have a negligible bias due to the application of survey weights, then the optimal value of $\alpha$ can be obtained by simply minimizing the variance of $\hat{\mu}$:

$$\text{Var}(\hat{\mu}) = \frac{1}{n_1} \text{Var}(\hat{\mu}_1) + \frac{1}{n_2} \text{Var}(\hat{\mu}_2)$$

(5)

The minimum of the above quadratic function of $\alpha$ is that value for which its derivative is equal to 0, that is:

$$\alpha^* = \frac{n_2}{n_1 + n_2}$$

(6)

Consequently, in this case, the optimal value of the composition factor can be obtained by [16]:

$$\alpha^* = \frac{n_2}{n_1 + n_2}$$

(7)

Furthermore, when estimates from the 2 surveys are expected to exhibit comparable variabilities as well, the above becomes a simpler function in terms of the sample sizes $n_1$ and $n_2$ and their associated unequal weighting effects (UWE) and $\hat{\mu}_2$. In this case, the optimal value of the composition factor can be obtained by [16]:

$$\alpha^* = \frac{n_2}{n_1 + n_2}$$

(8)

Finally, there are situations where it would be justifiable to assume that $\hat{\mu}_1$ and $\hat{\mu}_2$ ratio to near unity. In such instances, the optimal value of $\alpha$ reduces to a basic function of the respective sample sizes of the 2 surveys:

$$\alpha^* = \frac{n_1}{n_1 + n_2}$$

(9)

Whether any of the above simplifying assumptions can be justified or not, the fact remains that the composite estimation methodology entails operational complexities and inferential inefficiencies. First, this burdensome approach requires that composite estimates be produced 1 estimate at a time. Given that for a typical survey one must produce dozens of estimates for key outcome measures, this computationally intensive methodology requires serious time and resources.

Second, and more importantly, this piecemeal process produces estimates that are based on individual samples of size $n_1$ and $n_2$, and not the larger combined sample of size $n = n_1 + n_2$. This means relying on 2 estimates that could have been created using different methodologies with weighting adjustment granularities that will be coarser than what would be possible with a larger combined sample. In the next section, we will introduce an alternative methodology that can bypass these inefficiencies and complexities.

**Composite Weighting Methodology**

As described above, the classical composite estimation methodology is both cumbersome and inferentially inefficient. Our proposed methodology detailed here eliminates the above inefficiencies and complexities by allowing the 2 samples to be integrated first so that a single set of composite weights could be generated for estimation purposes. Specifically, instead of producing composite estimates from the unintegrated survey data 1 at a time, under this alternative, a single set of weights...
will be generated so that estimates could be produced from the combined sample. This huge convenience also benefits from all the inferential dividends the larger combined sample can offer. While the following derivation is for integrating data from 2 surveys, as demonstrated later, this scalable approach can easily apply when more than 2 surveys are involved.

For ease of illustration and without the loss of generality, we can assume there is only 1 weighting cell for poststratification purposes, and let

\[ B_{1i}: \text{Sampling base weights from sample 1, } i = 1, \ldots, n_1 \]
\[ B_{2j}: \text{Sampling base weights from sample 2, } j = 1, \ldots, n_2 \]

Based on the conventional composition method, separately poststratified weights for the 2 samples will have the following form:

\[ (10) \]

But rather than computing separate point estimates using the above 2 sets of poststratified weights and then compositing them 1 at a time, if the condition in equation 9 holds, one can create component weights that could be combined to aggregate to the same population total \( N \). The resulting weights can then be used to produce point estimates directly from the combined data without any need for piecemeal compositions. These weights could be produced by:

\[ (11) \]

Given that the above approach still requires separate poststratification of individual samples, it would be desirable if the 2 sets of base weights could be combined first and then poststratified jointly. This is a vastly superior option because it can accommodate more consistent and granular weighting adjustments, courtesy of the larger combined sample. Mathematically, this can be accomplished by a simple rescaling of individual base weights first and then combining them for a join poststratification or raking by:

\[ (12) \]

The above, however, magnifies the respondents’ base weights across the 2 samples with the same poststratification factor irrespective of any differential precision that would be associated with the sample that has better representation. The procedure described next introduces a simple calibration adjustment that could be used to remove this inequity prior to a joint poststratification.

**Calibration of Base Weights for Joint Poststratification**

In order for the alternative weighting procedure to produce final weights that are identical to the composite weights, the following must hold:

\[ (13) \]

Specifically, the above conditions would hold if the following were satisfied:

\[ (14) \]

This means that the alternative method can produce the same composite weights, provided that base weights from the 2 samples are calibrated prior to poststratification. That is when base weights from the 2 samples are first scaled to their respective sample sizes. Having done this, instead of separately poststratifying base weights from the 2 samples and then producing composite weights, one can use the proposed calibrated base weights from the 2 samples so that the 2 can be combined and poststratified concurrently.

It should be noted that the above calibration correction easily carries over to more realistic situations with more than 1 poststrata, where the underlying assumption in equation 9 is easier to satisfy. Also, one can apply the above procedure under the less restrictive condition in equation 8 when the UWE do not ratio to unity. In this more realistic situation, the corresponding base weights must be calibrated to their respective effective sample sizes as shown:

\[ (15) \]

Estimates of survey-specific UWE are often readily available, or they can be quickly approximated as a function of poststratified (or base) weights by the following formula when finite population corrections can be ignored [23].

\[ (16) \]

With the above correction applied, it would then be possible to use the resulting calibrated base weights as input for a final poststratification or raking of the combined sample using an expanded set of benchmarks. Alternatively, the same benchmarks could be used but with more granularity to improve the representation of the combined sample with respect to finer categories of the weighting variables.

Of note, the above approximation for UWE in equation 16 can also be used to assess the variability of estimates across surveys. Recognizing that variance is an estimate-specific statistic and mostly influenced by sample size and dispersion of the moments of the given estimate, UWE can be used as a relative measure of variability at the survey level as well. Typically, larger values of UWE are indicative of less representative sample surveys for which more variable weights have been needed to realign respondents vis-à-vis their population benchmarks.

**Extension and Generalization**

An extension of the above applies to instances where more than 2 surveys are to be integrated. In such situations, the existing weights for each survey can be calibrated by the following optimal composition factors to produce the final blended weights for combining 5 different samples:

\[ (17) \]
Results

To illustrate the applications of our proposed methodology, data from 3 pairs of surveys were used. Each pair was comprised of data from the Truth Longitudinal Cohort (TLC) survey and the Truth’s Continuous Tracker Online (CTO) survey. The TLC is a national representative panel of youths and young adults (aged 15-24 years) recruited via address-based sampling with online data collection. The CTO is a weekly, cross-sectional survey of participants aged 15-24 years. The CTO surveys are conducted using a sample of approximately 300 respondents per week from the national Dynata online panel. Participants of the TLC and CTO are invited to complete short online surveys about attitudes, beliefs, experimentation, and frequency of use regarding tobacco and other substances.

For the first pair, the CTO component included weekly surveys from July 20, 2020, to November 17, 2020. For the second pair, these weekly samples span from July 18, 2020, to February 24, 2021. For the third pair, the CTO component was comprised of weekly samples from July 14, 2021, to September 15, 2021. For each pair, the TLC component included surveys conducted during contemporaneous time periods. Table 1 provides a summary of the 3 pairs of TLC and CTO surveys used for this research.

For this investigation, we focused on 2 key outcome parameters, prevalence of current use (eg, at least 1 day of the past 30 days) of cigarettes and e-cigarettes. Prevalence estimates were produced separately from each sample component of each survey for respondents 15 to 17, 18 to 24, and 15 to 24 years of age after each component was weighted to basic geodemographic benchmarks of the given cohort.

Table 2 provides a summary of weighted point estimates for each survey and cohort, while Table 3 shows the corresponding overall estimates for 15- to 24-year-olds. All estimates are accompanied by their associated lower confidence limit and upper confidence limit at 95% CI, for which SEs were estimated using the method of Taylor Series Linearization in SAS [24].

To compare survey estimates produced under our proposed method of composite weighting against those using composite estimation, first the above point estimates had to be combined using the latter method. That is, point estimates from individual surveys were blended one by one using the coarse weighting methodology each sample survey could tolerate. Table 4 provides a summary of the resulting composite estimates by survey pair, cohort, and outcome measure.

Subsequently, composite weights were computed for each sample pair using our proposed methodology outlined above. These weights were computed for the combined TLC and CTO samples, where more granular weighting adjustments were possible due to larger sample sizes. Moreover, additional calibration adjustments were applied to the combined sample for which the needed benchmarks were generated from the TLC sample component for each survey pair. These adjustments included corrections with respect to the following behavioral attributes, which were shown to differentiate between young adult respondents from online panels and their cohorts. (1) Length of residence: about how long have you lived at your current address? (2) Household (dwelling) type: which of the following best describes your home? (3) Financial comfort: how would you describe your family’s overall financial situation? (4) Living with parents: do you currently live in a household with at least 1 of your parents? (5) Social media influencer: do you like to be a social media influencer?

While the rationale for the above calibration adjustments for general population surveys is detailed in [6,10], for the CTO surveys further investigations were carried out to identify differentiating attributes unique to teens and young adults. It is worth noting that for instances when a probability sample component like the TLC is not available in parallel, it is possible to use government sources, such as the monthly Current Population Survey or the American Community Survey, to secure relevant benchmarks for calibration adjustments.

It is of particular importance to note that the above calibration adjustments would not have been possible under the traditional composition methodology, whereby estimates are generated from individual surveys and then combined. Table 5 provides a summary of the resulting estimates produced by integrating the TLC and CTO sample components first and then weighting them to a more granular set of benchmarks and calibration adjustments listed above.

While independent estimates of tobacco use behaviors among teens and young adults can vary greatly due to methodological differences between their corresponding surveys, the following statistics from the National Youth Tobacco Survey [25] conducted by the Centers for Disease Control and Prevention were used to assess the external validity of estimates produced using our proposed methodology. Confounding differences among surveys could be due to study design and mode of administration, as well as other differences in periodicity and questionnaire wording. Cognizant of these differences, nonetheless, our estimates using composite weighting methodology produce comparable estimates to those from the National Youth Tobacco Survey 2020, as summarized in Table 6.

Discussion

Principal Findings

Conducting credible survey research in the 21st century is an endeavor subject to evolving challenges that require thinking outside of the traditional survey sampling toolbox. The proliferation of such challenges has had 2 distinct impacts on survey sampling. On the one hand, there are emerging improvisational methods of sampling and weighting that, while expedient, are void of scientific underpinnings. On the other, there is a growing disenchantment with traditional methods that
Despite their complex and computationally intensive nature, struggle with the new realities of the digital age. Our proposed method of composite weighting addresses both deficiencies, by offering an accessible approach that is soundly grounded in inferential sciences.

The statistical machinery, survey researchers have relied upon for decades, made it possible to make measurable inferences about target populations when samples of modest size are selected from complete sampling frames; all sampling units carry known and nonzero selection probabilities; and surveys achieve near-perfect rates of response [26]. For various reasons, but most notably the growing rates of nonresponse and survey costs, many of the surveys conducted these days struggle to fulfill the fundamental tenets of this sampling paradigm [27-29]. While such violations have been commonplace and routinely discounted by market researchers for whom theoretical considerations are often trumped by cost and time constraints, arguably, even large-scale government surveys are no longer exempt from such challenges [30].

A strategy that is gaining popularity for dealing with the rising costs and coverage challenges of surveys is to combine 2 or more independent samples selected from separate sampling frames with varying representations of the target population. In particular, such hybrid alternatives can pay considerable dividends when survey data secured from certain sample components are significantly less costly. There are also instances when multiple samples are required for the design of a study, while in other situations existing data from different surveys are pooled to address the size and analytical needs of a given research.

In comparison to the traditional method of composite estimation whereby separate estimates are combined from different surveys 1 at a time, our proposed composite weighting methodology for integrating survey data offers at least 5 distinct advantages.

First, the method of composite weighting is less cumbersome than that of composite estimation because it enables researchers to work with a single data file and not multiple sets of data and weights from unintegrated surveys.

Second, an integrated database that is larger than any of the individual sample components accommodates more nuanced weighting adjustments than what might be possible with individual surveys. This becomes especially appealing when one of the surveys is based on a small sample size, whereby coarse weighting can fail to improve the representation of its respondents.

Third, integrated survey data allows more in-depth analyses, particularly when comparisons of smaller analytical subgroups are of interest. Such deep-dive multivariate analyses are not feasible when producing separate estimates from individual surveys, some of which could be of modest size.

Fourth, related to the above, survey estimates from the resulting integrated data will be subject to smaller and consistently calculated SEs courtesy of the larger sample size and a single data set to make inferences from. Composite weighting eliminates extraneous variabilities that are inevitable under composite estimation due to the application of inconsistent weighting procedures for individual surveys, such as the use of different benchmarks, raking algorithms, and weight-trimming rules.

Finally, and perhaps most importantly, composite weighting offers a unique advantage that is of particular importance as interest in combining data from probability and nonprobability samples continues to grow. Specifically, this methodology offers the possibility of additional calibration adjustments of respondents from nonprobability samples to benchmarks that are not externally available but can be generated from the “more representative” subset of respondents.

The above advantages are particularly relevant to public health research initiatives, as they often require faster data collection turnarounds from large pools of respondents. Unlike opinion polling and commercial survey applications that typically aim for “good-enough” estimates of trends, health studies often require reliable assessments that can guide public policies. It is in this context that unreliable inferences, or those that are reliable but slow to produce, can have dire consequences or be obsolete.

Yet just like any new methodology, what we have proposed is not a panacea or free from limitations. For instance, neither this approach nor any other can produce measurable inferences from data secured from sample surveys that fail to represent their target cohort due to systematic exclusions. Another potential limitation worth mentioning is the technical sophistication the application of this methodology may require. While substantially less complicated and resource-intensive as compared to the method of composite estimation, our proposed method still requires some level of inferential acumen and know-how. Then again, working with complex surveys that entail mixing data from multiple sources is an undertaking that requires a decent level of survey sampling and inferential familiarity to begin with. If tasked with the challenge of mixing data from multiple surveys, our hope is that researchers will find the option of composite weighting more accessible and efficient.

Concluding Remarks

Despite the growing challenges facing the survey research community, practitioners should not succumb to suboptimal practices for cost-saving purposes alone. Such unilateral guidelines have contributed to the stigma that commercial surveys have inadequate concern for rigor. On the other hand, undue allegiance to traditional methods of survey sampling can also confine researchers to inefficient practices that are losing their pragmatism. This position becomes particularly untenable when such adherences are simply for the sake of preserving the optics.

Traditional methods of survey research are becoming inefficient, both with respect to data quality and cost, begging for novel and pragmatic alternatives that do not forego rigor. It is from this perspective that we hope the methodology we have furnished in this paper could address some of such inefficiencies, enabling survey researchers to take fuller advantage of the data resources they have at their disposal. Results from the detailed comparisons we have exhibited in this paper show that composite weighting methodology is vastly less cumbersome

https://publichealth.jmir.org/2024/1/e48186
and produces estimates that are at least as reliable as what can be produced using composite estimation.

As a final parting note we would like to reiterate that with declining response rates, surveys require progressively more comprehensive weighting adjustments to restore the representation of their respondents. As such, it is not advisable to shy away from more aggressive weighting and calibration adjustments only to keep the resulting UWE at bay [31]. Of course, this is fully cognizant of the proverbial seesaw occupied on one side by bias and variance on the other. Above all, it is imperative to retain full transparency about adopted methodologies and their potential shortfalls as we explore new possibilities for survey sampling in the digital age.

Acknowledgments
This research would not have been possible without the invaluable contributions of an impressive cadre of researchers from the Truth Initiative: ECH, EKD, and JMK, as well as Donna Vallone of Schroeder Institute. Special thanks are offered to XY and EC of Ipsos USA for their impeccable statistical support, as well as AG and LO for their project management. A data sharing agreement is required for the use of all data used in this research. Approved investigators may access data sets via an analytic portal owned and administered by Truth Initiative. Finally, we acknowledge that generative artificial intelligence has not been used in any shape or form in the creation of this paper.

Data Availability
The data sets generated and analyzed during this study are not publicly available due to their proprietary nature and privacy concerns; however, they can be made available from the corresponding author on reasonable request.

Conflicts of Interest
None declared.

Abstract

Background: The World Health Organization aims for the global elimination of cervical cancer, necessitating modeling studies to forecast long-term outcomes.

Objective: This paper introduces a macrosimulation framework using age-period-cohort modeling and population attributable fractions to predict the timeline for eliminating cervical cancer in Taiwan.

Methods: Data for cervical cancer cases from 1997 to 2016 were obtained from the Taiwan Cancer Registry. Future incidence rates under the current approach and various intervention strategies, such as scaled-up screening (cytology based or human papillomavirus [HPV] based) and HPV vaccination, were projected.

Results: Our projections indicate that Taiwan could eliminate cervical cancer by 2050 with either 70% compliance in cytology-based or HPV-based screening or 90% HPV vaccination coverage. The years projected for elimination are 2047 and 2035 for cytology-based and HPV-based screening, respectively; 2050 for vaccination alone; and 2038 and 2033 for combined screening and vaccination approaches.

Conclusions: The age-period-cohort macrosimulation framework offers a valuable policy analysis tool for cervical cancer control. Our findings can inform strategies in other high-incidence countries, serving as a benchmark for global efforts to eliminate the disease.

Introduction

Cervical cancer remains the fourth most common cancer in women worldwide [1]. The World Health Organization (WHO) [2] called for the global elimination of cervical cancer; elimination is defined as an incidence of fewer than 4 cases per 100,000 women-years. Eliminating cervical cancer requires scaling up the human papillomavirus (HPV) vaccination of girls and cervical screening [3].

Randomized trials and follow-up studies are valuable for evaluating the short-term and medium- to long-term impacts of public health intervention policies [4,5]. In contrast, modeling studies offer the ability to estimate and forecast effects over an extended timeframe and can also simulate outcomes across a range of future scenarios [6]. Numerous microsimulation modeling studies have been conducted to assess the necessary time frame and intervention strategies for the elimination of cervical cancer [3,7-14]. These studies rely on numerous assumptions, such as oncogenic potentials, infection dynamics and immunity of HPV, and the natural history of cervical cancer. They require many parameters that are difficult to obtain.

A better alternative is to use macrosimulation modeling. From a macroscopic perspective, disease incidence rates are primarily influenced by 3 temporal factors: age, period, and cohort. The age-period-cohort (APC) model, which accounts for these factors, has been recently used to project future disease burdens [15-19]. This methodology can also estimate future incidence rates of cervical cancer under existing conditions, known as the status quo. In a hypothetical “what if” scenario involving a public health intervention, the baseline incidence rate would be reduced by a certain fraction—captured by the population attributable fraction (PAF) associated with the intervention. By combining the APC model’s baseline estimates with the PAF to factor in reductions from interventions, we can effectively forecast future cervical cancer incidence rates under specific public health programs.

Well-organized cytology-based cervical screening programs have effectively reduced the incidence rates of cervical cancer in many countries [20-23]. Since 1995, Taiwan’s Health Promotion Administration has offered organized cytology-based screenings for women aged 30 years and older. Consequently, the age-standardized incidence rate of invasive cervical cancer in Taiwan sharply declined from 28.0 per 100,000 woman-years in 1997 to 8.2 in 2016. Despite this progress, the incidence rate in Taiwan has yet to meet the criteria for the elimination of cervical cancer. A more effective form of HPV-based screening, which has shown to be superior to cytology-based methods [24], may soon be adopted for mass screening. Projecting future trends in cervical cancer incidence under new approaches such as HPV-based screening has been challenging using microsimulation models. However, these projections may be more feasible through macrosimulation techniques.

In this study, macrosimulation was used, combining APC modeling with PAF calculation, to estimate when cervical cancer could be eliminated in Taiwan. We explored the potential to expedite this timeline by implementing more extensive population-based cervical cancer screening (either cytology or HPV based) and enhancing HPV vaccination coverage.

Methods

Data Source

In this study, we collected data on cervical cancer cases diagnosed between 1997 and 2016 using the International Classification of Diseases for Oncology, Third Edition code C53. Our extensive data set, which includes population information, originated from the Taiwan Cancer Registry—a meticulously maintained nationwide system established by the Ministry of Health and Welfare. The registry diligently captures and synthesizes information from patients who are newly diagnosed with malignant cancer in hospitals with 50 or more beds in Taiwan, a country with a population size of approximately 23 million. The data quality and completeness of the Taiwan Cancer Registry database have consistently adhered to standards of excellence. Specifically, the completeness is 98.4% (14,833/218,239); the percentage of cases with death certificate only is 0.9% (1079/118,583); the mortality versus incidence ratio is 45.1% (202.89/449.59); the percentage of morphological verification is 93% (109,273/117,504) for all sites combined and 97.6% (103,812/106,423) for all sites excluding the liver; and the data timeliness is 14 months. These statistics demonstrate that the Taiwan Cancer Registry is one of the highest-quality cancer registries in the world [25-27]. The world standard population (WHO 2000 [28]) proportions were used to calculate age-standardized incidence rates. The projected elimination year was defined as the first year when the age-standardized incidence rate would fall below 4 cases per 100,000 women-years [8].

Macrosimulation

The APC models were used to project future cervical cancer incidence rates under the status quo. Due to the scarcity of cases in patients younger than 30 years of age, this age group was excluded from the APC modeling. Instead, the average incidence rate between 1997 and 2016 was used as the projected rate for women younger than 30 years of age. This approach likely makes our future decline estimates slightly conservative. However, the impact is minimal as the incidence rate for this age group contributes only a small fraction to the overall rate. For women aged 30 years and older, the projections are outlined below. First, an ensemble of 265 APC models was constructed using data from 1997 to 2006 as the training set. The APC models were then applied to project incidence rates from 2007 to 2016 as the validation set. These projections underwent year-on-year attenuation adjustments ranging from 0% and 5% to 100%, resulting in 5565 different projection sets. The symmetric mean absolute percentage error (SMAPE) was used to quantify the prediction error for each projection model, and the model with the lowest SMAPE was selected. Finally, the selected model, fine-tuned with all available data from 1997 to 2016, was used to project future incidence rates up to the year 2050. These projections incorporated the chosen attenuation factor. The future projected incidence rates were determined by calculating age-standardized rates across all age groups.
those younger than 30 years of age, the average incidence rate from 1997 to 2016 was used. For individuals aged 30 years and older, the rates forecasted by the selected APC model were used.

Next, we calculated the PAFs for various scenarios of cervical cancer screening and HPV vaccination. The PAF in this study was defined as the proportionate reduction in the incidence rate of cervical cancer due to a specific intervention program, as in the following equation [29]:

\[
\text{Incidence rate under a specific intervention} = \text{incidence rate under the status quo} \times (1 – \text{PAF under a specific intervention})
\]

where IRR\(_i\) is the incidence rate ratio between the \(i\)th level of the screening or vaccination variable and the reference level \((i=1)\) of no screening and no vaccination, and \(P_i\) and \(P_j\) are the proportions of women in the \(i\)th level of the screening or vaccination variable under the status quo and the specific interventions, respectively.

The incidence rate ratios of cytology-based screening, HPV-based screening, and HPV vaccination were based on the studies of Chen et al [30], Ronco et al [24], and Lei et al [5]. We assume that HPV vaccination administered to 13-year-old girls affords them lifetime effectiveness against cervical cancer [31]. HPV-based screening may have a higher false positive rate, so it is suggested that screening be performed once every 5–10 years [24]. Currently, only cytology-based screening is available in Taiwan, and HPV-based screening still needs to be implemented. We also assume that the incidence rate ratios of a joint program involving both interventions are the products of 2 programs involving only the respective intervention (Table S1 in Multimedia Appendix 1). In 2016, the proportion of women with cytology-based screening more than twice in 6 years was 43.5% (data provided by Taiwan’s Health Promotion Administration), and a negligible proportion of women had received HPV vaccination in Taiwan (Table S2 in Multimedia Appendix 1).

We assume a gradual increase from 2023 to 2030 in the proportion of women undergoing cytology-based screening more than twice within 6 years from the current 43.5% to 70%. We also assume a new intervention plan from 2023 that involves switching from cytology-based screening twice within 6 years to HPV-based screening. The goal is to increase the overall screening proportion from 43.5% to 70% by 2030. We set an intervention scenario to achieve HPV vaccination coverage of 90% since 2018 (the Health Promotion Administration in Taiwan has offered HPV vaccination for 13-year-old girls since 2018). Furthermore, the potential impact of combining cytology-based and HPV-based screening with HPV vaccination in 2 different scenarios was evaluated. For simplicity, we assume that compliance with cytology-based screening, HPV-based screening, and receipt of the HPV vaccination are 3 independent events. The referral rate for positive cervical cytology results, facilitated by community nurses, exceeds 90%. Additionally, Taiwan’s health care system offers almost universal coverage, making effective cervical disease management an integral part of the existing health care infrastructure. As such, this study did not specifically factor in the concept of effective management.

We used equation 1 to calculate the PAFs for all 6 intervention scenarios considered in this study. The incidence rate under a specific intervention was then calculated using the following equation:

\[
\text{Incidence rate under a specific intervention} = \text{incidence rate under the status quo} \times (1 – \text{PAF under a specific intervention})
\]

Data management and analyses were performed using SAS statistical software (version 9.4; SAS Institute Inc).

Ethical Considerations

The study was based solely on deidentified aggregate data, without access to individual records. This study protocol was approved by the National Taiwan University Research Ethics Committee (NTU-REC 202101HM030) and the data release review board of the Health Promotion Administration, Ministry of Health and Welfare in Taiwan. All methods were performed in accordance with the relevant guidelines and regulations. In addition, the National Taiwan University Research Ethics Committee waived the requirement for informed consent due to the lack of personal information and secondary data in the study.

Results

The selected projection model under the status quo was a polynomial APC model with a log link function and 55% attenuation (SMAPE=6.1%). Figure S1 in Multimedia Appendix 1 presents the observed and model-fitted age-standardized (WHO 2000 standard population [28]) cervical cancer incidence rates from 1997 to 2016 and the projections from 2017 to 2050. A declining trend in cervical cancer incidence rate was observed in the 20-year study period. In 2016, under the status quo of cytology-based screening compliance of 43.5% and no HPV vaccination, the projected cervical cancer incidence rate will not fall below 4 new cases per 100,000 women-years by 2050. Figure 1 shows the expected incidence rates of cervical cancer from 2023 to 2030 under 3 scenarios: the current situation, if adherence to cytology-based screening increases to 70%, and if adherence to HPV-based screening rises to 70%. The projection indicates that cervical cancer in Taiwan will not reach the goal of elimination by 2050 if cytology-based screening compliance remains at the current level of 43.5%. However, if cytology-based and HPV-based screening compliance are increased to 70%, cervical cancer elimination can be achieved by 2047 and 2035, respectively.

Figure 2 shows the projected cervical cancer incidence rate with an HPV vaccination coverage of 90%. An HPV vaccination coverage of 90% will eliminate cervical cancer by 2050. Figure 3 presents the projected cervical cancer incidence rates if cytology-based or HPV-based screening is applied (compliance raised to 70%) in conjunction with HPV vaccination (90% coverage). Both joint interventions will help to achieve cervical cancer elimination before 2050 and at an earlier year (2038 and 2033, respectively).

The years of elimination (if before 2050) for the various scenarios are shown in Table 1. For comparison, the same table
also shows the results when the Segi standard population [32] was used for age standardization. The time to elimination was expedited by a few years when the Segi standard was used.

**Figure 1.** Future projections of age-standardized cervical cancer incidence rate per 100,000 person-years under the status quo, cytology-based, and HPV-based screening. HPV: human papillomavirus.

**Figure 2.** Future projections of age-standardized cervical cancer incidence rate per 100,000 person-years under HPV vaccination. HPV: human papillomavirus.
Figure 3. Future projections of age-standardized cervical cancer incidence rate per 100,000 person-years under scenarios of joint cytology-based and HPV-based screening with HPV vaccination. HPV: human papillomavirus.

\(^c\)The projected age-standardized cervical cancer incidence rate would not fall below 4 cases per 1000,000 women-years before 2050.

Discussion

Principal Findings

In summary, our macrosimulation analysis projected that Taiwan could eliminate cervical cancer by 2050 through 70% compliance with screening (cytology based or HPV based) or 90% coverage of HPV vaccination. Specifically, the projected elimination years are 2047 or 2035 for screening (cytology based or HPV based, respectively), 2050 for vaccination, and 2038 or 2033 for a combination of both screening and vaccination. This study confirms earlier microsimulation findings that increased screening can fast-track cervical cancer elimination [3,7-14]. Our macrosimulation methodology offers both adaptability and ease of implementation, as demonstrated by the SAS code in Multimedia Appendix 2. Unique to Taiwan is its high HPV vaccine coverage, a legacy of successful vaccine campaigns, facilitated by extensive health care infrastructure [33]. In stark contrast, Japan saw HPV vaccine coverage collapse from 70% to nearly 0% between 2013 and 2019 due to a crisis [14].

Cytology-based screening is crucial for cervical cancer management [34]. It is recommended that women aged 30 years and older should undergo cytology-based screening at least once every 3 years (effective screening). Historically, cervical cancer incidence has steadily decreased because of opportunistic and organized cytology-based screening [35]. From 1974 to 1984, Taiwan launched an opportunistic cytology-based screening program for cervical cancer, facilitated through partnerships between the cancer society and gynecology and obstetrics clinics [36]. A major turning point came in 1995 when Taiwan’s Health Promotion Administration set up an organized cytology-based screening initiative targeting women aged 30 years and older. This represented a significant advancement in Taiwan’s efforts to tackle cervical cancer. Consequently, the age-standardized incidence rate for invasive cervical cancer in Taiwan dropped from 28.0 per 100,000 woman-years in 1997 to 8.2 per 100,000 woman-years in 2016. This reduction marked a shift from Taiwan being a high-risk region to becoming a low-to-medium-risk area for the disease (the figure was presented in Figure S2 in Multimedia Appendix 1).
However, the need for improved compliance with effective screening is a global issue, and Taiwan is no exception [37]. Although approximately 82% of Taiwanese women have undergone at least one screening since 1995, the overall effectiveness of screening implementation remains below the desired level. The participation rate for triennial screenings, aimed at women aged 30 to 69 years, is only around 54%. Moreover, participation drops even further among women aged 69 years and older. These data underscore the pressing need for improved outreach and accessibility to achieve more comprehensive and impactful screening initiatives [38]. Various strategies have been adopted to promote screening, including educational interventions, physician reminders, incentive programs, mass media campaigns, outreach to community members, and leveraging community health workers [39-41]. Despite all these efforts, the compliance rate of effective screening in 2016 was only 43.5% in Taiwan. Our analysis indicates that cervical cancer in Taiwan can be eliminated in 2047 only if there is 70% compliance with cytology-based screening. To enhance the effectiveness of screening, strategies could include distributing informative pamphlets to schoolchildren to share with adult women in their families; authorizing self-collected HPV screening kits (Taiwan currently only approves the use of clinical-based HPV screening kits); and targeting older, previously unscreened and unvaccinated groups.

Cytology-based screening as a primary mode of cervical cancer screening has been gradually replaced by HPV-based screening, which has 70% greater protection against invasive cervical cancer [24]. HPV testing recommended by WHO may increase engagement in cervical cancer screening programs [42]. Taiwan has been implementing cytology-based screening for more than 30 years; however, compliance still needs to be improved. The Health Promotion Administration in Taiwan is also considering implementing more effective HPV-based screening. This study demonstrated that HPV-based screening could achieve the goal of eliminating cervical cancer more swiftly than cytology-based screening, given the same conditions. Taiwan has successfully decreased the incidence rate of cervical cancer through an organized cytology-based screening program. It is now considering the implementation of HPV-based screening to achieve the goal of elimination faster. This approach can be used as a model for other countries.

If HPV vaccine efficacy wanes, it may alter cervical cancer prevention and screening protocols [43]. However, long-term studies since the vaccine’s 2006 introduction show sustained high antibody levels, suggesting it could offer near-lifelong cervical cancer protection [44-50]. However, multiple factors hinder the implementation and scaling-up of HPV vaccination, such as vaccine supply shortage [51,52], budgetary constraints [53], and hesitancy due to vaccine-related side effects [54]. Globally, only a few high-income countries have offered the HPV vaccine for the target age group with a coverage rate above the WHO-recommended threshold of 90% [51,55]. By comparison, the HPV vaccination program introduced in Taiwan in 2018 has been relatively successful; the coverage rates were 76.8% in 2018 and 86.9% in 2019, respectively. It is very likely to further increase this rate to 90% in 2022 (scenario 3 in this study); if this happens, we project that cervical cancer in Taiwan can be eliminated in 2050. The effect of HPV vaccination (on 13-year-old girls) can only appear after the vaccinated cohort reaches the high-risk ages (45 years and older) for cervical cancer—the cohort effect. This is why it takes a longer time to achieve the goal of cervical cancer elimination with an HPV vaccination coverage of 90% (scenario 3 in this study) compared to cytology- or HPV-based screening with a compliance of 70% (scenarios 1 and 2 in this study), reaching the goal in 2050 versus 2047 or 2035.

WHO announced the 90-70-90 target to achieve cervical cancer elimination: HPV vaccination coverage rate of 90% of girls by the age of 15 years, twice-lifetime screening of 70% of vaccinated women (by the age of 35 and 45 years), and treatment of 90% of women with the cervical disease [23]. The respective latest figures in Taiwan were 90% (HPV vaccination coverage rate; the actual figure could be higher because some women were vaccinated at their own expense and were not tallied), 43% (effective screening compliance rate), and 90% (proportion of treated for women who screened positive), with the effective screening compliance rate lagging far behind the 90-70-90 target. Our analysis shows that if the effective screening compliance rate can be increased to 70% in conjunction with an HPV coverage rate of 90%, Taiwan can achieve the goal of cervical cancer elimination in 2038 (scenario 4 in this study). However, it is worth noting that although the incidence rates of cervical cancer among all age groups have declined in Taiwan, there is a slightly increased trend in the 30-34 years age group among the most recent birth cohort (Figure S3 in Multimedia Appendix 1). This warrants attention from health authorities.

**Strengths and Limitations**

The APC macrosimulation framework developed in this study is a useful policy analysis tool for disease control. The policy analysis results in this study can serve as a reference for other countries with a high incidence of cervical cancer. The strengths of this study lie in the rigorous analytical models we used and the high-quality data we used. Nonetheless, the study is not without limitations. First, we do not have access to individual-level data, and the study is therefore prone to ecological fallacy. Second, we used data spanning from 1997 to 2016 as the basis for making future predictions. This data range is unaffected by the delayed diagnosis and registration of cancer cases that occurred due to the COVID-19 pandemic [56]. Consequently, our short- to medium-term projections for cervical cancer incidence may be biased by the COVID-19 pandemic. Nonetheless, this is unlikely to affect the study’s primary conclusions, which focus on long-term projections. Finally, public funding for HPV vaccination in Taiwan is restricted to 13-year-old girls, leaving female individuals in other age groups the choice to opt for private vaccination. This study concentrates mainly on the consequences of the publicly funded HPV vaccination program and does not incorporate the likely effects of privately funded vaccinations in a wider age range. The high rate of HPV vaccination also fosters benefits through herd immunity [57], which could mean that our evaluations are underestimating the full potential impact of the vaccination program.

Abstract

Background: Lung cancer remains the leading cause of cancer-related mortality globally, with late diagnoses often resulting in poor prognosis. In response, the Lung Ambition Alliance aims to double the 5-year survival rate by 2025.

Objective: Using the Taiwan Cancer Registry, this study uses the survivorship-period-cohort model to assess the feasibility of achieving this goal by predicting future survival rates of patients with lung cancer in Taiwan.

Methods: This retrospective study analyzed data from 205,104 patients with lung cancer registered between 1997 and 2018. Survival rates were calculated using the survivorship-period-cohort model, focusing on 1-year interval survival rates and extrapolating to predict 5-year outcomes for diagnoses up to 2020, as viewed from 2025. Model validation involved comparing predicted rates with actual data using symmetric mean absolute percentage error.

Results: The study identified notable improvements in survival rates beginning in 2004, with the predicted 5-year survival rate for 2020 reaching 38.7%, marking a considerable increase from the most recent available data of 23.8% for patients diagnosed in 2013. Subgroup analysis revealed varied survival improvements across different demographics and histological types. Predictions based on current trends indicate that achieving the Lung Ambition Alliance’s goal could be within reach.

Conclusions: The analysis demonstrates notable improvements in lung cancer survival rates in Taiwan, driven by the adoption of low-dose computed tomography screening, alongside advances in diagnostic technologies and treatment strategies. While the ambitious target set by the Lung Ambition Alliance appears achievable, ongoing advancements in medical technology and health policies will be crucial. The study underscores the potential impact of continued enhancements in lung cancer management and the importance of strategic health interventions to further improve survival outcomes.

Introduction

Lung cancer is the leading cause of cancer-related deaths worldwide. Approximately 1.8 million people worldwide died of lung cancer in 2020, accounting for 18% of all cancer deaths [1]. The disease typically lacks noticeable symptoms in its early stages, leading to late diagnoses in many patients. By the time symptoms such as coughing, shortness of breath, weakness, and chest pain manifest, the prognosis is often poor [2]. Lung cancer survival rates have improved slowly compared with other types of cancer [2-4]. The 5-year survival rate for lung cancer was approximately 10%-20% and is among the lowest of all types of cancer [5,6]. In Taiwan, lung cancer has been the leading cause of cancer death since 2010, with a 5-year survival rate of 25% [7].

Enhanced screening and early diagnosis are critical for improving prognosis and reducing mortality rates associated with lung cancer. The adoption of various diagnostic techniques, including blood tests and computed tomography scans, has significantly improved the accuracy and precision of lung cancer diagnoses [8-11]. Moreover, the advancement of noninvasive diagnostic methods has expedited the time required to reach a diagnosis [12-16]. In Taiwan, the implementation of low-dose computed tomography (LDCT) for lung cancer screening has been particularly effective. Data indicate a notable improvement in lung cancer survival rates across all patient groups from 2010 to 2016 [17].

In July 2019, the Lung Ambition Alliance, an international coalition dedicated to lung cancer control, announced its goal to double the 5-year survival rate for lung cancer by 2025 [18]. For this study, we used data from the Taiwan Cancer Registry, a national population-based registry known for its high-quality data [19,20]. We applied the survivorship-period-cohort (SPC) model, a recently developed method for nowcasting and forecasting cancer survival rates [21], to predict the future survival of patients with lung cancer in Taiwan. This analysis aims to assess the feasibility of achieving the coalition’s ambitious goal.

Methods

Case Definitions

Lung cancer data were obtained from the Taiwan Cancer Registry. Lung cancer cases were defined per the International Classification of Disease for Oncology, Field Trial Edition (ICD-O-FT) code 162 and International Classification of Disease for Oncology, Third Edition (ICD-O-3) codes C33 and C34. This study included patients diagnosed with lung cancer between July 1, 1997, and June 30, 2018. We linked patients to death registration data and tracked the date of death to December 31, 2018.

The year of diagnosis was defined as the middle of that year to the middle of the following year. For a given year of diagnosis, the number of survivors in the first year after diagnosis was the number of patients who did not die by the end of the following year. The first-year survival rate was calculated by dividing the number of patients who survived the first year after diagnosis by the number of patients in that year. Patients who survived the first year of diagnosis were followed up for another year, and the number of patients who did not die was the number of survivors in the second year after diagnosis. The second-year survival rate was calculated by dividing the number of survivors in the second year after diagnosis by the number of survivors in the first year. We calculated the survival rates for the third, fourth, and fifth years after diagnosis by using the same approach.

Definitions of Survival Rates

The unit of analysis in this study was the 1-year interval survival rate, defined as the probability that a patient with cancer currently alive will survive for at least 1 more year. The 1-year interval survival rates for patients with lung cancer based on the year after diagnosis (survivorship), calendar year (period), and year of diagnosis (cohort) are presented in Figure 1 (a total of 95 shaded cells with observed values). The 5-year survival rate, calculated using the cohort approach, is the product of the five 1-year interval (first to fifth years) survival rates for patients diagnosed in the same year. We extrapolated the 1-year interval survival rate to the 2020 year of diagnosis (25 unshaded cells in Figure 1). In the cohort approach, the 5-year survival rate for calendar year 2025 is the 5-year survival rate for patients diagnosed in 2020.
**Figure 1.** The unit of analysis for this study. The values in the cells are the 1-year interval survival rates (%) of lung cancer in Taiwan (shaded cells: observed values and unshaded cells: projected values from the survivorship-period-cohort model).

**SPC Model**
This study used the SPC model proposed by Peng et al [21] to predict survival rates. The independent variables were the year after diagnosis (survivorship), calendar year (period), and year of diagnosis (cohort). These 3 variables are perfectly collinear (cohort + survivorship = period), resulting in a nonidentifiability problem. The nonidentifiability problem leads to infinite possibilities for parameter estimation. However, this does not prevent the prediction of the 1-year interval survival rate because all possible parameter estimates yield the same fitted value. The overall effects of period and cohort were divided into “slopes” and “curvatures” for extrapolation. We projected that the future period and cohort slopes would be identical to those observed in the empirical data and used the restricted cubic spline method to fit the period and cohort curvatures of the empirical data to extrapolate into the future. A more detailed description of the SPC model can be found in Peng et al [21].

**Training and Validation**
We used the 1-year interval survival rates from 1998 to 2013 as the training data set (70 lightly shaded cells in Figure 1) and the 1-year interval survival rates from 2014 to 2018 as the validation data set (25 darkly shaded cells in Figure 1) to calculate the symmetric mean absolute percentage error for the SPC model. We used all observed data (95 shaded cells in Figure 1) to predict the 1-year interval survival rates. We multiplied the 5 predicted 1-year interval (first to fifth year after diagnosis) survival rates (patients diagnosed between 2018 and 2020) or the partially observed and partially predicted 1-year interval survival rates (patients diagnosed between 2014 and 2017) for patients diagnosed in the same year to obtain the expected 5-year survival rate.

**Uncertainty in Prediction**
We used the bootstrap method to calculate CIs for the survival rates. We performed 10,000 bootstrap resampling and used the interval between the 2.5th and 97.5th percentiles as the 95% CI for the survival rates.

**Data Analysis Software Used**
All analyses were performed using SAS (version 9.4; SAS Institute Inc) and R (version 4.3.1; R Foundation for Statistical Computing).

**Ethical Considerations**
The study used deidentified aggregate data exclusively without access to individual records. Ethical approval was granted by the National Taiwan University Research Ethics Committee (NTU-REC 202101HM030) and the Data Release Review Board of the Health Promotion Administration, Ministry of Health and Welfare in Taiwan. All procedures were conducted in compliance with applicable guidelines and regulations. Additionally, the requirement for informed consent was waived by the National Taiwan University Research Ethics Committee due to the absence of personal information and the use of secondary data in the study.

**Results**

**Characteristics of the Study Population**
This study analyzed data from 205,104 patients with lung cancer, of whom 128,928 were men and 76,176 were women (Table 1). In total, 8236 (56.7%) patients were older than 65 years of age. The number of newly diagnosed cases significantly increased from 5762 in 1997 to 14,529 in 2017. Among all histological types, lung adenocarcinoma was the most prevalent in Taiwan, with its proportion rising sharply from 2202 (38.2%) in 1997 to 10,223 (70.4%) in 2017. Lung squamous cell carcinoma was the second most common type, with its proportion decreasing from 1448 (25.1%) in 1997 to 1856 (12.8%) in 2017. Regarding stage distribution, most patients with lung cancer in Taiwan were diagnosed at stages III and IV; however, this proportion gradually decreased from 5933 (83.8%) in 1997 to 8340 (66.8%) in 2017. Conversely, the proportion of stage I diagnoses increased from 927 (13.1%) in 1997 to 3659 (29.3%) in 2017.
Trends in Survival Rates

**Trends in Survival Rates**

Figure 2 displays the 1-year interval survival rates from the first to the fifth year after lung cancer diagnosis in Taiwan. The 1-year interval survival rates from the first to the fifth year had the same turning point at the diagnosis year of 2004: falling before this year and rising subsequently. The fastest increase...
in the 1-year interval survival rate is the first year after diagnosis. In the year of diagnosis 2020, the 1-year interval survival rates are projected to reach 69.4%, 78.7%, 85.2%, 89.4%, and 93.1% in the first, second, third, fourth, and fifth years after diagnosis, respectively.

Figure 3 displays the 5-year survival rate of lung cancer in Taiwan. The most recent 5-year survival rate that could be computed using the cohort approach was the 5-year survival rate for patients diagnosed in 2013 (23.8%). We used the SPC model (symmetric mean absolute percentage error=0.72%) to predict a 5-year survival rate of 38.7% for the year of diagnosis 2020. The absolute increase in the 5-year survival rate of lung cancer in Taiwan from the year of diagnosis 2013 to 2020 was 38.7% – 23.8% = 14.9%, and the fold increase was 38.7%/23.8% = 1.6-fold.

Figure 2. The 1-year interval survival rates (%) of lung cancer in Taiwan (dots: observed values; solid lines: fitted values from the survivorship-period-cohort model; dotted lines: projected values from the survivorship-period-cohort model; and color-shaded regions: 95% bootstrap CI).
Figure 3. The 5-year survival rates (%) of lung cancer in Taiwan (dots: observed values; solid line: product of 5 observed 1-year interval survival rates from the first to fifth years after diagnosis for patients in the same diagnosis year, 1997-2013; dashed line: product of 5 partially observed and partially predicted 1-year interval survival rates from the first to fifth years after diagnosis for patients in the same diagnosis year, 2014-2017; dotted line: product of 5 predicted 1-year survival rates from the first to fifth years after diagnosis for patients in the same diagnosis year, 2018 to 2020; and shaded region: 95% bootstrap CI).

**Trends in Relative Survival Rates**

This study also assessed the relative survival rate of patients with lung cancer (relative to the survival rate of the age-, sex-, and calendar year–matched population in Taiwan) [21,22]. Both the relative survival rates (Figures S1 and S2 in Multimedia Appendix 1) and the absolute survival rates (Figures 2 and 3) exhibited similar increasing trends. The absolute increase in the 5-year relative survival rate of lung cancer in Taiwan from year of diagnosis 2013 to 2020 was 44.6% – 27.9% = 16.7%, and the fold increase was 44.9%/27.9% = 1.6-fold.

**Subgroup Analysis**

In addition, we predicted the future survival rates of patients with lung cancer on the basis of sex, age, and histological type (Figures S3-S15 in Multimedia Appendix 1). The absolute increases (fold increases) in the 5-year survival rates of patients with lung cancer are as follows (Table S1 in Multimedia Appendix 1): men 9.8% (1.6-fold), women 19% (1.6-fold), younger than 55 years 23.4% (1.6-fold), 55 to 64 years 16.8% (1.5-fold), 65 to 74 years 15.5% (1.6-fold), older than 75 years 4.9% (1.5-fold), lung adenocarcinoma 18.6% (1.6-fold), lung squamous cell carcinoma 2.4% (1.2-fold), small-cell lung cancer 1% (1.2-fold), and other histological types of lung cancer 2.6% (1.2-fold).

**Weighted Average Predictions Across Patient Strata**

We also made predictions by calculating the weighted average of stratum-specific future 5-year survival rates based on the number of patients in each stratum in the year of diagnosis 2017 (Table 1). The results (Figure 4) closely matched the future 5-year survival rates predicted for all patients with lung cancer (Figure 3).
Figure 4. The 5-year survival rates (%) of lung cancer in Taiwan, weighted averaged by sex, age, and histological type of the number of patients diagnosed in 2017 (solid line: product of 5 observed 1-year interval survival rates from the first to fifth years after diagnosis for patients in the same diagnosis year, 1997-2013; dashed line: product of 5 partially observed and partially predicted 1-year interval survival rates from the first to fifth years after diagnosis for patients in the same diagnosis year, 2014-2017; dotted line: product of 5 predicted 1-year survival rates from the first to fifth years after diagnosis for patients in the same diagnosis year, 2018-2020; and color-shaded regions: 95% bootstrap CI).

Discussion

Principal Findings

This population-based cancer survival study demonstrates that the 5-year survival rate of patients with lung cancer in Taiwan decreased before 2004 but proceeded to increase afterward, corresponding to the trend of lung cancer mortality in Taiwan [23,24] and the trend of lung cancer survival in one hospital in Taiwan [24]. Patients with advanced lung cancer usually receive chemotherapy. Taiwan’s National Health Insurance has been reimbursing several targeted drugs for lung cancer treatment: gefitinib (since 2004), erlotinib (since 2007), afatinib (since 2014), and crizotinib (since 2015) [25]. These targeted drugs are mainly used in patients with lung adenocarcinoma, and their treatment effects are more favorable than chemotherapy [26-28]. Figure S15 and Table S1 in Multimedia Appendix 1 also reveal more favorable survival rates for patients with lung adenocarcinoma compared to other histological types. Taiwan’s National Health Insurance has also been reimbursing positron emission tomography for staging tumors since 2004 [29]. Previous studies have revealed that it is more accurate for staging tumors than computed tomography, enabling patients to receive appropriate treatment [30-32]. This may also be one reason the 5-year survival rate for lung cancer in Taiwan has increased since 2004. In addition, the Tobacco Hazards Prevention Act was implemented in 1997, and the smoking rate in Taiwan has dropped considerably. The incidences of small-cell lung cancer and lung squamous cell carcinoma, closely related to smoking, have also decreased yearly [33,34]. The reduced proportion of the poorer-survival histological types may contribute to the overall improvement in lung cancer survival.

Lung cancer screening can also help improve the survival rate of patients with lung cancer. The National Lung Screening Trial in the United States first demonstrated in 2011 that LDCT could effectively reduce lung cancer mortality [35]. The Lung Cancer Society in Taiwan has also conducted an LDCT screening study on nonsmoking lung cancer for high-risk populations [36]. LDCT can detect more early-stage patients and reduce lung cancer mortality compared to traditional chest radiography [35-38]. The proportion of patients with early-stage lung cancer diagnosed each year in Taiwan has been increasing since 2007,
and the rate of increase has accelerated since 2011 (Figure S16 in Multimedia Appendix 1). Lung cancer survival rates have rapidly increased since 2007 when stages I to IV were combined (see solid line in Figures S17 and S18 in Multimedia Appendix 1). In addition, the survival rate in each stage exhibits an upward trend (Figures S19-S23 in Multimedia Appendix 1). We believe that positron emission tomography during this period allowed for more accurate staging [30-32] and improved survival rates at various stages. Targeted therapy may also contribute to the increased survival rate of patients with advanced disease [39-42].

We simulated a lung cancer survival trend in the event that screening did not take place (see dot-dashed line in Figures S17 and S18 in Multimedia Appendix 1). The trend was calculated as the yearly weighted averages of the stage-specific lung cancer survival rates, assuming the proportion of patients diagnosed in each stage remained constant at the 2007 level (Figure S16 in Multimedia Appendix 1). The difference between the factual trend (see solid line in Figures S17 and S18 in Multimedia Appendix 1) and the simulated counterfactual trend (see dot-dashed line in Figures S17 and S18 in Multimedia Appendix 1) represents the benefit of lung cancer screening, although this may also reflect the effect of lead time bias. The Health Promotion Administration of Taiwan started implementing free LDCT screening for lung cancer for the high-risk population [43] in July 2022 (before that, LDCT screening was paid for by the public at their own expense). As a result, we speculate that the 5-year survival rate of patients with lung cancer will continue to increase in the future.

The novelty and strength of this study lie in its scope—a nationwide, population-based cancer survival analysis involving more than 200,000 patients with lung cancer. Furthermore, it uses the state-of-the-art SPC model for macrosimulation of future trends. To the best of our knowledge, this is the first study of its kind. However, this study has several limitations. First, the forecasts do not account for the impacts of health policy implementations or medical advancements post-2018, which may result in an underestimation of the future 5-year survival rates for lung cancer in Taiwan. Second, as this is a population-based cancer survival modeling analysis, the absence of individual-level data hampers our ability to make causal inferences and precise personal predictions. Additionally, the factors contributing to the decline in lung cancer survival rates in Taiwan between 1997 and 2004 remain unclear.

Conclusions

This study conducted a comprehensive analysis of lung cancer survival trends in Taiwan, using data from over 200,000 patients and using the SPC model to project future survival rates. Our findings indicate notable improvements in the 5-year survival rates, particularly noticeable from 2004 onward, attributed to advances in medical treatments and diagnostic methods, including the implementation of LDCT screening. The results suggest that the goal set by the Lung Ambition Alliance to double the 5-year survival rate by 2025 is ambitious yet potentially achievable within Taiwan. However, limitations such as the exclusion of post-2018 medical advancements and policy changes could affect the accuracy of our projections. This study highlights the critical role of continuous medical innovation and effective health policy implementation in achieving significant survival improvements for patients with lung cancer.

Acknowledgments

The content of this research may not represent the opinion of the Health Promotion Administration, Ministry of Health and Welfare in Taiwan. This study was based on the master thesis of FTM (the first author of this paper) completed at National Taiwan University under the supervision of WCL (the corresponding author of this paper). The authors used Grammarly (Grammarly, Inc) and ChatGPT (OpenAI) to correct the grammar in the paper. This work is supported by grants from the Health Promotion Administration, the Ministry of Health and Welfare in Taiwan (A1121004; Tobacco Health and Welfare Taxation), and the National Science and Technology Council in Taiwan (MOST 111-2314-B-002-089-MY3).

Abstract

Background: Current research on firearm violence is largely limited to patients who received care in emergency departments or inpatient acute care settings or who died. This is because standardized disease classification codes for firearm injury only represent bodily trauma. As a result, research on pathways and health impacts of firearm violence is largely limited to people who experienced acute bodily trauma and does not include the estimated millions of individuals who were exposed to firearm violence but did not sustain acute injury. Assessing and collecting data on exposure to firearm violence in ambulatory care settings can expand research and more fully frame the public health issue.

Objective: The aim of the study is to evaluate the demographic and clinical characteristics of patients who self-reported exposure to firearm violence during a behavioral health visit.

Methods: This study assessed early data from an initiative implemented in 2022 across a national network of ambulatory behavioral health centers to support trauma-informed care by integrating structured data fields on trauma exposure into an electronic health record behavioral health patient assessment form (SmartForm), as such variables are generally not included in standard outpatient medical records. We calculated descriptive statistics on clinic characteristics, patient demographics, and select clinical conditions among clinics that chose to implement the SmartForm and among patients who reported an exposure to firearm violence. Data on patient counts are limited to positive reports of exposure to firearm violence, and the representativeness of firearm exposure among all patients could not be calculated due to unknown variability in the implementation of the SmartForm.

Results: There were 323 of 629 (51%) clinics that implemented the SmartForm and reported at least 1 patient exposed to firearm violence. In the first 11 months of implementation, 3165 patients reported a recent or past exposure to firearm violence across the 323 clinics. Among patients reporting exposure, 52.7% (n=1669) were male, 38.8% (n=1229) were Black, 45.7% (n=1445) had posttraumatic stress disorder, 37.5% (n=1186) had a substance abuse disorder (other than nicotine), and 11.7% (n=371) had hypertension.

Conclusions: Current research on firearm violence using standardized data is limited to acute care settings and death data. Early results from an initiative across a large network of behavioral health clinics demonstrate that a high number of clinics chose to implement the SmartForm, resulting in thousands of patients reporting exposure to firearm violence. This study demonstrates that collecting standardized data on firearm violence exposure in ambulatory care settings is feasible. This study further demonstrates that resultant data from ambulatory settings can be used for meaningful analysis in describing populations affected by firearm violence. The results of this study hold promise for further collection of structured data on exposure to firearm violence in ambulatory settings.

Introduction

The escalation in firearm injury in the United States is reflected in epidemiologic trends, including the emergence of firearm violence as the leading cause of mortality in children ages 1-18 years since 2020—yet the public health burden of firearm injury is severely undercounted [1-3]. Current incidence and prevalence of firearm injury are largely limited to acute injury data from hospitals and emergency departments and death data. This is because clinical classification codes (International Classification of Diseases) for firearm injury currently only represent acute bodily trauma [4-9]. While millions of children and adults are estimated to have experienced primary or secondary exposure to firearm violence (direct witness of firearm violence or the acute aftermath), there is no standardized data collection system to support surveillance of this public health problem [10-12].

As a result, pathways, risk factors, and intervention strategies following exposure to firearm violence are poorly understood [13]. Collecting broader data on exposure to firearm violence and the physical and psychological injury following exposure is critically needed to identify risk factors and disease pathways, frame the full impact of firearm violence on society, and inform the development of comprehensive treatments for people impacted by firearm violence [12]. Ambulatory electronic health record (EHR) data are potentially rich sources of injury and exposure data that can broaden our understanding of the spectrum of health impacts of firearm violence.

In 2022, a large national network of community-based behavioral health safety–net clinics serving racial and ethnic minority groups, low-income and underserved rural communities, sexual and gender minorities, and other health disparate populations implemented a customized data collection tool (SmartForm) in their shared EHR to collect trauma history as part of the behavioral health assessment process for clients. All network clinics are located in medically underserved areas and serve minoritized populations most likely to experience disparate community firearm violence [14,15]. The SmartForm implementation included an associated workflow to collect standardized data on recent or past exposure to firearm violence among patients presenting for behavioral health care [16]. Implementation of the trauma SmartForm is part of a larger quality improvement initiative to optimize EHR solutions to support trauma-informed care across the network [17]. To our knowledge, this initiative is the first large-scale initiative to collect standardized firearm violence exposure data in outpatient care settings. In this paper, we present early results on exposure to firearm violence from the first 11 months of implementation of the SmartForm.

Methods

Study Design

We used EHR data from the OCHIN multistate network of community-based primary and behavioral health care clinics [16]. OCHIN is a nonprofit health care innovation center that offers a fully hosted, highly customized instance of Epic practice management and EHR solutions to 140 members representing 1071 clinic sites, 629 (59%) of whom provide behavioral health services. All OCHIN members are trained on common workflows. Data on “exposure to gun violence” are incorporated as an optional standardized, reportable field as part of the behavioral health trauma SmartForm within the patient history section of the EHR used by behavioral health clinicians. While associated workflows are recommended, clinics and clinicians within the network have full autonomy to determine their use (or nonuse) of the SmartForm. As a quality improvement initiative, it is accepted that the use of the SmartForm is not consistent across all network clinics.

EHR reportable data include “recent exposure to gun violence” and “past exposure to gun violence.” Our data set represents cross-sectional data from February 2022, when the trauma SmartForm was implemented in the EHR, to December 2022. The SmartForm in use during this time only collected patient-reported “yes” responses to firearm violence exposure; there was no ability to document “no” responses. As a result, there is no denominator of total patients assessed for exposure and no practical method for estimating the prevalence of self-reported firearm violence exposure within the population.

We identified all active patients with documentation of a recent or past exposure to firearm violence and extracted data on demographics (age, sex, etc) and the prevalence of a select, predefined list of active health problems including behavioral health diagnoses, diabetes, and hypertension [18]. The list of active health problems was extracted from the patient problem list within the EHR.

Ethical Considerations

This project used a deidentified data set from a data repository of clinical and administrative data of all patients seen in the OCHIN network. The data repository is under institutional review board oversight with Advarra (Pro00060082) and includes a waiver of consent and authorization. This project was reviewed by Norwich University Institutional Review Board (00005859) and OCHIN and met exemption criteria under 45 CFR 46.

Results

During the study period, there were 129 active OCHIN member organizations with 629 behavioral health clinic sites. Among those, 91 (70.5%) member organizations and 323 (51.3%) clinics implemented the SmartForm with at least 1 patient reporting exposure to firearm violence per clinic. Between February 1 and December 31, 2022, these clinics documented between 19 and 33,067 (median 1066, IQR 356-4309) patients with firearm violence exposure, with a median age of 17 (IQR 7-64) years. Of these, a median of 43% (IQR 39%-49%; range 2%-92%) of patients were male. Across the 323 clinics, 3165 behavioral
health patients had patient-reported and clinician-documented recent or past exposure to firearm violence noted in their EHR between February 2022 and December 2022 (Table 1). Among patients with noted firearm exposure, 52.7% (n=1669) were male, 41.4% (n=1308) were between 12 and 34 years of age, 11.5% (n=364) self-reported having a sexual orientation other than straight, 38.3% (n=1229) were Black or African American, and 42.5% (n=1334) were uninsured. The median age of patients with noted exposure to firearm violence was 20 (IQR 7-64; range 3-89) years. When described by behavioral health diagnosis, 45.7% (n=1445) had a diagnosis of posttraumatic stress disorder, and 37.5% (n=1886) had a substance abuse disorder (excluding nicotine dependence). A large percentage of patients with a documented exposure had hypertension (n=371, 11.7%), and 66.7% (n=2110) had 7 or more clinic visits (for either behavioral health or primary care) during 2022. Each clinic determines which social risks, if any, they measure. Among patients screened for social determinants of health, 69.8% (n=1213) reported one or more social risks such as food insecurity or transportation insecurity.

<sup>a</sup>A small number of patients with other or unknown sex were proportionally distributed to the female and male categories to avoid reporting small cell counts.

<sup>b</sup>Social determinants of health is a broad category, and each clinic has the autonomy to determine which, and how many, social determinants of health they collect for patients. Adverse social determinants of health include social risks including, but not limited to, food insecurity, housing insecurity, and transportation insecurity.

<sup>c</sup>PTSD: posttraumatic stress disorder.

**Discussion**

**Principal Findings**

Current firearm injury research, largely limited to acute injury and death, has many shortcomings [19] that can potentially be overcome by expanding the collection of standardized data on firearm violence exposure in ambulatory care settings. A review of EHR data from safety-net clinics within the OCHIN network, which initiated a standardized question on firearm violence exposure as part of collecting information on patient history during behavioral health care visits, demonstrates that data on firearm violence can be collected as part of routine behavioral health care. EHR data include patient-level variables not currently available in common firearm injury data sets (Healthcare Cost & Utilization Project; National Vital Statistics System/Web-Based Injury Statistics Query and Reporting System) used for research, including gender identity, sexual orientation, social determinants of health, experiencing homelessness, health care use, behavioral health, and chronic disease comorbidities [20-22].

**Strengths and Limitations**

Expanding the collection of firearm violence exposure data in outpatient EHRs opens new opportunities in firearm violence research; these novel data may be leveraged to support more precise prevalence estimates of firearm violence exposure and injury, assess population-level associations between exposure and medical or behavioral health outcomes, and support the application of machine learning to develop predictive analytics for treatment planning [1,12,23].

Some limitations of this analysis arise from the nonmandatory nature of the data collection form. As OCHIN implemented the EHR trauma SmartForm as part of a quality improvement behavioral health EHR optimization initiative, clinics and clinicians within the network had full autonomy to determine their use (or nonuse) of the SmartForm. As the SmartForm is not consistently used across all OCHIN member clinics, the data presented here are representative of neither OCHIN’s patient population nor clinician’s behavior. In addition, the SmartForm currently in use only collects patient-reported “yes” responses to firearm violence exposure; there is no place to document “no” responses. As a result, there is no denominator of total patients assessed for exposure and no practical method for estimating the prevalence of self-reported firearm violence exposure within the population.

This study broadens the discussion around firearm injury by demonstrating that standardized data on firearm violence exposure can be collected in outpatient settings. Such data can...
extend our knowledge of the burden of firearm violence, which is typically limited to acute care settings including inpatient and emergency department data or mortality data, by incorporating a broader understanding of both exposure to firearm violence and firearm injury through the availability of rich demographic, clinical, psychological, and social risk data collected in ambulatory care EHRs.

**Future Directions**

Results from this study demonstrate the potential value of screening for firearm violence exposure and suggest how collection of this novel data may be leveraged to support firearm injury surveillance, understand physical and psychological firearm violence sequelae, and support treatment. Ongoing work should include identifying opportunities for more systematic screening of exposure to firearm violence across health care settings.

Abstract

Background: The COVID-19 pandemic necessitated public health policies to limit human mobility and curb infection spread. Human mobility, which is often underestimated, plays a pivotal role in health outcomes, impacting both infectious and chronic diseases. Collecting precise mobility data is vital for understanding human behavior and informing public health strategies. Google’s GPS-based location tracking, which is compiled in Google Mobility Reports, became the gold standard for monitoring outdoor mobility during the pandemic. However, indoor mobility remains underexplored.

Objective: This study investigates in-home mobility data from ecobee’s smart thermostats in Canada (February 2020 to February 2021) and compares it directly with Google’s residential mobility data. By assessing the suitability of smart thermostat data, we aim to shed light on indoor mobility patterns, contributing valuable insights to public health research and strategies.

Methods: Motion sensor data were acquired from the ecobee “Donate Your Data” initiative via Google’s BigQuery cloud platform. Concurrently, residential mobility data were sourced from the Google Mobility Report. This study centered on 4 Canadian provinces—Ontario, Quebec, Alberta, and British Columbia—during the period from February 15, 2020, to February 14, 2021. Data processing, analysis, and visualization were conducted on the Microsoft Azure platform using Python (Python Software Foundation) and R programming languages (R Foundation for Statistical Computing). Our investigation involved assessing changes in mobility relative to the baseline in both data sets, with the strength of this relationship assessed using Pearson and Spearman correlation coefficients. We scrutinized daily, weekly, and monthly variations in mobility patterns across the data sets and performed anomaly detection for further insights.

Results: The results revealed noteworthy week-to-week and month-to-month shifts in population mobility within the chosen provinces, aligning with pandemic-driven policy adjustments. Notably, the ecobee data exhibited a robust correlation with Google’s data set. Examination of Google’s daily patterns detected more pronounced mobility fluctuations during weekdays, a trend not mirrored in the ecobee data. Anomaly detection successfully identified substantial mobility deviations coinciding with policy modifications and cultural events.
Conclusions: This study’s findings illustrate the substantial influence of the Canadian stay-at-home and work-from-home policies on population mobility. This impact was discernible through both Google’s out-of-house residential mobility data and ecobee’s in-house smart thermostat data. As such, we deduce that smart thermostats represent a valid tool for facilitating intelligent monitoring of population mobility in response to policy-driven shifts.

Introduction
The dynamics of human mobility are currently undergoing a remarkable transition. Rapid global urbanization, sedentary lifestyles, infectious diseases, air pollution, and climate change are some of the factors driving shifts in human mobility. Whether examined at the individual [1,2] or population level [3], human mobility patterns are associated with multiple public health and social issues. Dwindling mobility patterns are linked to chronic diseases including dementia and age-related physical decline. For infectious diseases, individual mobility is linked to the spread of infections such as COVID-19. Human mobility data can therefore be an effective tool for comprehending the complexities of human health and behavior [4].

The COVID-19 pandemic has served as an ideal case study to develop tools and knowledge in the field of human mobility research [5]. The World Health Organization declared COVID-19 an international public health emergency in late January 2020 and subsequently declared it a pandemic on March 11, 2020. To curb the spread of COVID-19 and avoid overwhelming health care institutions [6], many countries implemented restrictions on human mobility including social distancing, self-isolation, closure of nonessential services, work-from-home policies, and travel restrictions [7,8]. In the early stages of the pandemic, digital data sources found that the decrease in human mobility was closely paralleled by a reduction in the incidence of COVID-19 [1,7,9-15]. Thus, the COVID-19 pandemic provides an ideal opportunity to measure and extract meaning from human mobility and how it is affected by restrictive policies.

The study of human mobility has historically been retrospective with limited study participants. Interestingly, it was the technological advancements in smartphones and wearable devices that have had the largest impact on the field [16]. These innovations now provide direct access to human location, trajectories, opinions, and interactions [17]. Human mobility can now be tracked passively in real time from various sources: GPS-enabled smartphones, texts or photos via photo-sharing platforms like Twitter (X Corp) and Flickr (Altaba, Ludicorp), geolocation-enabled internet posts, public transport cards, satellite, flight traffic, and even credit card transactions. The data collected have a previously unprecedented level of detail, immediacy, and precision. These large data sets, equivalent to “big data” in volumes, are now being analyzed to describe human movement patterns, characteristics (such as sleep, stress, and activity), and interactions.

Google Maps is the most popular navigation app in the United States and Canada. The app surpassed 23 million downloads in 2020 with 154.4 million monthly users. Google passively generates and collects over 20 million pieces of mobility data per day. The information has now been made available to researchers and policy makers through Google’s open-source “COVID-19 Community Mobility Reports” [18]. The reported geographic movement, called macromobility, is grouped by category: retail and recreation, grocery and drug stores, parks, transit stations, workplaces, and residences [18]. While macromobility data are readily available through sources such as Google’s “COVID-19 Community Mobility Reports,” our understanding of micromobility at the population level remains limited. This study aims to fill this gap by analyzing smart thermostat data, thereby providing a more comprehensive picture of human mobility patterns. This study leverages the unprecedented access to real-time human mobility data provided by smart thermostats, a source that has not been extensively used in previous research. The high level of detail, immediacy, and precision of these data allows for a more granular understanding of human mobility patterns, particularly in-house mobility (micromobility), which has been less explored compared to macromobility. Unlike Google’s macromobility data, smart thermostat data can provide insights into in-house mobility patterns. This is particularly relevant in the context of the COVID-19 pandemic, where stay-at-home orders and work-from-home policies have significantly altered in-house mobility patterns.

Modular smart home thermostats offer a novel source of data on in-house human behaviors [19,20]. Not only can they report on indoor temperature, humidity, and air quality, but embedded motion sensors can capture mobility within the home. More than 90% of Canadian households had thermostats in 2018, with most opting for programmable thermostats. Smart thermostats, often known as internet of things (IoT) devices, are a type of programmable thermostat that may be connected to the internet. ecobee has the second-highest market share for smart thermostats in Canada. ecobee has a program called Donate Your Data (DYD), in which subscribers can opt to make their anonymized data available for research purposes. DYD currently has 1 million users including over 172,000 households in Canada. Here, we sought to compare mobility data obtained from ecobee smart thermostats to the “gold standard” mobility data from Google during the COVID-19 pandemic in Canada. We explored day-by-day, week-by-week, and month-by-month seasonality patterns and applied anomaly detection to both data sets.
Methods

Data Sources
Google Mobility data were collected for each province in Canada from February 15, 2020, to February 14, 2021 [18]. Google Maps uses aggregated and anonymized data to determine the daily total number of visits to specific destinations Textbox 1 visited by individuals who have enabled their location history [18]. Daily values are compiled across individuals and are compared to the baseline value for that day of the week to determine changes in mobility. The baseline is the median of corresponding days over the 5 weeks from January 3 to February 6, 2020 [18]. Out of the 6 categories, we focused on residential data. We curated mobility data from ecobee’s DYD program.

Textbox 1. Google mobility data categories and their description as described on the website [18].

Ethical Considerations
Per ethical research standards, this study exclusively used secondary data, and therefore, no additional consent from human subjects was necessary for this research. The original informed consent procedures or institutional review board approvals for primary data collection explicitly permitted the secondary analysis conducted in this study. Furthermore, robust privacy and confidentiality safeguards were implemented to ensure the anonymity and deidentification of study data. Ethics approval for this study was duly obtained from the University of Waterloo Office of Research Ethics (#31377), attesting to our commitment to upholding the highest ethical standards in research.

Data Preparation
ecobee’s data were transferred from Google’s BigQuery to the Microsoft Azure cloud services platform [25]. Data were prepared using Azure Databricks data analytics platform and Jupyter Notebook (Jupyter Team) using Python; detailed explanation of the whole process has been mentioned in our previous studies [20,23]. Data cleaning, analysis, and visualization were done in R studio (version 1.4.1106; Posit Software, PBC) with R software (version 4.0.5; The R Foundation) and data analysis packages tidyverse [26] and timetk [27].

Using ecobee data, we established a baseline mobility value akin to the Google data preparation approach detailed earlier for seamless comparison. To ascertain daily in-house mobility, we computed the total number of activated sensors within each 24-hour timeframe by summing all sensor statuses. A table containing date records alongside the average count of activated sensors per date was then saved as a CSV file.

As the timestamp of the DYD data set was in Coordinated Universal Time format, the time zones in the data set were converted by locating time zone information from the geolocation of the households in the metadata. In Quebec and Alberta, all the cities were in the same time zone. In the province of Ontario, 6 cities have different time zones than EST: namely, Drayton, Kenora, Kenora-Unorganized, Mitchell, Red Lake, and Sioux Lookout cities (1% of the DYD data set for Ontario). For British Columbia, 28 households were from different time zones than Pacific Standard Time and were excluded from the analysis. Once cleaned for the time zone, time-series data

analysis was performed on the adjusted data on the households included in this study. These numbers are presented in Table 1.

Data Analysis

To assess mobility variations, we aggregated daily province-level movement into weekly, monthly, and day-of-the-week periods and compared them to the respective baselines in both data sets. Time series plots were generated for each province using Google’s residential and ecobee mobility data. The statistical significance of the relationship between the 2 data sources was determined through Pearson and Spearman correlation coefficients [28].

We conducted seasonal diagnostic tests using the `timetk` [27] package in R software, tailored for time-series data analysis. Distinct approaches were employed to investigate daily, weekly, and monthly seasonality. To assess statistical significance [29] 1-way ANOVA was used.

For anomaly detection, we initially conducted seasonal and trend decomposition using the Loess method [27,30,31]. After removing the trend and seasonality components, we performed anomaly detection on the residual data. Anomalies were identified based on the IQR, specifically the difference between the 75th and 25th percentiles, establishing the distribution of the remaining data. Default boundaries were set at 3x above or below the IQR, designating values beyond these limits as anomalies.

To examine data granularity, we analyzed mobility data by days of the week for both Google and ecobee data sets. Additionally, we aggregated mobility data into 1-week intervals for all 4 provinces to explore seasonality in mobility changes following the onset of the COVID-19 pandemic.

Results

Positive Association Between Google and ecobee Mobility Data

The comparison of Google residential mobility data and ecobee mobility data across each province over a year revealed a positive association (Figure 1). Notably, the Google mobility data exhibited a recurrent weekly pattern, which was closely mirrored by the ecobee data (Figure 1). Both data sources exhibited a significant uptick in residential mobility, both indoors and outdoors, commencing around March 11, 2020, aligning with the declaration of the COVID-19 pandemic in Canada. It is worth noting that given Canada’s provincial health regulation framework [32], the official implementation dates of pandemic-related policies varied among the 4 provinces under investigation (March 17, 2020, for Ontario; March 16, 2020, for Quebec; March 17, 2020, for Alberta; and March 19, 2020, for British Columbia).
All provinces exhibited a notable increase in the percentage of mobility change coinciding with the commencement of the pandemic, as indicated by both Google and ecobee mobility data. Subsequently, from March 2020 to September 2020, a gradual decline in this trend was observed across all provinces in both data sets. Notably, a subsequent surge in residential mobility was linked to the onset of the second pandemic wave and the reinstatement of pandemic-related stay-at-home measures on specific dates (December 26, 2020, for Ontario; December 17, 2020, for Quebec; December 13, 2020, for Alberta; and October 19, 2020, for British Columbia).

For each province, we calculated the correlation between Google’s residential mobility data and ecobee’s mobility data. The trend line displayed a linear relationship between the 2 data sets (see Figure 2). Pearson and Spearman correlation coefficients revealed a statistically significant association, ranging from 0.67 to 0.73 (refer to Table 2). Consequently, the data obtained from ecobee’s smart home thermostat are demonstrably equivalent to Google’s mobility data.

Variations in Mobility by Day of the Week

There was a significant difference in daily mobility patterns across all 4 provinces when examining the Google residential mobility data set (Figure 3). Greater mobility changes were observed on the weekdays compared to weekends. Further, a 1-way ANOVA test (Table 3) showed that the day of the week had a statistically significant impact on residential mobility for all 4 provinces (Google; all $P<0.001$). On the contrary, these differences in daily mobility were only observed in Quebec when we used ecobee’s mobility data.

Monthly Variations in Mobility

To deepen our understanding of the pandemic-related changes in population behavior, we aggregated the Google and ecobee data to analyze month-by-month mobility changes. Interestingly, in contrast to the differences observed between Google and ecobee mobility data for days of the week, month-by-month patterns were similar between the 2 data sets (Figure 4). Across all provinces, the change in mobility above baseline spiked in April 2020 consistent with the implementation of COVID-19 policies to curb social mobility. Further, the variability within the data, specifically for ecobee data, was reduced drastically from April 2020 onwards. The increase in residential and in-home mobility slowly declined from April 2020 to September 2020. A subsequent rise in mobility from October 2020 to December 2020 corresponded to the second pandemic wave and the reimplementation of pandemic-related stay-at-home policies. Furthermore, 1-way ANOVA test showed a statistically significant change in both residential (Google) and in-house (ecobee) month-by-month mobility across all 4 provinces (all P<.001; Table 4).

Week-by-Week Mobility Changes

Beginning in February 2020, the initial 5 to 6 weeks had a similar level of mobility across all 4 provinces (Figure 5). Google residential mobility declined from week 7 to week 10. Although there was a high level of data variability at week 7, this was lost in subsequent weeks. ecobee in-house mobility followed a similar pattern but with a lag period of 1 week and a large degree of variability. Beginning at week 12 (corresponding to the week of March 16, 2020), Google residential data witnessed a sharp spike in residential mobility across all 4 provinces. This timing correlates to the date the pandemic was declared in Canada. A similar trend was observed for the ecobee data, however, mobility appeared to increase starting in week 11. Similar to the trends observed in month-by-month data (Figure 4), the elevated mobility steadily declined toward week 25 and stabilized above baseline until approximately week 40 (Figure 5). There was a subsequent steady increase in mobility from week 40 until the end of the year corresponding to the timing of the second wave of the pandemic in Canada. The ecobee mobility data showed a similar trend with the exception that the decline in mobility took place over a longer period and with a shorter period of stabilization before rising again. An ANOVA analysis for the week-by-week mobility data showed a statistically significant difference between weeks for both data sets and for all 4 provinces (all P<.001; Table 5).

**Social Mobility Policy Restrictions and Festive Periods Create Mobility Anomalies**

To determine whether Google and ecobee data analysis could pick out behavioral anomalies in mobility associated with policy changes, we performed an anomaly detection analysis (Figure 6). Neither Google residential data nor ecobee in-house mobility data showed any anomaly within 2020 for Ontario. For Quebec, Alberta, and British Columbia, anomalies were found at the beginning period in both the Google and ecobee data. Notably, these corresponded with the dates of COVID-19–related policy changes. In Alberta and British Columbia, ecobee’s in-house mobility analysis captured anomalies in May and June 2020, which correspond to phase-wise reopening plans and the lifting of social restrictions. Interestingly, Google residential data were able to capture anomalies corresponding to festive periods such as Christmas and New Year’s Eve in Quebec, Alberta, and British Columbia. These anomalies were not seen in the ecobee data. Overall, these results demonstrate the ability of Google’s residential data and ecobee’s thermostat data to capture notable shifts in population behavior as a result of policy changes and cultural festivities.
Discussion

This study aimed to investigate the potential application of in-house mobility data obtained from ecobee sensors in comparison to residential Google mobility data. The most significant differences between data sets were observed, particularly when mobility was analyzed by the day of the week. While Google’s residential data exhibited a significant correlation with the day of the week across all 4 provinces, ecobee’s data showed a significant impact only in Quebec. However, when scrutinized on a monthly and weekly basis, consistent findings were observed across all provinces and data sets. A notable surge in in-house and residential mobility occurred between March and April 2020, coinciding with the initiation of pandemic-related policy changes in Canada. These mobility shifts gradually diminished until September 2020, and the onset of the second wave of the pandemic, coupled with the reinstatement of social policies, corresponded with increased mobility from October to December 2020. In summary, a statistically significant association between the 2 data sets was identified. Anomaly detection analysis provided evidence supporting the capability of both data sets to detect deviations in population mobility, capturing events such as emergency declarations, reopening phases, and festive days such as December 25 (Christmas) and January 1 (New Year’s Eve). These findings underscore the benefits of employing public health surveillance mechanisms, especially during health emergencies of pandemic proportions.

Historically, monitoring individual mobility has been hampered by insufficient sample sizes, difficulty in collecting data, recall bias, and privacy concerns [33-35]. The advent of smartphones, wearable devices, and the IoT has paved the way for researchers to capture individual geolocation and movement within the home (micromobility) [36-40]. For both micro- and macromobility, it is necessary to integrate data from multiple sources [41]. Thermostat-based IoT data, such as the ecobee DYD data reported here, can provide new opportunities for calculating population-level mobility indicators. IoT is a modern, passive sensing tool that can quantify in-house movement. Understanding in-house movement is particularly relevant given that people now spend more than 80% of their time indoors [4,42]. The use of these large data sets, combined with geographical data and timestamps [16,17], has the potential to unravel different dimensions of human behavior and lifestyle.

In-house mobility data can measure changes in sleep [5,43], physical activity [44], sedentary behaviors [45-47], and movement patterns [48] with greater detail and granularity. Motion sensors are a next-generation tool with a wealth of opportunities for application in the field of public health. Integrated into smart cities, motion sensors have the power to detect overall human mobility from various sources. Data collection will enable effective planning and implementation of responsive and preventative public health strategies [37].

Monitoring real-time population mobility is important in public health as it plays a significant role in both chronic and infectious diseases. A dwindling mobility pattern is a predisposition to various chronic diseases including dementia and age-related physical decline. For infectious diseases, individual mobility is directly proportional to the transmission of infections such as COVID-19 [49]. Although the “stay-at-home” and “work-from-home” strategies were promoted globally to curb the spread of COVID-19, it is still unclear to what extent individuals complied with policy restrictions. Mobility data analysis has the potential to provide real-time information about the impact of such policies on individual and population behavior [12,50,51].

However, a notable limitation of our study was the absence of sociodemographic information in the ecobee data set. Consequently, our analysis was confined to spatiotemporal dimensions, and we were unable to examine the impact of sociodemographic features, including age, gender, and occupation. Varied perceptions surrounding infectious diseases, vaccinations, social mobility, and government policies across cultural and socioeconomic groups highlight the need for caution when generalizing the results [52]. Although the data were collected across 4 Canadian provinces, encompassing 87% of the population, the demographic represented by those with smart home thermostats likely skews toward a specific group—namely, young, tech-savvy individuals with higher socioeconomic status, who may be more inclined to work from home. Therefore, caution should be exercised in generalizing the reported results. Additionally, challenges arise in separating mobility patterns in multiperson households and eliminating sensor activation due to factors such as animals, rapid airflow, or other noises.

In conclusion, the real-time monitoring of population-level mobility using smartphones and IoT sensors has emerged as a...
recent development in public health, primarily in response to the COVID-19 pandemic. This study investigates the utility of IoT-based mobility data, specifically from smart thermostats, for assessing individual mobility within the context of social isolation policies. The findings demonstrate a close alignment between thermostat mobility data and the data presented in the Google Mobility Report, affirming its value as a mobility monitoring tool. The acquisition of real-time mobility data from smart thermostats has the potential to enhance our understanding of the intricate social determinants of health, providing valuable insights for the formulation of public health policies.

Acknowledgments
The authors would like to thank ecobee for sharing the data with us. The authors would also like to thank the teammates at the Ubiquitous Health Technology Lab (UbiLab) for their help in data management, quality checking of the code, and visualizations.

Data Availability
The Google mobility data can be readily accessed by the public [18]. In contrast, access to ecobee data is restricted to researchers and scientists through a data-sharing agreement. If you are interested in accessing ecobee data, please email the research division of ecobee.

Authors' Contributions
KSS and PPM conceived and designed this study, KSS performed data extraction, cleaning, and analysis. KSS wrote the paper under the supervision of PPM, JAD, SEM, and SL. All the authors have reviewed and approved the final manuscript and provided edits and feedback to strengthen it.

Conflicts of Interest
KSS is an Editorial Board member of JMIR Public Health and Surveillance at the time of this publication. The other authors have no conflicts of interest to declare.

Abstract

Background: The online pharmacy market is growing, with legitimate online pharmacies offering advantages such as convenience and accessibility. However, this increased demand has attracted malicious actors into this space, leading to the proliferation of illegal vendors that use deceptive techniques to rank higher in search results and pose serious public health risks by dispensing substandard or falsified medicines. Search engine providers have started integrating generative artificial intelligence (AI) into search engine interfaces, which could revolutionize search by delivering more personalized results through a user-friendly experience. However, improper integration of these new technologies carries potential risks and could further exacerbate the risks posed by illicit online pharmacies by inadvertently directing users to illegal vendors.

Objective: The role of generative AI integration in reshaping search engine results, particularly related to online pharmacies, has not yet been studied. Our objective was to identify, determine the prevalence of, and characterize illegal online pharmacy recommendations within the AI-generated search results and recommendations.

Methods: We conducted a comparative assessment of AI-generated recommendations from Google’s Search Generative Experience (SGE) and Microsoft Bing’s Chat, focusing on popular and well-known medicines representing multiple therapeutic categories including controlled substances. Websites were individually examined to determine legitimacy, and known illegal vendors were identified by cross-referencing with the National Association of Boards of Pharmacy and LegitScript databases.

Results: Of the 262 websites recommended in the AI-generated search results, 47.33% (124/262) belonged to active online pharmacies, with 31.29% (82/262) leading to legitimate ones. However, 19.04% (24/126) of Bing Chat’s and 13.23% (18/136) of Google SGE’s recommendations directed users to illegal vendors, including for controlled substances. The proportion of illegal pharmacies varied by drug and search engine. A significant difference was observed in the distribution of illegal websites between search engines. The prevalence of links leading to illegal online pharmacies selling prescription medications was significantly higher (P=0.001) in Bing Chat (21/86, 24%) compared to Google SGE (6/92, 6%). Regarding the suggestions for controlled substances, suggestions generated by Google led to a significantly higher number of rogue sellers (12/44, 27%; P=.02) compared to Bing (3/40, 7%).

Conclusions: While the integration of generative AI into search engines offers promising potential, it also poses significant risks. This is the first study to shed light on the vulnerabilities within these platforms while highlighting the potential public health implications associated with their inadvertent promotion of illegal pharmacies. We found a concerning proportion of AI-generated recommendations that led to illegal online pharmacies, which could not only potentially increase their traffic but also further
exacerbate existing public health risks. Rigorous oversight and proper safeguards are urgently needed in generative search to mitigate consumer risks, making sure to actively guide users to verified pharmacies and prioritize legitimate sources while excluding illegal vendors from recommendations.

**Introduction**

The internet has evolved into an increasingly popular platform for searching for health information and purchasing medications, with more people opting to turn to online marketplaces due to convenience and cost considerations. The online pharmacy market has experienced exponential growth during the past decade in parallel with the rapid proliferation of global e-commerce. The global online pharmacy market was valued at an estimated US $68 billion in 2021, with a compound annual growth rate of 16.8%, with research indicating that the internet (including social media) is now frequently used to purchase medicines online [1,2]. Properly regulated online pharmacies, often accessible via search engine results, dispense prescription and nonprescription medicines directly to patients especially benefiting individuals in remote areas and patients who are disabled or housebound. The COVID-19 pandemic further amplified behaviors associated with purchasing medicines via the internet; thus, most countries now have regulations in place to govern the delivery of medicinal products remotely.

However, the increasing global demand for online medication purchases has also attracted malicious actors, leading to the proliferation of illegal online pharmacies—websites that fail to meet national or international regulations and have not undergone regulatory review and verification. Illegal online pharmacies use extensive rogue digital marketing strategies and search engine optimization to boost their ranking and visibility on search engine results pages (SERPs) [3]. Due to the uncontrolled nature of the internet, patients often encounter both legitimate and illegitimate vendors while conducting searches for medicines online. While several national and international verification or accreditation systems exist, such as the National Association of Boards of Pharmacy (NABP)’s Digital Pharmacy Accreditation program and the “.pharmacy” domain registry (USA) [4] and the European Commission’s EU logo for online sale of medicines (EU) [5], patients and health professionals continue to have issues verifying the credibility of online pharmacy websites appearing in search engine results [6].

Illegal online vendors endanger health by selling medicines without requiring a valid prescription and supplying substandard and falsified medicines [7] that could lead to dangerous patient outcomes [3,8]. This illegal practice has broad public health consequences, including eroding trust in health care delivery, compromising pharmacy supply chain safety, and potentially contributing to antimicrobial resistance due to the presence of substandard and adulterated products [9]. Despite persistent warnings from researchers and regulators who have called for reform and enhanced monitoring, the continued online presence of illegal pharmacies remains largely unchecked. Law enforcement efforts have had limited effectiveness in keeping up with the growing number and diversity of illicit marketplaces, public awareness campaigns show limited efficacy in changing consumer behavior, and search engine providers have yet to enforce more stringent controls on their organic search results [10,11].

This lack of accountability, awareness, and inaction has facilitated the rampant growth of illicit online drug sales for a variety of therapeutic classes (eg, antibiotics, controlled substances, and weight loss drugs) [9,12,13]. A recent study revealed that compromised results redirecting to active illicit online pharmacies were present in search query results of several European countries, with the most affected regions having up to one-third of the SERP links associated with illegal online pharmacies [14]. Other recent public health threats include fake COVID-19 products offered via the internet during the pandemic [15,16]. Although no “magic bullet” exists, effective regulation of these websites likely lies in the hands of search engine providers, as these companies have effective methodologies to screen advertisements and prevent vendors of illegal products from using paid promotion for their services. However, unpaid organic results (ie, that are not sponsored ads) are seemingly uncontrolled.

Interest and commercial adoption of generative artificial intelligence (AI)-based conversational chat features and applications are rapidly expanding throughout society. Yet, improper integration of generative AI into search engine results could further complicate and exacerbate the illegal online pharmacy issue. As of June 2023, Google continued to dominate the global search market with 84.6 billion monthly visits, while Microsoft Bing was a distant second with 1.2 billion monthly visits according to web analytics data by Similarweb Ltd [17]. With the emergence of generative AI, especially after witnessing the surging popularity of OpenAI’s ChatGPT, search engine giants have rushed to integrate generative AI into their search interfaces, giving rise to Microsoft Bing’s Chat feature, also known as Microsoft Copilot, and Google’s Search Generative Experience (SGE). After Microsoft launched Bing Chat in February 2023, Bing search crossed 100 million daily active users for the first time in its history [18].

*(page number not for citation purposes)*
These recent developments will transform the way global users search for and interact with health information online. Large language models (LLMs) and generative AI, when implemented and used responsibly, have the potential to revolutionize search by delivering accurate, safe, and personalized results through a user-friendly experience. However, they also carry potential risks and ethical considerations, particularly when it comes to public health, as recently highlighted by the World Health Organization that has called for caution in using these technologies [19-21]. LLMs, lacking the ability to reason, may produce results with critical mistakes and have demonstrated significant drawbacks, such as generating misinformation and falsifying data, potentially leading to patient injury that in turn raises liability concerns [22] while concurrently heightening the need for a comprehensive framework to address present compliance and reliability issues, especially in regulated settings like health care [23]. Other published studies have examined the use, impact, and potential threat of LLMs in pharmacy education and practice (eg, answering clinical pharmacy questions), their use in medical consultations regarding drug-to-drug interactions and drug-related questions related to risk, and evaluated LLM-generated responses to prompts containing vaccine conspiracies and misconceptions [24-33]. However, no study to our knowledge has specifically evaluated LLMs in the context of popular search engine integration, and how they may generate content that could direct consumers to illegal websites selling medication online.

Hence, several questions arise that warrant further inquiry in the context of patient safety, information quality, and potential consumer exposure to harmful medication access associated with LLMs. The focus of this study is to conduct an exploratory study to identify whether these novel search tools will influence consumer interaction with the online pharmacy market and whether they will assist or potentially harm consumers by exposing them to illegal websites through SERPs. In response, this study conducts a structured comparative analysis using different prompts to conduct a comparative assessment of AI-generated recommendations of Google and Bing for hypothetical users looking to buy prescription drugs online.

Methods

Overview

In this study, we conduct a structured analysis of 2 generative AIs to assess the impact of commercial implementation of this new technology on search engine results associated with the online pharmaceutical market. The 2 platforms reviewed included Google SGE using converse mode, which is based on Google’s Bard generative AI chatbot, and Microsoft Bing’s Chat feature, which uses OpenAI’s GPT-4 LLM. The rationale for choosing a comparative analysis of these 2 platforms was to specifically conduct an assessment of the differences and similarities associated with generative AI integration into search engine results, with an emphasis on evaluating sourcing recommendations made that could be seen by the public.

For our investigation, we selected 6 globally popular medicinal products by proprietary name and their corresponding active pharmaceutical ingredients (APIs) with representation across multiple therapeutic categories (eg, medicines used to treat diabetes, erectile dysfunction, and bacterial infections) to assess the quality of AI-generated recommendations under a general prompt for a user seeking advice on where to buy prescription drugs from the internet and specifically requesting information on a recommended website. An additional group of controlled substances (eg, Xanax and fentanyl) were included to assess how AI-generated responses to this prompt would differ for drugs specifically subject to international control and regulation, as generally controlled substances are not permitted to be sold via internet sources, may not be trafficked online, and are subject to enhanced dispensing regulations in various countries.

AI Prompt and Website Classification

The following standard prompt was used on each generative AI platform with both the proprietary name and the APIs listed in the “Results” section: “Where can I buy [Proprietary Name/API] online?” and “I am looking for an online pharmacy to buy [Proprietary Name/API]. Please suggest a website where I can buy it!” All results were then analyzed and crosschecked with NABP’s not recommended list (maintained by the US NABP that provides a list of sites that may be fraudulent or illegitimate) and LegitScript database (an online service that monitors global online pharmacies for compliance with applicable laws and regulations and classifies illegal and legitimate websites) to determine the legitimacy of the online pharmacies recommended, a verification approach similar to those used in prior published studies on the topic [9,34,35]. Website evaluation and categorization were conducted independently by 2 authors (ARA and AF) and finalized following the initial categorization through a collaborative discussion of individual results to reach consensus in the event of any disagreement.

Initial categorization showed almost perfect agreement for interrater reliability with a κ value of 0.98. An internet pharmacy domain was classified as legitimate if it was approved by either or both the NABP and LegitScript databases. Additionally, pages were visually inspected to identify the presence of an official internet pharmacy verification logo with a functional redirection link to the website of the competent national authority. An internet pharmacy website was categorized as illegal whether the databases classified the domain as rogue or not recommended or if there was a clear indication of illegal activity, such as the sale of prescription-only medicines without requiring a valid medical prescription. In cases where users were redirected to third-party websites from the initial link, the classification was done based on the evaluation of the final destination website offering medicines for sale. Links leading to inaccessible sites (eg, error 404) underwent multiple periodic evaluation attempts and were categorized as nonreliable if domains remained inaccessible.

Generative AI searches were conducted between July 10, 2023, and July 12, 2023, using Microsoft Edge desktop browser (version 114.0.1823.37) for Bing Chat and Google Chrome desktop browser (version 114.0.5735.198) for the Google SGE platform.

Data Analysis

Data were analyzed using the SPSS Statistics (version 26; IBM Corp) program. Descriptive statistics were used to describe the
prevalence of link categories in AI-generated search engine results for each prompt. The initial level of agreement between the 2 authors’ (ARA and AF) categorization of websites was assessed with Cohen κ statistic to measure interrater reliability. Both nominal and frequency data were analyzed using a chi-square analysis, in which P values <.05 were regarded as statistically significant.

**Ethical Considerations**

All information collected from this study was from the public domain, and the study did not involve any interaction with users or user-related data.

**Results**

A total of 262 links were provided by the generative search engine replies to our queries, with 136 generated from Google SGE and 126 from Microsoft Bing Chat. Of the links provided, 47.33% (124/262) suggested an active online pharmacy website that dispensed medications. It is important to note that a larger proportion of the results provided by both search engines did recommend legitimate pharmacies (82/262, 31.29%), with Google SGE at 25.74% (35/136) and Bing Chat at 37.3% (47/126). However, we also observed a notable presence of recommended links to illegal or unlicensed online pharmacies on both platforms. Specifically, 13.23% (18/136) of Google SGE’s responses and 19.04% (24/126) of links provided in Bing Chat’s generative replies were found to direct users to known illegal online pharmacies. (Table 1 and Figure 1 for example of Google SGE recommendation for illegal online seller of antidiabetic drug semaglutide that has been reported as counterfeited and sold online, including a recommendation to the semaspace website, which has been issued a warning letter from the US Food and Drug Administration for introducing misbranded and unapproved semaglutide and has subsequently been shut down.) The remaining 61.02% (83/136) of Google’s and 43.65% (55/126) of Bing Chat’s recommendations were for informational sites, articles, or other online sources, that is, telemedicine consultation websites, not directly selling medications to consumers.

A closer examination of the results for prescription medications queried reveals distinct differences between the 2 search engines’ generative feature recommendations. This suggests that both have likely implemented some form of additional controls to filter illegal sellers from results or that these recommendations are filtered or reviewed by other training or referenced data, although correct classification is not consistent (Multimedia Appendix 1 for additional examples of illegal sellers in recommendations). Although the overall occurrence of legitimate pharmacy websites was higher (P=.08) in Bing Chat (38/86, 44%) compared to Google SGE (29/92, 31%), the number of recommendations leading to illegal online sellers was significantly higher (P=.001) for Bing Chat (21/86, 24%) compared to Google SGE (6/92, 6%). The proportion of links to rogue websites was notably higher for the antibiotic amoxicillin (9/24, 37%) and the proton pump inhibitor omeprazole (7/19, 37%) in Bing Chat. However, Google’s generative AI search results showed an absence (0%) of illegal seller recommendations for these medications. Instead, Google’s generative AI search results included several illegal websites (3/23, 13%) offering the sale of sildenafil or Viagra, a commonly counterfeited erectile dysfunction medication [36]. In contrast, Bing Chat appeared to exclude illegal sellers of this drug (Table 1).

Specific to controlled substance recommendations, these narcotic medications hold a high potential for abuse and dependence and are subject to special regulatory and legal requirements at the national (eg, national controlled substance acts) and international (eg, United Nation conventions and treaties) levels and are generally not available for purchase and dispensing online. Despite these prohibitions, suggestions for where to purchase controlled drugs were returned using the simple prompt used in this study, which led to a significantly higher (P=.02) number of rogue sellers in Google SGE’s suggestions (12/44, 27%) compared to 7% (3/40) from Bing Chat. Notably, for the popular anxiolytic alprazolam or Xanax, a substantially higher number of illegal pharmacy suggestions (10/20, 50%) was observed compared to legitimate pharmacies (2/20, 10%) in Google SGE results. Xanax is also a controlled substance subject to abuse and counterfeiting [37]. The results of recommendations for controlled substances carry heightened consumer risk due to the high potential for abuse and known counterfeiting of versions of these drugs laced with fentanyl, which has led to overdose deaths due to poisoning [38].

Bing Chat provides a generative response to every query and also provides sources by default for key parts of the generated response. However, these links do not always directly relate to the topic of the AI-generated text, and in some instances, these may even be contradictory. For instance, when we asked Bing Chat, “Where can I buy fentanyl online?” the generated response began with, “I’m sorry, but I cannot help you with that.” This was followed by a well-reasoned explanation that “fentanyl is highly addictive and dangerous and can cause serious harm or even death.” Subsequently, it explained that “it is illegal to buy or sell fentanyl without a prescription,” and added, “I strongly advise you to avoid buying fentanyl online or anywhere else and seek professional help if you are struggling with addiction.” Finally, Bing AI offered help in finding resources for addiction treatment (Figure 2, screenshot on the left).
Table 1. Recommendations by generative AI\(^a\)-powered searches conducted using Microsoft’s Bing Chat and Google search generative experience for prescription medicine purchase–focused search terms.

\(^a\)AI: artificial intelligence.

\(^b\)ATC code: Classification of the substance according to the World Health Organization’s anatomical therapeutic chemical (ATC) system, table indicates level-4 ATC terminology based on the ATC/DDD (defined daily dose) index.

\(^c\)API: active pharmaceutical ingredient name.
This response is perfectly appropriate and demonstrates that the AI recognized the inherent danger of the situation from the user’s query and generated a sound and constructive response. This indicates that chatbots can be programmed to produce highly aligned responses reflective of public health concerns about sourcing medications online. However, it is disconcerting to note that the links provided in the “Learn more” section are not effectively monitored. The first link given to the user for this prompt led to an illegal online pharmacy (Figure 2, screenshot on the right). This is a notable weakness of Bing Chat. The majority of concerns we observed were in the hyperlinks within the generated response or recommended links below the response in the “Learn more” section. This issue could be attributed to the lack of stringent oversight over reviewing whether organic search results generated by the search engine provider include illegal sellers, which consequently surface in generative AI-related responses. This laxity allows illegal pharmacies to rank high within the organic SERPs and, in turn, find their way into the recommendations offered to users.

At the time of the study evaluation, the Google SGE was still in early experimental access in the United States and was not available in other locations. Contrary to Bing Chat, Google SGE did not generate extensive detailed generative responses to all user queries, and at times, the generative response was simply limited to “Here are some results,” followed by recommended links. As Google SGE also provides links along with its responses, and since it relies on the organic results ranking high on the SERPs to recommend links to users, it also returned questionable recommendations as observed in Bing Chat’s responses. Specifically, we encountered instances where illegal pharmacy websites were directly recommended to the user both within the generative text and in the recommended links for both platforms.
Discussion

Principal Findings

Our study found that one-third (44/124, 35.48%) of the recommendations made for purchasing medications online from an active online pharmacy site made by 2 popular generative AIs directed users to rogue online pharmacies and that recommendations were also made for online sources of controlled substances. These findings are in line with previously published data on traditional, non-AI–generated results, including this study on the prevalence of illegal internet pharmacy links in Google search results of 12 European countries, where we identified 19.8% (380/1920) were compromised [14].

Our recent findings signal a concerning public health issue intersecting with emerging technology, particularly salient as these LLM applications enjoy widespread and rapidly growing appeal, with ChatGPT reaching 100 million users just 2 months after its launch, making it the fastest-growing consumer application in history [39]. With tens of millions of users prompting responses to these generative AI systems daily, the potential for user exposure to known unsafe and fraudulent online pharmacy websites needs further study and action.

Specifically, the inadvertent promotion of illegal and rogue online pharmacy websites by generative AI platforms may be linked to the rogue search engine optimization techniques used by bad actors to gain high rankings on SERPs. This presents a new potential vulnerability that could be exploited to influence generative AI’s responses and recommendations for other popular health questions, similar to our observations of suggestions made for high-ranking SERPs for illegal or unlicensed pharmacies. Although the total number of illegal sellers recommended by these mainstream generative AI platforms was not overwhelmingly high, the mere presence of illegitimate vendors still represents a significant potential safety risk and could introduce challenging health and safety issues, as studies have shown individuals tend to prefer computer-generated advice over human advice as tasks become more complex [15] and that they rely more on algorithmically generated advice if it aligns closely with their initial guess [16]. This confirmation bias combined with potentially erroneous AI-generated advice or recommendations could lead users to make decisions that could jeopardize their health and well-being, particularly in the context of controlled substances and other medications known to be counterfeited. It is crucial that these risks are fully acknowledged and addressed, highlighting the urgent need for greater scrutiny of the way search engines index and rank websites, as well as the sources they use for training their AI models.

From a regulatory standpoint, it is imperative that governments around the world intensify their efforts with informed,
responsible policy making to address these emerging challenges and establish a robust legal framework for rigorous regulatory oversight of AI operations, including conversational generative search engine results. In April 2021, the European Commission proposed a draft regulation on AI known as the EU AI Act, a set of requirements and obligations to gain access to the EU market, which is the first regulation of its kind on AI. The draft incorporated sensible elements such as establishing a technology-neutral definition of AI systems in EU law, paired with a risk-level–based classification for these systems, the introduction of prohibitions on AI systems presenting “unacceptable” risks [40], and a public database to enable public scrutiny and democratic oversight of AI systems. However, the EU AI Act also has certain shortcomings, largely due to it being constructed from a mix of product safety regulations, fundamental rights protection, surveillance, and consumer protection laws from the 1980s [41]. The recent approval [42] of amendments and revisions to the draft is a promising starting point, but there remains much more work to be done.

Currently, tens of thousands of websites are offering medicines for sale, with numerous rogue vendors easily accessible via traditional search engine results not assisted by generative AI. It is already challenging for consumers to differentiate between illegal and legitimate internet pharmacies. As we have previously emphasized [3], regulators and search engine providers have a shared responsibility to implement additional guardrails for AI-generated recommendations in order to ensure the protection and promotion of well-being, consumer safety, and public health. These should include real-time verification solutions built into AI systems to confirm the safety and legitimacy of online pharmacies before featuring them in search results. Search engine providers also need to take a more proactive role in directing users toward licensed and reputable pharmacies, whose lists are available on the national authority websites of many countries. Despite these calls to action, the chronic issue of illegal online pharmacies infiltrating search engine results remains unresolved and may be exacerbated by inaccurate suggestions generated by LLMs that are now integrated into search engines, as demonstrated in this study.

Limitations

We performed a comparative analysis of 2 leading generative AI-integrated search platforms accessed by millions of users daily. However, this approach has some limitations. The rationale for opting against having a nongenerative conventional search comparison group was based on the extensive pre-existing literature, already indicating the prevalence of illegal online pharmacy links in search results before generative AI integration. The primary objective of this study was instead to specifically identify and characterize whether questionable recommendations occurred with generative AI search results.

Further, it is challenging to compare structured search queries on conventional search (eg, buy [Drug Name] without a prescription) with more conversational user queries (eg, Where can I buy [Drug Name] online?) as the latter are not mere keywords but nuanced prompts for the LLM, shaping its human-like conversational response. Due to the dynamic nature of generative AI systems, similar queries might yield varied results and are not longitudinally comparable. One might perceive our findings as anomalies that are part of the development process and easy to mitigate; however, we urge stakeholders to consider this as a cautionary case study that signals a potential paradigm shift that could alter current infodemiology and infoveillance methodologies, reshaping our approach to studying online health–related information-seeking behaviors. Future studies should further explore the influence of generative AI systems on consumer search patterns while seeking medications online compared to conventional search engine queries, online forums, social media, and other user-generated content.

Conclusions

The emergence of generative AI–integrated search is a promising development with the potential to fundamentally reshape our interactions with the digital world, and its impact on public health is both unavoidable and inevitable. Our research has uncovered a concerning new trend: links to both legal and illegal online pharmacies appeared together in generative AI responses being integrated into search engine results delivered to the public, highlighting the urgent need for more comprehensive and focused oversight. With proper integration of generative AI, search engines can strategically prioritize linking to verified, legal pharmacies within generated responses, addressing the longstanding issue of illegal online medicine vendors appearing in search results. Improving generative AI search results in this manner could enhance patient safety by ensuring access to accurate information and authentic and safe pharmaceutical products. However, the realization of this potential is heavily contingent upon the decisions made by technology stakeholders about the development and deployment strategies of AI-assisted technologies. Through meticulous planning and effective regulation, we can fully harness the power of AI while prioritizing the safety of the online pharmaceutical market to safeguard public health.

Abstract

Background: The COVID-19 pandemic impacted mental health and health care systems worldwide.

Objective: This study examined the COVID-19 pandemic’s impact on ambulance attendances for mental health and overdose, comparing similar regions in the United Kingdom and Canada that implemented different public health measures.

Methods: An interrupted time series study of ambulance attendances was conducted for mental health and overdose in the United Kingdom (East Midlands region) and Canada (Hamilton and Niagara regions). Data were obtained from 182,497 ambulance attendance records for the study period of December 29, 2019, to August 1, 2020. Negative binomial regressions modeled the count of attendances per week per 100,000 population in the weeks leading up to the lockdown, the week the lockdown was initiated, and the weeks following the lockdown. Stratified analyses were conducted by sex and age.

Results: Ambulance attendances for mental health and overdose had very small week-over-week increases prior to lockdown (United Kingdom: incidence rate ratio [IRR] 1.002, 95% CI 1.002-1.003 for mental health). However, substantial changes were observed at the time of lockdown; while there was a statistically significant drop in the rate of overdose attendances in the study regions of both countries (United Kingdom: IRR 0.573, 95% CI 0.518-0.635 and Canada: IRR 0.743, 95% CI 0.602-0.917), the rate of mental health attendances increased in the UK region only (United Kingdom: IRR 1.125, 95% CI 1.031-1.227 and Canada: IRR 0.922, 95% CI 0.794-1.071). Different trends were observed based on sex and age categories within and between study regions.

Conclusions: The observed changes in ambulance attendances for mental health and overdose at the time of lockdown differed between the UK and Canada study regions. These results may inform future pandemic planning and further research on the public health measures that may explain observed regional differences.

Introduction

As the SARS-CoV-2 (COVID-19) pandemic has spread across the globe, it presents a major threat to mental health in general and is related to alcohol and substance use [1-3]. Government responses, in the form of travel restrictions and economic support for the COVID-19 pandemic, vary greatly from country to country [4]. Sweeping border closures and strict public health measures were variably implemented by many governments in an effort to contain the virus. However, inconsistencies in government responses may have contributed to fear and uncertainty, while strict public health measures may lead to social isolation [5].

Anxiety, depression, poor sleep quality, and psychological distress are mental health symptoms that have increased since the start of the COVID-19 pandemic [6]. Stress and poor mental health are being exacerbated by the uncertain future of the pandemic, misinformation, and social isolation brought about by physical distancing measures [7,8]. Factors such as sex and age have also been identified as risk factors for experiencing negative mental health effects of the COVID-19 pandemic [6,9].

Being younger and identifying as female have both been linked to experiencing lower psychological well-being throughout the course of the pandemic. Relatedly, there are also reports of an increase in overdoses during the COVID-19 pandemic [10,11]. This may be due to changes in the availability of illicit drugs during lockdown [2], possibly resulting in a higher rate of overdoses when access was restored, and also challenges in physically accessing pharmaceutical therapies (eg, methadone) [2]. In addition, a systematic review in 2022 reported that mental health and overdose are consistently found to be associated across studies, although the causal mechanism remains unclear [12]. In the context of COVID-19, it has been reported that social isolation has put at risk the vulnerable population of substance users, increasing the strain on mental health and subsequently further increasing the probability of an overdose [2]. Therefore, mental health and overdose are 2 related, but different, outcomes that should be examined in tandem.

Currently, studies examining the relationship between mental health and COVID-19 rely on self-reported measures [6,9,13]. Other indicators of population mental health and overdoses are of interest, especially for policy and resource planning. Emergency medical service (EMS) data, such as attendances, have previously been used to understand public health trends, which can help planning and resource allocation [14].

Due to variation in population characteristics and the government response to COVID-19 between countries, differences may exist in mental health effects. Specifically, the United Kingdom and Canada are 2 countries that experienced differing national responses to the ongoing pandemic. A report by the chief public health officer of Canada found that self-perceived mental health status decreased during the COVID-19 pandemic when compared to 2018 and that overdoses were increasing [11]. A comparison of the mental health and overdose effects of COVID-19 between Canada and the United Kingdom is of interest, as population characteristics and EMS attendance differ. Understanding the need for other indicators of mental health and overdose besides self-reporting, EMS data will be used to elucidate the impact of COVID-19 on EMS attendances.

Little is known about the trend in attendances before and after lockdown, especially for mental health and overdoses internationally. This paper aims to compare differences in the trends and volumes of mental health and overdose attendances before and after lockdown between specific regions in Canada and the United Kingdom. Evidence suggests that differences exist between mental health and overdose effects between sexes and age groups [6,9]. Therefore, this study will examine and describe the number of mental health and overdose attendances to 911 or 999 EMS calls in regions of the United Kingdom and Canada according to population subgroups.

Methods

Study Design

We used an interrupted time series design, analyzing weekly ambulance attendances before and after the COVID-19 lockdown from regions of the United Kingdom (East Midlands) and Canada (Niagara and Hamilton, Ontario). The East Midlands Ambulance Service NHS Trust is a regional EMS that operates in the East Midlands of the United Kingdom. In Canada, 2 services were examined: Niagara Emergency Medical Services is a moderate-sized EMS that operates in the Niagara region of Ontario, Canada, and Hamilton Paramedic Service is a moderate-sized EMS in Hamilton, Ontario. We purposefully selected these regions in the United Kingdom and Canada for comparison since they have similar population densities and median household incomes, and it was feasible to obtain their EMS call records.

Population

In Canada, the study population was those attended to by Niagara Emergency Medical Services and Hamilton Paramedic Service in Ontario. The population of Niagara and Hamilton was obtained from the 2021 Canadian Census Profile [15]. In the United Kingdom, the study population was the East Midlands region of England, which is served by East Midlands Ambulance Service NHS Trust. The population for the East Midlands region was obtained from the Office for National Statistics using the midyear population estimates [16] by age and sex.

Ethical Considerations

In the United Kingdom, the study was given NHS favorable ethical opinion (reference 20/SC/0307) by the South Central—Berkshire B Research Ethics Committee and is listed on the Integrated Research Application System as 286198. Patient records for this study were anonymized by the ambulance service, and informed consent could not be feasibly obtained for this retrospective study of administrative data. In Canada, the study was reviewed by the Hamilton Integrated Research Ethics Board, and a waiver letter was issued since individual patient data were not released by the paramedic services, and only weekly aggregated administrative data for the entire region were provided for this study.
Data Collection

Overview

The weekly number of ambulance attendances (Sunday to Saturday) was collected covering 2 adjacent time periods: the weeks leading up to the lockdown (December 29, 2019, until March 21, 2020, in the United Kingdom and March 14, 2020, in Canada) and the weeks during and following the lockdown (March 22, 2020 and March 15 in the United Kingdom and Canada, respectively, until August 1, 2020). The lockdown occurred on March 23, 2020, in the United Kingdom and March 15, 2020, in Canada.

Mental Health and Overdose

Ambulance call records for mental health and overdose were identified by the ambulance services through clinical impression (provisional diagnosis) codes recorded by ambulance staff when attending the patient. The UK and Canadian systems for assigning problem codes to paramedic-patient encounters are similar, though the actual codes available to select from are slightly different in each country. Work to map the 2 countries’ systems of paramedic coding is underway [17]. Where more than one problem code existed (Canada), data for all problem codes (primary, secondary, and final) were extracted. The mental health records were identified in Canada as clinical impression or problem code 45 (behavior or psychiatric) and in the United Kingdom as the clinical impressions “admission under mental health act,” “anxiety,” “attempted suicide,” “deliberate self-harm,” “depression,” “panic attack,” “psychosis,” and “other mental health.” For overdose, the records were identified in Canada as clinical impression or problem codes 81 (drug or alcohol overdose), 81.1 (opioid overdose), or 81.2 (alcohol intoxication) and in the United Kingdom as clinical impression “intentional drug overdose (mental health),” “accidental overdose or poisoning (medical),” “effects of alcohol,” and “query intoxicated (medical).”

Sex and Age Groups

Sex was recorded in Canada and the United Kingdom by the crew in attendance. Age was recorded from self-report or estimated by the crew in attendance where this was not possible. Age groups were used to categorize the data into 18 years and younger, 18-44 years, 45-65 years, and 65 years and older.

Statistical Analysis

Using an interrupted time series approach (Figure 1), the number of weekly attendances was modeled as the outcome using negative binomial regression, and the results were reported as incidence rate ratios (IRRs). As shown in Figure 1, for each regression, the prelockdown trend of weekly calls was modeled (per week), and then a counterfactual scenario was imagined, where the trend in the data would have continued without the interruption. The counterfactual scenario provided a comparison for the evaluation of the impact of the lockdown by examining the change in level at the time of the lockdown (lockdown) and the change in the slope during lockdown (lockdown trend) relative to this counterfactual scenario.

Figure 1. Interrupted time series study design used to model the change in weekly emergency medical service calls at the time of lockdown and the period following lockdown.

Negative binomial regression was identified as the most appropriate model since there was overdispersion observed in the outcome variables. The models were fitted using time (in weeks relative to the lockdown start week), lockdown (a binary categorical variable of before lockdown and during lockdown), lockdown trend (time in weeks following lockdown, which indicates the slope change following lockdown), and seasonality (an adjustment made via the categorical variable of month) with an offset of total population size. All statistical analysis was conducted using R (R Foundation for Statistical Computing).

Results

Table 1 shows there were 4.9 million people living in the area served by the ambulance service in the East Midlands region.
of the United Kingdom and 1.0 million in the Canadian regions of Hamilton and Niagara. The proportion of female individuals in each location was similar (n=2,457,905, 50.5% vs n=522,488, 51.2%), as were the proportions of individuals aged 65 years and older (n=902,947, 18.6% vs n=207,184, 20.5%). Household incomes and population densities were found to be similar, as well (Table 1). In the Canadian study regions, the ambulance services provided 1 vehicle per 14,776 persons, while in the UK study region, it was 1 per 9809 persons.

During the study period, there were 182,947 attendances for mental health and overdose in the study regions (Table 2 and Table S1 in Multimedia Appendix 1), with an average of 1042.9 calls per week for mental health and 776.4 calls per week for overdose in the UK regions, and 232.5 calls per week for mental health and 139.1 calls per week for overdose in the Canadian regions. The interrupted time series analysis showed that in the time prior to the lockdown, attendances in the UK region for mental health had a small but statistically significant increasing rate across weeks, whereas the rate of these attendances was steady week-over-week in the Canadian regions. When the lockdown was initiated (the interruption in the time series) the rate of attendances for mental health in the UK region had a statistically significant increase and then remained stable with no statistically significant slope for the weeks during lockdown, while the Canadian regions saw no change when the lockdown was initiated (interruption) or in the slope during lockdown.

Overdose attendances had a similar small but statistically significant weekly increase in both the UK and Canadian regions, and both had statistically significant drops in the rate of overdose attendances when the lockdown was initiated. However, while the UK study region rebounded to having a statistically significant positive slope in attendance rate after lockdown, the Canadian regions maintained this lower level of attendances after lockdown with a statistically nonsignificant slope.

Table 3 shows model estimates for the rate of mental health attendance by sex and age categories across the study weeks (also see Table S2 in Multimedia Appendix 1). For the Canadian regions, although the full sample showed no statistically significant changes in mental health attendances, this subgroup analysis demonstrates that there were substantial changes for male individuals. Specifically, at the time of lockdown (interruption), there was a statistically significant decrease in the rate of mental health attendances for male individuals, which then rebounded with a positive slope during the lockdown period. In contrast, both male and female individuals in the UK region had an increase in the rate of mental health attendances when the lockdown was initiated and then held steady at that new level.

\(^b\) IRR: incidence rate ratio.

\(^c\) IRRs statistically significant at \(P<.05\) are indicated in italics format.

While the Canadian regions showed no statistically significant changes in the rate of mental health attendances by age category, the UK region found that those younger than 18 years of age had a statistically significant decrease in mental health attendances when the lockdown was initiated, while those aged 45-65 years and 65 years and older had a statistically significant increase. In addition, for those aged 65 years and older, the rate of attendances for mental health continued to increase during the lockdown period.

Table 4 shows the attendances for overdose in each of the sex and age subgroups (also see Table S3 in Multimedia Appendix 1). Similar to what was observed for mental health attendances, in the Canadian Region, there was a statistically significant drop in attendances for overdose at the time the lockdown was
initiated; however, for this outcome, there was also a statistically significant drop for those aged 18-44 years. In the United Kingdom, a consistent statistically significant decrease in attendances for overdose was observed among all age and sex subgroups, followed by a statistically significant positive slope week-over-week for all subgroups in the period during lockdown.

Table 4. For each sex and age category strata, an interrupted time series of weekly emergency medical service calls for overdose from January 2019 to July 2020 using negative binomial regression offset by the total population, for regions in the United Kingdom and in Canada.\(^a\)

Discussion

Principal Findings

Our study found that there were statistically significant differences in the effects of lockdown on mental health and overdose attendances when comparing the United Kingdom and Canada. A web-based cross-sectional survey in the United Kingdom, 4 weeks into lockdown, found that 5% of participants were positive for a common mental health disorder [21]. In Canada, a cross-sectional survey found women of working age were most affected by a mental health condition, while 54% of Canadians reported good mental health [11]. While these surveys are helpful for understanding the self-reported mental health of populations, using EMS data as an indicator of mental health status among populations provides a powerful approach to understanding complex social changes in a novel way.

Both Canada and the United Kingdom experienced major societal changes during 2020 caused by the COVID-19 pandemic and took different approaches to addressing this event, which may explain observed differences in rates of mental health and overdose attendances for specific sex and age categories. The United Kingdom entered the first lockdown on March 23, 2020, while Ontario (Canada) had already reached this stage on March 15, 2020. Schools, colleges, and universities closed, and a large majority of the working population worked from home or was funded to not work (known as furlough in the United Kingdom). Hospitality services closed, and citizens were requested to remain at home. Primary care moved to web-based and telephone-based consultations, and general practitioners met patients in person only when necessary for examination. International borders were closed in Canada but remained largely open in the United Kingdom.

Financial benefits and emergency funding also differed between countries. The Canada Emergency Response Benefit paid a gross of CAD $2000 (equivalent to just under £1200 sterling or US $1480) per month for those who had lost their jobs or were unable to work. The United Kingdom relied on the standard benefit system, known as Universal Credit, for those who lost their jobs. Those still employed, but unable to work, were given 80% of their gross pay, up to a maximum of £2500 per month (equivalent to just over CAD $4200 or US $3100). Fiscal stimulus packages varied, with Canada investing 18.6% of gross domestic product and the United Kingdom 17.8% [22]. Finances are known to be a major cause of stress and mental health issues.

A measure of comparison between countries that actually allows us to compare the different approaches holistically is that of the stringency index. It is a measure of governmental and public health orders that took effect during the pandemic [4], allowing global comparisons due to a scoring system attributing values to components of lockdown (such as stay-at-home orders, business, and facility openings). A comparison of the United Kingdom’s and Canada’s stringency indices (shown in Multimedia Appendix 2) showed that, in fact, the United Kingdom and Canada experienced similar levels of lockdown, despite different governmental policies and other local public health unit mandates. The EMS data allow for health-related differences between countries that may be influenced by societal changes that have become evident, while contrasting comparisons of overall indices of lockdown stringency can concurrently be examined.

Mental Health and Overdose

This study found that prior to the pandemic lockdown, overall the rate of mental health presentations was holding constant in Canada, and there was a very small increase over time in the United Kingdom. When the lockdown was initiated, a difference in EMS attendance was seen between the countries; in the United Kingdom, nonoverdose attendance for mental health increased substantially, while in Canada, there was no change. These observed differences between Canada and the United Kingdom may, in fact, be due to the differences in the governmental lockdowns and orders. In particular, health care workers have experienced a high prevalence of anxiety, depression, and insomnia. This may be due to several factors, including fear of infection and the overwhelming influx of new information pertaining to caring for patients with COVID-19 [23-25].

Both countries also showed similar rises in rates of attendances for overdoses prior to lockdown. The immediate effect of the lockdown was similar, with a large reduction in attendances for overdose in both the United Kingdom and Canada, although the rate was increasing again during the lockdown period in the United Kingdom. The level of overdoses may be impacted by not only mental health stressors but also other societal changes resulting from the pandemic. Where the availability of drugs and alcohol becomes reduced and supplies dwindle due to a lack of prescribing or a lack of street drugs, overdose may become more likely in the subsequent period, as tolerance to these substances may have decreased.

Differences by Sex

In the UK study region, there were no sex differences for mental health and overdose attendances; both sexes had similar increases for mental health but decreases for overdose. However, in the Canadian study regions, there was a statistically significant decrease in both mental health and overdose attendances for male individuals, while there was no statistically significant change for female individuals. The reasons for these different trends among the sex strata within and between the UK and Canadian study regions are likely to be extremely complex and multifactorial, and therefore difficult to tease out in this paper without further study.

Differences by Age

There has been debate about the impact of lockdown on children and young adults [26]. Schools closed in both the United Kingdom and Canada, and school-age children were taught by parents or guardians. In the UK study region, the week-over-week rate of mental health attendances was increasing in a similar manner for all age categories in the period before lockdown, but at the time of lockdown, there was a substantial drop in the rate of attendances among the individuals younger than 18-years of age, whereas there was an increase among the individuals aged 45-65 years and those older than 65 years. In contrast, in the Canadian study regions, there were no statistically significant changes in the rate of mental health attendances for male individuals, while there was no statistically significant decrease in both mental health and overdose in both the United Kingdom and Canada, although the rate was increasing again during the lockdown period in the United Kingdom. The level of overdoses may be impacted by not only mental health stressors but also other societal changes resulting from the pandemic. Where the availability of drugs and alcohol becomes reduced and supplies dwindle due to a lack of prescribing or a lack of street drugs, overdose may become more likely in the subsequent period, as tolerance to these substances may have decreased.

Financial benefits and emergency funding also differed between countries. The Canada Emergency Response Benefit paid a gross of CAD $2000 (equivalent to just under £1200 sterling or US $1480) per month for those who had lost their jobs or were unable to work. The United Kingdom relied on the standard benefit system, known as Universal Credit, for those who lost their jobs. Those still employed, but unable to work, were given 80% of their gross pay, up to a maximum of £2500 per month (equivalent to just over CAD $4200 or US $3100). Fiscal stimulus packages varied, with Canada investing 18.6% of gross domestic product and the United Kingdom 17.8% [22]. Finances are known to be a major cause of stress and mental health issues.

A measure of comparison between countries that actually allows us to compare the different approaches holistically is that of the stringency index. It is a measure of governmental and public health orders that took effect during the pandemic [4], allowing global comparisons due to a scoring system attributing values to components of lockdown (such as stay-at-home orders, business, and facility openings). A comparison of the United Kingdom’s and Canada’s stringency indices (shown in Multimedia Appendix 2) showed that, in fact, the United Kingdom and Canada experienced similar levels of lockdown, despite different governmental policies and other local public health unit mandates. The EMS data allow for health-related differences between countries that may be influenced by societal changes that have become evident, while contrasting comparisons of overall indices of lockdown stringency can concurrently be examined.

Mental Health and Overdose

This study found that prior to the pandemic lockdown, overall the rate of mental health presentations was holding constant in Canada, and there was a very small increase over time in the United Kingdom. When the lockdown was initiated, a difference in EMS attendance was seen between the countries; in the United Kingdom, nonoverdose attendance for mental health increased substantially, while in Canada, there was no change. These observed differences between Canada and the United Kingdom may, in fact, be due to the differences in the governmental lockdowns and orders. In particular, health care workers have experienced a high prevalence of anxiety, depression, and insomnia. This may be due to several factors, including fear of infection and the overwhelming influx of new information pertaining to caring for patients with COVID-19 [23-25].

Both countries also showed similar rises in rates of attendances for overdoses prior to lockdown. The immediate effect of the lockdown was similar, with a large reduction in attendances for overdose in both the United Kingdom and Canada, although the rate was increasing again during the lockdown period in the United Kingdom. The level of overdoses may be impacted by not only mental health stressors but also other societal changes resulting from the pandemic. Where the availability of drugs and alcohol becomes reduced and supplies dwindle due to a lack of prescribing or a lack of street drugs, overdose may become more likely in the subsequent period, as tolerance to these substances may have decreased.
attendances at the time the lockdown was initiated for any of the age category strata. For rates of overdose attendances, there was no noticeable effect demonstrated by different age group strata in Canada or the United Kingdom.

In the United Kingdom, examinations were canceled for the General Certificate of Secondary Education (16-year-olds) and A-levels (18-year-olds), which may have reduced stress. In addition, there may have been decreased stress due to learning at home, without the need to attend school in person, with less exposure to school-related stressors. This is supported by existing literature describing how adolescents with existing mental health problems pre-COVID-19 had less during the pandemic [27]. In Canada, the education system has no equivalent to the General Certificate of Secondary Education and A-level examinations; therefore, pandemic schooling-related effects would have been different and may not have been as pronounced, resulting in no statistically significant mental health changes pre-COVID-19 compared to during the pandemic.

In both the United Kingdom and Canada, there was considerable distress caused by the volume of vulnerable people in care homes and the speed of government responses. This was seen by the number of deaths among care-home residents [28] over the period from March 20, 2020, to January 15, 2021. In the United Kingdom, 33% (n=30,851) of COVID-19–related deaths were among people residing in care homes. In Canada, long-term care home residents accounted for 59% (n=11,114) of COVID-19–related fatalities. As a result of these problems, care home residents were subject to significant restrictions, leading to reduced access to medical care and isolation-related stress. Although it could be expected that the older age groups (45-55 years and 65 years and older) would worry about income, poor COVID-19 outcomes due to higher rates of chronic diseases [29], and about family and parents in care homes (United Kingdom) or long-term care facilities (Canada), these age groups had a statistically significant increase in mental health–related calls in the United Kingdom but not in Canada. Other literature from the United Kingdom demonstrates worse mental health in age groups younger than 35 years; however, the data were from a cross-sectional survey during lockdown [21]. These differences might be explained by behavioral differences in the reasons for which it was deemed appropriate to call EMS in each country, by less stress overall in one country versus the other, or by differences in the data collection method used to determine mental health problems (calls to EMS vs self-reported survey). However, further research is needed to understand these differences, which are beyond the scope of this paper.

Strengths and Limitations
This study compares routinely collected observational data from 2 Western countries. Data were collected primarily for routine clinical recording, monitoring, and clinical auditing rather than for epidemiological research. These data have nevertheless allowed a careful examination of the ambulance response to mental health and overdose emergencies experienced by the populations, using data that are not self-reported. It should be noted that responses to mental health in both the United Kingdom and Canada tend to have similar patient pathways. Both countries have a national health system, in which health care is freely available to all; therefore, the pathways open to patients are to call 911/999 to visit a primary care doctor or facility where they can receive emergency or urgent care.

There will be confounders that may explain some of the predictions made by the statistical models. Age and sex were adjusted for, but data were not available to adjust for ethnicity or socioeconomic status. In the United Kingdom and Canada, there have been clear differences in the rates of COVID-19 between different ethnic groups and levels of affluence. These differences are also likely to contribute to differences in rates of mental illness and requirements for mental health support.

There were differences in the data collected between each country, and efforts were made to adjust for these underlying coding differences. Intentionality was not used to define overdose. Clinical impression (ambulance provisional diagnosis) codes were not entirely comparable between the 2 countries. In Canada, impression code 81 (drug or alcohol overdose) is captured by the 4 most relevant codes in the United Kingdom. There will be cases missed and documented as “other medical problem” or “acute behavioral disturbance,” for example, but that broadens the category too wide. The agreement was achieved by extracting comparable codes through discussion.

Conclusions
The EMS attendance data have demonstrated varying impacts of the COVID-19 pandemic on mental health and overdose between the study regions in the United Kingdom and Canada. While the countries implemented similar degrees of lockdowns and public health measures, as seen with the stringency index, there were differences in the specific measures taken; these differences may explain the divergence in mental health attendances between the regions. In contrast, overdose attendances followed similar patterns between the study regions. Future research is needed to explore the mechanisms behind these observed trends in EMS attendances following the lockdown and to examine whether the countries return to having similar rates of attendances over time as they did prior to the lockdown.

Improving Parental Health Literacy in Primary Caregivers of 0- to 3-Year-Old Children Through a WeChat Official Account: Cluster Randomized Controlled Trial

Yun Li¹,*, MM, MD; Qiuli Xiao²,*, MD; Min Chen¹, MD; Chunhua Jiang¹, MM, MD; Shurong Kang¹, MD; Ying Zhang¹, MD; Jun Huang¹, MD; Yulin Yang³, MD; Mu Li⁵, MD, PhD; Hong Jiang², MD, PhD

Abstract

Background: Parental health literacy is important to children’s health and development, especially in the first 3 years. However, few studies have explored effective intervention strategies to improve parental literacy.

Objective: This study aimed to determine the effects of a WeChat official account (WOA)–based intervention on parental health literacy of primary caregivers of children aged 0-3 years.

Methods: This cluster randomized controlled trial enrolled 1332 caregiver-child dyads from all 13 community health centers (CHCs) in Minhang District, Shanghai, China, between April 2020 and April 2021. Participants in intervention CHCs received purposefully designed videos via a WOA, which automatically recorded the times of watching for each participant, supplemented with reading materials from other trusted web-based sources. The contents of the videos were constructed in accordance with the comprehensive parental health literacy model of WHO (World Health Organization)/Europe (WHO/Europe). Participants in control CHCs received printed materials similar to the intervention group. All the participants were followed up for 9 months. Both groups could access routine child health services as usual during follow-up. The primary outcome was parental health literacy measured by a validated instrument, the Chinese Parental Health Literacy Questionnaire (CPLHQ) of children aged 0-3 years. Secondary outcomes included parenting behaviors and children’s health outcomes. We used the generalized linear mixed model (GLMM) for data analyses and performed different subgroup analyses. The β coefficient, risk ratio (RR), and their 95% CI were used to assess the intervention’s effect.

Results: After the 9-month intervention, 69.4% (518/746) of caregivers had watched at least 1 video. Participants in the intervention group had higher CPLHQ total scores (β=2.51, 95% CI 0.12-4.91) and higher psychological scores (β=1.63, 95% CI 0.16-3.10) than those in the control group. The intervention group also reported a higher rate of exclusive breastfeeding (EBF) at 6 months (38.9% vs 23.44%; RR 1.90, 95% CI 1.07-3.38) and a higher awareness rate of vitamin D supplementation for infants younger than 6 months (76.7% vs 70.5%; RR 1.39, 95% CI 1.06-1.82). No significant effects were detected for the physical score on the CPLHQ, breastfeeding rate, routine checkup rate, and children’s health outcomes. Furthermore, despite slight subgroup differences in the intervention’s effects on the total CPLHQ score and EBF rate, no interaction effect was observed between these subgroup factors and intervention factors.

Conclusions: Using a WHO literacy model–based health intervention through a WOA has the potential of improving parental health literacy and EBF rates at 6 months. However, innovative strategies and evidence-based content are required to engage more participants and achieve better intervention outcomes.

### Introduction

A child’s health and well-being are critical in the first 3 years of his or her life, over the short and long term [1,2]. During this period, a caregiver’s health literacy is crucial in the child’s development and health [3]. WHO (World Health Organization)/Europe (WHO/Europe) has proposed a 12D model that identifies 4 competencies for health literacy. These competencies include accessing, understanding, appraising, and applying health information across 3 domains: health care, disease prevention, and health promotion [4]. Studies have shown that caregivers with low health literacy were more likely to engage in risky parenting behaviors, such as not practicing breastfeeding (BF), not administering medications to children as prescribed, and allowing children long screen time [5-7]. These can lead to poor health outcomes for their children, such as poor disease management and high emergency service usage [8-10]. Despite this, few studies have evaluated the effectiveness of interventions aiming to improve parental health literacy.

The 2020 Chinese Health Literacy Surveillance Report revealed that only 35.9% of Chinese residents had basic health literacy [11]. Health professionals in China were confronted with a limited health workforce and high demand for childcare services [12]. In-person communication has also been restricted due to the COVID-19 pandemic, making it challenging for caregivers to access reliable health information [13]. Therefore, there is an urgent need for feasible and effective alternative approaches to deliver health promotion and support for caregivers of young children.

Social media has become a popular platform for individuals to obtain and share health-related information in recent years [14-18]. WeChat, one of China’s largest social media platforms, had over 1.3 billion monthly active users worldwide by the end of 2023 [19]. WeChat offers several innovative function modules, including WeChat official accounts (WOAs), which enable users to access information, services, and subscriber interaction [20]. A recent national survey showed that one-third of respondents regularly accessed health information via WeChat and nearly two-thirds considered WOAs a feasible medium for accessing health education material [21]. Studies have shown that using WeChat or WOAs for health intervention could significantly improve satisfaction, accessibility, and convenience compared to traditional health education [22,23]. By integrating diverse forms of information, including text, images, videos, and links to digital books and web pages, WeChat and WOAs have the potential to enhance parental health literacy. WeChat’s health education campaign for pregnant women has been proven effective in promoting exclusive breastfeeding (EBF) [24]. A WeChat-based family health education program also significantly raised parents’ awareness of children’s illness prevention [25]. However, most existing studies have only addressed limited aspects of health literacy. Our WOA intervention is grounded in the WHO/Europe comprehensive health literacy model. It aims to enhance parental health literacy, and its effectiveness is evaluated through a cluster randomized controlled trial among caregivers of children aged 0-3 years in an urban setting in China.

### Methods

#### Study Design

According to a prespecified study protocol, a cluster randomized controlled trial was conducted from April 7, 2020, to April 20, 2021, in Minhang District, Shanghai, China [26]. All 13 Minhang District community health centers (CHCs) were enrolled and randomly allocated to the intervention or control group through random sequence generation, with 1332 eligible caregiver-child dyads participating in the trial. The CHCs were responsible for providing child health care services in their catchments for children from birth to 3 years of age.

#### Participants

Since we planned a 9-month intervention, we recruited primary caregivers of children aged 0-3 years. The primary caregiver herein refers to the person who provided primary care to the child, including the child’s mother, father, grandmother, grandfather, and other caregivers including nannies. One caregiver at most was recruited within each family. In case of families with multiple children, the participating caregiver would designate only one of them to be involved in this study and provide their unique health record number.

When caregiver-child dyads attended child health care in CHCs, the CHCs’ staff approached and informed them about the study. Caregivers were eligible if they were adults (older than 18 years) and primary caregivers of children aged 0-3 years, completed at least the third grade of primary school, owned a smartphone and an individual WeChat account, were able to communicate verbally or in writing, and planned to stay in the recruitment area for at least a year. Immediately after recruitment, all participating caregivers were invited to subscribe to the designed WOA for data collection in both groups and intervention delivery only for the intervention group.

#### Blinding

Due to the nature of the intervention, service providers and participants were not blinded to the group allocation. Immediately after baseline data collection, group allocation was revealed to the participants.

#### Interventions

##### Contents of the WOA-Based Intervention

Contents of the intervention videos were developed in accordance with 12 subdimensions of health literacy by WHO/Europe [4]. Through literature review and expert consultation, 15 key topics about children’s health and development (10 physical and 5 psychological) were generated and categorized into 3 domains, including health care, disease prevention, and health promotion. Each key topic was designed to improve caregivers’ 4 types of capacity in accessing, understanding, appraising, and applying child health information. The detailed logic model for this WOA-based intervention program has been prespecified in our protocol [26].

##### The WOA Platform

The Scientific Parenting platform, specifically designed for this WOA-based intervention, was integrated into the WeChat app.
Participants were invited to subscribe and register upon providing informed consent. The registration involved entering their child’s unique health record number, date of birth, relationship with the child, and catchment CHCs. Once participants logged in, the platform automatically assigned them to different functions based on their catchment CHCs. All participants had access to the web-based survey module, while only those in the intervention CHCs could see and access the intervention module. Two electronic questionnaires were automatically delivered to each participant via the web-based survey module, one at recruitment and the other 9 months later. Figure 1 shows a detailed illustration of the participants’ journey through the Scientific Parenting platform.

**Figure 1.** Participants’ journey through the scientific parenting platform of the WeChat official account (WOA)–based intervention. BF: breastfeeding; CHC: community health center; CPHLQ: Chinese Parental Health Literacy Questionnaire; EBF: exclusive breastfeeding; VD: vitamin D.

**Intervention Group**

The intervention package was provided in the intervention module, consisting of videos developed on the basis of the previously mentioned WHO/Europe health literacy model. The videos included 4 video clips of experts’ talks between 13 and 33 minutes and 6 animated video clips of 1 to 5 minutes, totaling 2 hours. During the 9-month intervention, participants could self-navigate, select topics that they were interested in, and decide the order and pace of material they read or watch. Participants could watch the videos repeatedly, and the number of times the videos were watched was recorded automatically.
by the platform in each user’s account. Additionally, we provided participants with reading material from other trusted web-based sources as supplemented material to videos. Participants could access this web-based reading material by clicking on links, such as e-books, websites, and other WOAs in public. Furthermore, the contents were closely related to key topics of the videos, and the web-based reading material also covered other topics such as early education, healthy home environment, etc.

**Control Group**

Participants in the control group received printed educational material as an extension to routine child health care when they took their children for health checkups. The contents of the printed material resembled those of the videos delivered to the intervention group. The printed educational material is also detailed in our protocol [26].

Both groups received routine child health care services, including weight and length measurements, self-reported child feeding practice and dietary intake, and checkups of children’s health conditions [27].

**Outcome Measures**

The primary outcome measured was the change in total scores of parental health literacy (physical and psychological) using a validated questionnaire [28,29]. Secondary outcomes included (1) parenting behaviors, such as the EBF rate at 6 months, any BF rate at 12 months, the consumption rate of iron-fortified staple foods at 6 months, and the rate of routine checkup of the child’s vision and oral health; (2) the proportion of participants’ awareness of vitamin D (VD) supplementation for infants aged 0 to 6 months; (3) children’s anthropometric measures, including weight-for-length z score, length-for-age z score, weight-for-age z score, BMI-for-age z score, and head circumference-for-age z scores; and (4) children’s health outcomes, such as the incidence of anemia, unintended injuries, diarrhea, obesity, and hospitalization.

**Data Collection**

All participants completed the baseline survey through the web-based survey module on the WOA platform. The final survey will automatically be made available to the participants 9 months after the baseline survey.

In the baseline survey, we collected demographics and health-related variables, including participants’ relationship with their children, education level, source of parental information, family income, number of children in the family, children’s age, gender, and Hukou (the Chinese official permanent residency registration by location, which is closely linked with social welfare and administration [26,27]).

Parental health literacy was measured using a validated questionnaire, the Chinese Parental Health Literacy Questionnaire (CPhLQ) of children aged 0-3 years, at baseline and the end line [28,29]. The CPhLQ was designed by the research group based on the health literacy model proposed by WHO/Europe [4]. This questionnaire was validated among primary caregivers of children aged 0-3 years across different regions in China [28,30]. It consists of a 39-item subscale for physical health literacy and a 35-item subscale for psychological health literacy. Both the physical and psychological subscales were scaled on a score of 0-100, of which the total maximum score was 200.

In the final survey, we collected data on awareness of VD supplementation, parenting behaviors, including attendance in routine checkups for the children’s vision and oral health, and children’s health outcomes, such as unintended injury, diarrhea, and hospitalization. For awareness of VD supplementation, we asked the participants if they thought that administering VD supplements to their children after birth was necessary. For attendance in routine checkups, we asked if they had taken their children for regular visual and oral health checkups during the intervention. For children’s health outcomes, we asked about the occurrence of unintended injury, diarrhea, and hospitalization in the past 9 months. Participants’ engagement in the intervention, the frequency of video watching by participants, was automatically tracked by a function embedded in the WOA platform. However, due to administration rights, we could not track participants’ accessing links to reading materials on other web-based platforms.

Children living in the project district were required to take routine health checkups at specific ages: 1, 2, 4, 6, 9, 12, 18, 24, 30, and 36 months. During these checkups, child health care providers at CHCs would conduct face-to-face interviews to collect data on various parameters such as EBF, BF, introduction of solid foods, anthropometric measures, and health conditions such as obesity and anemia [31]. Project researchers would later extract all relevant health checkups’ data from baseline to 1 month after the 9-month intervention. Children younger than 6 months who were exclusively breastfed at baseline were eligible for the EBF analysis. Similarly, children younger than 6 months who had not been introduced to solid foods at baseline were eligible for the analysis of supplementation of iron-fortified staple foods at 6 months. Children younger than 12 months who were still breastfed at baseline were eligible for the BF analysis.

For the analysis of anthropometric measures and health conditions such as obesity and anemia, health checkup data closest to the final web-based evaluation survey were used, and baseline values were included as covariates.

**Sample Size Calculation**

We assumed an intervention effect size of 15 points for total scores on the CPhLQ, a coefficient of variation of 0.2, and an intracluster correlation coefficient of 0.05 [28]. A total of 1183 caregivers from 13 CHCs (clusters), with a mean cluster size of 91 per CHC, was estimated to detect the assumed effect size with 90% power at a 5% significance level. We also considered an approximately 20% rate of loss to follow-up.

**Statistical Analysis**

We conducted descriptive statistical analyses for all outcomes, presenting continuous variables as mean (SD) or median (IQR) values and categorical variables as proportions (%). To compare differences between the 2 groups, we used independent t tests for continuous variables and chi-square tests for categorical variables. Anthropometric indicators were calculated using the WHO Anthro (version 3.2.2) [32]. To compare within-group
differences (mean change from baseline) between the baseline and at the end of 9 months of the intervention, we used the paired \( t \) test.

To assess the intervention’s effects, we performed intention-to-treat analyses and generalized linear mixed models (GLMMs), as recommended for cluster randomized trials [33]. We used multiple imputations to handle missing values at the end of the trial. The GLMMs included CHC-level random intercepts to account for the correlation due to the clustering of participants within CHCs. For each outcome analysis, the model was adjusted for demographic characteristics. Additionally, the baseline CPHLQ score, anthropometric \( z \) score, and status of obesity and anemia were included in the model for evaluation of the intervention effects. By controlling the correlation between baseline and follow-up values, we avoided the need for time or a time × group interaction term to interpret intervention effects [34]. Given the relatively small number of clusters, Satterthwaite correction was used in GLMM to maintain an appropriate type I error [35]. Satterthwaite correction allowed us to estimate the degree of freedom on the basis of the residual variances at different variable levels [36].

We reported the intervention effect using \( \beta \) (95% CI) and \( P \) values for continuous outcomes. We used risk ratios (RRs), their 95% CIs, and \( P \) values to describe the intervention effect for categorical outcomes.

To identify any potential modifications, we conducted subgroup and interaction analyses for the total score on the CPHLQ and the EBF rate at 6 months. Participants were stratified into diverse subgroups based on their relationship with the child (mothers vs others), the child’s Hukou (Shanghai vs others), whether they had 1 child or more, the participant’s education level (university or higher vs less than university education), and source of parental information access (social media vs others). For the total score on the CPHLQ, we presented the \( \beta \) (95% CI) of GLMMs within each subgroup and the \( P \) value for interaction items of GLMMs in the overall group. For the EBF rate at 6 months, we presented the RR (95% CI) of GLMMs within each subgroup. Additionally, we used the multiplicative scale for multiplicative interaction and the relative excess risk due to interaction, attributable proportion due to interaction, and synergy index for additive interaction in the overall GLMMs.

Results with a type I error rate of \( P < 0.05 \) in 2-sided tests were considered statistically significant. Statistical analysis was performed using R statistical software (version 4.1.3; The R Foundation).

Ethical Considerations
The trial was approved by the ethics committee of Shanghai Minhang District Maternal and Child Health Hospital (approval number #2020-KS-01) and registered with the Chinese Clinical Trial Registry (#ChiCTR2000031711). All trial participants provided their written informed consent during the recruitment process.

Results
Study Participation
A total of 1332 caregiver-child dyads from 13 CHCs participated in the study. Six CHCs containing 746 dyads were randomly assigned to the intervention group, and 7 CHCs containing 586 dyads to the control group (Figure 2).
According to the baseline information, among 1332 participants, 81.7% (1088/1332) of primary participants were mothers and 82.9% (1104/1332) of participants had college or above education. The majority (92.7%, 1235/1332) of participants accessed parenting information from other social media sites (Table 1). Among all children aged 0-3 years, 71.2% (948/1332) of them were the only children in the family, 48.4% (645/1332) of them were boys, and 62.0% (826/1332) of them were in the Shanghai Hukou (Table 1).
Table. Baseline characteristics of the participants in the WeChat official account (WOA)–based intervention (April 7, 2020, to April 20, 2021, in Shanghai).

<sup>a</sup>P values for comparing the intervention and control groups.

<sup>b</sup>Not applicable.

<sup>c</sup>Italicized values are significant at P<.05.

<sup>d</sup>1 RMB=US $0.14.

There was no significant difference between the intervention and the control group regarding participants’ relationship with their child, the child’s age and gender, the number of children in the family, family monthly income, and child feeding mode (P>.05). However, compared to the control group, fewer participants in the intervention group had a university or higher level of education, children with Shanghai Hukou, and received information from other social media sites (P<.05).

Participants’ Adherence to the Intervention Program

During the 9-month intervention program, the WOA platform automatically tracked the frequency of participants watching the videos. Of 746 participants in the intervention group, 69.4%...
had watched at least 1 video. Participants who watched the videos tended to have younger children (8.12 vs 9.54 months, \(P=.01\)), not have a Shanghai Hukou (49.8% vs 33.3%, \(P<.001\)), be the children’s mothers (85.9% vs 78.1%, \(P=.01\)), have an education below university level (23.0% vs 14.0%, \(P=.007\)), and remain in the study (83.4% vs 76.8%, \(P=.04\)), compared to those who never watched any video during the intervention (Table S1 in Multimedia Appendix 1).

At each video level, less than 50% (range 14.9%-46.5%) of participants in the intervention group had ever watched the video. The 3 videos with the highest watching rate were scientific feeding guidance (46.5%), childhood pneumonia identification (41.7%), and childhood obesity prevention (41.6%). The average number of times viewing each video clip ranged from 0.14 to 1.35. The most frequently viewed video clips were scientific feeding guidance (1.35 times), unintentional injury prevention (0.91 times), and essential information on health care for children aged 0 to 3 years (0.81 times).

**Retention of the Study Participants**

At the end of 9 months, the retention rates of the intervention and control groups did not differ significantly (81.4% vs 81.2%, \(P=.95\)). Compared to participants enrolled at baseline, those lost to follow-up tended to be the child’s father or other caregivers (18.3% vs 30.1%, \(P<.001\)). Compared to participants who remained in the study, they also tended to be child’s father or other caregivers (15.6% vs 30.1%, \(P<.001\)) and have a child without a Shanghai Hukou (36.7% vs 43.8%, \(P=.04\); Table S2 in Multimedia Appendix 1). Please refer to Multimedia Appendix 2 for a detailed missing data report of this study.

**Intervention Effect**

**Parental Health Literacy**

The results of parental health literacy are presented in Figure 3. At the final evaluation, both the intervention and control groups showed increased scores on the CPHLQ compared to baseline. The intervention group had increased total, physical, and psychological part scores on the CPHLQ by 10.44, 5.86, and 4.01 points, the control group had an increase by 3.96, 3.82, and 0.15 points, respectively, compared to baseline. Using the GLMM and controlling for the baseline score and other potential confounders, we observed a significant intervention effect on the total CPHLQ scores (\(\beta=2.51, 95\%\ CI 0.12-4.91\)) and psychological scores (\(\beta=1.63, 95\%\ CI 0.16-3.10\)), while there was no significant difference in the physical parental health literacy score.
**Figure 3.** Effect of the WeChat official account (WOA)–based intervention (April 7, 2020, to April 20, 2021, in Shanghai) on the Chinese Parental Health Literacy Questionnaire (CPHLQ) and children’s anthropometric measures. \(^a\) \(P\) values describing the changes from baseline to follow-up in the intervention or control group. \(^b\)The results of the generalized linear mixed model (GLMM) with the group as a fixed factor, community health centers (CHCs) as the random intercept, follow-up values as outcomes, and baseline values, caregiver’s relationship with the child, education level, the child’s gender, Hukou, whether they are the only child or not, and source of parental information access as covariates. BAZ: BMI-for-age \(z\) score; HAZ: length-for-age \(z\) score; HCZ: head circumference–for-age \(z\) score; WAZ: weight-for-age \(z\) score; WHZ: weight-for-length \(z\) score. \(*P < .05; \***P < .001.\)

We analyzed the effect of watching at least 1 intervention video on CPHLQ scores (Figures 4 and 5). Within the intervention group, both participants who had not watched videos and those who watched at least 1 video demonstrated an increased total score. Using the GLMM, compared to participants who watched at least 1 video, those in the control group had a significantly lower total score (\(\beta=2.68, 95\% \text{ CI} 0.20-5.17\)) and psychological score (\(\beta=1.72, 95\% \text{ CI} 0.13-3.32\)), after controlling for the baseline score and other potential confounders.
Figure 4. Comparisons of total score on the Chinese Parental Health Literacy Questionnaire (CPLHMQ) among participants with different adherent statuses in the WeChat official account (WOA)–based intervention (April 7, 2020, to April 20, 2021, in Shanghai). \( ^a \)P values describing differences in the total score from baseline to follow-up using the paired t test. \( ^b \)P values describing the difference in change in the total score between participants with different adherent statuses using the t test. Participants with different adherent statuses: ① those in the intervention group who had never watched videos; ② those in the intervention group who had watched at least 1 video; and ③ those in the control group. ***P≤.001.
Despite slight differences in the intervention’s effects on the total score on the CPHLQ among different subgroups, no interaction effect was observed between these subgroup factors and the intervention (Figure 6).
Parenting Behaviors

The effect of the intervention on parenting behaviors is illustrated in Figure 7. According to the GLMMs controlled for potential confounders, the intervention group demonstrated a significantly higher EBF rate at 6 months than the control group (38.9% vs 23.44%; RR 1.90, 95% CI 1.07-3.38). Additionally, there were no significant between-group differences in the BF rate at 12 months, iron-fortified staple food supplementation at 6 months, and routine checkup of the child’s vision and oral health.
**Figure 7.** Effect of the WeChat official account (WOA)–based intervention (April 7, 2020, to April 20, 2021, in Shanghai) on parenting behaviors, awareness, and children’s health outcomes. The risk ratio (RR) and 95% CI values describe the results of the generalized linear mixed model (GLMM) with the group as a fixed factor, community health centers (CHCs) as the random intercept, follow-up values as outcomes, and baseline values for caregiver’s relationship with their children, education level, child’s gender, Hukou, whether they are an only child or not, and source of parental information access as covariates. BF: breastfeeding; EBF: exclusive breastfeeding; VD: vitamin D. *0.01<P≤.05; **0.001<P≤.01; ***P≤.001.

The results of subgroup analyses on EBF at 6 months are presented in Figure 8. Neither multiplicative nor additive interaction effects were observed between the subgroup factors and the intervention.
Figure 8. Subgroup analyses of the effects of the WeChat official account (WOA)-based intervention on participants’ exclusive breastfeeding (EBF) rate at 6 months. The risk ratio (RR) and 95% CI values describe the results of the generalized linear mixed model (GLMM) within each subgroup with the group as a fixed factor, community health centers (CHCs) as the random intercept, follow-up values as outcomes, and baseline values of caregiver’s relationship with the children, education level, child’s gender, Hukou, whether they are an only child or not, and source of parental information as covariates. The multiplicative scale described the multiplicative interaction between subgroup factors and intervention, while the relative excess risk due to the interaction (RERI), attributable proportion due to the interaction (AP), and synergy index (SI) describe the additive interaction. * $0.01 \leq P \leq 0.05$.

Awareness of VD Supplementation After Birth

The results of VD supplementation awareness are presented in Figure 7. After controlling for potential confounders, the GLMM showed that the intervention group had a significantly higher awareness rate of VD supplementation after birth than the control group (76.7% vs 70.5%; RR 1.39, 95% CI 1.06-1.82).

Children’s Anthropometric and Health Outcomes

The results of children’s anthropometric and health outcomes are respectively presented in Figures 3 and 7. Using the adjusted GLMM, no significant intervention effects were observed in children’s anthropometric and health outcomes between the intervention and control groups.
Discussion

Principal Findings

We developed a digital parenting health literacy intervention of purposefully designed videos, supplemented with reading material from other web-based platforms and evaluated the effectiveness of the intervention. The rate of viewing at least 1 intervention video was nearly 70%. The 9-month WOA-based intervention significantly improved the health literacy score among caregivers of 0– to 3-year-old children, EBF rate at 6 months, and their awareness of VD supplementation for young children.

Comparison With Previous Studies

Digital technology has been widely used as an educational tool for health information delivery [37,38]. WeChat is a popular Chinese instant messaging and social media application. It has also been used to overcome temporal and geographical constraints to deliver health-related information and provide health support [39]. Evidence has shown the effects of WeChat-based interventions on improving specific parenting knowledge or practices. For example, perioperative health education via a WeChat platform effectively enhanced parents’ knowledge of care for children with heart diseases [23]. A WeChat-based parenting training proved promising in improving parenting attitudes among mothers of children with autism during the COVID-19 pandemic [13]. A WeChat health education program in Qinghai, China, significantly increased the early-life EBF rate [24]. Our study results provide further evidence regarding the feasibility of improving parental health literacy via WeChat in a community setting.

The intervention group had significantly increased scores on the CPHLQ’s psychological component after the intervention and a significant group effect after controlling for baseline scores and other confounding factors. This finding suggests that the WOA-based intervention was superior in improving psychological health literacy compared to traditional paper-based health promotion interventions. A recent study supported our finding and reported that a WeChat-based program improved the psychospiritual well-being of patients with digestive cancers [40]. Psychological interventions delivered through WeChat were more effective probably because the contents were more diversified and engaging, such as text, images, audio, videos, and interactional games [20].

Since the caregivers’ educational level could be a significant determinant of parental health literacy [41], we performed subgroup analyses to evaluate the intervention’s effects among caregivers with different educational levels. Although we did not observe significant interaction effects, the results of subgroup analyses show that this WOA-based intervention might be effective only for caregivers with university-level or higher education. This could be possibly explained by the small proportion of caregivers with relatively lower education, only 13% of them with less than university-level education [42], which contributed to an insufficient sample size in the low-education subgroup analysis. Another reason might be that people with a higher education level were also equipped with higher eHealth literacy and thus had a better understanding of web-based information than others [43]. Therefore, future health literacy intervention research should focus on low education to further assess the effect of WOA-based interventions.

The intervention improved the EBF rate at 6 months. In China, many parents and caregivers believe that the right time for stopping EBF and introducing solid foods is approximately 4 months [31]. Although child health staff in Minhang District had promoted EBF for 6 months, at baseline, many caregivers were still unaware of the significance of the recommendation. In this study, we emphasized the importance of EBF for 6 months via a WOA-based intervention program, demonstrating an increase in the EBF rate in the first 6 months. No intervention effect was observed for any breastfeeding at 12 or 24 months. This could be explained by the influence of confounding factors, such as mothers returning to work before their children turn 6 months old and the lack of a supportive environment in the workplace [44]. Although the law mandates an hour of lactation leave per day for nursing mothers in the workplace, supports from society and the workplace for breastfeeding remain to be improved [45], especially in workplaces with a high female employment rate.

VD plays a crucial role in bone health and immunity and has been gaining growing attention for its role in children’s oral health [46,47]. During infancy, VD deficiency is associated with various disorders, such as dental caries and rickets [48]. In an animated video, we recommended that a liquid VD supplement of 400 international units per day begins within the first few days of life and continues throughout childhood, as suggested by the American Academy of Pediatrics [49] and the Chinese Dietary Guidelines for Children [50]. After the 9-month intervention, participants in the intervention group had a higher level of awareness of VD supplementation for infants aged 0-6 months than those in the control group. This finding is similar to that of a previous web-based intervention study [51].

Early screening for visual and oral disorders is an important content of routine health checkups for young children, which can identify related disorders, such as acquired blindness and dental caries [52,53]. Current evidence suggests that maternal education increased children’s visit to oral health care services [54]. Considering that social media has been widely used in health education [55], we hypothesized that a WOA-based intervention for caregivers could significantly improve children’s visit to routine checkups of visual and oral health. However, we did not find such an effect in our study. This might be due to the relatively low weight of the intervention contents on these topics compared to others such as nutrition. In addition, health education resources specified for children’s visual and oral health development need to be further strengthened in China to promote attendance in routine checkups [56].

Limitations

Although this study has shown promising results in enhancing parental health literacy, some limitations should be acknowledged. First, it was conducted only in 1 district of Shanghai, which limits its generalizability to nonurban areas or populations with diverse demographics. Second, despite using random sequence generation for cluster randomization, there was an imbalance between groups in participant’s education.
and child’s Hukou, etc. This might be mainly attributed to the small number of clusters [57]. To minimize bias, we included potential confounders in the multivariate analysis and corrected \( P \) values by the Satterthwaite method. Future study involving more clusters are recommended to evaluate the intervention’s effect more accurately. Third, the low viewing rate of the intervention videos suggests a lack of learning motivation among participants. Given that the intervention was delivered in a real-world setting, this could reflect the true compliance of the health education intervention among caregivers in real life. Unfortunately, we could not collect data on participants’ exposure to supplementary web-based reading material due to the unavailability of administration rights to access the information. Lastly, child psychological development was not included as an outcome measure because psychological assessment is not routinely conducted in child health checkups because there is a need for specialized training, additional resources, and participant cooperation.

**Conclusions**

We developed a comprehensive digital parental health literacy intervention program using WAOs. The intervention offered caregivers a reliable and trusted official source of parental health information. We demonstrated that the social media–based interventions delivered through a WOA could improve parental health literacy and parenting behaviors. Compared with traditional paper-based health materials, a WOA-based intervention can potentially be used for health education to address other public health challenges. Evidence-based content and innovative strategies are needed to engage more participants and achieve better intervention outcomes.

Abstract

Background: Varicella is a mild, self-limited disease caused by varicella-zoster virus (VZV) infection. Recently, the disease burden of varicella has been gradually increasing in China; however, the epidemiological characteristics of varicella have not been reported for Anhui Province.

Objective: The aim of this study was to analyze the epidemiology of varicella in Anhui from 2012 to 2021, which can provide a basis for the future study and formulation of varicella prevention and control policies in the province.

Methods: Surveillance data were used to characterize the epidemiology of varicella in Anhui from 2012 to 2021 in terms of population, time, and space. Spatial autocorrelation of varicella was explored using the Moran index ($I$). The Kulldorff space-time scan statistic was used to analyze the spatiotemporal aggregation of varicella.

Results: A total of 276,115 cases of varicella were reported from 2012 to 2021 in Anhui, with an average annual incidence of 44.8 per 100,000, and the highest incidence was 81.2 per 100,000 in 2019. The male-to-female ratio of cases was approximately 1.26, which has been gradually decreasing in recent years. The population aged 5-14 years comprised the high-incidence group, although the incidence in the population 30 years and older has gradually increased. Students accounted for the majority of cases, and the proportion of cases in both home-reared children (aged 0-7 years who are not sent to nurseries, daycare centers, or school) and kindergarten children (aged 3-6 years) has changed slightly in recent years. There were two peaks of varicella incidence annually, except for 2020, and the incidence was typically higher in the winter peak than in summer. The incidence of varicella in southern Anhui was higher than that in northern Anhui. The average annual incidence at the county level ranged from 6.61 to 152.14 per 100,000, and the varicella epidemics in 2018-2021 were relatively severe. The spatial and temporal distribution of varicella in Anhui was not random, with a positive spatial autocorrelation found at the county level ($I=0.412$). There were 11 districts or counties with high-high clusters, mainly distributed in the south of Anhui, and 3 districts or counties with high-low or low-high clusters. Space-time scan analysis identified five possible clusters of areas, and the most likely cluster was distributed in the southeastern region of Anhui.

Conclusions: This study comprehensively describes the epidemiology and changing trend of varicella in Anhui from 2012 to 2021. In the future, preventive and control measures should be strengthened for the key populations and regions of varicella.

https://publichealth.jmir.org/2024/1/e50673
**Introduction**

Varicella, also known as chickenpox, is a highly contagious, self-limited disease caused by varicella-zoster virus (VZV) that commonly infects children and could become reactivated following primary infection to induce herpes zoster (HZ), or shingles, infection in the future [1]. As a human-specific pathogenic alphaherpesvirus, primary VZV infection first acts on the upper respiratory mucosa with an incubation period of 10-21 days, followed by a generalized vesicular rash, which is accompanied by fever and headache [2,3]. VZV will remain latent in the human ganglia after the primary infection, which may then become reactivated to induce HZ, a localized, painful vesicular rash that can lead to the development of postherpetic neuralgia in some individuals [4,5]. Although varicella usually presents with mild symptoms, the World Health Organization (WHO) conservatively estimated that 4.2 million hospitalizations were associated with severe varicella complications annually worldwide [6], and that use of the vaccine has reduced the disease burden of varicella to a certain extent.

During the 1960s and 1970s, Japanese scientists developed a live attenuated varicella vaccine with the Oka VZV strain after several cell cultures and passages, which was subsequently used for the active immunization of varicella in many countries [7,8]. Varicella vaccines are commonly used globally in monovalent form or combined with the measles, mumps, and rubella vaccine; varicella vaccines have an overall effectiveness of 81% and effectiveness against moderate or severe varicella of 98% [9]. The WHO recommended that varicella vaccination coverage should be maintained at more than 80% and considered including varicella vaccination in the routine childhood immunization program [6]. Currently, 50 WHO member countries or territories have introduced the varicella vaccine in the routine vaccination schedule [10]. In countries such as the United States, Germany, and Costa Rica, the incidence and hospitalization rates of varicella have significantly reduced compared to those of the prevaccination era [11-14]; thus, the varicella vaccination program has had a positive impact on the epidemiology and disease burden of varicella. However, varicella vaccination is voluntary and self-paying in most areas of China, with few areas providing the vaccine for free and the two-dose schedule has not yet been introduced nationwide. The varicella vaccination rate in China was estimated to be 61% [15], and the reported incidence of varicella increased from 55 per 100,000 people in 2016 to 70 per 100,000 people in 2019, with an average of 1000 outbreaks occurring annually [16]. In addition, reports from some regions of China have shown that the incidence of varicella has increased by approximately 40% annually [17-19]. However, related data have not yet been reported for Anhui Province.

Spatiotemporal investigations based on geographic information systems have been increasingly used in modern epidemiology research [20], which could help to visualize the incidence trends and spatial distributions of infectious diseases, providing a new framework for analyzing their spatiotemporal changes and transmission patterns. Previous studies demonstrated the spatiotemporal aggregation and spatial correlation patterns of varicella occurrence [19,21]. However, no study has yet focused on the epidemiological characteristics or spatial and temporal distributions of varicella in Anhui. Since Anhui is an inland province in the east of China with vast differences in population distribution and geographical characteristics, a systematic epidemiological analysis of the current varicella prevalence could provide a basis for future studies and strategies targeting varicella in Anhui.

Toward this end, the aim of this study was to analyze the epidemiological characteristics of varicella in Anhui using the data of varicella incidence from 2012 to 2021, combined with spatiotemporal epidemiological methods. These findings can provide a basis for the formulation of varicella prevention and control policies and immunization strategies.

**Methods**

**Setting**

Anhui Province covers a total area of 140,100 km², located at longitude 114°54'-119°37' E and latitude 29°41'-34°38' N. Anhui covers the jurisdiction of 16 cities and 104 county-level administrative regions and is part of the Yangtze River Delta region of China. Anhui lies in the transition zone between the warm temperate zone and subtropics, with an average annual temperature of 14-17 °C. The Yangtze River and the Huai River run through the province, dividing the province into three parts, with an overall high elevation in the southwest and low elevation in the northeast. The population of Anhui was estimated at approximately 61.13 million by the end of 2021, showing a greater density in the north than in the south of the province.

**Data Sources**

Data on reported varicella cases and population statistics were obtained from the China Information System for Disease Control and Prevention (CISDCP), which is the world’s largest internet-based disease reporting system that was established by the Chinese government after the 2003 SARS epidemic. The CISDCP is based on the real-time reporting of individual cases and the relevant information of each case can be obtained, such as age, sex, occupation, and the specific location of the onset [22]. Clinical- and laboratory-confirmed cases of varicella reported in the CISDCP were selected for analysis in this study.

**Descriptive Analysis**

The annual and monthly incidence rates of varicella from 2012 to 2021 were collected and epidemic curves were plotted to reveal the incidence peaks. The distribution characteristics of varicella according to variations in age, sex, and occupation were also analyzed. The incidence of varicella in each county or city was associated with geographical information according to the administrative district code, and annual incidence maps were plotted to describe the distribution of varicella in Anhui. All statistical analyses and data visualization were performed using R Studio software (version 4.1.1).

**Spatial Autocorrelation Analysis**

GeoDa (version 1.20) was used to perform the spatial autocorrelation analysis. The Moran index (Moran I) reflects the correlation of attribute values in adjacent areas and can be used to judge the overall spatial distribution [23]. The Moran I
value ranges from –1 to 1, indicating a stronger negative or positive spatial autocorrelation, respectively. In this study, the spatial weight matrix was constructed according to the first-order Queen adjacency rule and the significance test of spatial autocorrelation was carried out. The null hypothesis was that varicella is randomly distributed in Anhui. The hypothesis test of local indicators of spatial association (LISA) [24] was performed and the Moran scatter plot was used to explore the association pattern of hotspot areas. The local association pattern can be divided into four categories: high-high, high-low, low-high, and low-low. The LISA significance test was performed using 999 permutations at a probability level of .05.

**Space-Time Scan Analysis**

The space-time scan statistic is defined by a cylindrical window with a circular (or elliptic or network-based) geographic base and a height corresponding to time. The base is defined as a circular window with changing radius size centered on several possible grid points throughout the study area, while the height reflects the time period of potential clusters. The cylindrical window then moves in space and time so that every possible geographic location and size for each possible time period is accessed. In this process, an infinite number of overlapping cylinders of different sizes and shapes could be obtained, jointly covering the entire study area with each cylinder reflecting a possible cluster. For this study, we adopted the discrete Poisson model described by Kulldorff [25] to conduct a retrospective space-time scan analysis of the spatiotemporal aggregation of varicella. Maximum-likelihood estimation was performed for the locations and sizes of all cylindrical windows, and the alternative hypothesis was that the incidences were higher in the windows than in the outside regions. The $P$ value of the likelihood ratio test was obtained by 999 Monte Carlo simulations based on a probability level of .05. The cylindrical window with the maximum-likelihood ratio was considered to be the most likely cluster and the secondary cluster was sorted according to the size of likelihood ratio test statistics. The maximum spatial cluster size and temporal cluster size were set to 20% of the population at risk and 30% of the study period, respectively. The space-time scan analysis was performed using SaTScan (version 10.1).

**Ethical Considerations**

This study used monitoring data from the CISDCP and no sensitive information was retrieved about the cases or patients. Since this study did not involve any human subjects, it did not require notification to the Ethics Committee according to national ethical review regulations [26].

**Results**

**General Epidemiological Characteristics**

From 2012 to 2021, there were 276,115 cases of varicella and 4 deaths in Anhui, and the average annual incidence was 44.8 per 100,000. Overall, there was an increasing trend of varicella incidence between 2012 and 2019, followed by a decline in 2020 and a slight rebound in 2021. The proportion of male cases among the total number of new annual cases showed a decreasing trend over the decade, whereas the number of female cases gradually increased ($\chi^2 = 269.18$, $P_{\text{trend}} < .001$); the overall sex ratio of cases was approximately 1.26. Details are shown in Table 1 and Figure 1A.

The main age of varicella incidence was 5-14 years, accounting for more than 50% of all cases. The proportion of varicella cases decreased gradually in people aged 0-9 years, whereas there was an increasing trend among those 30 years or older (Figure 1B). In addition, students (ie, children and adolescents 6 years and older who are already enrolled in school) accounted for approximately 60% of reported cases, and the proportion of cases in home-reared children and kindergarten children (aged 3-6 years) increased by 5% and decreased by 9%, respectively (Table 1).

The epidemic curve showed the typical seasonal distribution of varicella with peak incidence occurring twice annually. The incidence was usually higher in the winter peak (November to January of the following year) than in the summer peak (May to June). Only the winter peak occurred in 2020 (Figure 1C).

In terms of the geographical distribution, the incidence of varicella was commonly higher in southern Anhui than in northern Anhui from 2012 to 2021. The high-prevalence areas were the cities of Huangshan, Wuhu, and Ma’anshan, and the lower-prevalence areas were the cities of Huainan, Suzhou, and Anqing (see Multimedia Appendix 1). The incidence in most areas was lower than 50 per 100,000 from 2012 to 2016, whereas between 2018 and 2021, there were some relatively severe varicella epidemics along with clear regional differences (Figure 2). The average incidence at the county level ranged from 6.61 to 152.14 per 100,000.

<sup>a</sup> Home-reared children refer to infants and young children (from birth to 7 years old) who are not sent to nursery or kindergarten and are raised and educated at home.
Figure 1. (A) Incidence of varicella and number of cases by sex, 2012-2021. (B) Age (years) distribution of varicella, 2012-2021. (C) Monthly incidence of varicella in Anhui Province, 2012-2021.
Spatial Autocorrelation

Globally, a positive spatial autocorrelation of varicella incidence was found at the county level from 2012 to 2021, with Moran I of 0.412; this positive correlation was significant throughout the observation period, with Moran I ranging from 0.186 to 0.451 (Table 2). All of the hotspot clusters (high-high) were distributed in the southern region, including six districts and five counties in Huangshan, Wuhu, and Chizhou. The low-low clusters were mainly identified in Huainan, Anqing, and Suzhou. The high-low and low-high clusters included Tianjia’an District, Taihu, and Dangtu County (Figure 3).

Spatiotemporal Clusters

Space-time scan analysis identified five possible clusters of areas where varicella incidence was higher than that in other areas in the specific time period. The most likely cluster was located in southeastern Anhui, including parts of Ma’anshan, Wuhu, Huangshan, Tongling, and Chizhou and the whole territory of Xuancheng. The four secondary clusters were mainly distributed in Hefei, Bengbu, Fuyang, and the Xiangshan district of Huaihe (Figure 4).

Figure 3. Spatial autocorrelation local indicators of spatial association (LISA) cluster maps of varicella in Anhui Province, 2021-2021.
Discussion

Principal Findings

In this study, we comprehensively described the epidemiology of varicella in Anhui over the last decade. To our knowledge, this is the first study to analyze the changing epidemiological characteristics and identify the incidence hotspot areas of varicella from a province perspective. The reported incidence of varicella in Anhui increased by approximately 20% annually from 2012 to 2019, with a 10-year average incidence of 44.8 per 100,000, which is largely consistent with the rising trend in other regions of China [16,27,28]. The incidence peaked in 2019 at 81.2 per 100,000 people, which is higher than the national average but is lower than the averages for Guizhou, Hangzhou, and Dalian for the same period [28-30]. The higher incidence of varicella in Anhui may be related to the increased sensitivity of infectious disease surveillance in recent years but also may be related to the insufficient coverage of vaccination. In the United States, the routine varicella vaccination program began in 1995, and the Advisory Committee on Immunization Practices recommended adding a second dose for children 4-6 years of age in 2007 [31]; there has been a 97% reduction in varicella incidence in 2019 compared to that prior to the implementation of routine vaccination [32]. Japan introduced routine vaccination with two doses of varicella vaccine in 2014, and the number of varicella hospitalizations decreased by 88% in 2017, including an 88% decrease in hospitalization of children aged 1-4 years [33]. By 2019, the incidence of varicella in Japan had decreased by 78% from that reported in 2000-2011 [34]. In South Korea and Turkey, in which one-dose routine immunization was implemented, the incidence, hospitalization, and complication rates of varicella were significantly reduced due to high vaccination rates [14,35]. The varicella vaccine is not currently included in the routine immunization program in China and there is no universal two-dose varicella vaccination, which may explain the high disease burden of varicella in Anhui.

Similar to previous studies, there were more cases of varicella in males than females [16,19]. However, the sex difference has narrowed gradually in recent years, which was also found in the study in Chongqing, China [19]. This may be caused by the widespread transmission of VZV in susceptible populations as the community has not yet established immune barriers. The proportion of varicella cases among children and adolescents under 14 years of age decreased slightly, whereas the proportion among adults 30 years and older tended to increase in Anhui. More children are now vaccinated compared to the historical proportion, and the vaccine is demonstrated to be effective in reducing the risk of infection in younger age groups. This study found a shift in the age of onset to older age groups, which is consistent with previous studies [36,37]. However, this outcome differs from other studies that did not observe an increase in the average age of varicella incidence, likely due to herd immunity obtained from high vaccine coverage [14,38,39]. Nevertheless, enhancing surveillance of changes in varicella prevalence among adults in Anhui, especially those over 30 years of age, is warranted in the future. In addition, the proportion of varicella cases among kindergarten children gradually decreased, whereas the proportion increased among home-reared children, which slightly differs from the results of a previous study in Chongqing [19]. More children were
vaccinated before entering kindergarten according to confirmation of vaccination certificates, which also provides considerable protection despite the risk of clustered outbreaks. Suspected cases of varicella can also be detected in a timely manner through routine morning and noon physical examinations, thereby reducing the impact on other children. In general, home-reared children are less likely to be vaccinated because there is not a preadmission vaccination certificate requirement as is the case for enrolling in kindergarten. Moreover, since home-reared children typically accompany their guardians in their living and socializing activities, they are more likely to contact a wider variety of people compared to kindergarten children and do not have the immunity from vaccination; thus, home-reared children are more likely to come into contact with VZV-infected people, making them more susceptible to VZV infection. This suggests that more attention should be paid to home-reared children to improve their vaccination rate and protection, along with further education of their guardians regarding varicella in parallel with strengthening school outbreak surveillance.

Varicella showed a seasonal rise in winter and summer, which was consistent with previous studies [19,21]. In 2020, the incidence of varicella significantly declined and only a predominate winter peak occurred; this phenomenon has also been observed for other respiratory infectious diseases. The incidence of notifiable respiratory infectious diseases in China decreased significantly in 2020, with a 65% decrease in both measles and influenza [40]. Following the COVID-19 pandemic, many public health measures, including wider lockdowns, wearing masks, and social distancing, were taken to reduce the transmission of SARS-CoV-2 via droplets and aerosols [41]. These measures may have reduced the exposure to other respiratory viruses. In addition, concerns about COVID-19 infection and increased awareness of self-protection have led to fewer reports from health care facilities. According to the seasonal pattern of varicella (not considering 2020), health education, vaccination, and the sensitivity of surveillance should be strengthened during the low-incidence period to help reduce outbreaks and more severe prevalence during the high-incidence season.

The spatial and temporal distributions of varicella were not random in Anhui. Although spatiotemporal clusters of varicella have occurred in the cities of Bengbu, Huaiabei, and Fuyang in the northern region of Anhui from 2017 to 2021, on the whole, the reported incidence in southern Anhui was higher than that in northern Anhui. Several studies found that respiratory infectious diseases showed patterns of high-risk clusters in remote rural or urban-rural transition zones where economic, educational, and medical resources are often lacking [21,42,43]. However, the most likely clusters of varicella in Anhui were located in the more economically developed areas of Hefei and in the southeast region of the province. Geographically, Anhui is connected to Jiangsu Province in the east and Zhejiang Province in the southeast, and the prevalence of varicella was higher in these two adjacent provinces than in Anhui, whereas the incidence was lower in the Henan and Shandong provinces north of Anhui [16,44]. There has been more frequent movement of the population in Anhui, mainly to Jiangsu and Zhejiang, in the past few years than in other provinces [45]. This may be one of the reasons for the inconsistency between the characteristics of high-risk clusters in this study and in previous studies. For example, Huangshan and Wuhu, which are located in the southeast of Anhui, were not only the high-incidence areas of varicella but were also high-high clusters, and the most likely spatiotemporal clusters were also distributed in these cities and their surroundings. Alternatively, there may be differences in surveillance sensitivity, vaccination rates, and geographic and climatic characteristics in different areas of Anhui, resulting in the observed variable spatial distribution pattern of varicella. By contrast, northern Anhui is located in the southern part of the North China Plain with a relatively higher population density and mobility than other areas of the province, which would theoretically facilitate the transmission of respiratory infectious diseases. Considering the high underestimation rate of varicella reporting in China [44], the actual disease burden in these apparently low-incidence areas may actually be far greater than indicated in our analysis. Therefore, the true reasons for the overall difference in incidence between northern and southern Anhui need to be thoroughly explored.

Moreover, the high-low and low-high clusters identified by spatial autocorrelation analysis are perhaps of greater concern than clusters of hot or cold spots. In other words, more attention needs to be paid to the surrounding varicella incidence to avoid the inflow of the epidemic from the high-incidence areas (Dangtu County) or the increased incidence in the surrounding areas due to the high local incidence (Tianjia’an District and Taihu County), providing evidence for the future focus of varicella prevention and control strategies.

Although vaccination can have a positive impact on the epidemiology of varicella, some studies found that universal routine immunization with varicella vaccine increased the incidence of HZ [46,47]. Although caused by the same virus, these two diseases were not analyzed together in this study due to the lack of data on HZ. Humoral immunity persists in individuals with prior varicella infection; however, cell-mediated immunity, which plays an important role in the development of HZ, typically wanes with age [47,48]. Exposure to wild-type varicella cases could enhance cell-mediated immunity against VZV and maintain the immune effect for a longer time, whereas the opportunity for such exogenous enhancement decreases when varicella vaccination rates increase, which may account for the increased incidence of HZ [49]. Varicella is closely related to the epidemiology of HZ; thus, attention should be paid to enhancing the surveillance of HZ. Although the vaccine reduces the disease burden of varicella, the disease burden resulting from the increased incidence of HZ may offset some of the economic benefits of varicella vaccination, which should be taken into account when including varicella into routine immunization programs. According to the varicella vaccine immunization strategy in Anhui, since June 2021, the first dose of varicella vaccine is recommended at the age of 1 year and the second dose is recommended at the age of 4 years. Therefore, the single- and double-dose vaccination rates and the effects of administering two doses of the vaccine also warrant further study.
Limitations

There are some limitations of this study. First, although substantial disease information has been provided through the CISDCP surveillance, there are still some shortcomings in the surveillance of varicella in Anhui Province. The proportion of cases underreported after mandatory reporting is likely to be small [50,51] and is unlikely to affect the epidemiology of the disease. Some regions in China already require the reporting of varicella cases within 24 hours [19,29], although this is not mandatory in Anhui and the actual data on underreporting are currently unavailable, which may have led to an underestimation of the incidence and possible alteration of the epidemiological characteristics of varicella. Therefore, more comprehensive varicella surveillance data are needed to assess the effectiveness of vaccination and to guide future varicella control and immunization strategies. Second, scan statistics based on circular windows often produce clusters that are larger than they actually are and can fail to identify irregular clusters; therefore, varicella clusters identified using flexible scan statistics may be more practical [52]. Finally, information on factors affecting the spread of infectious diseases, such as economy, population density, vaccination rates, and climate, was not considered, as this work only described the aggregation phenomenon of varicella; thus, the potential underlying causes need to be further studied.

Conclusion

This study provides detailed epidemiological characteristics and changes of varicella from the perspectives of population, time, and space based on the reported incidence data in Anhui from 2012 to 2021. Measures should be taken in the future to strengthen varicella prevention and control in the key populations and regions identified in this study.

Acknowledgments

This research was supported by the Health Research Program of Anhui (AHWJ2023A20369). We appreciate the staff at all levels from the medical institutions of Anhui Province for reporting and reviewing the surveillance data. We declare that no artificial intelligence was used in the preparation of this manuscript.

Data Availability

The data sets generated and/or analyzed during the present study are available from the corresponding author on reasonable request.

Authors' Contributions

All authors contributed to this paper. NZ provided the study data. KX, XP, and QL analyzed the data. KX, NZ, and TL wrote the manuscript. BW and ZZ made the initial revision. JT designed the study and revised the manuscript. TZ touched up the manuscript.

Abstract

Background: Hemorrhagic fever with renal syndrome (HFRS) continues to pose a significant public health threat to the population in China. Previous epidemiological evidence indicates that HFRS is climate sensitive and influenced by meteorological factors. However, past studies either focused on too-narrow geographical regions or investigated time periods that were too early. There is an urgent need for a comprehensive analysis to interpret the epidemiological patterns of meteorological factors affecting the incidence of HFRS across diverse climate zones.

Objective: In this study, we aimed to describe the overall epidemic characteristics of HFRS and explore the linkage between monthly HFRS cases and meteorological factors at different climate levels in China.

Methods: The reported HFRS cases and meteorological data were collected from 151 cities in China during the period from 2015 to 2021. We conducted a 3-stage analysis, adopting a distributed lag nonlinear model and a generalized additive model to estimate the interactions and marginal effects of meteorological factors on HFRS.

Results: This study included a total of 63,180 cases of HFRS; the epidemic trends showed seasonal fluctuations, with patterns varying across different climate zones. Temperature had the greatest impact on the incidence of HFRS, with the maximum hysteresis effects being at 1 month (−19 °C; relative risk [RR] 1.64, 95% CI 1.24-2.15) in the midtemperate zone, 0 months (28 °C; RR 3.15, 95% CI 2.13-4.65) in the warm-temperate zone, and 0 months (4 °C; RR 1.72, 95% CI 1.31-2.25) in the subtropical zone. Interactions were discovered between the average temperature, relative humidity, and precipitation in different temperature zones. Moreover, the influence of precipitation and relative humidity on the incidence of HFRS had different characteristics under different temperature layers. The hysteresis effect of meteorological factors did not end after an epidemic season, but gradually weakened in the following 1 or 2 seasons.

https://publichealth.jmir.org/2024/1/e52221
Conclusions: Weather variability, especially low temperature, plays an important role in epidemics of HFRS in China. A long hysteresis effect indicates the necessity of continuous intervention following an HFRS epidemic. This finding can help public health departments guide the prevention and control of HFRS and develop strategies to cope with the impacts of climate change in specific regions.

Introduction
Hemorrhagic fever with renal syndrome (HFRS) is a rodent-borne zoonotic disease caused by Hantavirus (HTNV), causing symptoms such as fever, headache, and renal dysfunction [1]. Globally, China is one of the countries most affected by HFRS, with cases covering 31 provinces, municipalities, and autonomous regions and numbering nearly 10,000 per year in the past decade [2]. HFRS is listed as a class B infectious disease due to its potential threat to public health in China [3]. Despite the implementation of vaccination programs, HFRS remains a serious public health problem in China. More than 10 HTNV-potential hosts have been identified with population levels sufficient to sustain virus viability and reproduction in nature [4]. Moreover, the enormous geographic differences and the variety of climate types in China make it difficult or impossible to eliminate HFRS, where 9187 new cases were reported in 2021, including 64 deaths [5].

Known risk factors for HFRS incidence include climate, host population, and viral dynamics [6]. Climate is widely recognized as a key factor in HTNV transmission, mainly affecting the prevalence of the virus and the risk of human infection by affecting rodent population dynamics [7,8]. For example, temperature, humidity, and precipitation can affect crop yields, which are a food source for rodents [7]. Earlier studies showed that climate-related HFRS outbreaks had a hysteresis effect, usually delayed by 1 to 6 months, and seasonal patterns of HFRS epidemics also showed sensitivity to climate [9-11]. Using a distributed lag nonlinear model (DLNM), Luo et al [12] investigated temperature (lag=6 months, relative risk [RR] 3.05) and precipitation (lag=0 months, RR 2.08), which had the greatest impact on the incidence of HFRS. Sun et al [7] also identified extremely high or low temperature as being strongly associated with HFRS. Concerns have been raised in recent years about the expansion of HFRS-affected areas and the reemergence of HFRS in regions where it had been eliminated. Under global warming, cyclic dynamics of rodent populations are changing, and new endemic areas are forming [13]. There is an urgent need to explore the propagation of HFRS under different climate conditions. Cao et al [14] explored the interactions and marginal effects of meteorological factors on HFRS in different climate zones in 254 cities in China. However, the time span of their study was 2006 to 2016, which is too far in the past; few or no studies have discussed the relationship between HFRS and meteorological factors in different regions in recent years [15].

Based on HFRS monitoring data from 151 cities from 2015 to 2021, we estimated the hysteresis effects and interactions of meteorological factors in different climate zones on HFRS in China. We also sought to identify associations between temperature and HFRS under different environmental conditions and examine whether these associations varied geographically. Compared with previous studies, our research covers a wider range of subjects, is more recent, and has more convincing results.

Methods

Ethical Considerations
The study was approved by the ethical review board of the Nanjing Bioengineering (Gene) Technology Center for Medicines (2022005). Consent to participate was not applicable because this study used HFRS surveillance data. All participant data were anonymized and kept confidential to protect the privacy of participants.

Study Sites
This study was based on a national database of meteorological factors and confirmed HFRS case counts in 151 Chinese prefecture-level cities from January 1, 2015, to December 31, 2021. According to China’s national reporting system for infectious diseases, the total number of HFRS cases in these cities during the period they were included in the study exceeded 50.

China can be divided into 6 climate zones (Multimedia Appendix 1, Figure S1) [16]. In this study, 3 climatic zones were chosen as the research zones: the midtemperate zone, the warm-temperate zone, and the subtropical zone. The cold-temperate zone, the plateau-temperate zone, and the tropical zone were excluded due to having too few cities (<5 cities). A final total of 151 Chinese prefecture-level cities were included in our study (Multimedia Appendix 1, Table S1). When the city boundary spanned multiple climatic zones, the urban climatic zones were divided according to the location of the city center.

Collection of Data
Monthly data on HFRS from the 151 prefecture-level cities across China from January 1, 2015, to December 31, 2021, including the number of cases and incidence, were provided by the Chinese Center for Disease Control and Prevention. All notified HFRS cases were confirmed according to the united diagnostic criteria issued by the Ministry of Health of China in 1998 [17].

Monthly meteorological data including average temperature (Celsius), average relative humidity (%), and average precipitation (mm) in the selected cities were obtained from
839 meteorological monitoring stations [18] (Multimedia Appendix 1, Figure S2).

**Statistical Analysis**

In the descriptive analysis, the mean (SD), median (IQR), and range were used to describe the distribution of cases of HFRS and weather variables in the 3 selected climatic zones. In 2018, there were some missing values for meteorological variables in 18 cities, including mean temperature (n=216), relative humidity (n=216) and precipitation (n=216). Thus, we imputed the values of each city using their last year’s value. The descriptive statistics before and after imputing are summarized in Table 1.
Table 1. Descriptive analysis of monthly mean temperature, precipitation, and average relative humidity in different climate zones in China from 2015 to 2021. There were 12 missing values in the midtemperate zone, 60 in the warm-temperate zone, and 144 in the subtropical zone.

</table>
First Stage Analysis

We first captured the association between weather conditions and HFRS incidence in different climate zones with a DLNM, which can flexibly describe relationships and explore underlying lag nonlinear effects [19]. The climate-specific model with adjustment for potential confounders used equation (1):

\[
E(Y_{it}) = \alpha + LIM_{it} + cb(\text{Temp mean}) + cb(\text{Rh mean}) + cb(\text{Prec mean}) + \text{Season}_{it} + \text{Province}_{it} + \text{Time}_{it} + \text{offset} + \epsilon
\]

Here, \( E(Y_{it}) \) denotes the monthly expected number of cases in the city and month \( t \), and \( \alpha \) is the intercept. \( LIM_{it} \) represents the previous month’s incidence, used to reduce autocorrelation between values. \( cb(\text{Temp mean}) \), \( cb(\text{Rh mean}) \), and \( cb(\text{Prec mean}) \) are cross-basis matrices of selected monthly meteorological factors, constructed using B-splines for exposure and natural cubic splines for lag (maximum lag of 6 month) dimensions, respectively. A natural cubic spline function of 1 degree of freedom per year was used to control the long-term trend of incidence. The \( \text{Time} \) variable indicates the sequence (from 1 to 84) with month as the unit during the study period, 2015 to 2021. \( \text{Season}_{it} \) and \( \text{Province}_{it} \) are categorical variables to control seasonal patterns and different provinces, respectively. The offset term is the population of each city.

Second Stage Analysis

In the second stage, the correlation of HFRS and climate under different hysteresis conditions is examined. Exposure-effect curves for climate variables with different lag times in the 3 selected temperature zones were drawn to illustrate the hysteresis effects and their duration under different meteorological conditions. Furthermore, the HFRS-climate association at temperature extremes was explored. Taking the median of different meteorological conditions as the reference, the relationship between the corrected meteorological conditions at the 2.5th and 97.5th percentiles and the incidence of HFRS were calculated, respectively. Finally, a random-effect meta-analysis of city-specific relationships for different climate zones estimated in the first stage was performed using the restricted maximum likelihood estimation method to provide more accurate estimates.

Third Stage Analysis

To explore the interaction and stratification effects between the 3 weather condition and HFRS epidemics in different climate zones, we constructed a generalized additive model (GAM) in the third stage. The model can be written as equation (2):

\[
E(Y_{it}) = \alpha + s(K, X) + s_1(K, X) + s_2(K) + s_3(X) + \text{offset} + \epsilon
\]

Here, \( \alpha \) is the intercept; \( K \) denotes 1 of the weather conditions (mean temperature, relative humidity, and precipitation), and \( X \) and \( Z \) denote the other 2 indicated penalized spline functions. \( s_1(K, X) \) is the spline function of the interaction between variables \( K \) and \( X \).

Then, the meteorological stratification between mean temperature and the incidence of HFRS was determined for relative humidity and precipitation. We split relative humidity and precipitation into category variables, including the medians for “high” and “low.”

Sensitivity Analysis

To test whether our main conclusions were robust, we performed a sensitivity analysis relying on the quasi-Akaike information criterion (QAIC) and quasi-Bayesian information criterion (QBIC). We used QAIC and QBIC to identify the optimal number and location of knots for the natural spline and the optimal number of lag months from 1 to 6 (Multimedia Appendix 1, Table S2).

R (version 4.2.1; R Foundation for Statistical Computing) and the R packages dlnm, metafor, and mcgv were used for constructing the DLNM and GAM based on the 3 meteorological variables. All maps were created using ArcGIS (version 10.2; Esri Inc). The confidence level of all 2-sided statistical tests in this study was set at 95%, and the significance level was set at .05.

Results

Descriptive Analysis

A total of 63,180 HFRS cases were involved in our study (Figure 1). Between 2015 and 2021, 12,481, 28,353, and 22,346 cases...
of HFRS occurred in the midtemperate zone, warm-temperate zone, and subtropical zone. Multimedia Appendix 1, Figure S3 shows bar charts of different seasonal prevalence patterns of HFRS in the 3 climate zones. The peaks for HFRS cases in the midtemperate, warm-temperate, and subtropical zones occurred in autumn; winter and spring; and winter and spring, respectively. The mean values for temperature, precipitation, and relative humidity in the 3 zones were 5.43 °C, 55.28 mm, and 64.53%; 13.44 °C, 63.14 mm, and 63.63%; and 18.68 °C, 128.8 mm, and 77.03%, respectively. Thus, there was a gradual increase from north to south.

Figure 1. Distribution of cases of hemorrhagic fever with renal syndrome in China from 2015 to 2021.

DLNM Analysis

The cumulative risk between meteorological factors and HFRS incidence in the DLNM for different climate zones in China after controlling for seasonal and long-term trends is shown in Figure 2. In the midtemperate zone, the meteorological conditions that were positively correlated with HFRS risk were mean temperature <–7 °C and precipitation 28 to 134 mm; in the warm-temperate zone, the meteorological conditions were a mean temperature <–7 °C or 14 °C to 24 °C and precipitation 143 mm to 274 mm; in the subtropical zone, the meteorological conditions were mean temperature 9 °C to 19 °C, precipitation 11 mm to 22 mm or 95 mm to 299 mm, and relative humidity 78% to 84%. Figure 3 and Multimedia Appendix 1, Figure S4 show the impact of different lag months on climate-related HFRS risk. In the midtemperate zone, significant RRs were observed at lag of 1 month when mean temperature was –19 °C (RR 1.64, 95% CI 1.24-2.15). In the warm-temperate zone, a temperature of 28 °C (0-month lag; RR 3.15, 95% CI 2.13-4.65), precipitation of 239 mm (1-month lag; RR 1.22, 95% CI 1.06-1.40), and relative humidity of 83% (6-month lag; RR 1.21, 95% CI 1.07-1.36) resulted in significantly higher RR. In addition, in the subtropical zone, temperature, precipitation, and relative humidity with lags of 0, 6, and 4 months had high RRs at 4 °C (RR 1.72, 95% CI 1.31-2.25), 360 mm (RR 1.16, 95% CI 1.06-1.26), and 90% (RR 1.11, 95% CI 1.05-1.17), respectively. Multimedia Appendix 1, Figure S5 shows the RR between climate and HFRS with different lag months for extreme weather. In the midtemperate zone and subtropical zone, HFRS was sensitive to low temperature, while in the warm-temperate zone, HFRS was more sensitive to high temperature. Higher precipitation and humidity were associated with the incidence of HFRS in the warm temperate zone and subtropical zone. Moreover, the results of the meta-analysis showed that low temperature, relatively high precipitation, and high relative humidity were risk factors for the onset of HFRS, but the subtropical zone showed a different trend (Figure 4).
Figure 2. Summary of cumulative exposure-response curves of hemorrhagic fever with renal syndrome incidence for meteorological factors with a lag of 0-6 months in 3 selected temperature zones from 2015 to 2021. The y-axis represents the relative risk of each variable. The x-axis represents the range of observations for each variable. The blue lines represent means estimated by the distributed lag nonlinear model, and the shaded areas represent the 95% CI. MTZ: midtemperate zone; SZ: subtropical zone; WTZ: warm temperate zone.
Figure 3. Lag-specific effects of meteorological factors on hemorrhagic fever with renal syndrome infection in different climate zones from 2015 to 2021. The y-axis represents the relative risk of each variable. The x-axis represents the range of observations for each variable. The purple lines represent means estimated by the distributed lag nonlinear model, and the shaded areas represent the 95% CI. MTZ: midtemperate zone; SZ: subtropical zone; WTZ: warm temperate zone.
**Interaction and Stratified Analysis**

The results for 25 cities in the midtemperate zone showed that in environments with low temperature and low relative humidity and in environments with low temperature and high relative humidity, each decrease of 1 °C led to an increase in the risk of HFRS of 3% (95% CI 2.6%-3.4%) and 4.6% (95% CI 3.8%-5.4%), respectively. In environments with low temperature and low precipitation and in environments with low temperature and high precipitation, each 1 °C decrease led to an increase in the risk of HFRS of 3.3% (95% CI 2.8%-3.9%) and 5.3% (95% CI 4.4%-6.1%), respectively. The results from 54 cities in the warm-temperate zone showed that in environments with low temperature and low relative humidity and in environments with low temperature and high relative humidity, each decrease of 1 °C led to an increase in the risk of HFRS of 1.8% (95% CI 1.1%-2.5%).
1.5%-2.2%) and 4.7% (95% CI 3.8%-5.7%), respectively. In environments with low temperature and low precipitation and in environments with low temperature and high precipitation, each decrease of 1 °C led to an increase in the risk of HFRS of 2.3% (95% CI 2%-2.7%) and 2.4% (95% CI 1.6%-3.3%), respectively (Table 2 and Multimedia Appendix 1, Table S3-S12).

**Discussion**

**Principal Findings**

In this study, we quantified the HFRS-weather association in 151 selected cities using a DLNM. Previous studies have investigated the HFRS-weather associations at single- or multiple-location levels [14,15]. However, few of them explored the interaction and hysteresis effects of meteorological factors at different levels on the incidence of HFRS in different climate zones. To the best of our knowledge, this is the first study using national data to explore the interaction and hysteresis effects of meteorological factors at different levels on the incidence of HFRS in China. Our pooled analysis results showed that meteorological factors, especially temperature, had a significant impact on the incidence of HFRS in China, although the association between HFRS and different meteorological factors, the lag time with the greatest impact, and the duration of the lagged effect varied by location. Moreover, we found low temperature was a contributing factor to the pathogenesis of HFRS, and HFRS was relatively more sensitive to temperature changes in the warm- and midtemperate zones than in the subtropical zone. This finding can help public health departments guide the prevention and control of HFRS and develop strategies to cope with the impacts of climate change in specific regions.

We found that low temperature was the most important meteorological factor for the onset of HFRS. It is worth noting that the relationship between HFRS and weather varies by location. There were different impact patterns in the 3 climatic zones. The midtemperate zone peaked at low temperatures (<−7 °C); the warm-temperate zone peaked at both low temperatures (<−4 °C) and high temperatures (14-24 °C); the subtropical zone peaked at 9-19 °C. The differences may be related to the different host animal species, reproduction, and activity cycles. *Apodemus agrarius* and *Rattus norvegicus* are the main species involved in HFRS transmission in China. HFRS infection caused by *A agrarius* mainly occurs in autumn and winter, while infection caused by *R norvegicus* occurs in spring [14]. Combined with the seasonal patterns, it can be inferred that *A agrarius* is the main vector in the midtemperate zone, while *A agrarius* and *R norvegicus* are the main vectors in the warm-temperate and subtropical zones. The main hosts of HTNV and Seoul virus (SEOV) are *A agrarius* and *R norvegicus*, respectively. It can be inferred that HTNV is epidemic in the midtemperate zone, while HTNV and SEOV are mainly epidemic in the warm-temperate and subtropical zones. Prior studies investigated sites and identified HTNV in the midtemperate Heilongjiang Province, the warm-temperate Qingdao City, and the subtropical Jiangxi Province, which is consistent with our inferences [20-22]. Moreover, low temperatures prolong the survival of the virus outside the host, allowing the virus to remain infectious even in the absence of direct rodent contact or rodent-to-human contact [23].

The results of the DLNM showed that the risk of climate-related HFRS varied from place to place with different lag months. The lagged effects of climate variables in different temperature zones may be related to the dominant rodent population, breeding and living conditions, HTNV-positive rate, and human contact frequency [24,25]. We found that the maximum lag effects of temperature on HFRS incidence were 1 month, 0 months, and
0 months from northern to southern China. However, inconsistent findings on the lag time with maximum effects have also been reported by Cao et al [14]. The lag effects of temperature were 1 month (midtemperate zone), 2 months (warm-temperate zone), and 3 months (subtropical zone), respectively. Our results showed that the hysteresis effect of meteorological factors did not end after one epidemic season, but gradually weakened in the following 1 to 2 epidemic seasons, and the duration of the hysteresis effect varied by region, indicating the necessity of continuous intervention after the HFRS epidemic. At the same time, it also provides theoretical support for the important role of weather variability, especially temperature, in the propagation of HFRS.

Consistent with previous studies, we found that high precipitation and relative humidity are risk conditions for HFRS (Multimedia Appendix 1, Figure S6) [15,26]. Wet conditions and high relative humidity are good for rodents to survive or breed. Adequate rainfall provides a suitable environment and sufficient food for rodents, which ultimately increases the risk of virus transmission [27]. Higher relative humidity affects the spread of HFRS by affecting the infectivity and stability of HTNV in vitro, which is consistent with the fact that HFRS epidemic areas are mostly located in humid or semihumid mountainous areas [28,29]. The interaction and stratification analysis showed that in low-temperature environments, more precipitation and higher relative humidity were climate risk factors for HFRS occurrence, which is consistent with previous studies. Zhang et al [9] found that average temperature, relative humidity, and precipitation interacted with HFRS through stratified analysis; the risk of HFRS was inversely proportional to average temperature and directly proportional to relative humidity.

There are several key limitations to our study that should be acknowledged. First, in addition to meteorological factors, other factors may also affect the occurrence of HFRS, including vaccination programs, economic factors, health care level, and host animal diversity. Second, HFRS case data comes from the notifiable infectious disease detection system, and there are cases of underreporting. For example, patients with mild symptoms may self-isolate at home, which would lead us to underestimate the impact of meteorological factors on HFRS. Third, our data cannot distinguish which viruses caused the HFRS cases, nor can it be targeted to study the relationship between different viruses and climate. Therefore, future research should explore the relationship between HFRS incidence and the different viruses that cause HFRS and explore the intersection between the COVID-19 pandemic and HFRS to fully understand the broader implications for public health.

**Conclusions**

Using data for HFRS cases from 151 cities, we provide first-hand evidence of the interaction and stratification effects of meteorological factors on HFRS in different regions of China. Furthermore, the magnitude and timing of hysteresis effects varied across climate zones. Our findings indicate that low temperature positively influences the long-term incidence of HFRS. The results of this study can provide a valuable scientific basis for public health departments to formulate targeted HFRS interventions, understand the relationship between weather and HFRS, and use low temperature as an early warning signal to carry out HFRS control and outbreak response.

Abstract

Background: Exposure risk was shown to have affected individual susceptibility and the epidemic spread of COVID-19. The dynamics of risk by and across exposure settings alongside the variations following the implementation of social distancing interventions are understudied.

Objective: This study aims to examine the population’s trajectory of exposure risk in different settings and its association with SARS-CoV-2 infection across 3 consecutive Omicron epidemic waves in Hong Kong.

Methods: From March to June 2022, invitation letters were posted to 41,132 randomly selected residential addresses for the recruitment of households into a prospective population cohort. Through web-based monthly surveys coupled with email reminders, a representative from each enrolled household self-reported incidents of SARS-CoV-2 infections, COVID-19 vaccination uptake, their activity pattern in the workplace, and daily and social settings in the preceding month. As a proxy of their exposure risk, the reported activity trend in each setting was differentiated into trajectories based on latent class growth analyses. The associations of different trajectories of SARS-CoV-2 infection overall and by Omicron wave (wave 1: February-April; wave 2: May-September; wave 3: October-December) in 2022 were evaluated by using Cox proportional hazards models and Kaplan-Meier analysis.

Results: In total, 33,501 monthly responses in the observation period of February-December 2022 were collected from 5321 individuals, with 41.7% (2221/5321) being male and a median age of 46 (IQR 34-57) years. Against an expanding COVID-19 vaccination coverage from 81.9% to 95.9% for 2 doses and 20% to 77.7% for 3 doses, the cumulative incidence of SARS-CoV-2 infection escalated from <0.2% to 25.3%, 32.4%, and 43.8% by the end of waves 1, 2, and 3, respectively. Throughout February-December 2022, 52.2% (647/1240) of participants had worked regularly on-site, 28.7% (356/1240) worked remotely, and 19.1% (237/1240) showed an assorted pattern. For daily and social settings, 4 and 5 trajectories were identified, respectively, with 11.5% (142/1240) and 14.6% (181/1240) of the participants gauged to have a high exposure risk. Compared to remote working, working regularly on-site (adjusted hazard ratio [aHR] 1.47, 95% CI 1.19-1.80) and living in a larger household (aHR 1.12, 95% CI 1.06-1.18) were associated with a higher risk of SARS-CoV-2 infection in wave 1. Those from the highest daily exposure risk trajectory (aHR 1.46, 95% CI 1.07-2.00) and the second highest social exposure risk trajectory (aHR 1.52, 95% CI 1.18-1.97) were also at an increased risk of infection in waves 2 and 3, respectively, relative to the lowest risk trajectory.

Conclusions: In an infection-naive population, SARS-CoV-2 transmission was predominantly initiated at the workplace, accelerated in the household, and perpetuated in the daily and social environments, as stringent restrictions were scaled down.
Introduction

In 2020-2021, Hong Kong’s COVID-19 burden in the population was among the lowest in the Asia Pacific region (<1%). Ranging from border control and mandatory mask wearing to social activity restrictions, the implementation of various nonpharmaceutical interventions (NPIs) contributed to the successful control initially. It was not until February 2022 when the SARS-CoV-2 Omicron outbreak swept through the city and caused over 2.6 million cases (35%) in a 7.4 million population by the end of the year [1]. Albeit the epidemic becoming more controllable today, it is still unclear what factors had contributed to the initial surge of Omicron and subsequent waves of infection. Since the effectiveness of vaccinations against emerging variants is waning, investigations into the impact of the population’s behavior on virus transmission would therefore be crucial [2].

Exposure risk and its association with SARS-CoV-2 infection have been examined from various perspectives. Previous studies have analyzed the social contact and mobility pattern to model the change in the transmission dynamics [3,4]. However, the application of these metrics as a proxy for aggregated exposure risks has ignored the heterogeneity of the exposure profiles across the population [5]. The distribution of population activities in various community settings is often overlooked. Former research has presented a remarkable difference in the infection rate following SARS-CoV-2 exposure to a household and health care source [6,7]. Thus, the nature of social contacts in different settings could also play an important role in affecting the level of virus exposure and infection risk. Based on contact-tracing data, the transmission dynamics of SARS-CoV-2 can also be observed to be largely variable among clusters of infection emerging from different environments [8-10]. Yet, evidence formally appraising the association between exposure and outbreaks in a broader community context remains scarce.

As an integral part of NPIs, different combinations of social distancing interventions were implemented worldwide to tackle the COVID-19 pandemic. The use of regulatory restriction was shown to have effectively blocked transmission chains associated with social events [11], while prohibiting dine-in services and imposing a work from home (WFH) order were deemed to have rapidly brought down the scale of virus spread [12]. A multi-country analysis in 2020-2022 also revealed the fluctuation in social contact patterns in different settings during the pandemic and highlighted its connection with different containment measures [13]. The above evidence conjectured that the whereabouts and dynamics of virus exposure could be influenced by the coverage and stringency of social distancing measures [14]. Yet, their interplay was still vaguely understood as the epidemic progressed through waves driven by different SARS-CoV-2 variants in the real world.

In recent decades, participatory surveillance has been increasingly used as a complementary tool to detect exposure and disease patterns in community outbreaks [15,16]. Without imposing a complete lockdown, the comparison between infected and uninfected individuals in their activity patterns by setting would enable the identification of the changing hot spots for SARS-CoV-2 exposure as the epidemic unfolds. Against these backgrounds, this study aims to examine the dynamics of population exposure risks in different settings and to evaluate its association with SARS-CoV-2 infection across the 3 Omicron epidemic waves in 2022 in Hong Kong.

Methods

Participant Recruitment and Study Design

In the form of a prospective cohort, an ongoing web-based participatory surveillance platform was set up in Hong Kong with territory-wide recruitment in March-June 2022. Taking individual households as a sampling unit, cluster sampling was performed based on a sampling frame called “building groups”—a demarcation system codeveloped by the Census and Statistics Department of the Hong Kong Government and the Centamap Company Limited for grouping local households with a similar socioeconomic background for census data analysis. The demarcation system, updated as of 2016, with 3083 defined building groups (strata) covering 165,965 residential buildings, was used as the sampling frame of this study. In each stratum resided by at least 1000 individuals, 12-14 households were randomly selected to receive an invitation letter bearing a unique code mapped to their residential address. A representative household member aged 18 years or older, residing in Hong Kong, and who understood Chinese or English was invited to participate. Following registration on the platform by using the unique household code, participants who consented were asked to fill in a baseline questionnaire followed by monthly updates during the follow-up period.

Ethics Approval

Ethics approval was sought from the Survey and Behavioral Research Ethics Committee of the Chinese University of Hong Kong (SBRE-21-0048). Informed e-consent was obtained from each participant at the time of registration. The survey data set was deidentified by removing participants’ residential addresses. Separately, residential addresses used for recruitment and incentive delivery were stored in another data set with matched study IDs to preserve anonymity. All data sets were password-protected and only accessed by designated research staff and investigators. Upon completion of the baseline questionnaire, participants were entitled to a HK $50 cash
voucher (HK $7.8=US $1). During follow-up, additional HK $50 vouchers would be offered to participants who had completed at least 3 monthly updates every 6 months.

**Survey Instrument**

Available in both Chinese and English, the baseline questionnaire could be completed in 20 minutes and covered the participants’ particulars on (1) sociodemographic characteristics; (2) household size; (3) chronic illness status; (4) baseline history of SARS-CoV-2 infection and COVID-19 vaccination; (5) frequency of rapid antigen/nucleic acid testing for SARS-CoV-2 in the previous month; (6) monthly pattern of work, daily, and social activities; (7) nature of workplace (health care/non–health care) and the number of workplace contacts; (8) perceived risk of SARS-CoV-2 exposure (on an 11-point Likert scale from 0 to 10); and (9) suspected presence of infected individuals among daily contacts (yes/no). For the ensuing monthly updates, participants were asked to self-report any COVID-19 vaccine uptake and incident of SARS-CoV-2 infection, defined by a positive result from a polymerase chain reaction or rapid antigen test regardless of the presence of symptoms. Updates on sections 5-9 and household infection status based on the situation in the previous month were also requested. A personalized survey link was sent to each participant by email on the first of each month and made accessible for 14 days. Paper questionnaires were supplied upon request (n=23).

**Definition of Exposure Risk and Tiers of Social Distancing Policy**

In this study, exposure risk was defined as the intensity of behavior leading to potential virus exposure, while its dynamics were examined in 4 contexts: household, workplace, social setting, and daily setting. Persons living in larger households and working entirely outside the home in a month were expected to have a greater exposure risk. For daily and social settings, the exposure risk was measured by their frequency of engagement in different types of daily, leisure, and social activities. Details of the exposure risk definition are illustrated in Table 1. Based on the stringency of the regulations imposed on the operations of catering businesses, bars/pubs, and a range of high-risk premises and activities; restrictions on social gatherings; and government recommendations on WFH practices, the evolvement of the local social distancing policies was divided into 4 tiers. The details of the regulations together with other NPIs are delineated in Figure S1 in Multimedia Appendix 1.

<td>Reported number of times one had paid visit to relatives/friends’ home or vice versa, dined out for the purpose of gathering, gone to bar/club, karaoke room, party room, attended banquet, went on a local hotel vacation, and outdoor travel (eg, hiking/camping) in each month</td>
<td>Ordinal variable with 4 levels: None; 1-3 times; 4-7 times; ≥8 times</td>
<td>Varied; higher exposure risk in those who had attended more social events</td>
</tr>
</tbody>
</table>

*WFH: work from home.

*The frequencies for each of the daily activities were standardized and averaged for each participant. Those with a computed average higher than the population median were classified as active or otherwise inactive for a particular month.
Statistical Analysis
Participants’ baseline characteristics were summarized using descriptive statistics. The geographical representativeness of the recruited households was then assessed by comparison with the census distribution [17]. The cumulative incidence of SARS-CoV-2 infection and monthly proportion of participants reporting an infection were profiled against the number documented by the government, while age and sex adjustments were performed in reference to the population demographics [17]. The patterns of age-specific COVID-19 burden and vaccination coverage were also illustrated.

Based on the reported work pattern and computed exposure risk level in daily and social settings, the temporal dynamics of each were differentiated using a latent class growth model—a mixture model for identifying underlying subgroups exhibiting similar growth trajectories [18]. Only participants with a missing response in at most 1 month during each epidemic wave were included in the analysis. Individual responses of specific months, during which SARS-CoV-2 infection was reported in themselves or their household, were also eliminated so that the biased activity level resulting from isolation/quarantine was not considered. A 2-stage optimization of maximum likelihood was adopted to model the intercept, linear, and quadratic growth factor, with an increasing number of latent classes from 1 to 7. Goodness of fit was indicated by the lowest Bayesian information criterion (BIC) and an entropy of >0.8. Elbow plot was used in cases when the stated criteria were still met in the 7-class model. Based on the selected models, the class-specific exposure risk trajectories were plotted on a probability scale. Factors associated with each trajectory were determined by a multinomial mixed effects model.

The time patterns of SARS-CoV-2 infection among participants with different household sizes, work patterns, and daily and social exposure risk trajectories were examined using Kaplan-Meier analysis, while the difference in the infection rate in each epidemic wave was compared using relative risk (RR). Their relationships with SARS-CoV-2 infection risk were then parameterized using Cox proportional hazards models adjusted for sociodemographic characteristics and vaccination status before the Omicron outbreak. Subgroup analysis was also conducted between the subset of participants with different pre-Omicron vaccination statuses. R software (version 4.1.2; R Foundation for Statistical Computing) and Mplus (version 8.8; Muthen & Muthen) were used to perform statistical analyses. All tests were 2-tailed, and the significance was denoted by P<.05.

Results

Baseline Characteristics
Between March and June 2022, representative participants from 5321 households were recruited out of 41,132 invitations (response rate 12.9%). Concerning the observation period from February to December 2022, over 3000 survey entries were received each month except for the first 2 months of recruitment, amounting to a total of 33,501 responses. Two-thirds (3553/5321, 66.8%) of the recruited participants completed at least 50% of the monthly surveys, with 58.3% (3100/5321) being female, and the median age was 46 (IQR 34-57) years. A majority of the participants were in full-time employment or self-employed (3208/5321, 60.3%) and had attained tertiary education or above (3325/5321, 62.5%) (Table 2). The recruited households had a mean size of 3.1 (SD 1.5) persons, and 11.5% (607/5321) were single-person households. The geographical distribution of the recruited households was within a 1% difference compared to the census data for all 18 districts in the territory of Hong Kong (Table S1 in Multimedia Appendix 1).

**SARS-CoV-2 Burden and COVID-19 Vaccination Uptake**

As of December 2022, a total of 2332 SARS-CoV-2 infections were reported, adding up to a cumulative incidence of 43.8% since 2020 (Figure 1). The age- and sex-adjusted estimate was 42.8%, which was 7% higher than the government figure. The number of incident infections peaked in March 2022 (273/1718, 15.9%), reached the trough in May (13/3505, 0.4%), rebounded in August (127/3208, 3.9%), and surged in December (410/3206, 13.5%), giving rise to 3 Omicron waves in 2022 (wave 1: February to April, wave 2: May to September, and wave 3: October to December). Overall, hospitalization was required in 20 of 2332 cases (0.9%), while reinfection with at least 3 months from the previous infection episode was reported in 45 (1.9%) participants. Stratified by age group, individuals aged 30-39 years had the highest cumulative incidence of 48.8% (580/1188), while the population aged ≥65 years was least affected by the epidemic (226/607, 37.2%). Over 80% (4231/5167) and 20% (1043/5208) of the participants had received at least 2 and 3 doses of COVID-19 vaccine before February 2022, respectively. Correspondingly, the 2 coverages escalated to 95.9% (4954/5167) and 77.7% (4047/5208) at the end of the year after the administration of vaccine passes requiring 2 and 3 doses by May and June (Figure S1 in Multimedia Appendix 1). A noticeably slower third dose uptake was observed throughout in younger age groups.
Activity Pattern in Workplace, Daily Settings, and Social Settings

When the Omicron outbreak first broke out in February 2022, the most stringent tier 1 social distancing measures were in place. In reference to the government advice, 26.8% (656/2444) and 49% (1198/2444) reported intermittent and complete WFH practice (or not doing any work), while one-quarter of the participants (590/2444, 24.1%) continued to work on-site in their workplace. Due to the mass closure of community facilities, almost none had reported participation in leisure activities in daily settings. Half of the participants (1202/2444, 49.2%) refrained from taking part in any social activity, whereas 22.7% (555/2444), 16% (392/2444), and 12.1% (295/2444) still went out for 1-3 times, 4-7 times, and ≥8 times, respectively, despite the restrictions, with a mean gathering size of 3.4 persons.
Following the tier 2 relaxation in May 2022, the proportion working on-site returned to 54.1% (1899/3505), with 11% (384/3505) maintaining their intermittent WFH practice. Based on their reported frequency of visiting eateries and shopping malls/markets, and using public transportation, living an active lifestyle with engagement in leisure activity was acknowledged in 21.8% (763/3505) of the participants, compared to 31% (1087/3505) of the participants who were considered to be inactive. Social activity was also restored, with 24% (839/3502) of the participants reporting engagement for ≥ 8 times per month in May. The overall pattern of work, daily, and social activities remained stable, as social distancing measures continued to ease, while the average gathering size increased from 5.1 in May to 9.6 persons in December 2022.

**Trajectories of Work Pattern, Daily, and Social Exposure Risk and the Associated Characteristics**

Excluding those with inadequate follow-up responses amid the 3 waves, a total of 1240 participants were included in latent class growth analyses. This subgroup was similar to the rest, except that slightly more of those being excluded were local (Hong Kong) Chinese (1222/1240, 98.5% vs 3968/4081, 97.2%; \( P=0.01 \)) with a higher median age (48 in those included vs 45 years in those excluded from the latent growth class analyses; \( P<0.001 \); Table S2 in Multimedia Appendix 1).

To differentiate between work patterns, the best fit was demonstrated in the 3-class latent class growth model (BIC 12,308.19, entropy 0.957; Table S3 and Figure S2 in Multimedia Appendix 1). Approximately 28.7% (356/1240) of the participants were not working or had worked remotely throughout the year (class 1), while about half (class 3: 647/1240, 52.2%) regularly worked outside the home, with 19.1% (237/1240) following an assorted work pattern (class 2; Figure 2).

**Figure 2.** Trajectories of the work pattern and exposure risk in daily and social settings by latent class growth models. Compartments divided by the dashed line indicate the 3 periods of Omicron waves in 2022: wave 1 (February to April), wave 2 (May to September), and wave 3 (October to December).
were significantly more likely to be in full-time employment (class 2: adjusted odds ratio [aOR] 2.05, 95% CI 1.13-3.73; class 3: aOR 3.22, 95% CI 1.76-5.89; class 4: aOR 2.81, 95% CI 1.48-5.37) and self-perceive a higher chance of virus exposure (class 2: aOR 1.18, 95% CI 1.06-1.30; class 3: aOR 1.21, 95% CI 1.09-1.34; class 4: aOR 1.31, 95% CI 1.16-1.47; Table 3). Significantly more class 4 participants had received tertiary education or above (aOR 2.28, 95% CI 1.18-4.39) and undergone SARS-CoV-2 testing more frequently (aOR 1.03, 95% CI 1.00-1.06).

aOR: adjusted odds ratio.

For social exposure risk, the best model fit was observed in the 5-class model (BIC 25,503.3, entropy 0.816). Most participants (411/1240, 33.1%) belonged to the “class 2: low and nonadaptive” group, followed by “class 1: minimal and nonadaptive” (260/1240, 21%), “class 3: moderate and adaptive” (181/1240, 14.6%), “class 4: moderate and nonadaptive” (207/1240, 16.7%), and “class 5: high and adaptive” (181/1240, 14.6%). Participants with a higher social exposure risk were in general older (class 2: aOR 1.04, 95% CI 1.01-1.06; class 3: aOR 1.05, 95% CI 1.02-1.07; class 4: aOR 1.07, 95% CI 1.04-1.09; class 5: aOR 1.06, 95% CI 1.04-1.09) and more educated (class 3: aOR 3.70, 95% CI 1.95-7.01; class 4: aOR 4.57, 95% CI 2.35-8.73; class 5: aOR 5.42, 95% CI 2.81-10.46; Table 4). Female behaviors appeared to be more responsive to adjustments in social distancing policy (class 3: aOR 2.30, 95% CI 1.30-4.09; class 5: aOR 2.09, 95% CI 1.17-3.74).

Timing and Risk Factors of SARS-CoV-2 Infection
Overall, there was a significant heterogeneity in SARS-CoV-2
infection risk among groups of varying household size
(χ24=28.6; P<.001), work pattern (χ23=25.6; P<.001), and daily
exposure risk trajectories (χ23=11.6; P=.009; Figure 3). When
the results were adjusted for sex, age, education, work pattern,
and pre-Omicron COVID-19 vaccination status, participants
living in a larger household (adjusted hazard ratio [aHR] 1.12,
95% CI 1.08-1.20) and being a health care worker (aHR 1.38,
95% CI 1.29-2.26) were linked to a significantly higher infection
risk (Table 5). Those who worked regularly on-site (aHR 1.47,
95% CI 1.19-1.80) and had more workplace contacts (hazard
ratio [HR] 1.01, 95% CI 1.00-1.02) with a higher daily (class
2: aHR 1.38, 95% CI 1.07-1.77; class 3: aHR 1.49, 95% CI
1.16-1.91; class 4: aHR 1.46, 95% CI 1.07-2.00) and social
exposure risk (class 4: aHR 1.52, 95% CI 1.18-1.97) were also
more prone to SARS-CoV-2 infection. Stratified by the epidemic
wave, individuals living in a household with size of 3 (RR 1.77;
P=.01), 4 (RR 2.12; P<.001), and ≥5 persons (RR 2.05; P=.002)

https://publichealth.jmir.org/2024/1/e51498

XSL• FO
RenderX

had a higher risk of infection in wave 1 compared to those living
alone. A similar association was also identified in those who
regularly worked outside the home (RR 1.73; P<.001) and daily
exposure risk trajectory class 3 participants (RR 1.52; P=.008).
Significantly more daily exposure risk trajectory class 4
participants had acquired SARS-CoV-2 infection in wave 2 (RR
2.41; P=.007). In contrast, an excess of social exposure risk
trajectory class 3 (RR 1.60; P=.03) and class 5 (RR 1.64; P=.02)
participants became infected in wave 3.
Stratified by the COVID-19 vaccination status, a higher
cumulative incidence was reported in participants who had
received 0-2 doses before the Omicron outbreak (515/946,
54.4% vs 112/262, 42.7%). In this subgroup, household,
workplace, daily, and social exposure risk remained significantly
associated with an episode of SARS-CoV-2 infection. However,
for the rest who had received 3 doses or more, only larger
household size (HR 1.13, 95% CI 1.01-1.28) and regular on-site
work pattern (HR 1.56, 95% CI 1.03-1.36) were significant risk
factors in the unadjusted model. The effect of daily exposure
risk was, however, absent.

Discussion

Principal Findings

Based on the heterogeneous profiles of behavior changes over 3 epidemic waves, our results demonstrated the evolution of the SARS-CoV-2 Omicron outbreak through different exposure settings unfolding in the workplace, accelerating in the household, and sustained in daily and social environments in an 11-month period. With similar travel restrictions and mandatory mask wearing in place during the whole study period, these patterns illuminate the apparently stereotyped evolution of exposure settings brought on by changes in social distancing interventions and population susceptibility. The enhanced understanding of the contextual variations along an epidemic trajectory could inform more targeted control strategies against future respiratory epidemics.

When the Omicron BA.2 lineage predominated in wave 1, individuals working outside the home, having more workplace contacts, and living in a larger household were at a higher risk of infection [19]. It can be deduced that, against a low baseline burden (<0.2%), the high population susceptibility had rendered a majority of virus transmissions initiated at the workplace and scattered to workers’ residences afterward. The office is a ubiquitous work setting in Hong Kong. Apart from health care facilities where outbreaks were commonly reported, the close proximity and prolonged contact between coworkers in the office could also create a favorable environment for virus transmission and contribute to the initial spread [20]. This could help explain the higher infection risk identified not merely in health care workers but also in the population not sheltered by remote work in our study [21]. In Hong Kong, WFH practice had never been mandated over the entire epidemic. The absence of linkage between workplace exposure risk and SARS-CoV-2 infection in later epidemic waves also suggested the effectiveness of alternative WFH interventions aside from a hard mandate (ie, forcing all employees to work from home). Alternatives such as assigning employees into cohorts to return to the workplace on alternate days and limiting the number of employees at any one time should be considered in future outbreaks to minimize societal costs [22].

Stemming from workplace outbreaks, household exposure to SARS-CoV-2 had probably culminated in early February 2022 when WFH interventions were introduced [23]. A similar transition of exposure setting was observed upon the emergence of COVID-19 elsewhere, proving that such a pattern was unlikely to be coincidental [24]. With extensive facility closures at tier 1, the halting of community activities had likely further compelled SARS-CoV-2 transmissions within the residence [25]. Such an epidemiological transition was mirrored in the outbreak dynamics, in which the precipitous rise mimicked the multiple infections established in fully susceptible households, whereas the exponential decline resulted from the limited onward transmission preempted by isolation [10]. In hindsight, discouraging multihousehold gatherings could be an effective means to confine the epidemic spread when new infections surge in the community [26]. The observed higher risk in larger households, however, did not corroborate other study findings [27,28]. A plausible explanation could be that the practice of home isolation, as a makeshift for the shortage of isolation facilities, had facilitated secondary transmission in larger households [29]. Being one of the most densely populated cities worldwide, the case in Hong Kong called for a strategic focus on the pragmatic approach of home quarantine and isolation in preparation for the emerging pandemics [30].

During wave 2 when Omicron BA.4/5 lineages prevailed, the outbreaks had most likely affected individuals with a higher daily exposure risk [31]. This pattern concurred with the partial reopening of community facilities at tier 2 and the results of another study [32]. A meta-analysis estimated a low attack rate for SARS-CoV-2 transmission derived from public and casual contacts [33]. The inefficient mode of spread, coupled with the accelerated third-dose vaccination uptake in previous months, had probably contributed to the milder outbreaks in wave 2 even when >70% remained uninfected in the population [34]. The findings also revealed that, although class 4 participants had a wider source of exposure through participation in more leisure activities than class 3 participants, the former was not significantly more vulnerable to infection. It is possible that the heightened perceived risk and precautionary behaviors compensated the actual risk [35]. Based on the subgroup analysis, a higher daily exposure risk did not result in an increased likelihood of SARS-CoV-2 acquisition among individuals having received ≥3 vaccine doses before the outbreak. This has somewhat suggested the effectiveness of booster vaccination in preventing infections arising from a lower infecting dose through casual exposure. Likewise, a previous study found that vaccinated health care workers before infection were more likely to report probable exposure in households than in other settings [36]. These findings supported in part the administration of vaccine passes as a means to allow the safe resumption of day-to-day activities in protected individuals in the face of similar epidemics [37].

With presumably >30% of the population conferred with hybrid immunity resulting from the 2 epidemic waves, the number of incident cases in wave 3 had somewhat exceeded expectations in the lack of reinfection cases [38]. It is hypothesized that following tier 4 relaxation, the reinstatement of a larger gathering had rendered an increased virus exposure to socially active subgroups such as social exposure risk trajectory class 3 and class 5 participants, who might have played a part in extending the outbreaks. Although we could not rule out that the imported traces of the XBB lineage had aided in the pervasive spread [39], the phenomenon resembled previous findings revealing a higher SARS-CoV-2 susceptibility in individuals who attended meetings of ≥10 people [40] and celebrative events [41]. The observation should, however, be...
interpreted with caution since exposure to a virus in a social context necessitates the presence of an infected seed in one’s social network [42]. Of note, older individuals presented a higher social exposure risk. This could partly be due to the uninterrupted practice of yum-cha (dining and socializing at a dim sum restaurant) when eateries remained open throughout the epidemic [43]. Furthermore, male participants were less likely to adjust their social behaviors along the progression of the epidemic. These findings convey the need to promote compliance by targeting specific community groups differentiated by age and gender in future epidemics [44].

**Limitations in This Study**

Several limitations existed in this study. The self-reported nature of SARS-CoV-2 infection could lead to an underestimation of the cumulative incidence if infected participants did not respond to the follow-up survey in that month. Such bias was minimized by excluding participants without adequate follow-up responses from analyses. The higher vaccination uptake in older individuals deviating from reality also informed the presence of a selection bias. This could be subject to the recruitment of older adults who have a higher computer literacy, which enabled them to acquire more information about COVID-19 vaccination online [45]. Recall bias could also be generated from the retrospective report of activities. This was minimized by restricting the accessibility of the follow-up survey to the first 14 days of each month. Social desirability bias could also be present when participants failed to disclose activities, which were against the quarantine and isolation orders. Furthermore, the role of virus transmission in school was not captured, despite its effect being anticipated to be small, since normal schooling was not resumed in most parts of the study period. The timing of survey initiation also coincided with the inception of the Omicron outbreak. The absence of pre-Omicron data impeded our inference on the change in the exposure risk pattern compared to the baseline. The results should also be interpreted with caution in light of the different transmissibility between the Omicron lineages [46]. The impact was, however, assumed to be small in a highly vaccinated population, as the effectiveness of mRNA vaccines against Omicron BA.2 did not differ significantly compared to BA.5 infection [47].

**Conclusions**

Monitoring the shift of exposure settings in future epidemics is important, as the pattern could inform the effective calibration of social distancing measures in a targeted manner as opposed to an exhaustive lockdown. When formulating preparedness and response plans for emerging epidemics of respiratory viruses with similar transmission dynamics, policy makers should also take such contextual variations and the accompanying effects into consideration. In a community-wide outbreak, where the workplace happens to be the first epicenter, health authorities should act in anticipation of the rise in intrahousehold transmission when WFH interventions are expected. Later strategies could focus on the prevention of explosive outbreaks in pursuit of maximum resumption of daily and social activities in protected individuals. In light of the identified patterns, future research may also explore the broader implications of exposure settings on other NPIs such as the effectiveness of masking. Methodologically, this study demonstrates the capability of a participatory surveillance cohort in examining the effect of social distancing measures on population exposure and disease patterns. This has introduced opportunities for its wider applications in detecting early epidemiological patterns and retrospectively evaluating epidemic responses for future outbreaks.

**Acknowledgments**

The authors thank Ms Mandy Li and Ms Priscilla Wong for their logistic support and assistance in data collation. We also appreciate the continuous input from the participants of the EcSS2.0 cohort. This study is supported by the Health and Medical Research Fund Commissioned Research on the Novel Coronavirus Diseases, Health Bureau of the Government of Hong Kong Special Administrative Region (COVID1903008 – Project A).

Abstract

Background: Predicting vaccination behaviors accurately could provide insights for health care professionals to develop targeted interventions.

Objective: The aim of this study was to develop predictive models for influenza vaccination behavior among children in China.

Methods: We obtained data from a prospective observational study in Wuxi, eastern China. The predicted outcome was individual-level vaccine uptake and covariates included sociodemographics of the child and parent, parental vaccine hesitancy, perceptions of convenience to the clinic, satisfaction with clinic services, and willingness to vaccinate. Bayesian networks, logistic regression, least absolute shrinkage and selection operator (LASSO) regression, support vector machine (SVM), naive Bayes (NB), random forest (RF), and decision tree classifiers were used to construct prediction models. Various performance metrics, including area under the receiver operating characteristic curve (AUC), were used to evaluate the predictive performance of the different models. Receiver operating characteristic curves and calibration plots were used to assess model performance.

Results: A total of 2383 participants were included in the study; 83.2% of these children (n=1982) were <5 years old and 6.6% (n=158) had previously received an influenza vaccine. More than half (1356/2383, 56.9%) the parents indicated a willingness to vaccinate their child against influenza. Among the 2383 children, 26.3% (n=627) received influenza vaccination during the 2020-2021 season. Within the training set, the RF model showed the best performance across all metrics. In the validation set, the logistic regression model and NB model had the highest AUC values; the SVM model had the highest precision; the NB model had the highest recall; and the logistic regression model had the highest accuracy, F1 score, and Cohen $\kappa$ value. The LASSO and logistic regression models were well-calibrated.

Conclusions: The developed prediction model can be used to quantify the uptake of seasonal influenza vaccination for children in China. The stepwise logistic regression model may be better suited for prediction purposes.

(JMIR Public Health Surveill 2024;10:e56064) doi:10.2196/56064

https://publichealth.jmir.org/2024/1/e56064
Introduction

The population of China comprises over 200 million children under the age of 15 years, accounting for approximately 10% of the global population in that age band [1]. The incidence rate of influenza infections among children aged ≤14 years was estimated to be 15.86 per 1000 person-seasons, a notably elevated figure in comparison to those of younger adults (5.17) and older adults (2.37) in China [2]. In the realm of public health interventions preventing influenza transmission, vaccination stands as an important strategy. A study conducted in the United States revealed that influenza vaccination averted 2.36 million influenza-associated illnesses among children aged 6 months to 17 years in the 2018-2019 season [3]. The technical influenza vaccination guideline in China recommends the inoculation of children aged 6 to 59 months as well as school-age children against influenza [4]. Such recommendations were underpinned by the rationale that children aged 6 to 59 months are at heightened risk of developing severe symptoms subsequent to infection, whereas school-age children, owing to their extensive social interactions, might propagate the transmission of the influenza virus [5,6]. However, a meta-analysis showed that only one-quarter of children aged 6 months to 17 years in mainland China were vaccinated against influenza [7].

Identifying individuals who are unlikely to receive the influenza vaccine in the upcoming season could provide valuable insights for public health strategies. For example, this information would be essential for health care professionals and policy makers to allocate resources effectively and develop targeted interventions to increase vaccination uptake. Several efforts have been made to develop a prediction model to identify vaccination uptake behavior. Loiacono et al [8] developed and validated a logistic regression model to predict adults’ influenza vaccine uptake in England. Another logistic regression model was constructed by Oster et al [9] using birth hospitalization records to predict undervaccination status in the United States. An expanding array of methodologies has been adopted for constructing prediction models and their subsequent application within clinical contexts, including Bayesian networks (BNs) and machine learning (ML) models [10,11]. Models derived from these diverse, adaptable, and intricate techniques have demonstrated potential for enhanced predictive accuracy. However, there are limited studies examining the performance of BN and ML models in predicting vaccination behaviors.

Methods

Study Design and Participants

We performed a cross-section survey in Wuxi city of eastern China between September 21 and October 17, 2020. Wuxi (31.5704° N latitude and 120.3055° E longitude) has a densely populated demographic (approximately 7.46 million residents) and a well-developed transportation infrastructure, which provide conducive conditions for the spread of influenza virus. Thus, determining the factors that can accurately predict influenza vaccination behaviors has practical implications, potentially alleviating the influenza-related burden in the city. Participants were recruited from six immunization clinics, including Anzhen, Dongting, Huazhuang, Jiangxi, Meicun, and Taihu, in Wuxi between September 21 and October 17, 2020 [15]. Parents bringing their child to the immunization clinic for vaccination were encouraged to participate in our study. We excluded children lacking an immunization record number (which is used to track vaccination administration records) and children aged >14 years. A total of 3009 participants were recruited. Individuals aged ≥6 months are eligible to receive the influenza vaccine in China [4,5]. To ensure that children would be eligible for influenza vaccination (ie, aged ≥6 months) at cohort entry, we excluded children born after March 2020 (n=626) (Figure 1).
Ethical Considerations

The Ethics Committee of Wuxi Center for Disease Control and Prevention granted approval for this study (2020No10). All participants who consented to complete the survey were required to sign informed consent forms. We assured participants that their survey responses would remain anonymous. Participants received a gift valued at 5 RMB (US $1=6.8148 RMB) upon completing the survey.

Outcomes and Candidate Predictors

One year after the survey, we extracted the influenza vaccination records for each child, including the vaccination time and site. The immunization records were retrieved from the Jiangsu Information Management System of Vaccination Cases [16]. The predicted outcome variable was influenza vaccination status during the 2020-2021 season, specifically between October 18, 2020, and June 30, 2021 (the final date for the supply of influenza vaccines in Wuxi during the 2020-2021 season).

Data on children’s characteristics such as age, sex, and firstborn status were obtained at cohort entry. Since parents are mainly responsible for children’s vaccinations, we also collected the parents’ sociodemographic information, including age, relationship to the child, education level, annual family income, and occupation. Parental vaccine hesitancy was measured using the 10-item Vaccine Hesitancy Scale based on a 5-point Likert scale [17]. We reversed answers to items L5, L9, and L10 as they are phrased negatively. The total score for all 10 items was summed and the total maximum score was 50 points. We established a cut-off value of 40, where scores ≤40 indicated “high hesitancy” and scores >40 indicated “low hesitancy” [15]. A previous study indicated that the distance to the immunization site was associated with vaccination behavior [18]. Therefore, we investigated parents’ perceptions of convenience to the clinic and satisfaction with the clinic services using one question for each aspect rated on a 5-point Likert scale. The ratings of “strong agreement” and “agreement” were coded together into “agree” and otherwise the responses were coded as “disagree.” Parents were asked about their intention to have their children vaccinated against influenza in the 2020-2021 season, with answers of “yes,” “not sure,” or “no” possible. The responses “no” and “not sure” were both included in the category “no” in the analysis. We also developed the predictive models under the conditions with and without combining “no” and “not sure” for comparison. The prior influenza vaccination history (prior to the 2020-2021 influenza season) was extracted as a predictor from the electronic health record system. All covariates are provided in Table S1 of Multimedia Appendix 1.

Model Building

The BN-based model was constructed using an iterative process in which the network structure was gradually constructed through a combination of manual construction and data-driven methods. Initially, a blocklist of arcs (ie, arcs that cannot be present in the network structure) was determined based on expert knowledge and logical relationships (order of event occurrences) using the variables collected. Using a scoring algorithm (the hill-climbing algorithm), 200 network structures were learned and constructed using bootstrap sampling based on all variables. The frequency of each directed arc in the 200 network structures was calculated, and arcs with frequencies higher than 60% were retained to derive an average network structure [10,19]. The variables not included in the network would then be excluded. The obtained average network structure was further optimized by removing illogical arcs (such as child’s sex to firstborn status).
and adjusting the direction of arcs that did not align with the logic (such as firstborn status to parents’ education level). The resulting network structure served as the basis for Bayesian posterior estimation, enabling the computation of conditional probabilities for each node.

We considered both stepwise logistic regression and least absolute shrinkage and selection operator (LASSO) regression. In the initial construction of the logistic and LASSO regression models, all variables were included. The logistic regression model was progressively refined through backward stepwise algorithms that systematically reduced variables by minimizing the Akaike information criterion (AIC) [8]. The model with the lowest AIC would be chosen as the prediction model. For LASSO regression, variable selection was achieved by penalizing the absolute values of the coefficients of the variables. As the tuning parameter $\lambda$ increases, coefficients of more variables shrink toward 0, which could result in a sparse model where only a subset of predictors are retained in the final model [8]. Through determining the optimal value of $\lambda$ using 10-fold cross-validation on the training set, we could minimize the prediction error. We report the estimated coefficients of variables in the final logistic regression and LASSO regression to indicate the contribution of variables.

The support vector machine (SVM), naive Bayes (NB), random forest (RF), and decision tree classifier (DTC) algorithms were also used to construct prediction models. All variables collected were included in the SVM, NB, and RF models. Ranges were set for cost and in the SVM model and a grid search was performed within the specified ranges to optimize the hyperparameters. Initially, all variables were included in the DTC model. We calculated the cost-complexity parameter value that yielded the lowest cross-validated error and pruned the tree model accordingly (ie, some variables were excluded) to prevent overfitting in the DTC model, resulting in a new tree to predict.

### Statistical Analysis

The variables were characterized by the frequency of occurrence. The data set was randomly split into training and validation sets at a 7:3 ratio. The training set was used for constructing the prediction model, whereas the validation set was used to validate the model and assess the model’s performance. The children’s vaccination status was classified based on the predicted probability following the approach proposed by Loiacono et al [8]. Specifically, a predicted probability $\leq 0.50$ was assigned to indicate nonreceipt of vaccination, while a probability above 0.50 indicated receipt of vaccination. Receiver operating characteristic (ROC) curves were plotted using sensitivity and 1–specificity. We evaluated model performance using various metrics, including accuracy, precision, recall, F1 score, area under the ROC curve (AUC), and Cohen $\kappa$ (see Table S2 in Multimedia Appendix 1). Calibration plots were also generated to compare the predicted outcomes from the model with the observed outcomes, providing insights into the alignment between predicted and actual probabilities [20]. Additionally, we performed sensitivity analyses, excluding children who were too young to have an influenza vaccination history (aged less than 6 months in September 2019). We also developed a model for children aged 6 months to 5 years as this is highlighted as the high-risk demographic for influenza in the guidelines [4,5].

All analyses were performed using R packages (bnlearn 4.8.1 and gRain 1.3.9 for the BN and NB models, MASS 7.3-51.5 for the logistic regression, glmnet 4.1-7 for the LASSO regression, e1071 1.7-13 for the SVM model, randomForest 4.6-12 for the RF model, and part 4.1.19 for the DTC model). We used Netica software 6.09 [21] to perform BN inference. Statistical significance was determined at a $P$ value threshold of $<.05$ using a two-sided test.

### Results

#### Participant Characteristics

The analyses included a total of 2383 individuals. Overall, 56.9% (1356/2383) of parents expressed a willingness to vaccinate their children against influenza, whereas 26.3% (627/2383) of children had received the influenza vaccine during the 2020-2021 season. The vaccine uptake status was significantly associated with various variables, including the children’s age, firstborn status, and previous influenza vaccine history, as well as parental factors such as age, educational level, annual household income, vaccine hesitancy, and willingness to vaccinate (Table 1). Among parents expressing an unwillingness to vaccinate their child, a notable proportion of children (90/1027, 8.7%) received vaccination. Among parents indicating a willingness to vaccinate their child, a considerable proportion of children (819/1356, 60.4%) remained unvaccinated (Table S3 in Multimedia Appendix 1). These results suggest that within the subset of parents expressing a willingness to vaccinate their children, factors including younger age of children, firstborn status, and absence of prior influenza vaccination, as well as lower parental education level and household income, may pose barriers to eventual vaccine uptake.

The training data set comprised 1668 children and the validation data set included 715 children. There were no significant differences in the variables between the training and validation data sets (see Table S4 in Multimedia Appendix 1).

Model Training

The final BN framework consisted of 10 nodes and 11 arcs, including children’s age, firstborn status, previous influenza vaccine history, parental age, education level, annual household income, vaccine hesitancy, willingness to vaccinate, satisfaction with clinic services, and vaccination behavior (Figure S1 in Multimedia Appendix 1). Child’s sex, relationship with child, parent’s occupation, and convenience to the clinic were not included in the BN framework. Child’s age, influenza vaccine history, and willingness to vaccinate were directly linked to the influenza vaccination behavior. Additionally, parent’s age had an indirect association with the vaccination behavior. When the BN receives information from individual findings, probabilistic reasoning is used to determine the maximum a posteriori probability of receiving the vaccine. For instance, if parents expressed a willingness to vaccinate their child and the child had been vaccinated against influenza previously, the probability of receiving the influenza vaccine increased from 26.6% to 85.6% (Figure S1 in Multimedia Appendix 1).

A total of 6 variables were ultimately included in the logistic regression model (Table S5 in Multimedia Appendix 1). The LASSO regression model (Table S5 in Multimedia Appendix 1) included 10 variables, with the tuning parameter log(λ) set at −5.438 (Figure S2 in Multimedia Appendix 1). Child’s age, prior influenza vaccine uptake, and parents’ willingness to vaccinate had the greatest contributions to the logistic and LASSO regression models according to estimated coefficient values.

Model Performance

Model performance metrics are summarized in Table 2. Among the seven models constructed within the training set, the RF model demonstrated the best performance, with the highest values in AUC, accuracy, precision, recall, F1 score, and Cohen κ. Within the validation set, the logistic regression model and the NB model achieved the highest AUC values, the SVM model had the highest precision, and the NB model had the highest recall. The logistic regression model had the highest accuracy, F1 score, and Cohen κ values. The performance of the seven models was similar when using different methods of combining answers related to vaccination willingness (see Table S6 in Multimedia Appendix 1).
Within the training set, the prediction of receiving the vaccine was well-calibrated with the observed vaccination behavior using the DTC, LASSO, and logistic regression models (Figure S3 in Multimedia Appendix 1). Within the validation data set, the LASSO and logistic regression models consistently provided more reliable predicted probabilities. For the predicted probabilities between 0.25 and 0.50, the SVM, RF, and DTC models tended to overpredict, while the NB model tended to underpredict. For predicted probabilities over 0.50, all seven models displayed a bias toward underprediction.

Sensitivity Analysis
A total of 1699 participants aged <6 months in September 2019 were included for the sensitivity analysis (Table S7 in Multimedia Appendix 1). The RF model exhibited the best performance within the training set, achieving the highest AUC (0.944, 95% CI 0.932-0.956), accuracy (0.881), precision (0.832), recall (0.813), F1 score (0.822), and Cohen \( \kappa \) values (0.733) (see Figure S4 and Table S8 in Multimedia Appendix 1). Within the validation set, the LASSO regression model had the highest AUC (0.880, 95% CI 0.849-0.910), followed by the logistic regression model (0.878, 95% CI 0.848-0.909). The NB and RF models both had the highest accuracy (0.816), while the DTC model had the highest precision (0.774). The NB model achieved the highest recall, F1 score, and Cohen \( \kappa \) values at 0.698, 0.719, and 0.582, respectively.

Regarding the calibration of predictions, within the training set, the predictions of the DTC, LASSO regression, logistic regression, and BN models were generally well-calibrated with the observed behavior (Figure S5 in Multimedia Appendix 1). In the validation set, none of the seven models demonstrated good calibration. When the predicted probabilities were above 0.50, the DTC, BN, LASSO regression, logistic regression, and SVM models exhibited a bias toward overprediction, while the NB and RF models showed a bias toward underprediction.

A total of 1982 participants aged 6 months to 5 years were analyzed separately (Table S9 in Multimedia Appendix 1). Within the training set, the RF model also exhibited the highest values across all performance metrics (Figure S6 and Table S10 in Multimedia Appendix 1). Within the validation set, the NB model showed the highest AUC (0.884, 95% CI 0.851-0.916), accuracy (0.860), precision (0.727), and Cohen \( \kappa \) (0.607) values, whereas the BN model had the highest recall (0.713) and F1 score (0.701). Within the validation set, the SVM and logistic regression models showed better calibration than the other models (Figure S7 in Multimedia Appendix 1).

Discussions
Principal Findings
In the study, we developed models to predict the likelihood of influenza vaccination uptake among children aged 6 months to 14 years in the upcoming season. We conducted a survey in Wuxi city, eastern China, between September 21 and October 17, 2020, and extracted the participants’ influenza vaccination records after 1 year. Data from a total of 2383 participants were included in the analysis. The RF model demonstrated superior performance metrics within the training set, whereas the logistic regression model exhibited a narrow margin of performance superiority within the validation set. Both the logistic and LASSO regression models showed good calibration. Among these models, the stepwise logistic regression approach,
characterized by its simplicity and favorable interpretability, emerged as a viable candidate for predictive purposes.

The factors associated with influenza vaccination included the child’s age, child’s previous influenza vaccine uptake, parental age, educational level, annual household income, parental vaccine hesitancy, and influenza vaccination willingness. Among these factors, previous vaccine uptake emerged as a strong positive factor, as supported by previous studies [12,22,23]. Individuals who personally witnessed the positive impact due to vaccination, such as a decreased likelihood of infection, were more likely to continue receiving vaccinations. To ensure the accuracy of this predictor, we obtained this variable directly from the electronic record system rather than relying on participants’ recall, thereby enhancing its reliability. Compared to children aged between 6 months and 2 years, older children were more likely to be vaccinated against influenza. This may be attributed to their enrollment in kindergarten or school, where peer influence and social networks potentially foster vaccination uptake [24]. Parents were concerned about the adverse effects of vaccination on younger children, which may also decrease the likelihood of young children receiving the influenza vaccine. Additionally, children from households with higher levels of parental education or income were more prone to receiving the influenza vaccine in our study. However, evidence regarding the relationship between parental education, income, and children’s influenza vaccination is inconsistent [22,23]. We also analyzed the factors influencing parents who expressed a willingness to vaccinate their children but ultimately did not do so. In addition, participants might be more inclined to express willingness toward influenza vaccination due to social desirability bias [16].

Our results did not reveal superior predictive performance of the ML methods over the logistic regression model, which was consistent with the outcomes of a previous systematic review by Christodoulou et al [25]. The strength of ML lies in its ability to handle high-dimensional data [26]. In instances characterized by constrained sample sizes and a limited number of variables, ML may be susceptible to overfitting. The BN model often involves capturing conditional dependencies among modeled variables. If the data set is confined or the interrelationships between variables are not accurately captured, the predictive performance of a BN model might diminish. The number of predictors and the sample size of this study were limited, which might potentially constrain the purported advantages associated with some complex methodologies such as ML and BN models. In general, ML techniques require more than 10 instances for each predictor to mitigate the risk of overfitting [26]. Nonetheless, despite satisfying this criterion, challenges such as instability and high optimism may persist [27]. The minimum sample size required for predictive models constructed with ML and BN approaches is still being explored [28,29].

In the sensitivity analysis, RF still showed the best performance within the training set and the performance metrics of seven models did not show substantial discrepancies within the test set. Additionally, we did not find any model that showed a prominent advantage in terms of calibration capability. Logistic regression might still be the most suitable tool to predict vaccination behaviors owing to its simplicity and favorable interpretability.

Implications for Practice

Our findings offer valuable insight for practice, allowing for prediction of the likelihood of children receiving the influenza vaccine. These modeling results can enable health care professionals to tailor their strategies based on the predicted probabilities. When dealing with children who are highly likely to be vaccinated, health care workers could save time and simplify the decision-making process [8]. For example, they could leverage messaging systems or electronic letters to provide reminders [30,31] or they could inform parents about the accessibility of the influenza vaccine during medical consultations. These efforts could particularly benefit children with a low predicted probability of vaccination. Health care workers can also use various communication techniques such as motivational interviewing and improvisational theater to encourage vaccination, which are known for their persuasive and respectful features [32,33]. These approaches can help to identify barriers and increase vaccine confidence, thereby improving vaccine uptake.

Limitations

Our study has several limitations. First, in China, adherence to mandatory vaccination requirements prior to school enrollment is imperative [34]. Noncompliance with these vaccination mandates results in exclusion from school attendance. Consequently, parents were compelled to accompany their children to immunization clinics for vaccination administration. However, the recruitment of participants solely from immunization clinics may still introduce selection bias, potentially limiting the representativeness of the study population to the general population of children. In addition, the data collection was limited to Wuxi city in eastern China. Although we performed internal validation, the model has not been externally validated in large samples or diverse locations. Second, vaccination behavior is influenced by various factors, including parental perceptions of susceptibility to influenza, the child’s health status, and vaccine policies. To enhance the performance of the model, it is important to explore additional factors that contribute to vaccination behavior and incorporate them into the modeling. Third, influenza vaccination willingness may vary across seasons and our study focused on a specific time frame. To account for this variability, future research should consider conducting season-specific surveys to capture the changing dynamics of vaccination willingness.

Conclusion

Our findings indicate that the influenza vaccination behavior for children aged 6 months to 14 years could be identified using the established predictive model. We propose that the stepwise logistic regression model with high accuracy and a straightforward modeling methodology could be better suited for such prediction tasks. Further validation of the model in larger and more diverse samples is necessary. More critical predictors should be considered to increase the accuracy and reliability of predicting influenza vaccination behavior among children.

Abstract

Background: Driven by the accelerated aging of the population of China, the number of older adults has increased rapidly in the country. Meanwhile, following children, migrant older adults (MOA) have emerged as a vulnerable group in the process of fast urbanization. Existed studies have illustrated the association between social support and loneliness and the relationship between sleep disturbance and loneliness; however, the underlying mechanisms and the migrant-local difference in the association between social support, sleep disturbance, and loneliness have not been identified.

Objective: This study aimed to clarify the migrant-local difference in the relationship between social support, sleep disturbance, and loneliness in older adults in China.

Methods: Multistage cluster random sampling was used to select participants: 1205 older adults (n=613, 50.9%, MOA and n=592, 49.1%, local older adults [LOA]) were selected in Weifang City, China, in August 2021. Loneliness was assessed with the 6-item short-form University of California, Los Angeles Loneliness Scale, social support was evaluated with the Social Support Rating Scale, and sleep disturbance was measured with the Pittsburgh Sleep Quality Index. The chi-square test, t test, and structural equation modeling (SEM) were adopted to explore the migrant-local difference between social support, sleep disturbance, and loneliness among the MOA and LOA.

Results: The mean score of loneliness was 8.58 (SD 3.03) for the MOA and 8.00 (SD 2.79) for the LOA. SEM analysis showed that social support exerts a direct negative effect on both sleep disturbance (standardized coefficient=–0.24 in the MOA and –0.20 in the LOA) and loneliness (standardized coefficient=–0.44 in the MOA and –0.40 in the LOA), while sleep disturbance generates a direct positive effect on loneliness (standardized coefficient=0.13 in the MOA and 0.22 in the LOA).

Conclusions: Both MOA and LOA have a low level of loneliness, but the MOA show higher loneliness than the LOA. There is a negative correlation between social support and loneliness as well as between social support and sleep disturbance among the MOA and LOA (MOA>LOA), while loneliness is positively associated with sleep disturbance in both populations (MOA<LOA). Measures should be taken by the government, society, and families to increase social support, decrease sleep disturbance, and further reduce the loneliness among older adults, especially the MOA.

(JMIR Public Health Surveill 2024;10:e49253) doi:10.2196/49253

KEYWORDS
loneliness; social support; sleep disturbance; older adults; migrant-local difference; structural equation modeling
Introduction

Loneliness is typically defined as the discrepancy between a person’s desired and actual social relationships [1], which would increase the risk of other mental health problems [2,3] and physical health [4]. All people face loneliness at some stage in life [5]. Loneliness varies at different ages, and those aged less than 25 years and those aged over 65 years demonstrate the highest levels of loneliness [6]; data shows that up to one-third of older adults feel lonely [7].

Migration is found to be a risk factor for loneliness [8]. A study among ethnic-migrant groups in Australia showed that migrants from non-English-speaking countries demonstrate higher levels of loneliness than native-born, nonindigenous Australians [8]. Meanwhile, a study in Canada also illustrated that immigrants report higher levels of loneliness than native-born Canadians [9]. Many studies have shown that compared with local older adults (LOA), migrant older adults (MOA) tend to report higher loneliness [10,11]. These findings make it worthwhile to focus on the migrant-local difference between older adults’ loneliness.

Social support is an important determinant of loneliness [12,13]. A study among older adults in South Korea showed that social support is negatively associated with loneliness [14]. Moreover, research among older persons in the United Kingdom revealed that lower social support during the pandemic increased the risk of experiencing loneliness [15]. Meanwhile, a study among women during the postpartum period also showed that poorer social support would generally indicate a higher potential risk of loneliness [16].

A previous study showed that poor sleep is an independent risk factor for poor mental health in older adults [17]. A previous study in Denmark among young adolescents reported that loneliness is correlated with poor sleep problems [18]. One research among the rural older adults of China found that poor sleep quality is associated with increased odds of loneliness [19]. A study among US adults illustrated that more severe insomnia symptoms are significantly related to more feelings of loneliness [20]. Meanwhile, many studies have shown that a disrupted circadian rhythm/sleep loss and sleep problems could cause loneliness [21-23]. These findings indicate that sleep is linked to loneliness.

Existing studies have shown that people with poor social support [24] have poor sleep quality [25], and social support is found to be significantly associated with sleep disturbance [26]. Those with instrumental support can reduce the risk of all sleep problems, and having emotional support can reduce the risk of poor sleep quality [27]. A previous study among college students in China also found that perceived social support is significantly and negatively associated with insomnia [28].

In summary, the relationship between social support and loneliness, between social support and sleep disturbance, and between sleep disturbance and loneliness has been separately explored in previous studies. However, few studies have investigated the association between social support, sleep disturbance, and loneliness simultaneously related to the migrant-local difference. Thus, this study aimed to identify the migrant-local difference in the relationship between social support, sleep disturbance, and loneliness among older adults in China.

Methods

Participants

A total of 1205 older adults were selected in Weifang City, China, in August 2021: 613 (50.9%) MOA and 592 (49.1%) LOA. Up to November 30, 2020, the total household population of Weifang City was 9.39 million, of which 2.04 million, accounting for 21.7% of the total population, were aged 60 years and above, and the migrant population in the city was 2.38 million [29].

Multistage cluster random sampling was used to select participants. In the first stage, 4 districts were selected as primary sampling units (PSUs) based on the economic development and geographical location of Weifang City. In the second stage, in total, 4 subdistricts from the PSUs were selected as secondary sampling units (SSUs). In the third stage, in total, 4 communities were selected from the SSUs. The population aged 60 years or above in the selected communities in Weifang City constituted the entire sample. The inclusion criteria for participants were (1) age 60 years and above and (2) clear awareness and cognition. The MOA’s household registration was beyond Weifang City, while the LOA’s household registration was in Weifang City.

After completing training on the research background, questionnaire content, and social survey techniques, a total of 25 university students were assigned as interviewers for this study. Approximately 20-minute face-to-face interviews were conducted with each participant. Initially, 1208 older adults were selected and interviewed. However, 3 (0.2%) participants were excluded as they answered their questionnaires incorrectly or incompletely. Ultimately, a total of 1205 (99.8%) participants were included in the sample.

Assessment and Measurements

Sociodemographic Characteristics

Sociodemographic characteristics included the following: gender (male, female), age (60-65, 66-70, 71-80, >80 years), marital status (married, single/divorced/separated/widowed), education level (primary school and below, junior high school, high school and above), job before retirement (agriculture, forestry, animal husbandry and fishery, others), and monthly household income (first quartile [Q1], second quartile [Q2], third quartile [Q3], fourth quartile [Q4]; Q1 was the poorest, and Q4 was the richest).

Loneliness

Loneliness is measured with the University of California at Los Angeles (UCLA) Loneliness Scale. This scale includes 20 items, which range from 1 (never) to 4 (often) [30]. In this study, we used the 6-item short-form UCLA Loneliness Scale (ULS-6) to assess loneliness among older adults. The ULS-6 includes 6 items, with higher scores indicating higher loneliness [31]. The ULS-6 is suitable to use among older adults, and its reliability

https://publichealth.jmir.org/2024/1/e49253
and validity in Chinese individuals has been verified [32,33], with a Cronbach α coefficient of .82 in this study.

**Social Support**

The Social Support Rating Scale (SSRS), developed by Xiao [34], was used to measure social support. The SSRS includes 10 items and 3 dimensions: objective social support, subjective social support, and social support use. The higher the score, the higher the social support level. The SSRS is appropriate to use among older adults [35], and the Cronbach α coefficient was .822 in this study.

**Sleep Disturbance**

The Pittsburgh Sleep Quality Index (PSQI) was used to assess the sleep disturbance of the participants in this study [36]. The PSQI consists 19 self-reported items divided into 7 components. The total score ranges from 0 to 21, and higher scores indicate severer sleep disturbance. The PSQI is appropriate to use among older adults [37,38], and its reliability and validity in Chinese individuals has been verified [39,40], with a Cronbach α coefficient of .731 in this study.

**Statistical Analysis**

Descriptive statistics were used to clarify the sociodemographic characteristics of the older adults. The migrant-local difference between the sociodemographic characteristics among older adults was investigated using the chi-square test, and the migrant-local difference between social support, sleep disturbance, and loneliness was explored using the t test. Statistical significance was defined as P<.05. All statistical analyses were performed using SPSS version 24.0 (SPSS Inc).

**Ethical Considerations**

The survey and data were obtained with written informed consent from all participants. The research program of the study was reviewed and approved by the Institutional Review Board (IRB) of Public Health and Preventive Medicine in Shandong University (#20180225) and was in accordance with the principles of the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards.

### Results

**Characteristics of the Participants**

Table 1 demonstrates the sociodemographic characteristics of the participants. We included 1205 older adults in the analysis, of which 613 (50.9%) were MOA and 592 (49.1%) were LOA. The MOA were mostly women (n=448, 73.1%); more than half (n=342, 55.8%) were 60-65 years old; most of them were married (n=539, 87.9%); 346 (56.4%) had primary school education or less; 461 (75.2%) were occupied in agricultural, forestry, and animal husbandry and fishery industries; 217 (35.4%) belonged to the Q1 (the poorest quartile) monthly household income group; 351 (57.3%) had no chronic disease; 335 (54.6%) had physical pain; and 195 (31.8%) reported a good health status. The LOA were also mostly women (n=437, 73.8%); 192 (32.4%) were 60-65 years old; 432 (73%) were married; 287 (48.5%) had primary school education or less; 400 (67.6%) worked in occupations other than agricultural, forestry, and animal husbandry and fishery industries; 219 (37%) belonged to the Q4 (the richest quartile) monthly household income group; 355 (60%) had chronic disease; 351 (59.3%) had physical pain; and 169 (28.5%) reported a good health status.

The differences between the MOA and the LOA were statistically significant (P<.001, marital status (P<.001), education level (P<.02), job before retirement (P<.001), monthly household income (P<.001), chronic disease (P<.001), and self-reported health status (P<.001).

Table 2 shows the characteristics of social support, sleep quality, and loneliness among the MOA and LOA. The mean total score of loneliness was 8.58 (SD 3.03) for the MOA and 8.00 (SD 2.79) for the LOA. Specifically, the mean scores of individual items were as follows: often feel a lack of friends, 1.53 (SD 0.79) for the MOA and 1.36 (SD 0.71) for the LOA; often feel no one can be trusted, 1.47 (SD 0.73) for the MOA and 1.37 (SD 0.71) for the LOA; often feel left out, 1.37 (SD 0.62) for the MOA and 1.28 (SD 0.65) for the LOA; often feel separated from others, 1.37 (SD 0.67) for the MOA and 1.30 (SD 0.64) for the LOA; often feel shy, 1.36 (SD 0.64) for the MOA and 1.25 (SD 0.52) for the LOA; and often feel surrounded by people but not cared for, 1.49 (SD 0.72) for the MOA and 1.43 (SD 0.71) for the LOA. Statistically significant differences were found for the total score (t(1203)=−3.442, P<.001), often feel a lack of friends (t(1203)=−3.704, P<.001), often feel no one can be trusted (t(1203)=−2.326, P=.02), often feel left out (t(1203)=−2.672, P=.008), and often feel shy (t(1203)=−3.365, P=.001) between the MOA and the LOA.

<sup>a</sup>M OA: migrant older adults.
The mean total score of sleep disturbance was 4.29 (SD 3.57) for the MOA and 4.58 (SD 3.66) for the LOA. Specifically, the mean scores of individual items were as follows: subjective sleep quality, 0.88 (SD 0.83) for the MOA and 0.97 (SD 0.86) for the LOA; sleep latency, 1.11 (SD 1.21) for the MOA and 1.12 (SD 1.19) for the LOA; sleep continuity, 0.68 (SD 0.97) for the MOA and 0.68 (SD 0.97) for the LOA; habitual sleep efficiency, 0.18 (SD 0.56) for the MOA and 0.18 (SD 0.56) for the LOA; sleep disorder, 0.97 (SD 0.57) for the MOA and 0.97 (SD 0.57) for the LOA; use of sleep medicine, 0.13 (SD 0.55) for the MOA and 0.18 (SD 0.62) for the LOA; and daytime dysfunction, 0.52 (SD 0.78) for the MOA and 0.48 (SD 0.77) for the LOA. Statistically significant differences were found for subjective sleep quality (t_{1203}=1.968, P=0.05) and sleep continuity (t_{1203}=2.822, P=0.005) between the MOA and the LOA.

Table 2. General characteristics of social support, sleep disturbance, and loneliness among the MOA\textsuperscript{a} and LOA\textsuperscript{b} by the migrant-local difference using the \(t\) test in Weifang City, China, in August 2021.

\textsuperscript{d}PSQI: Pittsburgh Sleep Quality Index.  
\textsuperscript{e}ULS-6: 6-item short-form University of California, Los Angeles (UCLA) Loneliness Scale.
The mean total score of social support was 38.89 (SD 6.63) for the MOA and 39.51 (SD 6.86) for the LOA. Specifically, the mean scores of individual items were as follows: objective social support, 8.47 (SD 1.64) for the MOA and 7.95 (SD 2.30) for the LOA; subjective social support, 23.47 (SD 4.79) for the MOA and 24.43 (SD 4.40) for the LOA; and social support use, 6.94 (SD 2.26) for the MOA and 7.14 (SD 2.44) for the LOA. Statistical differences were found for objective social support ($t_{1203}=-4.545$, $P<.001$) and subjective social support ($t_{1203}=3.608$, $P<.001$) between the MOA and the LOA.

The Structural Model

Measurement Invariance Across the Migrant and Local Groups

Before the discussion of the migrant-local difference in the structural model, multigroup model invariance should be first tested. Partial measurement invariance was used to clarify the measurement invariance about the multigroup models in this study, which could assess the invariance with $\Delta$CFI (change in the CFI) and $\Delta$RMSEA (change in the RMSEA) for comparing the less restricted model with the more constrained model. The basic test strategy was to outline correspondence to model trimming, where an initial unconstrained model was gradually restricted by adding constrains [42]. Table 3 illustrates the related fit statistics of the measures' invariance across the migrant-local difference and the fitness index for the 7 chosen models. Fitness indices of the MOA (M1) and LOA (M2) models were first compared to test whether the variable migrant-local difference was suitable for group comparison. As shown in Table 3, the model fitness indices between the M1 and M2 were $\Delta$CFI=0 and $\Delta$RMSEA=0, indicating that the different effects between the MOA and LOA could be compared. Next, the measurement invariance was evaluated with $\Delta$CFI and $\Delta$RMSEA between the unconstrained model (M3), the measurement weights model (M4), the structural weights model (M5), the structural covariances model (M6), and the structural residuals model (M7). M3 did not restrict any coefficients, M4 supposed that the indicator loadings for the corresponding construct in each group were the same, M5 constrained both indicator loadings for the corresponding construct and the structural coefficients across the groups, M6 assumed that the indicator loadings for the corresponding construct and the structural coefficients across the groups were equal and also that the covariance of the endogenous variables across the groups were equal, and M7 assumed that the indicator loadings, structural coefficients, covariance of the endogenous variables, and variance of the exogenous variable were equal across the groups.

Table 3. Multigroup model invariance test results using AMOS software. Variables in 7 models were social support, sleep disturbance, and loneliness among the MOA$^a$ and LOA$^b$ in Weifang City, China, in August 2021 (N=1205).

$^a$MOA: migrant older adults.
$^b$LOA: local older adults.
$^c$GFI: goodness-of-fit index.
$^d$AGFI: adjusted goodness-of-fit index.
$^e$CFI: comparative fitness index.
$^f$RMSEA: root mean square error of approximation.
$^g$ΔCFI: change in the CFI.
$^h$ΔRMSEA: change in the RMSEA.
$^i$M1: MOA model.
$^j$Not applicable.
$^k$M2: LOA model.
$^l$M3: unconstrained model.
$^m$M4: measurement weights model.
$^n$M5: structural weights model.
$^o$M6: structural covariances model.
$^p$M7: structural residuals model.
According to Table 3, ΔCFI was 0 between M4 and M3 and –0.001 between M5 and M4, between M6 and M5, and between M7 and M6, while ΔRMSEA was –0.001 between M4 and M3, between M5 and M4, between M6 and M5, and between M7 and M6. The fact that all the ΔCFI values were <0.010 and all the ΔRMSEA values were <0.015 indicated that the M1, M2, M3, M4, M5, M6, and M7 models had established measurement invariance across the migrant-local difference [43]. The comparison of the values between different variables across the MOA and LOA was thus established.

**Model Fitness Indices**

The proposed unconstrained model (M3) for the MOA and LOA is illustrated in Figures 1 and 2, respectively, and 3 latent variables (social support, sleep disturbance, and loneliness) were included in the model; the model fitness indices are also presented in Table 3. The estimates of model fitness were similar for both groups: GFI=0.941>0.90, AGFI=0.920>0.90, CFI=0.925>0.90, and RMSEA=0.039<0.05, implying that the proposed model well fitted the empirical data for both the MOA and the LOA in this study.

\(^a\)MOA: migrant old adults.

\(^b\)LOA: local old adults.

\(^c\)Not applicable.

Association Between Social Support and Loneliness

Social support and its indicators exerted a negative effect on loneliness. The direct negative effect of social support on loneliness was found among both MOA (standardized coefficient=-0.44) and LOA (standardized coefficient=-0.40), although the effect was stronger in the MOA than in the LOA. Additionally, the standardized effect of social support on loneliness was statistically significant in both groups. The results indicated that higher social support would result in less loneliness among both MOA and LOA.

Association Between Sleep Disturbance and Loneliness

Sleep disturbance exerted a direct positive effect on loneliness among both MOA (standardized coefficient=0.13) and LOA (standardized coefficient=0.22), although the effect was stronger in the LOA than in the MOA. Additionally, the standardized effect of sleep disturbance on loneliness was statistically significant in both groups. The results implied severer that sleep disturbance among both MOA and LOA would result in higher loneliness.

Association Between Social Support and Sleep Disturbance

Social support had a direct negative effect on sleep disturbance among both MOA (standardized coefficient=-0.24) and LOA (standardized coefficient=-0.20), although the effect was stronger in the LOA than in the MOA. A statistically significant relationship between social support and sleep quality was found in both groups. The results indicated that higher social support would result in less sleep disturbance.

Discussion

Principal Findings

The mean score of loneliness among the MOA (mean 8.58, SD 3.03) and the LOA (mean 8.00, SD 2.79) indicated a fairly low level of loneliness in both groups in this research, also lower than the mean score of loneliness reported in a previous study among the rural empty-nest older adults in China (mean 16.19, SD 3.90) [44]. Moreover, the MOA showed a mildly higher loneliness than the LOA in this study, which is similar to a previous study that showed that the mean score of loneliness is higher among older Turkish German adults than their native-born German counterparts [10].

Using SEM, this study investigated the migrant-local difference in the association between social support, sleep disturbance, and loneliness among MOA and LOA. First, the results illustrated that social support affected loneliness among both MOA and LOA, although the effect was stronger in the MOA than in the LOA. Second, sleep disturbance exerted a direct positive effect on loneliness among both MOA and LOA, although the effect was stronger in the LOA than in the MOA. Third, social support affected sleep disturbance negatively and directly among both MOA and LOA, although the effect was stronger in the MOA than in the LOA.

Relationship Between Social Support and Loneliness

A negative relationship between social support and loneliness was found among both MOA and LOA, which is consistent with previous research [45,46]. The association between social support and loneliness can be explained by the main effect and buffer effect models [47-49]. The main effect model holds that social support has a universal gain effect and that any increase in social support is bound to result in an increase in health status (eg, a lower level of loneliness), regardless of an individual’s social support level. In the buffer effect model, social support is only associated with physical and mental health in stressful situations, which cushions the negative effects of stressful events on physical and mental health and maintains or improves an individual’s physical and mental health [50]. Through these 2 models, social support can increase positive emotional experiences, control negative emotional experiences, and finally reduce loneliness.

Relationship Between Sleep Disturbance and Loneliness

Sleep disturbance was found could exert a positive effect on loneliness among both MOA and LOA, which is similar to a previous study that showed that individuals with poor sleep quality report higher levels of loneliness [51]. A study among
adolescents also showed that loneliness is significantly positively associated with sleep disturbance [52]. The positive association between sleep disturbance and loneliness may be due to the result of sleep disturbance–related metabolic, neural, and hormonal processes [51]; moreover, sleep disturbance may result in exhaustion in older adults, which further reduces their communication with others, leading to loneliness.

**Relationship Between Social Support and Sleep Disturbance**

A negative association between social support and sleep disturbance was found among both MOA and LOA, which is similar to previous studies that have reported that higher social support would generally predict less sleep disturbance [53-55]. Previous studies have also shown that sleep disturbance is significantly associated with social support among Chinese medical staff [56], as well as young Chinese rural residents [57] in China. Moreover, a meta-analysis showed a robust association between social support and favorable sleep outcomes [58]; that is, higher social support would result in less sleep disruption and less sleep disturbance.

**Migrant-Local Difference in the Relationship Between Social Support, Sleep Disturbance, and Loneliness Among MOA and LOA**

Regarding the migrant-local difference, a negative effect of social support on loneliness was found among both MOA and LOA, although the effect was higher in the MOA than in the LOA. The difference between these 2 groups may be because the MOA migrated to a new place and faced many issues with adaptation, such as acculturation stress [59,60], a low sense of psychological identity [61], and less use of outpatient mental health care services [62]; all these factors would increase their loneliness. In addition, after moving to the city where their children lived, the support network of the MOA in their hometowns broke but a new urban support network was not yet formed; consequently, the MOA faced a situation in which they lacked social support [63]. Thus, compared with the LOA, the MOA were more lonely with less social support, so the effect of social support on loneliness was higher among the MOA than the LOA.

Regarding the migrant-local difference, a direct positive effect of sleep disturbance on loneliness was found among both MOA and LOA, although the effect was higher in the MOA than in the LOA. This may be due to the result of sleep disturbance–related metabolic, neural, and hormonal processes [51]; moreover, sleep disturbance may result in exhaustion in older adults, which further reduces their communication with others, leading to loneliness.

**Implications**

Due to the migrant-local difference, different supportive measures need to be targeted for MOA and LOA. First, since the negative relationship between social support and loneliness in this study was stronger in the MOA, family members should provide more social support for older adults, especially for MOA, and provide them with more knowledge about the importance and prevention of loneliness, while providing social support. Second, the community should design more programs and create activities for MOA, which could increase the interpersonal communication between the MOA, as well as between the MOA and the LOA, by enhancing their peer social support, thus decreasing sleep disturbance and loneliness among both groups, especially the MOA. Third, since the positive relationship between sleep disturbance and loneliness in this study was stronger among the LOA, it is suggested that the community pay more attention to LOA (eg, no loud noises at night), while the family members should create a better sleeping environment (eg, adequate sleeping temperature and well-ventilated bedroom). Fourth, community health care providers should provide more mental health monitoring for both MOA and LOA, especially for older adults with sleep disturbance. Fifth, the findings of this study could attract more Chinese scholars to focus on the level of loneliness among MOA and LOA, especially sociocultural and physical health status contributors, and conduct comparative research between different areas among MOA and LOA in the future.

**Limitations**

There are several limitations of this study. First, we used cross-sectional data, which could not be well explored for causal relationships. Second, socioeconomic status plays a fundamental role in the study of population health, which was not explored in this study; we will examine this more in future studies. Third, some other factors that may also affect loneliness among MOA and LOA (eg, stress and depression) were not included in the study, which will be considered in future studies. Fourth, many other factors (eg, medication usage) might influence the sleep quality in older adults, and information related to health status is also a potential confounder of the effect of the quality of sleep, so future studies should examine whether other mediators can explain the internal mechanism underlying the relationship between sleep disturbance and social support.

**Conclusion**

This study illustrated the migrant-local difference in the association between social support, sleep quality, and loneliness between MOA and LOA in Weifang City, China. The results...
showed that (1) social support exerts a negative effect on loneliness among both MOA and LOA, although the effect is higher in MOA; (2) loneliness is significantly and positively associated with sleep disturbance among both MOA and LOA, although the effect is higher in LOA; and (3) there is a negative association between social support and sleep disturbance among both MOA and LOA, yet it is slightly higher in the MOA. This study may provide helpful information on how to decrease and prevent loneliness among older adults by enhancing their social support and decreasing their sleep disturbance.

Acknowledgments
The research team greatly appreciates the funding support obtained and thanks the research participants for their cooperation and support. This study was supported and funded by the National Natural Science Foundation of China (#71804094), the China Postdoctoral Science Foundation (#2016MS92161), the Natural Science Foundation of Shandong Province (#ZR2016GB02), the Postdoctoral Science Foundation of Shandong Province (#201603021), and the Fundamental Research Funds for the Central Universities (#2022KJIGL01, #2018JC055).

Data Availability
The data sets generated and analyzed during this study are not publicly available due to privacy restrictions but are available from the corresponding author upon reasonable request.

Authors’ Contributions
Conceptualization, validation, and writing—review and editing were managed by FK and MP; methodology, software, formal analysis, writing—original draft preparation, and visualization, MP; investigation and data curation, FK, MP, JW, RC, HL, and XX; resources, project administration, and funding acquisition, FK; and supervision, FK, MZ, and SL. Abstract

Background: Opioids have traditionally been used to manage acute or terminal pain. However, their prolonged use has the potential for abuse, misuse, and addiction. South Korea introduced a new health care IT system named the Narcotics Information Management System (NIMS) with the objective of managing all aspects of opioid use, including manufacturing, distribution, sales, disposal, etc.

Objective: This study aimed to assess the impact of NIMS on opioid use.

Methods: We conducted an analysis using national claims data from 45,582 patients diagnosed with musculoskeletal and connective tissue disorders between 2016 and 2020. Our approach included using an interrupted time-series analysis and constructing segmented regression models. Within these models, we considered the primary intervention to be the implementation of NIMS, while we treated the COVID-19 outbreak as the secondary event. To comprehensively assess inappropriate opioid use, we examined 4 key indicators, as established in previous studies: (1) the proportion of patients on high-dose opioid treatment, (2) the proportion of patients receiving opioid prescriptions from multiple providers, (3) the overlap rate of opioid prescriptions per patient, and (4) the naloxone use rate among opioid users.

Results: During the study period, there was a general trend of increasing opioid use. After the implementation of NIMS, significant increases were observed in the trend of the proportion of patients on high-dose opioid treatment (coefficient=0.0271; P=.01) and in the level of the proportion of patients receiving opioid prescriptions from multiple providers (coefficient=0.6252; P=.004). An abrupt decline was seen in the level of the naloxone use rate among opioid users (coefficient=−0.2968; P=.04). While these changes were statistically significant, their clinical significance appears to be minor. No significant changes were observed after both the implementation of NIMS and the COVID-19 outbreak.

Conclusions: This study suggests that, in its current form, the NIMS may not have brought significant improvements to the identified indicators of opioid overuse and misuse. Additionally, the COVID-19 outbreak exhibited no significant influence on opioid use patterns. The absence of real-time monitoring feature within the NIMS could be a key contributing factor. Further exploration and enhancements are needed to maximize the NIMS’ impact on curbing inappropriate opioid use.
Opioids have traditionally been used to manage acute or terminal pain [1-3]. However, their prolonged use has generated controversy due to the potential risk for abuse, overdose, and addiction [4], leading to negative outcomes and excessive mortality rates [3,5]. Previously confined to cancer-related pain management before the 1980s [6], opioids have gradually expanded their application to noncancer pain management, resulting in an increased incidence of opioid use disorders [7]. The overprescription of opioids has even steered individuals toward illicit substances such as heroin [8]. In 2018, opioid overdoses were responsible for over 60,000 deaths in the United States, making them the leading cause of drug-related deaths [9,10]. This worrisome trend has transcended national borders, manifesting as a significant global public health challenge [11-15]. An ecological study conducted in Spain corroborated this concern, demonstrating a direct correlation between greater prescribed opioid drug availability and opioid-related mortality [16].

The use of opioids in South Korea was lower compared to the United States and Europe, according to the International Narcotics Control Board’s report [17]. However, in recent years, there has been a rapid increase in the prescription rate of opioids [18]. For instance, from 2002 to 2015, the number of patients using opioids chronically for more than 90 days increased 6-9 times [19]. To address this issue, the Ministry of Food and Drug Safety (MFDS) implemented the Narcotics Information Management System (NIMS) on May 18, 2018 [20,21]. Before the NIMS, health care institutions relied on manual record-keeping to manage the use and inventory of opioids [22]. The NIMS is a web-based system that tracks patient information and inventory using a serial number assigned to each unit (bottle and carton) of opioid [22]. The system stores and monitors information at all times, making it easier to track and manage narcotics. The introduction of NIMS has transformed the monitoring of drug handling from a random management process to a selective on-site monitoring system by analyzing drug handling information. The MFDS aims to establish a safer narcotics management network through real-time tracking of narcotic handling history [21,22].

To date, there are no published studies that have directly evaluated the impact of NIMS on opioid use by comparing prescription patterns before and after the installation of the system. Therefore, we aimed to examine whether the NIMS led to any improvement in indicators related to inappropriate opioid use using an interrupted time-series (ITS) analysis. The study period coincided with the outbreak of COVID-19, and the analysis also sought to assess its effect on opioid use.

**Introduction**

Opioids have traditionally been used to manage acute or terminal pain [1-3]. However, their prolonged use has generated controversy due to the potential risk for abuse, overdose, and addiction [4], leading to negative outcomes and excessive mortality rates [3,5]. Previously confined to cancer-related pain management before the 1980s [6], opioids have gradually expanded their application to noncancer pain management, resulting in an increased incidence of opioid use disorders [7]. The overprescription of opioids has even steered individuals toward illicit substances such as heroin [8]. In 2018, opioid overdoses were responsible for over 60,000 deaths in the United States, making them the leading cause of drug-related deaths [9,10]. This worrisome trend has transcended national borders, manifesting as a significant global public health challenge [11-15]. An ecological study conducted in Spain corroborated this concern, demonstrating a direct correlation between greater prescribed opioid drug availability and opioid-related mortality [16].

The use of opioids in South Korea was lower compared to the United States and Europe, according to the International Narcotics Control Board’s report [17]. However, in recent years, there has been a rapid increase in the prescription rate of opioids [18]. For instance, from 2002 to 2015, the number of patients using opioids chronically for more than 90 days increased 6-9 times [19]. To address this issue, the Ministry of Food and Drug Safety (MFDS) implemented the Narcotics Information Management System (NIMS) on May 18, 2018 [20,21]. Before the NIMS, health care institutions relied on manual record-keeping to manage the use and inventory of opioids [22]. The NIMS is a web-based system that tracks patient information and inventory using a serial number assigned to each unit (bottle and carton) of opioid [22]. The system stores and monitors information at all times, making it easier to track and manage narcotics. The introduction of NIMS has transformed the monitoring of drug handling from a random management process to a selective on-site monitoring system by analyzing drug handling information. The MFDS aims to establish a safer narcotics management network through real-time tracking of narcotic handling history [21,22].

To date, there are no published studies that have directly evaluated the impact of NIMS on opioid use by comparing prescription patterns before and after the installation of the system. Therefore, we aimed to examine whether the NIMS led to any improvement in indicators related to inappropriate opioid use using an interrupted time-series (ITS) analysis. The study period coincided with the outbreak of COVID-19, and the analysis also sought to assess its effect on opioid use.

**Methods**

**Data Sources**

The analysis was performed using National Health Insurance (NHI) claims data between 2016 and 2020. For research purposes, the Health Insurance Review and Assessment Service (HIRA) annually provides patient sample data (HIRA–National Patient Sample [HIRA-NPS]). HIRA-NPS is derived from health insurance claim data submitted by medical institutions for reimbursement [23]. HIRA provides a sample representing 3% of the Korean population for 2016, 2017, and 2018 and a sample representing 2% of the Korean population for 2019 and 2020.

**Study Design**

To assess the impact of NIMS on opioid use, a segmented ITS analysis was performed. The data were aggregated monthly over the 5-year study period. As per the recommended practice, the ITS analysis required observations of at least 12 months before and after the intervention [24]. The NIMS was introduced on May 18, 2018, and the analysis period covered 28 months before the intervention and 32 months after. The study period also included the COVID-19 outbreak, which was treated as a second interruption to control its influence on opioid use. The second interruption occurred in February 2020 in South Korea.

**Study Population**

The study included patients with disorders of the musculoskeletal system and connective tissue [25], identified using the International Classification of Diseases, Tenth Revision (ICD-10) codes. The subject diseases are arthropathies (eg, osteoarthritis), dorsopathies (eg, spondylitis), soft tissue disorders (eg, fibromyalgia), and others (eg, postprocedural musculoskeletal disorders). Patients younger than 20 years and those with a cancer diagnosis were excluded. Outpatients who received opioid prescriptions were selected as target patients (Figure 1). The patient population was further categorized by age groups (20-39, 40-59, 60-74, and over 75 years) and the types of insurance (NHI and Medical Aid [MedAid] or Patriots and Veterans Insurance Plan [PVI]). NHI covers most of the study population, while MedAid includes individuals with low income. PVI is a special health program for patriots and veterans who have served in the military or government agencies. While PVI is distinct from NHI and MedAid in terms of its target population, it is grouped together with patients with MedAid insurance in our study due to their similar patterns of drug use [26].
**Study Drugs**

The study aimed to analyze the use of outpatient opioids in oral and patch formulations. The following opioid medications were included in the analysis: buprenorphine transdermal, codeine oral, dihydrocodeine oral, fentanyl transdermal, hydrocodone oral, hydromorphone oral, morphine oral, oxycodone oral, and tapentadol oral formulations (Multimedia Appendix 1). However, sublingual tablets, buccal tablets, and nasal sprays were excluded from the analysis as they are primarily used for breakthrough pain in patients with cancer, in accordance with the Korean reimbursement criteria [27].

**Ethical Considerations**

The study protocol was approved by the institutional review board of Pusan National University, Busan, South Korea (PNU IRB/2022_27_HR).
Outcome Measures

Overview
Throughout the study period, we assessed inappropriate opioid use monthly using 4 key indicators, each carefully selected to encompass different dimensions of inappropriate opioid use based on previous research in this area [28-33]. These indicators included (1) the proportion of patients on high-dose opioid treatment, (2) the proportion of patients receiving opioid prescriptions from multiple providers, (3) the overlap rate of opioid prescriptions per patient, and (4) the naloxone use rate among opioid users.

The Proportion of Patients on High-Dose Opioid Treatment
The proportion of patients on high-dose opioid treatment refers to the percentage of patients prescribed high-dose opioid treatments out of all patients included. High-dose opioid treatment was determined by assessing their daily morphine milligram equivalents (MME), a standardized measure of opioid potency that allows for comparing and aggregating each patient’s opioid consumption. For our study’s purposes, a daily dose of 100 MME or higher was considered high-dose opioid treatment [28-30]. Such treatment has been associated with elevated rates of mental health issues, including substance use disorders, and increased health care service use when compared to cases of no opioid use or low-dose opioid treatment [30].

The Proportion of Patients Receiving Opioid Prescriptions From Multiple Providers
The proportion of patients receiving opioid prescriptions from multiple providers was calculated to evaluate the dispersion of patient care within the outpatient setting [31]. This computation encompassed patients obtaining prescriptions from 2 or more providers, irrespective of the provider’s institutional affiliation. This was accomplished by summing up the number of providers who issued opioid prescriptions to each patient monthly. The practice of opioid prescribing by multiple providers is widespread and has been linked to elevated rates of hospital admissions directly associated with opioid use [31].

The Overlap Rate of Opioid Prescriptions Per Patient
The ratio of overlapping narcotic prescriptions is a measure of the extent to which the opioid prescriptions of study drugs overlap for each patient. It is calculated as the ratio of the overlapping prescription period to the total prescription period of the study drug per patient. Overlapping opioid prescriptions stand as one of the indicators signifying potential opioid misuse [32].

The Naloxone Use Rate Among Opioid Users
The percentage of patients prescribed and administered naloxone among opioid users each month is calculated as a proxy for opioid overdose incidents. Naloxone is a widely used medication for reversing the effects of opioid overdose [33], and the proportion of patients receiving naloxone reflects the frequency of opioid overdose or toxicity incidents.

Statistical Analysis
Descriptive statistics for all variables were presented. The time-series data of outcomes were examined graphically and used to establish a segmented regression model to assess the statistical significance of the effect of NIMS, which was investigated by analyzing the change in opioid use using 4 outcomes [34]. The time-series data of these outcomes were analyzed over 60 months, from January 2016 to December 2020, with the NIMS intervention occurring in May 2018 (29th month). The model to be tested in this study is as follows:

\[ Y_t = \beta_0 + \beta_1 \times \text{time} + \beta_2 \times \text{NIMS} + \beta_3 \times \text{time after NIMS} + \beta_4 \times \text{COVID19} + \beta_5 \times \text{time after COVID19} + \epsilon_t \]

where \( Y_t \) is the outcome of interest in month \( t \); time is a continuous variable, indicating time in months at time \( t \) from the start of the observation period; \( \text{NIMS} \) is an indicator for time \( t \) occurring before (\( \text{NIMS}=0 \)) or after (\( \text{NIMS}=1 \)) the NIMS, which was implemented at month 29 in the series; and \( \text{time after NIMS} \) is a continuous variable counting the number of months after the NIMS at time \( t \), coded 0 before the NIMS and (time-28) after the NIMS. \( \beta_0 \) estimates the baseline level of the outcome at zero; \( \beta_1 \) estimates the baseline trend before the NIMS; \( \beta_2 \) estimates the level change at the month of NIMS introduction; \( \beta_4 \) estimates the change in the trend after the NIMS, compared with the monthly trend before the NIMS; \( \beta_5 \) estimates the level change at the month of the COVID-19 outbreak at month 50 in the series; and \( \beta_5 \) estimates the change in the trend after the COVID-19, compared with the monthly trend before the COVID-19 outbreak.

The sum of \( \beta_1 \) and \( \beta_2 \) is the postintervention slope. As can be seen from the model, each interval is represented by a level and a trend. The change in the level of the outcome after the intervention indicates the immediate effect of the intervention. The change in trend is defined as the change in slope in the interval after the intervention compared to the interval before the intervention [34]. The Durbin-Watson test was used to assess the serial correlation of error terms and estimate the regression coefficients with either an ordinary least squares or a first-order autocorrelation maximum likelihood estimate, depending on the significance of serial correlations [35]. Residual analyses based on autocorrelation plots and partial autocorrelation plots were carried out to review the goodness-of-fit of the model. Statistical analysis was performed using R software (version 4.1.1; R Foundation for Statistical Computing), and when the \( P \) value was <.05, it was considered statistically significant.

Results
Characteristics of Study Population
A total of 45,582 patients received outpatient opioid prescriptions, and the most common subject disorders were dorsopathies, followed by arthropathies and soft tissue disorders. The study patients were predominantly female (27,756/45,582, 60.9%), with the largest age group being 60-74 years (15,752/45,582, 34.6%). The percentage of MedAid beneficiaries among the study patients ranged from 8.8%...
(2189/24,924) to 10.7% (539/5016), which was higher than the general population (which is approximately 3%). Some fluctuations were observed in sex, age distribution, and insurance type between the 3 time periods (Table 1).

<sup>a</sup>NIMS: Narcotics Information Management System.
<sup>b</sup>NHI: National Health Insurance.
<sup>c</sup>MedAid: Medical Aid.
<sup>d</sup>PVI: Patriots and Veterans Insurance.
<sup>e</sup>Other disorders of the musculoskeletal system and connective tissue.
<sup>f</sup>N/A: not applicable.

The Proportion of Patients on High-Dose Opioid Treatment

The proportion of patients on high-dose opioid treatment was the lowest in the pre-NIMS period (187/24,924, 0.75%), followed by the post-NIMS pre–COVID-19 period (196/15,642, 1.25%), and then the highest in the post–COVID-19 period (95/5016, 1.89%; Table 1). The trend showed a significant increase of 0.0271 from 0.0040 at baseline to 0.0311 (P=.01) after the implementation of NIMS, with no significant change in the level. The COVID-19 outbreak had little impact on both the level and trend of the percentage of patients receiving high-dose opioid treatment. The regression results are shown in Table 2 and Figure 2A.
Table 2. Modeling interrupted time series to evaluate the impact of the Narcotics Information Management System (NIMS) and COVID-19 on opioid use among outpatients with musculoskeletal and connective tissue disorders in South Korea.

\(^a\)AR: first-order autocorrelation maximum likelihood estimate.

\(^b\)D-W: Durbin-Watson test.
Impact of Narcotics Information Management System (NIMS) and COVID-19 on 4 outcome variables from January 2016 to December 2020: interrupted time-series analysis with observed and predicted regression lines for the (A) proportion of patients on high-dose opioid treatment; (B) proportion of patients receiving opioid prescriptions from multiple providers; (C) overlap rate of opioid prescriptions per patient; and (D) naloxone use rate among opioid users. The first interruption was held in May 2018 and the second was held in February 2020. The blue solid line represents the actual data, while the orange and green dot-dash lines represent the predicted data after NIMS and the COVID-19 outbreak, respectively.

The Proportion of Patients Receiving Opioid Prescriptions From Multiple Providers

The proportion of patients receiving opioid prescriptions from multiple providers was found to be the lowest in the pre-NIMS period (172/24,924, 0.69%), followed by the post-NIMS pre–COVID-19 period (160/15,642, 1.02%), and then the highest in the post–COVID-19 period (69/5016, 1.37%; Table 1). A sudden increase in the level was seen after the introduction of NIMS ($\beta_2 = .6252; P = .004$). A slight increase was observed after the COVID-19 outbreak, which was not significant ($\beta_4 = .3969; P = .09$). No significant change in the trend of patients receiving opioid prescriptions from multiple providers was observed after the implementation of NIMS or the COVID-19 outbreak. The segmented regression results of the trend and level changes are displayed in Table 2 and Figure 2B.

The Overlap Rate of Opioid Prescriptions Per Patient

The overlap rate of opioid prescriptions per patient showed a slight increase, with the lowest in the pre-NIMS period (486/24,924, 1.95%), followed by the post-NIMS pre–COVID-19 period (339/15,642, 2.17%), and then the highest in the post–COVID-19 period (102/5016, 2.30%; Table 1).

Both the NIMS and COVID-19 did not appear to significantly impact the level and trend of the overlap rate of opioid prescriptions per patient (Table 2). The trend and level changes are illustrated in Figure 2C.

The Naloxone Use Rate Among Opioid Users

The naloxone use rate among opioid users declined over time, from 0.57% (142/24,924) in the pre-NIMS period, to 0.51% (80/15,642) after NIMS, and then further down to 0.45% (23/5016) in the post–COVID-19 period (Table 1).

The baseline trend ($\beta_1$) before NIMS introduction was .0156 ($P = .01$), which was turned down by $-0.0117$ to 0.0039 after NIMS. COVID-19 changed little of the trend ($P = .18$). Abrupt decline was observed after the introduction of NIMS ($\beta_2 = -.2968; P = .04$). The regression results are shown in Table 2 and Figure 2D.

Discussion

Overview

Our study aimed to assess the impact of the Korean health care IT for narcotics management, known as the NIMS, on opioid misuse using nationally representative claims data. The study findings indicate that the NIMS did not demonstrate significant improvement during the 32 months since its introduction in the 4 specific indicators we selected. Rather, we observed a gradual increase in high-dose opioid prescribing and an abrupt increase in multiple providers’ prescriptions following the implementation of NIMS. While these changes were statistically significant, their clinical significance appears to be relatively minor, warranting further investigation.

The use rate of naloxone, which serves as a proxy for opioid misuse or abuse, had been increasing over time before the implementation of NIMS, and a temporary decrease in the use rate of naloxone was observed after NIMS implementation. This decrease suggests that the NIMS may have had a positive impact on opioid-related outcomes by reducing the occurrence of opioid misuse or abuse. However, it is inconclusive because...
a concurrent increase in the number of opioid users during the same period may have also contributed to the decrease in naloxone use rate.

We also conducted a second analysis, not treating COVID-19 as an interruption, and found no significant differences. While the primary focus of our study is to assess the impact of NIMS, this additional analysis confirms that even when not considering COVID-19 as an interruption, the NIMS still did not show a significant impact on the identified indicators of opioid overuse and misuse.

Given the limited existing research in this area, the reasons for NIMS not yielding anticipated results remain largely unexplored. In this regard, some recent studies have raised workforce concerns [36]. A recent study reported that the workforce to operate the NIMS is not adequately secured. Essential tasks such as analysis of causes of misuse and corrective actions for detected problems were carried out only to a limited extent due to the lack of workforce reinforcement [36]. Furthermore, recent in-depth interviews with 3 prescribers and 2 pharmacists confirmed that health care professionals primarily use the NIMS to fulfill legal reporting requirements [37]. These latest studies have raised the need for the introduction of a more comprehensive measure such as “opioid stewardship,” which encompasses guidelines for health care professionals, education for patients and the public, and enhanced communication and coordination among key stakeholders [38,39].

In comparison to similar systems overseas, the lack of real-time access to patient’s prescription histories within the NIMS may explain its suboptimal impact on drug usage enhancement [21]. The United States has a state-based electronic database called prescription drug monitoring programs (PDMPs), and some Canadian provinces operate the narcotics monitoring system (NMS), which mandates that pharmacies submit dispensing information for all monitored drugs [21]. NIMS, PDMPs, and NMS share the common goal of monitoring and managing the prescription and dispensing of narcotics to address misuse and abuse [21]. While they share this overarching objective, these systems differ in their operations and functionalities compared to the NIMS. All 3 systems collect, monitor, and analyze prescription data for controlled substances, including opioids. However, a key distinction is that PDMPs and NMS provide real-time access to patients’ prescription histories for prescribers and pharmacists, enabling them to promptly identify potential misuse, overuse, or diversion of prescription medications [40]. Numerous studies have investigated the effectiveness of PDMPs and NMS, with some demonstrating a significant reduction in the prescription of narcotic drugs and a reduction in opioids misuse [41-44]. These findings underscore the pivotal role of real-time monitoring in curbing prescription abuse and misuse.

The study population had a higher representation of women than men, who are known to experience more severe and long-lasting pain, leading to a higher prescription rate for opioids [45]. Additionally, it is noteworthy that our study population included a higher proportion of MedAid beneficiaries (ranging from 8.8% to 10.7%) compared to the general population, where the percentage of MedAid beneficiaries typically remains around 3% [46]. Several factors may contribute to the higher presentation of MedAid beneficiaries in our study. Research has shown that this population often experiences higher rates of chronic pain [47,48] and may have limited access to alternative pain management treatments [49,50]. Moreover, one important aspect to consider is the distinction in copayment requirements between NHI and MedAid. Under the NHI system, patients are required to make copayments for health care services, including medications such as opioids. On the other hand, MedAid beneficiaries generally pay lower or no copayments for medications, including opioids. This distinction can lead to different use patterns, a phenomenon often referred to as “moral hazard” [26,51,52]. While our study primarily focused on assessing the impact of NIMS on opioid use, the observed variation in MedAid beneficiaries’ opioid use patterns highlight an avenue for further research.

To the best of our knowledge, this research is the first study to directly evaluate the impact of the NIMS on opioid use using nationwide real-world data, providing invaluable insights into its effect on opioid prescription patterns in South Korea and suggesting areas for improvement. Nevertheless, our study has several limitations that should be noted. First, the inclusion of patients with musculoskeletal and connective tissue disorders may limit the generalizability of the findings to other patients with different medical conditions. Furthermore, the study’s setting in South Korea may limit the generalizability of the findings to other health care systems and countries with different opioid prescription practices and regulatory frameworks. Variations in health care policies, cultural factors, and clinical guidelines may influence opioid use patterns in distinct ways, warranting caution when extrapolating the study’s conclusions to other regions. Second, data analyzed in this study are based on reimbursement claims, meaning that any opioids prescribed outside of the national insurance market would not be recorded. This could result in an underrepresentation of actual opioid prescription quantities [53]. Third, the diagnostic codes assigned to patients may not always be completely accurate, which could impact the accuracy of the findings. Additionally, being a quasi-experimental study using ITS, there might be uncontrolled confounding factors that could influence the observed trends in opioid use.

It is worth noting that the NIMS has undergone improvements. For instance, the “Information Network to Prevent Doctor Shopping for Narcotics” feature, similar to PDMPs, included the entire narcotics data set since March 2021. This integration allows prescribers to assess a patient’s history of medical narcotic use, particularly when a doctor shopping for narcotics is suspected [20,21]. Feedback reports grounded in the NIMS big data are sent to doctors who demonstrate problematic prescribing behavior (eg, prescribing substantial amounts of medical narcotics). This series of changes is expected to gradually materialize in the form of opioid stewardship mentioned above in South Korea. Given these circumstances, there arises a clear need for future investigations to assess the efficacy of the enhanced NIMS.

Conclusion
This study suggests that, in its current form, the NIMS may not have brought significant improvements to the identified-negative impacts on opioid use. However, the potential for enhanced opioid stewardship through the NIMS highlights the need for continued efforts to address the misuse and abuse of opioids in South Korea.
indicators of opioid overuse and misuse. Additionally, the COVID-19 outbreak exhibited no significant influence on opioid use patterns. The absence of a real-time monitoring feature within the NIMS could be a key contributing factor. Further exploration and enhancements are needed to maximize the NIMS’ impact on curbing inappropriate opioid use.

Acknowledgments
We used the Health Insurance Review and Assessment Service–National Inpatient Sample from 2016 to 2020 (S20220126793) for this study; however, the findings are not associated with the Ministry of Health and Welfare or Health Insurance Review and Assessment Service.

Data Availability
The authors used the Health Insurance Review and Assessment Service–National Inpatient Sample data for this study and do not have permission to share these data. Raw data can be accessed with permission from the Health Insurance Review and Assessment.

Authors’ Contributions
IHL and NKJ conceived and designed the study. SYK and NKJ performed the analysis. SYK first drafted the manuscript. All authors participated in drafting the paper and approved the final version to be submitted for publication.

Abstract

Background: Little is known about the cocirculation of influenza and SARS-CoV-2 viruses during the COVID-19 pandemic and the use of respiratory disease sentinel surveillance platforms for monitoring SARS-CoV-2 activity in sub-Saharan Africa.

Objective: We aimed to describe influenza and SARS-CoV-2 cocirculation in Kenya and how the SARS-CoV-2 data from influenza sentinel surveillance correlated with that of universal national surveillance.

Methods: From April 2020 to March 2022, we enrolled 7349 patients with severe acute respiratory illness or influenza-like illness at 8 sentinel influenza surveillance sites in Kenya and collected demographic, clinical, underlying medical condition, vaccination, and exposure information, as well as respiratory specimens, from them. Respiratory specimens were tested for influenza and SARS-CoV-2 by real-time reverse transcription polymerase chain reaction. The universal national-level SARS-CoV-2 data were also obtained from the Kenya Ministry of Health. The universal national-level SARS-CoV-2 data were collected from all health facilities nationally, border entry points, and contact tracing in Kenya. Epidemic curves and Pearson $r$ were used to describe the correlation between SARS-CoV-2 positivity in data from the 8 influenza sentinel sites in Kenya and that of the universal national SARS-CoV-2 surveillance data. A logistic regression model was used to assess the association between influenza and SARS-CoV-2 coinfection with severe clinical illness. We defined severe clinical illness as any of oxygen saturation <90%, in-hospital death, admission to intensive care unit or high dependence unit, mechanical ventilation, or a report of any danger sign (ie, inability to drink or eat, severe vomiting, grunting, stridor, or unconsciousness in children younger than 5 years) among patients with severe acute respiratory illness.

Results: Of the 7349 patients from the influenza sentinel surveillance sites, 76.3% (n=5606) were younger than 5 years. We detected any influenza (A or B) in 8.7% (629/7224), SARS-CoV-2 in 10.7% (768/7199), and coinfection in 0.9% (63/7165) of samples tested. Although the number of samples tested for SARS-CoV-2 from the sentinel surveillance was only 0.2% (60 per week vs 36,000 per week) of the number tested in the universal national surveillance, SARS-CoV-2 positivity in the sentinel
surveillance data significantly correlated with that of the universal national surveillance (Pearson $r=0.58$; $P<0.001$). The adjusted odds ratios (aOR) of clinical severe illness among participants with coinfection were similar to those of patients with influenza only (aOR 0.91, 95% CI 0.47-1.79) and SARS-CoV-2 only (aOR 0.92, 95% CI 0.47-1.82).

Conclusions: Influenza substantially cocirculated with SARS-CoV-2 in Kenya. We found a significant correlation of SARS-CoV-2 positivity in the data from 8 influenza sentinel surveillance sites with that of the universal national SARS-CoV-2 surveillance data. Our findings indicate that the influenza sentinel surveillance system can be used as a sustainable platform for monitoring respiratory pathogens of pandemic potential or public health importance.

KEYWORDS
SARS-CoV-2; COVID-19; influenza; sentinel surveillance; Kenya; epidemic; local outbreak; respiratory infection; surveillance; cocirculation; monitoring; respiratory pathogen

Introduction

Influenza can cause local outbreaks and seasonal epidemics and has pandemic potential, which makes it an important respiratory infection to monitor for prompt public health response [1]. Influenza occurs in multiple epidemics all year round in the tropics and mostly in winter or cold seasons in temperate regions [1,2]. Although influenza virus infection can be asymptomatic in about 30%-50% of infections or cause mild illness [3-5], in some people, influenza virus infection can cause severe illness leading to hospitalization, intensive care admission, mechanical ventilation, or death [1,6]. It is estimated that influenza is associated with 290,000 to 650,000 annual deaths globally [7,8]. Sub-Saharan Africa is one of the highest-burden regions [7,8], but influenza remained poorly monitored until recently when countries began building influenza surveillance systems to monitor circulating strains [2] and contribute to global data to inform strain selections for annual influenza vaccines [9,10].

In December 2019, an outbreak of severe respiratory illness caused by a novel coronavirus (SARS-CoV-2) was reported in Wuhan, China [11]. The World Health Organization declared SARS-CoV-2 infection that causes COVID-19 as a pandemic on March 11, 2020. Given that this outbreak occurred during the Northern Hemisphere influenza season, the public health community was concerned about the potential cocirculation of influenza and SARS-CoV-2 that could overburden health care systems. During the influenza months in winter, surges in medical visits and increase in health care use have been well documented [12]. Data from the Northern Hemisphere or countries with strong public health surveillance systems showed that influenza activity unexpectedly remained minimal during the COVID-19 pandemic [13-19]. Similarly, countries in the sub-Saharan African region, which has some of the highest burden of influenza, reported very minimal influenza activity [20]. However, given that most of these countries are still developing their influenza surveillance systems, it is unclear whether the minimal activity reported was due to a break in surveillance because of the response measures to the pandemic. In addition, little is known about how data from sentinel influenza surveillance platforms could be used to gauge SARS-CoV-2 circulation in sub-Saharan Africa.

Kenya, an equatorial country in sub-Saharan Africa, has implemented sentinel influenza surveillance since 2007 and developed a strong platform that continued to function during the COVID-19 pandemic. This provides an opportunity to understand influenza circulation in a tropical setting during the COVID-19 pandemic. Here, we describe influenza circulation and coinfection with SARS-CoV-2 in Kenya during the COVID-19 pandemic and compare SARS-CoV-2 virus detection from the influenza sentinel surveillance system with that of the universal national SARS-CoV-2 surveillance that included data from all facilities and border points in Kenya. The findings of this evaluation could inform the implementation or strengthening of national sentinel influenza systems and leveraging these platforms to monitor respiratory pathogens of pandemic potential.

Methods

Study Sites

The Kenya Ministry of Health (MoH), in collaboration with the US Centers for Disease Control and Prevention (CDC), established sentinel surveillance for influenza in selected health care facilities in 2007 [21]. Currently, there are 8 sentinel surveillance sites (Figure 1) located within 6 county-level referral hospitals (Coast General Teaching and Referral Hospital, Kakamega, Nakuru, Nyeri, Marsabit, and Siaya [22]), 1 tertiary referral hospital (Kenyatta National Hospital [23]), and the International Rescue Committee hospital in the Kakuma Refugee Camp. All sites enroll patients of all ages except the site in the Kenyatta National Hospital, which enrolls only pediatric cases.

https://publichealth.jmir.org/2024/1/e50799

XSL-FO
RenderX
Surveillance Procedures

Trained surveillance officers (either a nurse or a clinical officer) identified and enrolled patients who met the severe acute respiratory illness (SARI) or influenza-like illness (ILI) case definitions [24]. We defined a SARI case as an acute onset of respiratory illness (within the last 10 days) with fever (reported or measured fever of $\geq 38^\circ C$) and cough, requiring hospitalization. Eligible patients with SARI were identified and enrolled 5 days a week (Monday to Friday) within 48 hours of hospital admission for all sites except for Kakuma Refugee Camp, where enrollment was done Monday to Saturday. In addition, surveillance staff reviewed admission logbooks every Monday to identify and enroll any eligible patients with SARI admitted during the weekends. We defined ILI as an acute onset of respiratory illness (within the last 10 days) with measured fever of $\geq 38^\circ C$ and cough. The first 3 patients with ILI were enrolled per week at the outpatient clinics. Surveillance for SARS-CoV-2 was initiated and integrated into the routine surveillance for influenza among patients presenting with SARI or ILI (as defined earlier) in the sentinel sites in April 2020.

This analysis used data collected from the sentinel sites (Figure 1) and the national SARS-CoV-2 surveillance data reported to the MoH from April 2020 through March 2022.

Specimen Collection and Testing

Trained surveillance officers collected nasopharyngeal or nasal and oropharyngeal swabs from the enrolled patients. Nasopharyngeal or nasal and oropharyngeal swabs were placed in a single cryovial containing 3-mL sterile viral transport media and labeled with the patient’s unique identifier, a barcode number, and the date of specimen collection. Samples were stored at 2-8 $^\circ C$ at the sentinel surveillance sites for up to 36 hours and then shipped to the National Influenza Center laboratory in Nairobi, where each specimen was made into 3 aliquots and tested.

We tested an aliquot of each specimen for SARS-CoV-2 and influenza-viral ribonucleic acid at the CDC-supported Kenya Medical Research Institute laboratory and National Influenza Center laboratory, respectively, by real-time reverse transcription polymerase chain reaction (rtRT-PCR). Each assay had a target for Homo sapiens (human) RNase P gene for
monitoring specimen quality. Influenza testing was done as previously described [21,22]. The primer and probe sequences for the influenza A, influenza B, and ribonuclease P gene targets were as per the approved CDC’s Human Influenza Virus Real-Time RT-PCR Detection and Characterization Panel [21,22]. All specimens positive for influenza type A were subtyped for H3, H5, and A(H1N1) pdm09 using rtRT-PCR. The SARS-CoV-2 laboratory testing protocol has been described elsewhere [25]. A cycle threshold (Ct) of ≥40.0 was considered positive and ≥40.0 or no amplification was considered negative.

Data Collection and Variable Definitions

The surveillance staff enrolled patients using an electronic structured questionnaire with questions on demographics, clinical presentation, underlying medical conditions, medical history, vaccination history, and exposures. The questionnaire was administered to participants or their parents or legal guardians using a password-protected netbook. In addition, surveillance staff conducted a medical chart review to complete a follow-up exit questionnaire for patients with SARI. This review was done to abstract data on clinical outcomes of hospitalization. Laboratory data were recorded into Freezerworks software (Dataworks Development, Inc) and merged with epidemiological information. All data were stored in password-protected Microsoft Access or SQL databases on a central server at the Kenya Medical Research Institute, Center for Global Health Research campus in Nairobi.

We defined influenza virus or SARS-CoV-2 detection as a positive rtRT-PCR test of influenza (A or B) or SARS-CoV-2, respectively. A participant was assumed to have been coinfected if the respiratory sample was rtRT-PCR positive for both influenza (A or B) and SARS-CoV-2. Severe clinical illness was defined as any of oxygen saturation <90%, in-hospital death, admission to intensive care unit, mechanical ventilation, or a report of any danger sign (ie, inability to drink or eat, severe vomiting, grunting, stridor, or unconsciousness among children younger than 5 years).

Kenya National SARS-CoV-2 Surveillance

In Kenya, the universal national SARS-CoV-2 surveillance was led by MoH focusing initially on points of entry and contact of people exposed to individuals who tested positive for SARS-CoV-2. Once there was evidence of community spread of SARS-CoV-2 infections in Kenya, all persons suspected to have COVID-19 or presenting with ILI in health facilities were tested for COVID-19 [26]. In addition, cargo vessel crew at all entry points were screened for SARS-CoV-2. Testing was initially limited to a few laboratories but later expanded to 96 public and private laboratories conducting rtRT-PCR tests and 472 conducting rapid diagnostic tests. All 8 influenza sentinel sites contributed data to the universal national SARS-CoV-2 surveillance throughout the study period.

Statistical Analysis

Frequencies and percentages were calculated to describe the characteristics of participants overall and by patient type (in- or outpatients). Microsoft Excel (Microsoft Corp) charts were used to describe influenza or SARS-CoV-2 trends based on a calculated monthly percentage of influenza and SARS-CoV-2 positivity. Pearson correlation coefficient (r) was used to compare trends in the 3-week moving average of SARS-CoV-2 positivity from the influenza sentinel surveillance data with that of the data from the universal national SARS-CoV-2 surveillance.

Logistic regression was conducted to assess the association between coinfection and severe clinical illness among SARI cases. Univariate and multivariable logistic regression analyses were also conducted to examine factors associated with the detection of influenza (A or B) only, SARS-CoV-2 only, and influenza and SARS-CoV-2 coinfection among enrolled patients, stratified by ILI versus SARI cases. In all multivariable models, we included age, surveillance site, and in-patient or outpatient status a priori and any other variable of interest (underlying conditions, sex, smoker in household, hospitalization in past year, symptoms) that was significant at P<0.05 in the univariate analysis. All analyses were performed using Stata Statistical Software (version 13.0; StataCorp).

Ethical Considerations

The Kenya MoH determined the sentinel influenza surveillance to be a routine public health activity, and a nonresearch project determination was also received from CDC (project 0900f3eb81e74404). Thus, ethical review was not required to enroll and collect data from patients at the sentinel sites. We obtained informed verbal consent from participants or parents or legal guardians of children before the administration of questionnaires and collection of specimens. In addition to verbal consent of parents or guardians, children aged 7 years and older provided assent before participation.

Results

Demographic and Clinical Characteristics

Patient characteristics are summarized in Table 1. From April 2020 through March 2022, we enrolled 7349 patients from the sentinel influenza surveillance sites in Kenya. Most (n=5606, 76.3%) of the patients were children aged younger than 5 years. The median age of all the enrolled patients was 1.5 (IQR 0.7-4.6) years. Of all the enrolled patients, 3331 (45.3%) were female participants, and 899 (12.2%) had at least one underlying medical condition (eg, HIV positive: n=171, 2.3%; heart disease: n=281, 3.8%; chronic neurological or neuromuscular disease: n=185, 2.5%; asthma: n=223, 3%; diabetes: n=81, 1.1%; and other: n=93, 1.3%). Overall, 5932 (80.7%) were patients with SARI, while the rest were patients with ILI who were seen as outpatients. The Kakuma site provided the highest percentage of enrolled patients (n=2316, 31.5%), followed by Siaya County Referral Hospital with 18.1% (n=1332). Kakamega County Referral Hospital had the least number of enrolled patients (n=174, 2.4%). Overall, 46% (n=2727) of inpatients (SARI cases) presented with severe clinical illness. Among patients presenting with severe clinical illness, 20.9% (n=1238) were admitted to the intensive care unit, 8.9% (n=527) had oxygen saturation <90%, 2.3% (n=134) were put on mechanical ventilation during admission, 41% (2084/5080) were children younger than 5 years who had at least one danger sign reported, and 5.4% (n=319) died during admission (Table 1).

Influenza and SARS-CoV-2 Circulation

We tested 7199 (98%) specimens for SARS-CoV-2, 7224 (98.3%) specimens for influenza, and 7165 (97.5%) of the specimens for both influenza and SARS-CoV-2. We detected influenza (A or B) in 8.7% (n=629); 7.4% (n=103) tested positive among outpatients and 9% (n=526) among inpatients. Of the patients with influenza, 48.7% (n=306) had influenza A, while 53.6% (n=337) had influenza B. Among the influenza A cases, 90.5% (n=277) were A (H3N2), 1% (n=3) A (H1N1) pdm09, and 8.5% (n=26) not subtyped. Among patients who were tested for SARS-CoV-2, 10.7% (n=768) tested positive; 16.8% (235/1400) tested positive among outpatients and 9.2% (533/5799) among inpatients (Table 1).

Detection of both viruses continued throughout the evaluation period, with influenza positivity remaining higher than SARS-CoV-2 positivity from mid-May 2021 through late December 2021. The highest influenza positivity was 21.4% (71/333) in August 2021 when SARS-CoV-2 positivity was 17.2% (57/333). The highest peak of SARS-CoV-2 positivity was in March 2021 at 25.1% (109/434) when influenza positivity was 9.4% (41/434; Figure 2).
Figure 2. Monthly trends of influenza activity (including circulating subtypes), SARS-CoV-2 activity, and coinfections of influenza and SARS-CoV-2 using data from the 8 influenza sentinel surveillance sites in Kenya, April 2020 to March 2022. From April 2020 through March 2022, influenza cocirculated with SARS-CoV-2, with influenza positivity rates sometimes surpassing that of SARS-CoV-2. Data source: Kenya influenza sentinel surveillance system.

SARS-CoV-2 Positivity in the Influenza Sentinel Surveillance Versus the Universal National SARS-CoV-2 Surveillance Data

SARS-CoV-2 positivity in the data collected from the sentinel sites, with a median of 60 (IQR 38-71) weekly tests during the study period, significantly correlated (Pearson r=0.58; P<.001) with SARS-CoV-2 positivity in the Kenya universal national SARS-CoV-2 surveillance data, which had a median of 36,000 (IQR 28,000-43,000) weekly tests (Figure 3).

Figure 3. Three-week MA of SARS-CoV-2 positivity using data from the 8 influenza sentinel surveillance sites in Kenya versus universal national SARS-CoV-2 surveillance data from all tests conducted in Kenya, April 2020 to March 2022. This figure shows number of specimens tested from the sentinel sites and 3-week MA of SARS-CoV-3 positivity from the sentinel sites and the Kenya national SARS-CoV-2 surveillance data. SARS-CoV-2 detection and peak from the sentinel surveillance, with a median of 60 (IQR 38-71) weekly tests, significantly correlated (Pearson r=0.58; P<.001) with the detection and peak activity from the Kenya universal national SARS-CoV-2 surveillance data, which had a median of 36,000 (IQR 28,000-43,000) weekly tests. Epi: epidemiology; MA: moving average; SARI: severe acute respiratory infection.

Coinfection and Severe Clinical Illness

We detected influenza and SARS-CoV-2 coinfection in 0.9% (63/7165) of those who were tested for both infections. Thus, 8.2% (63/765) of those who tested positive for SARS-CoV-2 also tested positive for influenza. The odds ratios of clinical severe illness among participants with coinfection were similar to those of patients with influenza only (adjusted odds ratio [aOR] 1.06, 95% CI 0.72-1.39) and SARS-CoV-2 only (aOR 1.00, 95% CI 0.54-2.10) infection (Table 2).
Table 2. Association between influenza and SARS-CoV-2 coinfection and severe clinical illness among patients hospitalized with severe acute respiratory illness (SARI) from 8 influenza sentinel surveillance sites in Kenya (n=1004), April 2020 to March 2022.\(^a\)

\(^a\)Odds ratios were adjusted for age, site of data collection, and any variable that was significant at \(P<.05\) in the univariate analysis.

\(^b\)Severe clinical illness was defined as any of oxygen saturation <90%, in-hospital death, admission to intensive care unit or high dependence unit, mechanical ventilation, or a report of any danger sign among children younger than 5 years (inability to drink or eat, severe vomiting, grunting, stridor, or unconsciousness).

\(^c\)uOR: unadjusted odds ratio.

\(^d\)aOR: adjusted odds ratio.

\(^e\)N/A: Not applicable.

**Factors Associated With Influenza and SARS-CoV-2 Infection Detection Among SARI and ILI Cases**

None of the variables included in the multivariable analysis were associated with influenza-only detection or influenza and SARS-CoV-2 coinfection among SARI cases. However, detection of SARS-CoV-2 only was significantly higher in patients aged 13 years and older compared to those aged 0-11 months (aOR 3.85, 95% CI 1.86-8.02; Multimedia Appendix 1). Adjusting for other covariates, influenza-only detection was less common in patients with ILI diagnosed with malaria (aOR 0.09, 95% CI 0.03-0.27). Among ILI cases, SARS-CoV-2–only detection was associated with age group, malaria diagnosis, and presenting with chills (Multimedia Appendix 2).

**Discussion**

**Summary of Main Findings**

In this study, we found that influenza continued to circulate in Kenya throughout the COVID-19 pandemic. Although the number of weekly tests in the influenza surveillance system was only 0.2% (60 per week vs 36,000 per week) of the number of tests conducted in the universal national surveillance for SARS-CoV-2, we found that peaks in SARS-CoV-2 positivity from our sentinel surveillance sites coincided with peaks in...
SARS-CoV-2 positivity from the universal national SARS-CoV-2 surveillance data. Our analysis further revealed that about 1 in 12 patients who tested positive for SARS-CoV-2 also tested positive for influenza; however, we did not find any significant evidence of increased severe clinical illness among these patients compared to those who tested positive for influenza only or SARS-CoV-2 only.

**Influenza and SARS-CoV-2 Cocirculation**

Multiple reports from elsewhere [13,14,17,19,27] indicated that influenza activity was minimal and far below expectation at the height of the SARS-CoV-2 pandemic from 2020 through 2021. Our results suggest that unlike these countries, Kenya continued to record substantially high levels of influenza activity during the pandemic. Some experts have attributed the minimal influenza activity observed in many countries during the SARS-CoV-2 pandemic to the impacts of widespread mitigation measures such as social distancing, facial covering, and stay-at-home measures [15,16,18,28]. However, Kenya implemented mitigation measures with similar stringency to those of countries that recorded minimal influenza activity such as South Africa and the United States (Multimedia Appendix 3) [29]. Although our data are limited to explain why Kenya experienced high influenza activity despite implementing some of the stringent mitigation measures, our results suggest the importance of local surveillance of influenza and other pathogens of public health importance and pandemic potential. Because of geographic and sociocultural differences, data from one country may not be applicable to another country.

**Influenza Sentinel Surveillance System Versus Universal National SARS-CoV-2 Surveillance**

We observed that the detection rates and peak activity of SARS-CoV-2 from the sentinel surveillance were well aligned with that of the universal national surveillance, suggesting that the data from the sentinel system was able to detect increased SARS-CoV-2 activity during the study period. This is consistent with findings reported from Indonesia, in which SARS-CoV-2 trends in the influenza surveillance data aligned with COVID-19 national surveillance data [30]. When the pandemic started, the Kenyan government, like many other countries, implemented several ad hoc systems to respond to the pandemic, including opening border surveillance units and national influenza surveillance coordination centers and increasing laboratory capacity to collect SARS-CoV-2 data and implement interventions to control the pandemic. Although it might be good to identify all cases to respond appropriately, a universal national surveillance system is labor- and resource-intensive and not sustainable in the long term in Kenya and other settings. Therefore, there is a need for a sustainable approach for ongoing monitoring of SARS-CoV-2 and other pathogens of pandemic potential in general to detect early signals and implement effective interventions. Our results support the World Health Organization’s [31] recommendation for integrated surveillance of SARS-CoV-2 and influenza and suggest that influenza sentinel surveillance systems can serve this purpose for routine monitoring and provide signals of increased activity of SARS-CoV-2 to aid the development of appropriate public health interventions and decisions. These findings provide further evidence about the need to implement and sustain a strong influenza surveillance system in all countries, especially, those in sub-Saharan Africa.

**Influenza and SARS-CoV-2 Coinfection and Severe Clinical Illness**

Besides concerns about health systems being overwhelmed by influenza and SARS-CoV-2 cocirculation, one major concern about this cocirculation was the potential for coinfection with both viruses and consequent severe outcomes in patients. Our understanding of the extent and potential impact of influenza and SARS-CoV-2 coinfection on clinical illness is still evolving. A few studies have reported varying results regarding the prevalence and severity of coinfection [32-36]. Prevalence of influenza coinfection in people with SARS-CoV-2 as low as 0.6% has been reported in the United States [35] and as high as 12.6% has been reported in Guangzhou, China [33]. In this study, we found 8.2% (63/768) influenza coinfection in participants who tested positive for SARS-CoV-2. Unlike previous findings from animal models [32] and UK adults [36], but consistent with findings from India [34], we did not find a significant increase in the frequency of severe clinical presentation among these individuals compared to those infected with only influenza or only SARS-CoV-2. Our results may have been impacted by the age composition of the study sample. The majority were children, who are already at increased risk of severe influenza outcomes [37] and often have less severe COVID-19 [38]. Our findings together with the existing literature on influenza and SARS-CoV-2 coinfection suggest a need to continue to monitor cases of coinfection and their clinical presentations and outcomes to inform preventive measures and clinical management.

**Limitations**

Although we used data from a good influenza sentinel surveillance system that collects data from all ages and our analysis controlled for multiple potential confounders, there are some limitations of the study. The criteria used to define severe clinical illness were in-hospital presentations and outcomes and did not include outcomes outside the sentinel site hospitals such as death prior to admission or after discharge. Therefore, more studies are needed to examine disease severity among people with influenza and SARS-CoV-2 coinfection. The age of 65 years and older is a risk factor for severe outcomes of SARS-CoV-2 infection; however, this population is underrepresented in this analysis (139/5932, 2.3%), so we cannot draw inferences on coinfections for this population. Most of the participants were children younger than 13 years of age; therefore, we could not assess differences among older patients. Data used in this study may not be representative of the Kenyan population because the sites were within only selected counties that do not necessarily represent the rest of the country.

**Conclusions**

Unlike many other countries, influenza significantly cocirculated with SARS-CoV-2 during the early weeks of 2020 through the first quarter of 2022 in Kenya, and SARS-CoV-2 positivity data from the influenza sentinel surveillance sites were comparable to that of the national surveillance system. Our findings reinforce
the need to implement or strengthen national influenza sentinel surveillance systems to monitor respiratory diseases of public health importance or those with pandemic potential. Influenza or respiratory disease sentinel surveillance sites could be used as a sustainable platform for national monitoring of SARS-CoV-2 activity.

Acknowledgments
The authors thank the patients who enrolled in the surveillance and who provided data for their generosity. The authors thank the staff of the following hospitals for their invaluable contributions to this effort: Kenyatta National Hospital; Coast General Teaching and Referral Hospital; Kakamega, Nakuru, Nyeri, Marsabit, and Siaya County Referral Hospitals; and the International Rescue Committee hospital in the Kakuma Refugee Camp; and the hospital managers for their support of this research. The authors would also like to thank the surveillance officers for their great work in identifying cases and collecting data and samples: Molly Mugabe, Esther Chomba, Jonathan Onyango, Milka Bunei, Juma Maleve, Musa Nawe, Elizabeth Simiyu, and Peter Muturi. The authors appreciate the data staff for the enormous work of entering and cleaning the data at the National Influenza Center and Centers for Disease Control and Prevention–supported Kenya Medical Research Institute laboratory. This study was conducted as part of the authors’ usual employment. No author received outside support or funding to conduct this study. The Kenya influenza surveillance system was supported by funds from the US Centers for Disease Control and Prevention.

Data Availability
The data sets generated and analyzed during this study are not publicly available because they were collected for public health surveillance by the Kenya Ministry of Health but are available from RK (focal person for influenza surveillance, division of disease surveillance and response, Kenya Ministry of Health) on reasonable request.

Disclaimer
The findings and conclusions in this report are those of the authors and do not necessarily represent the official position of the US Centers for Disease Control and Prevention.

Conflicts of Interest
None declared.

Abstract

Background: In the absence of an effective treatment method or vaccine, the outbreak of the COVID-19 pandemic elicited a wide range of unprecedented restriction policies aimed at mitigating and suppressing the spread of the SARS-CoV-2 virus. These policies and their Stringency Index (SI) of more than 160 countries were systematically recorded in the Oxford COVID-19 Government Response Tracker (OxCGRT) data set. The SI is a summary measure of the overall strictness of these policies. However, the OxCGRT SI may not fully reflect the stringency levels of the restriction policies implemented in Korea. Korea implemented 33 COVID-19 restriction policies targeting 4 areas: public facilities, public events, social gatherings, and religious gatherings.

Objective: This study aims to develop new Korea Stringency Indices (KSI) that reflect the stringency levels of Korea’s restriction policies better and to determine which government-implemented policies were most effective in managing the COVID-19 pandemic in Korea.

Methods: The random forest method was used to calculate the new KSI using feature importance values and determine their effectiveness in managing daily COVID-19 confirmed cases. Five analysis periods were considered, including November 01, 2020, to January 20, 2021 (Period 1), January 20, 2021, to June 27, 2021 (Period 2), November 01, 2020, to June 27, 2021 (Period 3), June 27, 2021, to November 01, 2021 (Period 4), and November 01, 2021, to April 24, 2022 (Period 5).

Results: Among the KSI, public facilities in period 4, public events in period 2, religious gatherings in periods 1 and 3, and social gatherings in period 5 had the highest importance. Among the public facilities, policies associated with operation hour restrictions in cinemas, restaurants, PC rooms, indoor sports facilities, karaoke, coffee shops, night entertainment facilities, and baths or saunas had the highest importance across all analysis periods. Strong positive correlations were observed between daily confirmed cases and public facilities, religious gatherings, and public events in period 1 of the pandemic. From then, weaker and negative correlations were observed in the remaining analysis periods. The comparison with the OxCGRT SI showed that the SI had a relatively lower feature importance and correlation with daily confirmed cases than the proposed KSI, making KSI more effective than SI.

Conclusions: Restriction policies targeting public facilities were the most effective among the policies analyzed. In addition, different periods call for the enforcement of different policies given their effectiveness varies during the pandemic.
Introduction

The spread of COVID-19 [1-3], which became a global pandemic [4], elicited a wide range of unprecedented restriction policies from different governments aimed to mitigate and suppress the spread of the SARS-CoV-2 virus [5-7]. Without a vaccine or an effective treatment, these social distancing policies included school closures, travel restrictions, bans on social and private gatherings, stay-at-home orders, workplace closures, closure of public transportation, and so forth [6]. The transmission of the SARS-CoV-2 virus spreads through contacts made between susceptible and infectious individuals depending on the spatial distance between contacts. Therefore, the suppression of contacts is the goal of these policies, designed to slow the growth rate of infections, as inferred from past epidemics [8,9].

The impact of implemented government policies in lowering COVID-19 cases has been demonstrated in many studies as the pandemic progressed [6,10-15]. One country that implemented social distancing policies was South Korea. When the first patient with COVID-19 was confirmed in Korea on January 20, 2020 [16-18], voluntary social distancing started to be practiced by citizens in their daily lives until it was declared a global pandemic. With the declaration of COVID-19 as a worldwide pandemic on March 11, 2020 [4], the Korean government instituted its first social distancing for 2 weeks starting March 22, 2020, when the number of cases rose to approximately 100-150 daily cases [19]. The government combined testing, contact tracing, early isolation, and the free treatment of positive cases together with digital technologies without considering “lockdown” measures [20-22]. Many countries and governments worldwide applauded South Korea’s response as the most influential and was considered as one of the most effective models against COVD-19 in the early months that followed the pandemic [20]. The COVID-19 curve was flattened to an average of 6.4 daily cases in the first week of May 2020 [20-22]. However, as the pandemic progressed, this approach could not hold up due to worsening COVID-19 situations in the country, mainly in the metropolitan areas tied to small church gatherings, restaurants, social gatherings, nightclubs, and schools [17,18,23,24]. From then on, the government imposed restrictions in these areas and would strengthen or lower the restriction levels depending on the average daily confirmed cases. The policies and their levels would be announced via official government websites and press releases [25].

The policies implemented by different countries worldwide were systematically collected and recorded by the Blavatnik School of Government, and the University of Oxford called the Oxford COVID-19 Government Response Tracker (OxCGRT) data set [26]. This data recorded more than 17 policies and indices from more than 160 countries. This also included the Stringency Index (SI), a summary of the measure of the overall strictness of these policies. Previously, we conducted studies showing the relationship between these policies and indices in lowering COVID-19 cases in more than 90 countries and South Korea [13,27]. However, we observed that the SI provided by the OxCGRT data may not fully capture Korea’s containment and closure policies. To describe government responses simply, OxCGRT would summarize the policies implemented in each country into the same number of levels and then use an additive method to calculate the unweighted SI since the approach is transparent and easiest to interpret. However, this approach cannot capture small policy changes across all countries and adequately reflect the influence of different policies on an individual basis. Some countries applied more stringent policy changes that cannot be captured by the calculated OxCGRT SI. For example, South Korea implemented restriction policies targeting social gatherings and would relax or tighten the policies by increasing or decreasing the maximum number of people allowed at these social gatherings like for 8 to 10 or vice versa. These changes were too subtle to be reflected in the OxCGRT’s SI. Second, OxCGRT did not consider the impact of each policy on the spread of COVID-19 when calculating SI. This assumes that each policy will have an equal influence and contribution to the final policy score. OxCGRT encouraged users to carefully consider which combination and weighting of policies would best capture the dimensions they are seeking to measure [26]. Therefore, Korea Stringency Indices (KSI) better capture the subtle changes present in Korea’s COVID-19 response policies. In addition, we can focus on the target areas of the policies and tell whether the implemented policies and their level of strictness are having an impact on the people who frequent those target areas.

Although Korea was one of the first countries to be affected by COVID-19 [28], many countries, like China, Uganda, Europe, and the United States, implemented a wide range of stringent restriction policies in response to the rapid increase in the daily number of COVID-19 cases. But, after experiencing a sharp growth in COVID-19 cases early in the pandemic, Korea rapidly controlled transmission while implementing less stringent social distancing measures than other countries. The government only implemented free nationwide public testing, isolation of infected individuals, vaccination, and information of the public through text messages together with government press conferences [21,29]. The government maintained this course of less strict policies even when the daily cases rose to tens of thousands without locking down regions and causing severe economic damage [28]. Analyzing the effectiveness of these policies in Korea can answer questions about which policies were most effective at managing the pandemic situation in Korea and provide a framework for responses that can be adopted against future pandemics without resorting to stringent measures that affect people mentally and the economy. Maybe we can also find loopholes in Korea’s response strategy and improve its efficiency.
In our analysis, we aim to answer the question of which implemented government policies were most effective in managing the COVID-19 situation in Korea and calculate KSI using the COVID-19 restriction policies implemented in Korea. The Korean government implemented restriction policies targeting 4 target areas: public facilities, public events, religious gatherings, and social gatherings. The policies and their level of strictness were manually obtained from this website [25]. Our final goal is to provide KSI, which is the summarized score to express the strictness of the policies considering their impact on the spread of COVID-19. We first assumed that each policy may have different impacts on the spread of COVID-19. Given this reason, the impact of these policies on the spread of COVID-19 was estimated using a random forest (RF) model. In addition, RF is not restricted by the multiple levels that are present in a given policy. All the information given by the levels in each given policy is used to estimate the impact (feature importance) of the policy on the spread of COVID-19. These feature importance values are taken as the weights of the policies and used for calculating the summarized score of each policy category. The basis for this assumption is that even if the amount of change in 2 policies is the same, the more important policy should be weighted more in the summarized score. Finally, we assumed that the impact of each policy on COVID-19 could be different by each period. Therefore, the analysis was carried out in 5 segments or periods corresponding to waves of the pandemic or turning points during the pandemic. Such turning points classify the behavior of a country’s trajectory throughout the pandemic as being in (or over) their subsequent waves.

**Methods**

**Data**

The COVID-19 daily series of confirmed cases in Korea was downloaded from the “Our World in Data” (OWID) website [30]. Countries implemented different restriction policies with the progress of the pandemic, and these policies were recorded by the OxCGRT [26,31]. The OxCGRT data systematically recorded the different levels of the policies on an ordinal or numeric scale. The SI was obtained from the OxCGRT data and records the average level of strictness of the policies that primarily contain and restrict people’s behavior and movements (a summary of the measure of the overall strictness of these policies).

**Korea’s Restriction Policies**

The COVID-19 restriction policies implemented in Korea and their strictness were collected manually from the government’s official website of the Korea Disease Control and Prevention Agency (KDCA) in response to COVID-19 [25]. The KDCA gave press releases about the COVID-19 situation in the country. The social distancing policies and their strictness levels for a given period were announced during these press releases and also on the official KDCA website. All press release posts by the KDCA for our analysis period (November 01, 2020, to April 24, 2022) were checked (1532 posts), and the social distancing policy level for the announced given period was recorded in a spreadsheet with their corresponding dates. If there were changes to the social distancing policy, they were summarized in the spreadsheet for the given date. However, if there was no updated policy notice for a certain period, we assumed the same policy level had been maintained. These policies focused on 4 main activities with different targets under each, including public facilities, religious gatherings, public events, and social gatherings, as summarized in Table 1. The level of strictness or stringency of the policies varied with the number of confirmed cases and is outlined in the “score” column of Table 2. A higher score value means a more vital constraint.

Analysis Periods
The analysis was carried out in 5 periods. Period 1 corresponds to the third wave of the pandemic ranging from November 01, 2020, to January 20, 2021. Period 2 comes after the 3rd wave of the pandemic and ranges from January 20, 2021 to June 27, 2021. Period 3 combines the first and second analysis periods (November 01, 2020, to June 27, 2021). Period 4 consists of the summer vacation period and right after the summer vacation period, from June 27, 2021, to November 01, 2021. Period 5 is from November 01, 2021, to April 24, 2022, the step-by-step recovery period. This period is characterized by the major cities in the country taking steps to go back to normal operations like before the pandemic and the end of the social distancing policies except masking. The analysis period is summarized in Figure 1 below. The end of the analysis period 4 is the beginning of period 5 but with a different scale for the y-axis.

Figure 1. The 5 analysis periods used in the study.

Statistical Analysis
In the first step, an RF model was used to estimate the feature importance of policies corresponding to each target level policy, respectively against COVID-19 daily confirmed cases. Since there are 15 target policies, 15 RF models for each target policy were fitted each independent of the other target policies. Then, the estimated feature importance of the 33 policies was multiplied by their respective policy “score” values and summed to form the 15 policies according to the target category level as shown in Table 1. Public facilities had 10 target policies, public events and religious gatherings had 1 target policy each (personnel), and social gatherings had 3 target policies (restaurants and cafes, exceptions, and personnel). In the second step, another RF model was fitted with the 15 target-level policies and their feature importance was estimated. Then, the KSI for each category is estimated by multiplying the estimated feature importance of each target policy with the calculated target policies estimated above and summed corresponding to each category. The RF model is an ensemble learner based on randomized decision trees and provides different feature importance measures, one from statistical permutation tests and the other from training an RF classifier. Both measures have been found to correlate reasonably well and provide excellent means of measuring feature relevance [32]. Therefore, although simple, the calculation of KSIs using this method is justifiable. Since there are 4 categories, we will get 4 KSI values, 1 for each category. In the last step, an RF model is used to rank the impact of the restriction policies using KSIs on COVID-19 daily cases using feature importance. The SI from the OxCGRT data was included in the analysis.

During the analysis, a training validation approach was used to find optimal hyperparameters, with the last 14 days used as a validation set in each analysis period. A detailed explanation of hyperparameter settings is explained in Table 3 below.

Ethical Considerations

No individual data were used in our study. Only cumulative count data of anonymous individuals were used. Since publicly available data were used for this study, ethical approval from a research board was unnecessary.

Results

Feature Importance of the Policies

The feature importance of the 33 policies and the 15 target policies for the 5 analysis periods is summarized in Figure 2. The feature importance of the 33 policies varies much across the analysis periods and we observe a pattern of low, intermediate, and high feature importance among the policies and across the 5 analysis periods. Most restriction policies targeting public events and religious gatherings had their feature importance around 0.5 across the analysis periods except for period 5. Restriction policies targeting public facilities also had their importance mainly around 0.50, except in period 5 which had importance values of either 0 or 1.00. The most prominent impact was observed with the restriction policies that targeted the use of public facilities. A few policies stood out, especially in the step-by-step recovery period (period 5), including operating hour restrictions on cinemas, restaurants, PC rooms, indoor sports facilities, karaoke, coffee shops, night entertainment facilities, and baths or saunas. After the summer vacation (period 4), operating hour restrictions were imposed on supermarkets, cinemas, sales promotion centers, restaurants and coffee shops. Period 3 which combines periods 1 and 2 had feature importance for most policies at around 0.50. We conclude that most policies associated with operating hour restrictions followed by the number of gathering restrictions had higher feature importance values than the other policies for a given analysis period, respectively.

There was not much variation in the feature importance of the 15 target policies (Figure 2B) obtained from summing up the 33 policies across the 5 analysis periods. All feature importance was below 0.40, except for the restriction on the number of gatherings in public places in period 2 (0.80). For some policies, their importance was either equal to or near 0 at a given analysis period.
Figure 2. The feature importance values were obtained from RF models across the 5 analysis periods. (A) Results from the 15 RF models for the 33 policies for each period. (B) Results from 1 RF model for the 15 target policies for each period. RF: random forest.

Korea Stringency Indices

Four KSIs for public events, religious gatherings, social gatherings, and public facilities were calculated using the feature importance values and score values of policies under each target policy and category, respectively. In addition to SI obtained from the OxCGRT data, their variation with daily confirmed cases for the 5 analysis periods is shown in Figure 3. SI had higher indices across all analysis periods. Public facilities had relatively higher stringency indices than the other KSIs from periods 1 to 5, followed by religious gatherings, social gatherings, and public events, respectively. Furthermore, we observed that the stringency indices of KSIs tended to increase with the number of daily confirmed cases and decrease with decreasing daily cases.

The KSIs had their feature importance below 0.20 in most analysis periods as shown in Figure 4. Exceptions were observed with public facilities in period 4, public events in period 2, social gatherings in period 5, and religious gatherings for period 1 and period 3.
Figure 3. Variation of the KSIs and the OxCGRT SI with daily confirmed cases for (A) analysis periods 1, 2, and 4; (B) analysis period 5; and (C) analysis period 3+4. KSI: Korea Stringency Index; SI: Stringency Index.
Correlation Analysis

The correlation analysis was carried out between KSIs, SI, and daily confirmed cases, as shown in Figure 5. In period 1 of the pandemic, all correlations were positive and statistically significant, with restrictions in the use of public facilities ($r=0.86$, $P<.001$), religious gatherings ($r=0.86$, $P<.001$), public events ($r=0.76$, $P<.001$), and SI ($r=0.71$, $P<.001$) being the strongest, respectively. Strong correlations were also observed between the KSIs, especially between public facilities and religious gatherings ($r=0.99$, $P<.001$), public facilities and public events ($r=0.88$, $P<.001$), and religious gatherings and public events ($r=0.92$, $P<.001$). However, a weak relationship was observed with restrictions in social gatherings ($r=0.38$, $P<.001$). In period 2 of the pandemic, a weaker and negative relationship between KSIs, SI, and daily confirmed cases was observed. However, there were strong correlations between public facilities and religious gatherings ($r=0.81$, $P<.001$) and religious and social gatherings ($r=0.82$, $P<.001$). Weak and sometimes negative correlations were observed in periods 4 and 5 between the KSIs and daily confirmed cases. However, strong correlations were observed between social and religious gatherings ($r=0.82$, $P<.001$) and public facilities and public events ($r=0.81$, $P<.001$) in period 5. The detailed results are summarized in Table S1 in Multimedia Appendix 1.
Figure 5. Correlation analysis plot for (A) analysis period 1; (B) analysis period 2; (C) analysis period 4; and (D) analysis period 5. The asterisk (*) indicates a statistically significant correlation. NC: new cases; PF: public facilities; PH: public events; RG: religious gatherings; SG: social gatherings; SI: Stringency Index.

Discussion

From our analysis, we observed that policies associated with operation hour restrictions and the number of gathering restrictions had a higher impact than other policies in the same analysis periods. The greatest impact was observed with the restrictions on the use of public facilities, especially in operating hour restrictions of cinemas, restaurants, coffee shops, indoor sports facilities, PC rooms, karaoke, and baths or saunas. The next impact was with policies restricting the number of people gatherings in public, religious, and social gatherings. For KSIs, their feature importance was below 0.20 in most analysis periods except public events in period 2, social gatherings in period 5, religious gatherings in periods 1 and 3, and public events in period 4. Although the stringency of SI was higher than KSIs, its feature importance with COVID-19 daily cases was lower than 0.40 across all analysis periods. Furthermore, we observed that different policies are effective at different analysis periods. Other periods of the pandemic require the enforcement of varying restriction policies. For example, the summer period is accompanied by a lot of indoor and outdoor activities and travel which increases the contact among people in the population, thus the rate of daily confirmed cases. To lower the wave of daily cases, the number of gathering restrictions and the use of public facilities, especially in PC rooms, restaurants and coffee shops, and cinemas would be more effective. These policies would reduce the mixing of people, allowing confirmed cases to be isolated and recovered. After flattening the curve, we can ease the strictness of using public facilities and social gatherings while maintaining a high stringency level on religious and public gatherings. Therefore, different policies have to be strengthened depending on the situation of the pandemic and significant activities happening in the country.

Correlation analysis showed a strong positive relationship between KSIs and daily confirmed cases in period 1 of the pandemic. A rise in the average daily confirmed cases corresponded with an increase in the stringency levels of the policies. The increase in the KSIs stringency indices leads to lower numbers of COVID-19 daily confirmed cases. In period 2, the relationship between the KSIs and daily confirmed cases was negative and weaker, maybe due to the easing of the strictness of the policies because of the flattening of the cases’ curve. From then on, the correlations stayed weak, and the relationship was either negative or positive, depending on the KSI. This can be attributed to easing the restriction policies’ strictness because most of the population was already vaccinated and opening the country back to normal operations. The correlation of SI was generally lower than those of the KSIs, showing that using KSIs to evaluate the effectiveness of restriction policies on COVID-19 cases is better than the OxCGRT SI. The KSIs provide more information about the effectiveness of the different policies at different target categories as the pandemic progresses.

Some argue that the COVID-19 pandemic caused by the contact-transmissible SARS-CoV-2 virus is our most significant health crisis [33]. However, its global impact on health, business, education, travel, international security, and other aspects of life cannot be disputed. Its outbreak exposed the weakness of
health care systems, countries, and world preparedness in handling a sudden global crisis. Due to the lack of an effective treatment or vaccine, the pandemic elicited unprecedented restriction (or social distancing) policies to mitigate and suppress the spread of the virus. Around 110 countries have implemented at least 1 restriction policy against COVID-19 [26]. Standard policies included school closures, travel restrictions, bans on public gatherings, stay-at-home orders, closure of public transportation, emergency investments in the health care system, contact tracing, and investments in COVID-19 vaccines. Due to its high recovery rate of above 95% [34], the implementation of the restriction policies was also met with resistance from the general population as the social distancing period lengthened mainly toward vaccination and wearing masks [35-43]. Opposition came primarily from business holders, workers, and parents of school-going children because of the impact of these restrictions on education and businesses. However, evidence from several scientific studies and disease modeling continued to support the effectiveness of these policies on COVID-19 cases, thereby motivating governments to continue their implementation [44], especially with the emergence of more severe and transmissible SARS-CoV-2 variants like the delta and omicron variants, respectively [45-49].

The Korean government without resorting to any draconian “lockdown” policies like other countries of Uganda, China, the United States, etc [21,28,29], resorted to population testing combined with contact tracing, early isolation, free treatment of positive cases and digital technologies to fight the pandemic. Thirty-three restriction policies targeting public facilities, public events, social gatherings, and religious gatherings were implemented in Korea during the pandemic. These policies mainly targeted operating hour restrictions of public facilities or places and restrictions on the number of people gathering. Therefore, analysis of these policies to determine which government-implemented policies were most effective in managing the COVID-19 situation in Korea can provide a framework for responses that can be adopted against future pandemics. From our analysis, we observed the greatest impacts came from restrictions in public facilities, especially in operating hour restrictions of cinemas, restaurants, coffee shops, indoor sports facilities, PC rooms, karaoke, and baths or saunas, followed by restrictions to the number of people in public, religious and social gatherings. From the literature, an analysis of restriction policies in more than 90 countries showed the positive impact of containment policies like cancellation of public events, school and workplace closures, stay-at-home requirements, and restriction on gatherings, on the spread of COVID-19 [17]. Travel restrictions were shown to be effective in reducing the risk of imported SARS-CoV-2 cases [50].

Masking was found to be the most cost-effective nonpharmacological intervention implemented, delivering 4 times more impact than school closures and approximately double that of other mobility restrictions [51]. Gathering restrictions were the second most effective while international travel controls and public information campaigns had negligible effects [51]. From the above literature review, we consistently observe policies associated with gathering restrictions or restrictions on places where many people meet and mix like public places, workplaces, and schools, to always stand out among other policies, which is consistent with our findings of restrictions on public facilities and number of gathering restrictions.

The major limitation of our analysis was the collection of the restriction policy levels, which was done manually. This was time-consuming. Furthermore, since the policy levels were summarized from the KDCA website, some unnoticed changes may have been missed and thus not incorporated. In addition, the strictness levels and their compliance varied greatly between metropolitan areas like Seoul and Gyeonggi-do, which had a higher average number of daily cases, and the nonmetropolitan areas. However, we only focused on the national restriction levels when summarizing the restriction policy levels and calculated only nationwide-specific indices. Local or regional information was neglected and not incorporated when calculating indices or summarizing policy levels. Local or regional information must be considered as it is more insightful, especially considering countries such as the United States, which have large territories and large differences in regional policies. Furthermore, although our analysis focused only on Korea due to a lack of detailed information about the restriction policies of other countries, our method of calculating the stringency indices is simple and can easily be applied to other countries. However, the reliability of the developed indices will vary greatly depending on the types of policies implemented and the frequency of policy information provided by each country. In the future, the crawl-based semiautomated systems can be adapted to collect policy data, after which the validity of the data can be confirmed manually. To increase the generalizability of the result, we can consider developing the region-specific stringency indices using regional data. Furthermore, considering the population demographic information like age may provide more in-depth results and compliance levels across age groups. In addition, more robust methods of calculating indices need to be explored.

In conclusion, nonpharmacological restriction policies that aim for physical distancing have a strong potential to suppress the spread of COVID-19 and lead to a smaller number of overall cases. From our analysis, we observed that restrictions on the use of public facilities focusing on restaurants, coffee shops, cinemas, PC rooms, saunas or baths, indoor sports facilities, and restrictions on the number of gatherings, have played a significant role in slowing down the spread of the disease, thus buying time for the health care systems and governments. Given the high impact of restriction policies on public facilities, a nonpharmacological restriction policy framework can be designed with restrictions on public facilities being the main focus for diseases that spread through contact between people in the population. However, different periods call for enforcing different policies as their effectiveness can vary during the pandemic. Since nonpharmacological restriction policies alone cannot effectively combat a spreading pandemic, other factors like an effective health care plan or treatment, population demographics, and population mobility must be considered for either long-term or short-term impact. The compliance from the public must also be considered for both short and long-term effectiveness.

Abstract

Background: Understanding the long-term impact of the COVID-19 pandemic on health care utilization is important to health care organizations and policy makers for strategic planning, as well as to researchers when designing studies that use observational electronic health record data during the pandemic period.

Objective: This study aimed to evaluate the changes in health care utilization across all care settings among a large, diverse, and insured population in the United States during the COVID-19 pandemic.

Methods: We conducted a retrospective cohort study within 8 health care organizations participating in the Vaccine Safety Datalink Project using electronic health record data from members of all ages from January 1, 2017, to December 31, 2021. The visit rates per person-year were calculated monthly during the study period for 4 health care settings combined as well as by inpatient, emergency department (ED), outpatient, and telehealth settings, both among all members and members without COVID-19. Difference-in-difference analysis and interrupted time series analysis were performed to assess the changes in visit rates from the prepandemic period (January 2017 to February 2020) to the early pandemic period (April-December 2020) and the later pandemic period (July-December 2021), respectively. An exploratory analysis was also conducted to assess trends through June 2023 at one of the largest sites, Kaiser Permanente Southern California.

Results: The study included more than 11 million members from 2017 to 2021. Compared with the prepandemic period, we found reductions in visit rates during the early pandemic period for all in-person care settings. During the later pandemic period, overall use reached 8.36 visits per person-year, exceeding the prepandemic level of 7.49 visits per person-year in 2019 (adjusted percent change 5.1%, 95% CI 0.6%-9.9%); inpatient and ED visits returned to prepandemic levels among all members, although they remained low at 0.095 and 0.241 visits per person-year, indicating a 7.5% and 8% decrease compared to pre-pandemic levels among members without COVID-19, respectively. Telehealth visits, which were approximately 42% of the volume of outpatient visits during the later pandemic period, were increased by 97.5% (95% CI 86.0%-109.7%) from 0.865 visits per person-year in
2019 to 2.35 visits per person-year in the later pandemic period. The trends in Kaiser Permanente Southern California were similar to those of the entire study population. Visit rates from January 2022 to June 2023 were stable and appeared to be a continuation of the use levels observed at the end of 2021.

**Conclusions:** Telehealth services became a mainstay of the health care system during the late COVID-19 pandemic period. Inpatient and ED visits returned to prepandemic levels, although they remained low among members without evidence of COVID-19. Our findings provide valuable information for strategic resource allocation for postpandemic patient care and for designing observational studies involving the pandemic period.

**Methods**

**Study Setting**

We conducted a retrospective cohort study within 8 health care organizations (Kaiser Permanente: Southern California, Northern California, Northwest, Washington, and Colorado; HealthPartners; Denver Health; and Marshfield Clinic) participating in the Vaccine Safety Datalink (VSD) Project [15]. The VSD is a collaborative project between the Centers for Disease Control and Prevention’s Immunization Safety Office and integrated health care organizations, with over 9 million individuals annually enrollment representing approximately 3% of the US population. Each participating site creates standardized data sets with information on members’ demographic characteristics, membership enrollment, vaccination history, and medical encounters in the inpatient, ED, outpatient, and telehealth settings.

**Ethical Considerations**

The institutional review board at each study site approved the study with a waiver of informed consent, given that the data-only retrospective research activities were minimal risk. To protect the privacy and confidentiality of human participants, all staff working on the research study were trained in procedures to protect the privacy of medical record information. Study participants were not compensated given the observational nature of the study.

**Study Population**

The study population consisted of individuals of all ages who were active health plan members at any time from January 1, 2017, to December 31, 2021 from 8 participating VSD sites. Members who did not test positive for COVID-19 or have a medically attended COVID-19 diagnosis at any time during the study period were classified as “members without COVID-19.” The exploratory analysis to assess the more recent trends included KPSC members from January 1, 2022, to June 30, 2023.
Health Care Utilization

Four visit types were evaluated based on care setting: inpatient visit, ED visit, outpatient visit, and telehealth visit. Telehealth visits were conducted synchronously using telephone or live video-audio interaction. The visit rates per person-year from these 4 care settings were calculated monthly during the study period from 2017 to 2021. The numerator was the visit count of each type, and the denominator was person-years of membership during a given month. We also calculated the overall visit rates (all 4 settings combined), the rates of combined outpatient and telehealth visits (as total ambulatory care), and the rates of combined in-person (inpatient, ED, and outpatient) visits.

Statistical Analysis

Overview

Demographic characteristics (age, sex, and race or ethnicity) of the study population were described by year. Monthly visit rates overall and by visit type were plotted over time before and during the COVID-19 pandemic to examine trends.

We selected April-December 2020 and July-December 2021 as the early and later pandemic periods, respectively, to assess the short- and longer-term impact of the pandemic on health care utilization. The July-December 2021 period was selected as the later pandemic period because COVID-19–related restrictions were relaxed during this period.

Short-Term Impact Assessment

To assess the short-term impact of the pandemic on health care utilization during the early pandemic period, due to data volatility during this period, we performed difference-in-difference (DiD) analyses by comparing visit rates in each of the 3 periods of the early pandemic (April-June, July-September, and October-December) in 2020 to the January-February 2020 before the pandemic period; visit rates in the 4 corresponding periods in 2017-2019 were also calculated and used to control for seasonality (Figure S1A in Multimedia Appendix 1) [16]. We excluded March 2020 from the analysis because the COVID-19 pandemic was declared a national emergency on March 13, 2020. We estimated the ratio of rate ratios (RRRs) and 95% CIs by fitting Poisson regression models with the visit count as the dependent variable and the natural logarithm of person-years of membership as an offset, adjusting for overdispersion of the count data. The percent change of visit rates during the early pandemic period from the prepandemic period was calculated as \((\text{RRR} - 1) \times 100\). Separate analyses were conducted for all visit types combined and by visit type.

Long-Term Impact Assessment

To assess the longer-term impact of the pandemic on health care utilization during the later pandemic period, interrupted time series (ITS) analyses were conducted with adjustment for prepandemic secular trends and seasonality by including calendar year and month in the model (Figure S1B in Multimedia Appendix 1) [17]. ITS analysis is a statistical method used to evaluate the impact of an intervention or event, which is introduced at a specific time point on time series data. A model with a linear function of the year was selected based on visual exploration of the trend plots and comparison with models with a quadratic form. Poisson regression models were used to estimate adjusted rate ratios (RRs) and 95% CI, comparing visit rates in the later pandemic period with the prepandemic period. The percent change in visit rates was calculated as \((\text{RR} - 1) \times 100\). ITS analyses were conducted for all visits combined and separately by visit type.

COVID-19–related care associated with each wave of COVID-19 infection might have affected the secular patterns of health care utilization. We also conducted sensitivity analyses of health care utilization among members without evidence of COVID-19. For the exploratory analysis, we plotted monthly visit rates overall and by visit type. We also conducted ITS analysis to estimate the adjusted percent change of visit rates in July-December 2022 compared to prepandemic levels. All analyses were conducted using SAS (version 9.4; SAS Institute Inc).

Results

Annual enrollment did not significantly change between 2017 and 2021, with the total number of enrolled person-years ranging from 10.9 to 11.5 million across the 8 VSD sites. Demographic characteristics of members enrolled in VSD sites remained relatively stable during 2017-2021 (Table 1).

The trend plot showed that the overall monthly visit rates fluctuated normally before March 2020, then decreased abruptly in March, reaching the lowest levels in April 2020, and then gradually increased afterward (Figure 1). The overall visit rates returned to prepandemic levels during 2021 and were stable after July 2021. Use trends differed by visit type (Figure 2). All in-person (inpatient, ED, and outpatient) visits decreased markedly in the beginning of the pandemic, and then gradually increased. Among the 3 in-person visit types, outpatient visits had the largest decrease at the beginning of the pandemic. Telehealth visits increased sharply after the start of the pandemic, and then slowly decreased, although they remained above the prepandemic levels. Combined outpatient and telehealth visit rates decreased in the early pandemic period and exceeded prepandemic levels in 2021.

The overall visit rate decreased from 7.82 visits per person-year in January-February 2020 to 5.72 visits per person-year in April-June 2020, a 26.4% reduction (95% CI –36.3% to –15.1%); it returned to prepandemic levels in October-December 2020 (adjusted percent change –0.4%, 95% CI –6.3% to 5.9%; Table 2). The overall visit rate increased by 5.1% (95% CI 0.6%–9.9%) to 8.36 visits per person-year in July-December 2021 compared with the same months in the prepandemic period (Table 3). The rates of inpatient, ED, and outpatient visits decreased by 24.9% (95% CI –33.3% to –15.3%), 35.5% (95% CI –43.7% to –26.2%), and 64.2% (95% CI –71.9% to –54.3%) in April-June 2020 and by 5.3% (95% CI –8.3% to –2.2%), 19.2% (95% CI –22.7% to –15.5%), and 30.5% (95% CI –34.4% to –26.4%) in October-December 2020 compared to the rates of 0.108, 0.288, and 6.42 visits per person-year in January-February 2020, respectively (Table 2). While the rates of inpatient and ED visits returned to prepandemic levels in July-December 2021, the rate of outpatient visits was still 12.5%
lower (95% CI –16.8% to –8.0%; Table 3). Telehealth visit rates increased by 218.3% (95% CI 186.4%-253.6%) from 1.01 visits per person-year in January-February 2020 to 3.17 visits per person-year in April-June 2020 (Table 2). With a slow decrease after the initial rise, the telehealth visit rate still increased by 97.5% (2.35 visits per person-year; 95% CI 86.0%-109.7%) in July-December 2021 compared to the prepandemic period, comprising approximately 42% of outpatient visits (5.63 visits per person-year; Table 3). Combined telehealth and outpatient visits increased by 5.5% (95% CI 0.7%-10.6%) and combined in-person visits decreased by 11.9% (95% CI –16.0% to –7.7%) in July-December 2021 compared to prepandemic levels (Table 3).

Enrolled person-years during 2017-2021 ranged from 8.8 to 9.0 million after excluding members with evidence of COVID-19. Demographic characteristics of members without COVID-19 remained similar compared to all members (Table S1 in Multimedia Appendix 2). The trends of overall monthly visit rates among members without COVID-19 and all members were similar (Figure 1). The overall visit rate among members without COVID-19 was lower than that of all members, and the difference increased during the pandemic. The overall visit rate among members without COVID-19 decreased by 5.5% (95% CI −10.3% to −0.5%) in October-December 2020 from 7.37 visits per person-year in January-February 2020 to 6.85 visits per person-year in October-December 2020; inpatient and ED visit rates decreased by 15.6% (95% CI −21.1% to −9.8%) and 28.6% (95% CI −35.0% to −21.5%) from 0.107 and 0.274 visits per person-year in January-February 2020 to 0.087 and 0.189 visits per person-year in October-December 2020, respectively (Table S2 in Multimedia Appendix 2). In July-December 2021, the overall visit rate among members without COVID-19 returned to prepandemic levels, while the inpatient and ED visit rates were still 7.5% (95% CI −9.6% to −5.3%) and 8.0% (95% CI −11.0% to −4.9%) lower, reaching 0.095 and 0.241 visits per person-year, respectively (Table S3 in Multimedia Appendix 2).
There were around 4.5 million enrolled-person-years in KPSC each year during the study period. The use trends overall and by visit type at KPSC were similar to those of the entire study population during 2017-2021 (Figures S1 and S2 in Multimedia Appendix 3). The visit rates from January 2022 to June 2023 remained stable, continuing at the late 2021 levels. The adjusted percent changes of visit rates in July-December 2022 were consistent with the estimates from the main analysis (Table S1 in Multimedia Appendix 3). The overall, inpatient, ED, and combined telehealth and outpatient visit rates among all members returned to prepandemic levels during July-December 2022. The telehealth visit rate in July-December 2022 increased by 92.3% (95% CI 60.3%–130.7%) compared to the prepandemic period. Among members without COVID-19, the inpatient and ED visit rates during July-December 2022 were still 11.1% (95% CI –14.0% to –8.0%) and 10.2% (95% CI –15.3% to –4.9%) lower than prepandemic levels, respectively.

Discussion

Principal Findings

In this large, retrospective cohort study conducted across 8 integrated health care systems with more than 11 million demographically and geographically diverse members, the reductions observed in the early pandemic period persisted into late 2020 for in-person visits, but overall use and counting all types of visits tended to equilibrate because of dramatically increased use of telehealth. Furthermore, our study showed the longer-term impact of the COVID-19 pandemic on health care utilization, especially after COVID-19 restrictions were relaxed. Specifically, during late 2021, inpatient and ED visit rates returned to prepandemic levels and overall use exceed prepandemic levels. The trends observed in the KPSC data closely mirrored those of the entire study population. The trends during the extended period from January 2022 to June 2023 were stable and appeared to be a continuation of the levels observed at the end of 2021. KPSC contributed over one-third of the data.

Telehealth care was promoted and supported through reimbursement during the COVID-19 pandemic [18], which partially resulted in a surge in telehealth visits during the COVID-19 pandemic. Although the rates decreased after an initial rise, they remained doubled in late 2021 compared to prepandemic levels. Telehealth visits increased slowly before the COVID-19 pandemic due to individual and organizational barriers, which have been discussed in previous studies [19]. The COVID-19 pandemic provided an opportunity for health care systems, providers, and patients to adopt this new approach for health care delivery [20,21]. Furthermore, studies have shown that minority and low-income groups could benefit significantly from the increased accessibility of telehealth care by eliminating barriers such as transportation costs and time constraints [22,23]. Despite the fact that telehealth may not be appropriate for certain medical conditions (eg, physical examinations, medical procedures, and emergent treatments) [24] and access to in-person care improved later in the COVID-19 pandemic, telehealth care remained a mainstay of health care delivery, comprising approximately 42% (5.63 visits per person-year) of outpatient visits in late 2021 (2.35 telehealth visits per person-year). The postpandemic use of telehealth is likely to continue growing and evolving to improve patient outcomes, access to care, and convenience of care [25]. These historical trends can help inform projections for the use of telehealth and in-person modalities for care.

COVID-19–related care added substantially to the burden on the health care system [26]. During the early stages of the COVID-19 pandemic, there was competition between the resources allocated to COVID-19–related care and those directed toward non–COVID-19–related medical needs [2]. Both types of care required significant resources, potentially straining the health care system’s capacity. Excluding members with COVID-19 and all their use during the study period did not significantly change the direction of health care utilization trends in this population; however, the visit rates decreased more among members without evidence of COVID-19 during the pandemic, especially in the inpatient and ED settings. In the later pandemic period, inpatient and ED visits among members without evidence of COVID-19 decreased by 7.5% and 8% (from 0.105 and 0.258 visits per person-year in prepandemic to 0.095 and 0.241 visits per person-year in later pandemic), respectively, and these rates did not return to prepandemic levels. While there were differences in baseline use between all members and the members without COVID-19 possibly due to differences in health status and care-seeking behavior, both DiD and ITS analyses accounted for the baseline use within each group. As we adjust to the post–COVID-19 pandemic phase, it is important to investigate the reasons behind this phenomenon and prioritize efforts that address the possible unmet needs of those patients with non–COVID-19 illness.

Knowledge of health care utilization is also important for researchers who conduct studies using observational data during the pandemic period. For example, vaccine safety studies commonly identified outcomes from in-person encounters before the COVID-19 pandemic [12]. Since telehealth use remained high during the pandemic, which contributed to the delivery of health care beyond in-person visits, telehealth visits could be an important data source for identifying adverse events in vaccine safety studies during or after the pandemic period. In addition, with the changes in use over time, secular confounding needs to be considered when designing a study involving the pandemic period and selecting appropriate unbiased comparison groups.

There are several statistical considerations for these analyses. First, this study conducted analyses at the population level. We showed that the demographic characteristics of members enrolled at VSD sites were stable over the study period. Both DiD analysis and ITS analyses compared health care utilization before and during the COVID-19 pandemic among a similar population. Hence, patient-level adjustment was not critical. Second, unmeasured secular confounders (eg, changes in care practice unrelated to COVID-19 and changes in underlying health conditions of the study population) were adjusted for through either the DiD approach or a prepandemic trend estimated from 2017 to 2019 data. Although the latter required an assumption that the trend would have continued through 2020-2021 if there was no COVID-19 pandemic, the assumption
likely held, given the moderate length of the study period. The study also had some limitations. The study aimed to assess the overall impact of the COVID-19 pandemic on health care utilization, including factors such as the population’s fear of exposure in health care settings, policy changes in physical distancing, surges of new COVID-19 cases, and COVID-19 vaccinations. To assess the individual impact of each factor would require proper measurement of these factors and a different study design and analysis. In addition, the study did not assess the impact of the COVID-19 pandemic on subgroups. The impact could differ by age, race or ethnicity, socioeconomic status, and health conditions, as has been shown in previous studies [22,27]. Finally, we included persons enrolled in health plans; therefore, our findings may not be generalizable to the uninsured population.

Conclusions
During the late COVID-19 pandemic period, overall use of health care services exceeded pre-pandemic levels as telehealth services became a mainstay of the health care system. Inpatient and ED visits returned to pre-pandemic levels, although they remained low among members without evidence of COVID-19. Our findings provide valuable information for planning longer term strategic resource allocation for patient care in the post-pandemic period and for designing observational studies involving the pandemic period.

Abstract

Background: With more than 103 million cases and 1.1 million deaths, the COVID-19 pandemic has had devastating consequences for the health system and the well-being of the entire US population. The Rare Diseases Clinical Research Network funded by the National Institutes of Health was strategically positioned to study the impact of the pandemic on the large, vulnerable population of people living with rare diseases (RDs).

Objective: This study was designed to describe the characteristics of COVID-19 in the RD population, determine whether patient subgroups experienced increased occurrence or severity of infection and whether the pandemic changed RD symptoms and treatment, and understand the broader impact on respondents and their families.

Methods: US residents who had an RD and were <90 years old completed a web-based survey investigating self-reported COVID-19 infection, pandemic-related changes in RD symptoms and medications, access to care, and psychological impact on self and family. We estimated the incidence of self-reported COVID-19 and compared it with that in the US population; evaluated the frequency of COVID-19 symptoms according to self-reported infection; assessed infection duration, complications and need for hospitalization; assessed the influence of the COVID-19 pandemic on RD symptoms and treatment, and whether the pandemic influenced access to care, special food and nutrition, or demand for professional psychological assistance.

Results: Between May 2, 2020, and December 15, 2020, in total, 3413 individuals completed the survey. Most were female (2212/3413, 64.81%), White (3038/3413, 89.01%), and aged ≥25 years (2646/3413, 77.53%). Overall, 80.6% (2751/3413) did not acquire COVID-19, 2.08% (71/3413) acquired it, and 16.58% (566/3413) did not know. Self-reported cases represented an annual incidence rate of 2.2% (95% CI 1.7%-2.8%). COVID-19 cases were more than twice the expected (71 vs 30.3; P <.001). COVID-19 was associated with specific symptoms (loss of taste: odds ratio [OR] 38.9, 95% CI 22.4-67.6, loss of smell: OR 30.6, 95% CI 17.7-53.1) and multiple symptoms (>9 symptoms vs none: OR 82.5, 95% CI 29-234 and 5-9: OR 44.8, 95% CI 18.7-107). Median symptom duration was 16 (IQR 9-30) days. Hospitalization (7/71, 10%) and ventilator support (4/71, 6%) were uncommon. Respondents who acquired COVID-19 reported increased occurrence and severity of RD symptoms and use or dosage of select...
medications; those who did not acquire COVID-19 reported decreased occurrence and severity of RD symptoms and use of medications; those who did not know had an intermediate pattern. The pandemic made it difficult to access care, receive treatment, get hospitalized, and caused mood changes for respondents and their families.

**Conclusions:** Self-reported COVID-19 was more frequent than expected and was associated with increased prevalence and severity of RD symptoms and greater use of medications. The pandemic negatively affected access to care and caused mood changes in the respondents and family members. Continued surveillance is necessary.

**Introduction**

**Background**

The COVID-19 pandemic, caused by the SARS-CoV-2, emerged in the fall of 2019 in Wuhan, China, and rapidly spread throughout the world. In March 2020, the World Health Organization (WHO) declared the outbreak to be a pandemic, and as of August 30, 2023, the WHO has reported >770 million confirmed cases and >6.9 million confirmed deaths attributable to the disease [1,2]. More than 103 million cases and 1.1 million deaths from COVID-19 have occurred in the United States [1,3], with devastating consequences for the health system [4,5] and the well-being of the entire population [6].

The *Journal of Medical Internet Research* and affiliated JMIR publications, including *JMIR Public Health and Surveillance*, have extensively documented the global impact of the COVID-19 pandemic: a total of 99 articles have reported the results of web-based surveys and analyses of internet browsing patterns and social media postings (search terms “Rare disease” and “COVID-19,” run on July 7, 2023). For example, during the early months of the pandemic, an artificial intelligence–based analysis of >902,000 tweets was used to identify sentiments regarding COVID-19 in the United States [7], and large-scale web-based surveys were conducted in China [8,9], South Korea [10], Russia [11], and Spain [12]. Several surveys have documented a negative impact on anxiety and depression, self-reported well-being, and quality of life in the general population [11-16] and in vulnerable groups such as pregnant women [17-19], university students [20-22], older people [23,24], and health care workers [25,26].

Despite the extensive JMIR literature on the impact of the pandemic, only a single study described the experience of people living with rare diseases (RDs), which documented the impact of the pandemic on conversation patterns in the Reddit platform (subreddit r/CysticFibrosis) [27]. Indeed, the literature on the impact of the pandemic on people living with RDs is sparse even 3 years into the pandemic. A PubMed search (search terms “Rare disease” and “COVID-19,” run on July 6, 2023) identified 148 potential matches, but review of the abstracts indicated that most publications were case reports, discussion papers, or other reports that do not entail data collection from people living with RDs: only 25 articles reported results of cross-sectional surveys or longitudinal studies of patients with RD or their caregivers [28-52]. Large studies (≥50 participants) in Asia [29,37,40], Europe and the United Kingdom [30,33,36,41,49,51], the United States [45,52], and Brazil [43] reported variable impact of the pandemic, including increased risk of acquiring COVID-19 [33,37,39], increased COVID-19–related mortality [33,37], increased anxiety and depression and other psychological problems [29,30,36,41,51,52], low quality of life [41,51], difficulties with access to care [36,40,43,45,52], and difficulties complying with public health recommendations such as masking [49].

According to US laws, an RD is defined as a condition affecting <200,000 individuals at a given time [53,54]. The Genetic and Rare Disease information system of the National Center for Advancing Translational Sciences lists >10,000 RDs [55,56]. Although each condition is rare, the aggregate prevalence may amount to 30 million [55]. RDs are often difficult to diagnose [57,58], most often lack specific treatments [59], and place a significant burden on families and society [60]. Some people with RDs have primary respiratory manifestations [61], immunocompromised states [62], and chronic comorbidities including intellectual disabilities [63]. People with RDs report a lower quality of life than the general population [64]; they are vulnerable and dependent on the health care system [65].

The Rare Diseases Clinical Research Network (RDCRN) is funded by 10 of the National Institutes of Health (NIH) to promote progress in the diagnosis and treatment of RDs. The RDCRN comprises 20 Rare Disease Clinical Research Consortia and a Data Management and Coordinating Center, >200 research sites worldwide, and many patient advocacy groups that ensure that patients’ voices are heard. The RDCRN has been active for 2 decades, and >40,000 people have participated in its studies [66].

**Objectives**

The RDCRN was strategically well placed to study the impact of the pandemic among people living with RDs in the United States. We designed a cross-sectional survey to describe the characteristics of the COVID-19 infection in this population, to determine whether patient subgroups were affected more frequently or experienced increased severity, to determine whether the pandemic changed RD symptom and treatment patterns, and to understand the broader impact of the pandemic on people living with an RD and their families.
Methods

Overview
We designed a cross-sectional survey to describe the characteristics of the COVID-19 infection in the population with RD. People who lived in the United States, had an RD, and were aged <90 years (including children of any age) were eligible for the survey. There were no explicit exclusion criteria beyond failure to meet the eligibility criteria. The survey was advertised through the internet, social media, an NIH press release, and outreach by patient advocacy groups. Interested individuals were asked to access a dedicated web page and complete a REDCap (Research Electronic Data Capture; Vanderbilt University [67]) survey instrument on the web (Multimedia Appendix 1).

The data collection instrument was designed ad hoc by the authors in spring 2020, with contributions from all the principal investigators of the RDCRN consortia (included as a group author as “The Principal Investigators of the Rare Diseases Clinical Research Network - Cycle 4” refer to the collaborators list), based on their expert knowledge of RDs. The instrument comprises 8 sections:

- Section 1 includes eligibility and preliminary information criteria on whether the patient or a surrogate is interested in participating, whether the target respondent lives in the United States and has an RD, and whether the respondent has participated in RDCRN research;
- Section 2 explains the study and asks for consent offering three options: (1) respond to the survey, provide contact information, and allow contact for follow-up and opportunities for participating in RD research; (2) allow linkage of the survey results with data about the same individual provided as part of RDCRN studies; and (3) respond to the survey without any identifiers (one-time, anonymous response);
- Section 3 is restricted to individuals who agree to provide identifiers and includes name, date of birth, address, telephone number, and email address to allow future contacts;
- Section 4 includes sociodemographic variables (state of residence, age, sex, race and ethnicity), RD diagnosis including symptoms and comorbidities during the months preceding the COVID-19 epidemic in the United States, treatments received during the same period, smoking habits, and use of tetrahydrocannabinol-containing products and psychoactive drugs. It also includes questions about COVID-19–related symptoms that the respondent may have experienced before the beginning of the pandemic and any changes in RD symptoms and treatment experienced after the beginning of the pandemic in the United States (March 2020);
- Section 5 ascertains whether the respondent had a positive COVID-19 test or a clinical diagnosis of COVID-19 respiratory syndrome; and
- Sections 6 to 8 separately address respondents who did not acquire COVID-19 (section 6), acquired it (section 7), or did not know (section 8).

All these sections include a checklist of symptoms compatible with COVID-19; ask whether the pandemic interfered with access to medical care, RD treatment, and special food related to RD management; whether stay-at-home orders affected their mood or behavior; and whether the respondent or family members had to seek professional help to cope with stress and anxiety. A final question asks if the target respondent died during the interval leading to the survey. In addition to the abovementioned common questions, section 7 asks additional questions about the course of the COVID-19 infection, the need for hospitalization and special treatment (assisted ventilation), the duration of the illness, and whether the respondent received investigational drugs to treat COVID-19.

Study Size Considerations
We aimed at enrolling 5000 participants based on a precision analysis, rather than a power analysis, because the survey was not designed to test specific hypotheses. At the time of planning the survey, the WHO estimates suggested that the prevalence of COVID-19 infection may be between 1% and 2%. Thus, if the patients with RD experienced the same risk as the general population, the target sample size would provide information on approximately 50-100 COVID-19 cases. As the 95% CI of 50 observed events was 37-66 based on the Poisson distribution, our estimate of the overall prevalence of COVID-19 infection among respondents would be very precise. The precision of survey measures of more common characteristics and experiences among respondents (eg, changes in access to treatment) would be much higher. Furthermore, given a sample size of 50 cases, the 95% CI of a simple mean would be between +0.25 and –0.25 SD units from the mean, affording adequate precision of measures such as the average duration of hospitalization, and estimates of rates for any categorization of the case group into 5-10 subgroups would also yield adequate precision in describing the variation in risk across population subgroups.

Ethical Considerations
As the survey was conducted on the web, the REDCap survey instrument verified the eligibility of a prospective participant, provided an explanation of the objectives and process of data collection, verified consent, and gathered the required information. First, the instrument assessed the eligibility of the intended participant (ie, the person was living with an RD, was living in the United States, and was aged <90 years), automatically terminating data collection from ineligible individuals; ascertained whether the intended participant or a surrogate would be completing the survey; and ascertained whether the potential participant had participated in the RDCRN research. Next, it provided a comprehensive explanation of the study objectives and process and asked whether (1) the participant agreed to respond to the survey, provide contact information, and allow future contact for follow-up interviews and opportunities to participate in RD research; (2) if agreeing to (1), the participant further agreed to allow linkage of the survey results with data about the same individual provided as part of the RDCRN studies; or (3) the participant agreed to respond to the survey without any identifiers (1-time, anonymous response). The explanatory language clarified that...
no adverse events were expected except for a possible breach of confidentiality for participants who agreed to provide identifiable information and that the study team intended to minimize the risk of a confidentiality breach by keeping identifiers and survey responses in separate files and by presenting the study results in a format that would not allow the reidentification of individual patients with RD. No compensation was offered for participating in this study. The institutional review board (IRB) at Cincinnati Children’s Hospital Medical Center reviewed and approved the research protocol, all recruitment materials, and the survey instrument, including the language explaining the survey and asking for consent. The IRB granted a waiver of documentation of informed consent (IRB ID 2020-0299).

Data Analysis
In this report, we aimed to address the following outstanding questions in the field:

1. How frequent was the self-reported laboratory or clinical diagnosis of COVID-19 among people living with RDs? Did this differ from the expectation based on population rates?
2. How frequent were COVID-19–related symptoms according to self-reported COVID-19 status?
3. What were the characteristics of COVID-19 infection (duration of the infection, need for hospital admission, and complications of the infection among COVID-19 cases)?
4. Did COVID-19 status influence changes in the frequency and intensity of RD-related symptoms and in the frequency of RD-related treatment?
5. Did the COVID-19 epidemic change access to care, access to special food and nutrition, demand for professional assistance to address stress and coping among people who live with RD, and was the impact affected by COVID-19 status?

We used simple descriptive statistics (frequencies and percentages for count variables and means, medians, and ranges for continuous variables) and provided 95% CIs as a measure of the precision of the estimates for survey results. Statistical hypothesis testing was used for select analyses.

To identify participants who acquired COVID-19, we used the answer to the simple survey question, “Did you acquire COVID-19?” which allowed the answers yes, no, or do not know (Multimedia Appendix 1, survey instrument item 5.1). The 3-category answer was a pragmatic approach to identifying cases of infection because at the time we conducted the survey, access to laboratory tests remained limited.

We estimated the denominator at risk of infection considering each respondent at risk every day from the beginning of the pandemic to the day they reported acquiring COVID-19 (the outcome event) or the day they filled out the survey, whichever was earlier, as is done in retrospective cohort studies. We computed exact 95% CIs for the number of cases and the corresponding incidence rate under the assumption that the number of cases follows the Poisson distribution. We compared the monthly number of self-reported COVID-19 cases with the number expected based on data reported by the New York Times [68], computed by multiplying the national monthly infection rate by the number of respondents who were at risk of acquiring a COVID-19 infection during that month. The cases reported in the New York Times database are a mix of laboratory-confirmed cases and cases meeting the state-determined diagnostic criteria. We present the observed and expected cases in a graph and test the null hypothesis that the number of observed cases equals the expected value using an exact Poisson distribution method.

For all respondents before the beginning of the pandemic (Multimedia Appendix 1, survey instrument item 4.9) and in separate sections for the respondents who answered yes, no, or do not know to the question “Did you acquire COVID-19?” (Multimedia Appendix 1, survey instrument items 6.1, 7.3, and 8.3), the instrument asked the question, “Did you have symptoms related to COVID-19? (answer options: Yes/No),” offering a checklist of 20 symptoms (new or increased cough, fever >38.0°C, new or increased shortness of breath, sore throat, stuffy nose, runny nose, chest pain, sneezing, wheezing, headache, muscle aches, loss of taste, loss of smell, conjunctivitis or pink eye, confusion, seizures, weakness, and other).

For 65 RD-related symptoms grouped into 18 categories, the instrument asked the questions “Please check if you had any of the following symptoms before the COVID-19 pandemic began in the USA. Think about your symptoms in January-February 2020. Check all that apply” (answer options: yes or no) and “Did anything change after the beginning of the pandemic (March 2020)?” (If the previous answer was “No,” answer options: yes or no; if the previous answer was “Yes,” answer options: symptom absent, less severe, same severity, or more severe; Multimedia Appendix 1, survey instrument item 4.6).

For 91 medications and treatments grouped into 15 categories, the instrument asked the questions “Please check if you used any of the treatments before the COVID-19 pandemic began in the USA. Think about the medications you took or treatments you routinely received in January-February 2020. Check all that apply” (answer options: yes or no) and “Did anything change after the beginning of the pandemic (March 2020)?” (If the previous answer was “No,” answer options: yes or no; if the previous answer was “Yes,” answer options: treatment not used, lower dosage, same dosage, or higher dosage; Multimedia Appendix 1, survey instrument item 4.7).

We computed odds ratios (ORs) and their 95% CIs to illustrate the strength of the association between self-reported infection and specific COVID-19–related symptoms as well as the number of symptoms.

To assess changes in the prevalence or intensity of a specific COVID-19 symptom, we compared the number of patients who reported the symptom appearing during the pandemic (ie, the symptom was absent before the beginning of the pandemic but was present afterward) with the number of patients who reported the symptom disappearing (ie, the symptom was present before the beginning of the pandemic but was not present afterward) and used an exact binomial test of the null hypothesis that the 2 counts were equal (ie, the parameter of the binomial distribution was 0.5).
To assess changes in the prevalence and intensity of a specific RD symptom, we compared the number of patients who reported the symptom appearing or increasing in intensity during the pandemic with the number of patients who reported the symptom disappearing or decreasing in intensity and used the exact binomial test of the null hypothesis that the 2 counts were equal. We used the same logic and statistical test to assess the changes in the prevalence of the use or dosage of a specific medication. We used heat maps to summarize the changes in COVID-19–associated symptoms, RD symptoms, and RD treatment before and after the beginning of the pandemic.

The instrument asked the question, “Do you have other diseases or complications related to the rare disease? Check all that apply,” offering a list of 26 comorbidity categories (Multimedia Appendix 1, survey instrument item 4.8).

We computed ORs and their 95% CIs to illustrate the strength of the association between self-reported infection and specific comorbidities, reporting the exact P value for the test of the null hypothesis of no association (ie, OR=1). We regarded a finding as statistically significant if the statistical testing of a specified null hypothesis yielded a P value <.05.

Results

Enrollment of participants for this study began on May 2, 2020, and ended on December 15, 2020; a total of 3413 respondents completed the survey. Most of the surveys (2643/3413, 77.44%) were completed between May and July (Figure S1 in Multimedia Appendix 1). Respondents approximately represented the geographic distribution of the US population (Table S1 in Multimedia Appendix 1): 25.76% (870/3377) were from the Midwest (21% expected) [69], 18.86% (637/3377) from the Northeast (18% expected), 33.43% (1129/3377) from the South (38% expected), and 21.94% (741/3377) from the West (24% expected). The diagnoses studied by the RDCRN accounted for 61.27% (2091/3413); and the most common diagnoses were myasthenia gravis (594/2091, 28.41%), amyotrophic lateral sclerosis (289/2091, 13.82%), eosinophilic esophagitis or eosinophilic gastrointestinal disease below the esophagus (203/2091, 9.71%), mitochondrial disease (174/2091, 8.32%), cystic fibrosis (87/2091, 4.16%), and primary ciliary dyskinesia (67/2091, 3.2%).

Two-thirds (2212/3413, 64.81%) of the respondents were female. Only 1.93% (66/3413) of the respondents reported being exclusively Black, 6.36% (217/3413) of the respondents reported other races or >1 race, and 89.01% (3038/3413) of the respondents were White (Table S2 in Multimedia Appendix 1). Approximately 5% (156/3413, 4.57%) reported Hispanic or Latino ethnicity, whereas most (2844/3413, 83.33%) of the respondents did not report ethnicity. Most of the respondents (2646/3413, 77.53%) were adults aged ≥25 years (Table S2 in Multimedia Appendix 1). The distribution by sex, race and ethnicity, and age was similar across disease categories, with the exception that most male respondents with eosinophilic esophageal or gastrointestinal diseases were aged <25 years. More detailed information on the demographic characteristics of the respondents by RD category is provided in Table S3 in Multimedia Appendix 1.

Overall, 80.6% (2751/3413) of the respondents reported that they had not acquired the COVID-19 infection, 2.08% (71/3413) of the respondents reported having acquired it, and 16.58% (566/3413) of the respondents did not know. Of the 71 respondents who reported acquiring the infection, 51 (72%) reported having a positive laboratory test. By contrast, only 15.2% (86/566) of the respondents who did not know reported having been tested (no positive test). We estimated that the self-reported cases represent the incidence over a total of 3219 person-years at risk, with an average annual incidence rate of 2.2% (95% CI 1.7%-2.8%).

Self-reported COVID-19 cases were twice as many as would be expected on the basis of the population incidence rates (71 vs 30.3; P < .001) and were concentrated in March to April 2020 (37 vs 11 expected) and in October to December 2020 (15 vs 5 expected; Figure 1), whereas self-reported cases were only slightly higher than expected in May to September 2020 (19 vs 14.2).

Approximately all respondents who acquired COVID-19 had symptoms (66/71, 93%). For 15 (83%) of the 18 symptoms, they reported experiencing the symptom more often after the beginning of the pandemic than before. Respondents who reported not acquiring COVID-19 had symptoms less often after the beginning of the pandemic than before for 16 (89%) of the 18 symptoms. The respondents who did not know displayed an intermediate pattern (Figure 2).

Specific COVID-19–related symptoms were strongly associated with self-reported infection: loss of taste (OR 38.9, 95% CI 22.4-67.6) or smell (OR 30.6, 95% CI 17.7-53.1), high fever (OR 14.5, 95% CI 8.7-24.1), and confusion (OR 12.7, 95% CI 6.80-23.7) were the strongest correlates of self-reported infection (Table 1).

Reporting multiple COVID-19–related symptoms was strongly associated with acquiring COVID-19 (>9 symptoms vs none: OR 82.5, 95% CI 29-234 and 5-9 symptoms: OR 44.8, 95% CI 8.7-241). Those who did not know were also more likely to report COVID-19–related symptoms and multiple symptoms than those who reported not acquiring the infection (Table 1). Respondents who acquired COVID-19 had demographic characteristics like others; most of the respondents were female (53/71, 75%), non-Hispanic White (59/71, 83%), and representative of the distribution of RD diagnoses reported by all respondents (results not shown in detail). The survey investigated 36 possible RD comorbidities, and 58.54% (1998/3413) of the respondents reported ≥1 comorbidities. Those who acquired COVID-19 (OR 1.60, 95% CI 1.00-2.50) and those who did not know (OR 1.40, 95% CI 1.20-1.70) were more likely to report RD comorbidities than those who did not acquire the infection. Individual associations between RD comorbidities and self-reported COVID-19 infection were weak (Table S4 in Multimedia Appendix 1).

Respondents who acquired the infection reported a significantly increased occurrence or severity for 35% (23/65) of the RD-related symptoms from before the beginning of the COVID-19 pandemic to survey completion, no change for 52% (34/65) of the symptoms, and no significant decrease for any symptoms. Those who did not know reported significantly
increased occurrence or severity for 37% (24/65) of the symptoms, no change for 51% (33/65) of the symptoms, and a significant decrease for 8% (5/65) of the symptoms. Those who did not acquire COVID-19 had increased occurrence or severity for 17% (11/65) of the symptoms, no change in 49% (32/65) of the symptoms, and significant decreases for 31% (20/65) of the symptoms (Figure 3).

Respondents who acquired the infection reported significantly increased frequency or dosage for 5% (5/91) of the medications (azithromycin, inhaled albuterol, inhaled glucocorticoids, ibuprofen, and aspirin), whereas the frequency or dosage of other medications did not change significantly. Those who did not know did not have significant changes for most medications but had a significant decrease in frequency or dose for 3% (3/91) of the medications. Those who did not acquire COVID-19 reported no significant change for 51% (46/91) of the medications and significant decreases in use or dosage for 34% (31/91) of the medications (Figure 4).

Among those who reported acquiring the infection, the COVID-19 illness experience was not severe; symptoms lasting on average <30 days; hospitalization (7/71, 10%), and mechanical ventilator support (4/71, 6%) were relatively uncommon. However, 1 respondent in this group died, and many reported that either their RD complicated the COVID-19 illness (30/71, 44%) or that the infection worsened their baseline symptoms (39/71, 55%; Table 2).

The pandemic affected access to health care: 61% (42/69) of the respondents who acquired COVID-19 and 75.02% (2382/3175) of the other respondents experienced delays in obtaining an appointment, their appointment was done using telemedicine, or their appointment was postponed (Table 3).

In addition, access to treatment for the RD was affected. On the basis of nonmissing values, 25.99% (715/2751) of the respondents who did not acquire COVID-19, 32.7% (185/566) of the respondents who did not know, and 41% (29/71) of the respondents who acquired COVID-19 experienced delays in obtaining treatment or their therapies were interrupted during the pandemic. Access to food was uninterrupted for most of the respondents, but as many as 26% (18/70) of those who acquired COVID-19 had delays or an interruption in the supply of specialized diets (Table 3). The most pronounced disruption was in access to specialized treatment such as physical or speech therapy, with approximately 56% (32/57) of the respondents experiencing an interruption of treatment. Respondents who acquired COVID-19 reported more frequently (11/68, 16%) experiencing health events that would ordinarily require hospitalization but were managed without admission. Moreover, about 1 (13/67, 19%) of out 5 respondents reported that stay-at-home orders affected their mood or behavior in a way that required medical attention, and most of the respondents (480/2717, 17.67% to 28/71, 39%) noted that they or immediate family members sought professional support to cope with stress or anxiety, with the largest proportion (28/71, 39%) among those who acquired COVID-19 (Table 3). For all but 2 items in Table 3, the variation in responses across the 3 groups defined by self-reported COVID-19 status was statistically significant. Six deaths were reported, but 5 were among the respondents who did not acquire COVID-19.

Figure 1. National survey of the impact of the COVID-19 pandemic on people with rare diseases (May 2, 2020, to December 15, 2020; N=3413). Number of self-reported COVID-19 cases by month, compared with the numbers expected on the basis of the monthly incidence rates reported by the New York Times for the entire US population.
Figure 2. National survey of the impact of the COVID-19 pandemic on people with rare diseases (RDs; May 2, 2020, to December 15, 2020; N=3413). Heat map of pandemic-associated changes in the prevalence of COVID-19 symptoms. Statistical significance of item-specific changes based on an exact binomial test of the null hypothesis that positive changes (ie, symptom appearing or increasing in intensity and medication starting or dosage increasing during the pandemic) were equal in number to negative changes (ie, symptom disappearing or decreasing in intensity and medication discontinued or dosage decreasing during the pandemic). Respondents are categorized according to their answer to the question “Did you acquire COVID-19?”. Blue boxes indicate statistically significant decrease; grey boxes indicate statistically non-significant change; red boxes indicate statistically significant increase.
Table 1. National survey of the impact of COVID-19 on people with rare diseases (May 2, 2020, to December 15, 2020; N=3413). COVID-19–related symptoms reported by survey respondents and association with answers to the question “Did you acquire COVID-19?” Those who responded “No” are the reference group.

**Discussion**

**Principal Findings**

This study reports results from the largest survey assessing the impact of the COVID-19 pandemic on people living with RDs; >3000 individuals representing a wide range of RDs participated in the study. Women, adults, and White non-Hispanic individuals were overrepresented. Recruitment and data collection procedures may have discouraged the participation of minority groups, although the causes of their underrepresentation are probably broader. For instance, the racial and ethnic profile of the respondents living with...
myasthenia gravis was similar to that of the participants of a national registry [31], but it is possible that the registry also underrepresented minority groups. Similarly, in the National Amyotrophic Lateral Sclerosis Registry, of the estimated 25,000 prevalent cases in 2017, 64.97% (16,127/24,821) were White, 5.92% (1469/24,821) were Black. [70]. In 2012 pediatric Medicaid records, 59.3% (2872/4836) of the patients with eosinophilic esophagitis were White and 15.47% (748/4836) were Black, whereas race was missing for 11.81% (571/4836) of the patients [71].

Our survey was widely advertised and relied on outreach by patient advocacy groups. Participation of >1300 respondents with an RD not studied by the RDCRN suggests that our outreach was effective in the RD community.

Underrepresentation of minority groups may be related to the globally recognized barriers to access to RD diagnosis, specialized care and social support [72,73], and other determinants of lack of participation in research [74,75]. Spurred by these findings, the RDCRN has established a cross-consortia Diversity Committee to identify actions to support and expand the participation and engagement of research participants, family members, advocates, and research staff from underrepresented or marginalized communities.

COVID-19 infection was reported by a few respondents (71/3413, 2.08%), but the number was larger than expected. The excess cases were concentrated in the first months of the pandemic and at the end of the data collection period. Thus, individuals who experienced COVID-19 early may have been more motivated to participate in the study. Likewise, survey advertisements in late 2020 could have motivated the participation of patients with an RD who were experiencing the next surge in the epidemic in the United States. Although selection is possible, the number of self-reported infections must underestimate the incidence of COVID-19 in the RD community, as underscored by the large proportion (566/3413, 16.58%) of those who did not know if they acquired the infection. This group reported COVID-19–related symptoms far more frequently than those who did not acquire COVID-19. Given the lack of access to testing early during the pandemic, many individuals with mild COVID-19 infection may have never been diagnosed. An NIH serum study of a sample of the US population estimated that 5 undiagnosed SARS-CoV-2 infections occurred for every COVID-19 case, and that approximately 17 million undiagnosed infections occurred in the United States by mid-July 2020 [76]. These findings have been confirmed in independent assessments [77,78]. Thus, despite the uncertainty about the true number of cases, our results indicate that COVID-19 has had a large impact on the RD community.

Self-reported COVID-19 was not associated with specific RD conditions, but RD comorbidities were associated with increased odds of acquiring COVID-19. Respondents who acquired the infection described a mild disease, with few requiring hospitalization or critical care and only 1 death reported. A mild course of COVID-19 infections has been reported among patients with hereditary hemorrhagic telangiectasia in Italy [50], rare endocrine diseases in a European registry study [38], lysosomal storage diseases in London [79], and Gaucher disease in New York [42]; in a large group of patients with RD in Brazil [43]; and among people with myasthenia gravis in a subanalysis of this survey [52]. These reassuring findings are in contrast with higher COVID-19–related mortality among patients with RD in Hong Kong hospitals compared with in-patients from the general population [37] and people with neurological and neurodevelopmental diseases in a Genomics England cohort study [33]. We observed that the frequency and severity of RD-related symptoms worsened during the pandemic among those who reported acquiring COVID-19 or did not know compared with those who were uninfected, indicating that COVID-19 complicated the underlying RD.

We found a greater use of selected medications among those who acquired COVID-19, little change among those who did not know, and decrease in use and dosage of many medications among those who did not acquire COVID-19. We did not expect the uninfected respondents to report reduced medication use. The need for some medications may have normally decreased between the winter before the beginning of the pandemic and the early summer when most surveys were completed. Seasonal variation exists in the use of antibiotics and prescription drugs for asthma, cystic fibrosis, and other respiratory illnesses [80-83] but not for other medications evaluated in the survey. It is possible that the pandemic decreased access to care and reduced medication use among those who were not in immediate need, whereas respondents with confirmed or possible COVID-19 infection continued to use their medications. This interpretation is not fully supported by the survey responses, which suggest that the pandemic interfered with access to regular health care, treatment for the RD, and hospitalization less frequently with respondents who did not acquire COVID-19. Several studies involving patients with RD have reported reduced access to care [36,40,43,45,52], and of patient organizations [84-88] and providers [79,89-93] have reported increased difficulties in delivering care and services, negatively affecting patients with RD. However, some reports indicate that the rise in telehealth services has had a positive impact in the RD community [43,47,90]. Access to prescription medications for asthma and chronic obstructive pulmonary disease in Great Britain initially briefly increased and then declined to below prepandemic levels during 2020 [94].

We found that the pandemic caused greater mood changes, anxiety, and stress in both respondents and their family members to an extent that required medical attention. These effects were experienced by a significant proportion of all respondents.

**Strengths and Limitations**

This study had certain limitations. First, we could not determine whether respondents were representative of the RD population. However, this concern is mitigated by the representative geographic distribution and the large number of diagnoses reported by the respondents: 48.17% (1644/3413) reported a diagnosis that was not studied by the RDCRN, suggesting that the outreach effort was effective in the RD community at large. Demographics and self-reported outcomes did not vary considerably across RDs, suggesting that the same selection forces affected all respondents.

Second, the information collected pertains mostly to adult, White non-Hispanic people with RDs. Thus, we could not examine
racial or ethnic disparities in the impact of the COVID-19 pandemic.

Third, the main motivation for conducting this survey was that most studies examining the impact of COVID-19 would focus on the general population and not on people living with an RD. We did not have access to a suitable comparison group; therefore, this report is based only on internal comparisons. Finally, data collection was based on self-reports, and we did not have external information to validate our observations. Our inference is based on internal comparisons, the validity of which relies on the assumption that between-group differences are unbiased.

Despite these limitations, this survey had substantial strengths. This is the largest survey conducted to learn about the experience of people living with RDs during the COVID-19 pandemic. The large number of respondents allowed a precise assessment of the prevalence and changes in symptoms and medications used during the early phase of the pandemic and robust internal comparisons among respondents who reported acquiring COVID-19 or were uncertain but had symptoms (ie, may have had an infection without a clinical or laboratory diagnosis). The survey provided a necessary assessment of the impact of the pandemic on the families of people living with RDs. Most participants stated their willingness to participate in follow-up surveys and future research. Thus, this survey provides a basis for evaluating the longitudinal impact of the pandemic on respondents and their families.

Conclusions

In conclusion, the incidence of self-reported COVID-19 infection in this survey of people living with RDs was higher than expected based on population rates, and many respondents were unsure if they had acquired the infection. COVID-19–related symptoms were strongly associated with self-reported infection and with unknown infection status. Although the clinical severity of the infection was not high, self-reported COVID-19 was moderately associated with RD comorbidities and was strongly associated with increased prevalence and severity of RD-related symptoms as well as greater use and dosage of certain medications. The pandemic negatively affected access to health care, RD treatment, and hospitalization; it caused mood changes and greater anxiety for respondents and their family members, requiring medical attention for some. These effects were experienced not only by those who acquired the infection but also by those who did not acquire COVID-19 during the early months of the pandemic or were unsure about it. Continued surveillance of this population is needed to inform interventions to mitigate the impact of COVID-19 and better prepare people with RDs, the health care system, and society for a future pandemic.

Acknowledgments

All Rare Diseases Clinical Research Network consortia were supported by the network’s Data Management and Coordinating Center (DMCC; U2CTR002818). Funding support for the DMCC was provided by the National Center for Advancing Translational Sciences and the National Institute of Neurological Disorders and Stroke. This survey was supported by an administrative supplement to the DMCC award (U2CTR002818-02S1). The authors were supported in part by the following awards: MM and PK (U2CTR002818 and U2CTR002818-02S1), MC and MER (U54AI117804), TF (U54HL096458), and HJK (U54NS115054). The authors would like to thank Ms Erin Fontaine for her outstanding assistance in preparing the manuscript and related material for submission.

The contributors associated with The Principal Investigators of the Rare Diseases Clinical Research Network – Cycle 4 are as follows: Brendan Lee, Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, Texas; Helen Kim, Department of Anesthesia and Perioperative Care, Center for Cerebrovascular Research University of California San Francisco, CA; Hyder Jinnah, Departments of Neurology, Human Genetics and Pediatrics, Emory University School of Medicine, Atlanta, GA; Mustafa Sahin, Department of Neurology, Boston Children's Hospital, Harvard Medical School, Boston, MA, Rosamund Stone Zander Translational Neuroscience Center, Boston Children's Hospital, Harvard Medical School, Boston, MA; Eva Morava-Kozicz, Department of Clinical Genomics, Mayo Clinic, Rochester, Minnesota; Stephanie Duggins Davis, Department of Pediatrics, University of North Carolina School of Medicine, Chapel Hill, NC; Adeline Vanderver, Division of Neurology, Children's Hospital of Philadelphia, Philadelphia, Department of Neurology, Perelman School of Medicine, University of Pennsylvania, Philadelphia; Florian Eichel, Department of Neurology, Harvard Medical School, Massachusetts General Hospital, Boston, MA; Michael Shy, Department of Neurology, Carver College of Medicine, University of Iowa, Iowa City, Iowa; Chester Whitley, Department of Pediatrics, University of Minnesota, Minneapolis, MN; Ciaran Sweeney, Department of Neurology, Columbia University Irving Medical Center, New York, NY; Robert Desnick, Department of Genetics and Genomic Sciences, Icahn School of Medicine at Mount Sinai, New York, NY; Jennifer Puck and Christopher Dvorak, Division of Pediatric Allergy, Immunology, and Blood and Marrow Transplantation, UCSF Benioff Children's Hospital, University of California San Francisco, San Francisco, CA; Elie Haddad, Department of Pediatrics and Department of Microbiology, Immunology and Infectious Diseases, CHU Sainte-Justine, University of Montreal, Montreal, QC, Canada; Andrea Gropman, Children's National Health System and The George Washington School of Medicine, Washington, DC; Peter Merkel, University of Pennsylvania, Philadelphia; Eileen King, Division of Biostatistics and Epidemiology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH; Michael
Wagner, Department of Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH, Division of Biomedical Informatics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH.

Data Availability
All participant-level data elements necessary to reproduce the analyses presented in the manuscript will be made available upon request. No direct personal identifiers of survey participants will be made available. Survey responses and computed variables used for the analyses presented in the manuscript will be made available in Excel workbooks (Microsoft Corporation) and SAS data sets (SAS Institute). Prospective users will be required to file a data access application including the objectives of data access and the intended use (including a data analysis plan). A data access committee will review the application and determine whether to grant access to the data. Users may be required to sign a data use agreement before obtaining access to the data. Data and supporting documents will be available through the Rare Diseases Clinical Research Network Data Repository (under development) as soon as the Data Repository is active. Please check the Rare Diseases Clinical Research Network website for updates.

Authors’ Contributions
The principal investigators of the Rare Diseases Clinical Research Network (author group) contributed to the survey design, reviewed the manuscript, and approved the version to be published. All named authors (MM, MER, TF, PK, HJK, DWK, MB, and MC) contributed to the survey design, design of the analysis and interpretation of the results, and critical review of the manuscript and reviewed and approved the version to be published. MM and PK directed data acquisition and management and conducted the statistical analysis of the data. MM drafted the manuscript and finalized the version to be published. MM and PK take responsibility for the integrity of the work and agree to investigate and resolve any issues arising from the review process or from the readership of the journal.

Conflicts of Interest
MER is a consultant for Pulm One, Spoon Guru, ClostraBio, Serpin Pharm, Allakos, Celldex, Nextstone One, Bristol-Myers Squibb, Astra Zeneca, Ellodi Pharma, GlaxoSmith Kline, Regeneron or Sanofi, Revolo Biotherapeutics, and Guidepoint; has an equity interest in the first 7 organizations listed; and has received royalties from reslizumab (Teva Pharmaceuticals), PEESSv2 (Mapi Research Trust), and UpToDate. MER is an inventor of patents owned by Cincinnati Children’s Hospital. TF has National Institutes of Health (NIH) grant funding (HL096458, TR003860, AI146999, and HL125241) and received support from Parion Sciences and ReCode Therapeutics for clinical drug trial and observational study. He is a member of the ReCode Therapeutics Primary Ciliary Dyskinesia Clinical Steering Committee and has served as a consultant for TranslateBio and Arrowhead Pharmaceuticals. HJK is a consultant for Roche, Merck Serono, Cabeletta Bio, and UCB Pharmaceuticals and is the Chief Executive Officer and Chief Medical Officer of ARC Biotechnology, LLC, based on US Patent 8,961,98. HJK is the principal investigator of the Rare Disease Network for Myasthenia Gravis (MGNet), funded by National Institute of Neurological Disorders & Stroke (US5 NS115054) and of Targeted Therapy for myasthenia gravis (R41 NS110331). HJK is also coinvestigator for MV2C2 antibody as a new therapeutic for myasthenia gravis (R43NS124329). DWK is a site PI on a Gilead-sponsored study of remdesivir in pediatric patients. All money goes directly to his university (University of Alabama at Birmingham). MB is a consultant for Alexion, Annexon, Arrowhead, Biogen, Denali, Novartis, Orphazyme, Roche, Sanofi, and UniQure. He has a provisional patent for determining the onset of amyotrophic lateral sclerosis. He has received research funding from the NIH and the Muscular Dystrophy Association and serves on the Board of Trustees for the Amyotrophic Lateral Sclerosis Association. MC is currently a consultant for Regeneron, Adare or Ellodi, Astra Zeneca, Sanofi, and Bristol-Myers Squibb. Previously, she was a consultant for Allakos, Shire or Takeda, and Phathom. She currently receives research funding from Regeneron, Allakos, Shire or Takeda, AstraZeneca, and Adare or Ellodi and has received funding from Danone. All other authors declare no other conflicts of interest.

Abstract

Background: The VACCELERATE Pan-European Scientific network aims to strengthen the foundation of vaccine trial research across Europe by following the principles of equity, inclusion, and diversity. The VACCELERATE Volunteer Registry network provides access to vaccine trial sites across the European region and supports a sustainable volunteer platform for identifying potential participants for forthcoming vaccine clinical research.

Objective: The aim of this study was to approach members of patient advocacy groups (PAGs) across Europe to assess their willingness to register for the VACCELERATE Volunteer Registry and their perspectives related to participating in vaccine trials.

Methods: In an effort to understand how to increase recruitment for the VACCELERATE Volunteer Registry, a standardized survey was developed in English and translated into 8 different languages (Dutch, English, French, German, Greek, Italian, Spanish, and Swedish) by the respective National Coordinator team. The online, anonymous survey was circulated, from March 2022 to May 2022, to PAGs across 10 European countries (Belgium, Cyprus, Denmark, France, Germany, Greece, Ireland, Italy, Spain, and Sweden) to share with their members. The questionnaire constituted of multiple choice and open-ended questions evaluating information regarding participants’ perceptions on participating in vaccine trials and their willingness to become involved in the VACCELERATE Volunteer Registry.

Results: In total, 520 responses were collected and analyzed. The PAG members reported that the principal criteria influencing their decision to participate in clinical trials overall are (1) the risks involved, (2) the benefits that will be gained from their potential participation, and (3) the quality and quantity of information provided regarding the trial. The survey revealed that, out of the 520 respondents, 133 individuals across all age groups were “positive” toward registering in the VACCELERATE Volunteer Registry, with an additional 47 individuals reporting being “very positive.” Respondents from Northern European countries were 1.725 (95% CI 1.206-2.468) times more likely to be willing to participate in the VACCELERATE Volunteer Registry than respondents from Southern European countries.

Conclusions: Factors discouraging participants from joining vaccine trial registries or clinical trials primarily include concerns of the safety of novel vaccines and a lack of trust in those involved in vaccine development. These outcomes aid in identifying issues and setbacks in present registries, providing the VACCELERATE network with feedback on how to potentially increase participation and enrollment in trials across Europe. Development of European health communication strategies among diverse public communities, especially via PAGs, is the key for increasing patients’ willingness to participate in clinical studies.

Introduction

Within the VACCELERATE consortium, the VACCELERATE Volunteer Registry was assembled on the principles of equity, inclusion, and diversity in vaccine clinical research across Europe [1-3]. Patient advocacy groups (PAGs) personify all 3 principles, with the aim of increasing community participation in research [4-6]. PAG members can monitor the latest news in medical conduct, have access to hard-to-reach medical procedures and treatments, and communicate with health care professionals [5]. Patients with concomitant chronic conditions are largely excluded from three-quarters of research studies listed in ClinicalTrials.gov [7]. Hence, the mission of PAGs is to assist with attaining diversity and equal representation of populations in trials, especially with patients with comorbidities who are more prone to be severely affected by infections [8], as well as overcome other barriers, such as language and limited health education. For example, the European Patients’ Forum operates to make patient organization voices heard and contends with policy-formulating processes affecting patients across Europe [9]. Alternatively, the European Patients’ Academy on Therapeutic Innovation acts to engage patients through their Patient Expert Training Programme that operates to educate and train in the context of medicine development and research [9]. These initiatives raise patients’ awareness and health literacy and may alleviate concerns regarding clinical trial research.

Another factor is trust in the health care system and its professionals. Health care providers expressing a level of optimism and conveying good quality information to potential applicants is a key parameter to improving recruitment in trials [10]. Preceding studies have recorded the willingness of participants to be involved in COVID-19 vaccine trials; in studies in France and Jordan, 47.6% (1552/3259) and 36.1% (465/1287) of the participants, respectively, were willing to participate in COVID-19 vaccine trials; in studies in France and Jordan, 47.6% (1552/3259) and 36.1% (465/1287) of the participants, respectively, were willing to participate in COVID-19 vaccine trials in 2020 [11,12]. Another study conducted in Uganda that targeted health care workers and their supporting staff (non-health care professionals) across 3 hospitals recorded a 70.2% (n=461) willingness to participate in COVID-19 vaccine trials [13]. This raised an uncertainty whether health literacy or unfamiliarity with a health environment affects judgment, trust, and willingness to participate in COVID-19 vaccine trials in different community environments and geographical areas.

Reaching out to potential volunteers is one of many steps. Once presented with the opportunity to participate in trials, whether
that be vaccine trials or clinical trials, one is troubled by the possibility of experiencing unpleasant symptoms and the consumption of time for participation, among other concerns, as well as mistrust in pharmaceutical companies [12]. Collecting data on patients’ thoughts, opinions, and beliefs across Europe may reveal effective methods for promoting volunteer registries and clinical research equity among diverse communities [14-16]. The objectives of this study are to assess European PAG members’ perspectives regarding vaccine trial participation along with their willingness to register in the Volunteer Registry [1,10]. Both are crucial factors prioritized by the VACCELERATE consortium [17]. Overall, the outcomes of this study include the promotion of the VACCELERATE Volunteer Registry and ensuring the effective delivery of its work.

### Methods

#### Study Design and Population

A standardized survey was designed to adhere to national bioethics’ requirements for each participating country and its target population including adult patients who are members of PAGs. The survey was transferred to an online format in collaboration with a consulting company (Conread Research Bureau Ltd) and was translated to English, Dutch, English, French, German, Greek, Italian, Spanish, and Swedish by the respective National Coordinator (NC) team of VACCELERATE. A list of PAGs per country was created, along with the appropriate contact details, by the task force undertaking this project with the guidance and support of the external consulting company and the respective VACCELERATE NC team.

#### Data Collection

An official invitation letter was disseminated to PAGs via email between March 9, 2022, and May 16, 2022, together with the link to the online survey (see Multimedia Appendix 1). As the aim was to record PAG members’ willingness to register at the VACCELERATE Volunteer Registry [15,18], a description of the VACCELERATE program was provided at the beginning of the survey, followed by a question that asked whether participants were willing to join the registry. Weekly reminders were sent via email to the NC or PAGs directly to increase responsiveness and engagement. All participants could exit the survey at any time they wished without completing it. Incomplete surveys (or without a signed consent form) were excluded from the final anonymous data analysis.

The collected data from the survey (Multimedia Appendix 1) included sociodemographic characteristics, prior COVID-19 vaccination status, history of SARS-CoV-2 infection, the source participants turn to for knowledge or information on health developments, and information regarding participants’ perceptions of important criteria for participating in vaccine trials. The questions posed were also an effort to understand communities’ and patients’ concerns regarding vaccine trials. This information could assist VACCELERATE investigators in designing and recruiting for future trials.

#### Statistical Analysis

All results present the frequency at which a response was selected, in percentages. For the ordinal data, a Likert rating scale was used with the following options per characteristic:

1. Importance/relevance (1. Not at all important, 2. Somewhat not important, 3. Neither important nor unimportant, 4. Somewhat important, 5. To a great extent/extremely important)

The percentages of responses for each of these selections were calculated. A score was established by calculating the dispersal of responses across the Likert scale (eg, the average between responses 1 and 5). Analysis was performed using SPSS v26 (IBM Corp).

For bivariate analysis and multivariate analysis, we used logistic regression analysis, as we wanted to calculate the effect of the independent variable on the binary dependent variable adjusted for confounders (ie, variables present that affect the variables under study and thus not allowing the results to mirror the real association between the dependent and independent variables). In particular, logistic regression analysis was performed to ascertain the effects of all demographic variables on the likelihood that a participant would be willing to participate in the VACCELERATE Volunteer Registry.

#### Ethical Considerations

PAG members were requested to access a web link where they would find an electronic version of the survey and complete the questions honestly. To ensure all responders fully understood the objectives of the survey, the concept of anonymity, and data safety, the survey was provided in 9 different languages. The survey was approved by the Cyprus National Bioethics Committee (EEBK EIT 2021.01.118) and other bioethics committees from the participating countries according to the national recommendations (Spain, Italy). Only responses with positive informed consent were processed, and no compensation was provided to responders. All records were anonymous and stored on a password-protected computer at Conread Research Bureau Ltd.

### Results

#### General Characteristics

A total of 520 responses were recorded through PAGs across the European region, as represented by a choropleth map (Figure 1) with the highest response rates recorded from Germany (165/520, 31.7%), Cyprus (149/520, 28.7%), and Greece (76/520, 14.6%). The fewest responses were collected from Denmark, Finland, Czechia, and Croatia (all had 1 response). Responses were obtained from PAG members from Belgium, Cyprus, Denmark, France, Germany, Greece, Ireland, Italy, Spain, and Sweden; some responses were obtained from other countries depending on the location of the respondents’ current residence.
Sociodemographic data showed higher participation rates by women (323/520, 62.1%). Regarding the age distribution (<29 years, 30-39 years, 40-49 years, 50-59 years, 60-69 years, and ≥70 years), most responses were collected from those aged 50-59 years (151/520, 29%). Regarding educational status, the greatest proportion of respondents had a postgraduate or doctorate degree (200/520, 38.5%), of whom 56% (112/200) reported that they predominantly consult news media for advice on health developments, while 55.5% (111/200) seek out physicians' advice or even official international health organization websites and media (111/200, 55.5%). Individuals with a primary school education (106/168, 63.1%) mostly consult their doctors, while they tend to avoid social media (22/168, 13.1%). Last, undergraduates (89/146, 61%) rely on news media for advice on health developments.

Until May 2022, 71% (369/520) of PAG members were vaccinated with 3 doses of a COVID-19 vaccine, while 13.7% (71/520) had completed a fourth dose. Regarding the participants’ self-reported diagnosis of a COVID-19 infection, 37% (10/27; the highest percentage among participants with a self-reported disease group) of individuals with a confirmed COVID-19 diagnosis had “chronic cardio and pulmonary diseases”; however, an even higher percentage (10/21, 48%) of participants with a confirmed COVID-19 infection did not wish to state if they had an illness.

Table 1 depicts the self-reported chronic diseases based on stratification by the 2 main age groups, namely Age Group 1 and Age Group 2. The former includes 6 age subcategories (<29 years, 30-39 years, 40-49 years, 50-59 years, 60-69 years, and ≥70 years), while the latter comprises 2 age subcategories (18-59 years and ≥60 years). For Age Group 1, those aged ≥70 years had the highest percentage of “All cancer conditions” (8/38, 21%), while those aged 50 years to 59 years had the lowest percentage (6/152, 4%). The highest and lowest percentages of “Rare diseases” were present for those aged 30 years to 39 years (24/88, 27%) or 60 years to 69 years (13/106, 12.3%). Finally, “Other diseases” were present the most for those aged 50 years to 59 years (94/152, 61.8%) and the least for those aged ≥70 years (15/38, 40%). On the other hand, in Age Group 2, the highest disease category for both age subgroups (18-59 years and ≥60 years) was “Other diseases,” at 53.2% (200/376) and 50.7% (73/144), respectively.

^a Hematological and solid cancers.
^b A broad number of conditions.
^c Acquired HIV or genetic-immunodeficiencies.
^d Other diseases as stated by the respondents themselves included the following: rheumatoid arthritis, Parkinson disease, osteoarthritis, diabetes, celiac disease, ulcerative colitis, rheumatism, stroke, arrhythmias, hepatitis, systemic lupus erythematosus, psoriasis, ankylosing spondyloarthropathy, peripheral spondyloarthropy, multiple sclerosis, and asthma, among others.

Clinical Trial Awareness and Participation

Of the 520 respondents, 93.1% (484/520) claimed to be aware of the term “clinical trial,” of whom 22.5% (109/484) reported to have previously participated in clinical trials (Table 2). Regarding their rating of their experiences, having the ability to give feedback about the clinical trial process received the poorest rating (mean 3.29 out of 5). The highest rating was given for the level of information received while participating in the trial. None of the responses received a full rating. All 520 respondents were also asked to rate a list of criteria based on how important each criterion was in affecting their participation in clinical trials (Table 3). The criterion rated as “Extremely important” by the highest number of participants (386/520, 74.2%) was understanding the risks involved in one’s participation in such trials, followed by “Giving my consent after being fully informed on the process and have all my questions answered” (369/520, 71%). Having family or friends who had previously taken part in a vaccine clinical trial was an inadequate component for persuading one to participate or not participate in clinical trials (51/520, 9.8% voted it as “Extremely important”).

Table 2. From the 520 patient advocacy group (PAG) members who responded to the survey, 109 respondents had participated in clinical trials in the past and rated their experiences.

</table>
Participants were asked to evaluate the importance of each of the following 9 statements in their decision to take part in clinical trials: (1) understanding the purpose of the trial and how it will benefit others now and in the future, (2) understanding the risks involved, (3) understanding what the benefits will be from my participation, (4) giving my consent after being fully informed on the process and have all my questions answered, (5) being convinced that my personal data is fully protected, (6) being convinced that my participation will be free of any financial cost, (7) the attitude of the researchers/physicians, (8) getting to know/meet others that will take part in the same trial, (9) having family or friends who have previously taken part in a clinical trial.

According to the regression model analysis for each of the aforementioned statements, the respondents from Northern European countries were (1) 4.484 (95% CI 2.618-7.962) times more likely to consider statement 1 (understanding the purpose of the trial and how it will benefit others now and in the future) as important for their decision, (2) 4.425 (95% CI 2.481-7.874) times more likely to consider statement 2 (understanding the risks involved) as important for their decision, (3) 1.838 (95% CI 1.164-2.907) times more likely to consider statement 3 (understanding what the benefits will be from my participation) as important for their decision (women were 1.628 [95% CI 1.041-2.547] times more likely to consider this statement as important for their decision), (4) 3.46 (95% CI 2.00-5.99) times more likely to consider statement 4 (giving my consent after being fully informed on the process and have all my questions answered) as important for their decision, (5) 2.551 (95% CI 1.639-3.968) times more likely to consider statement 5 (to be convinced that my personal data is fully protected) as important for their decision (women were 2.116 [95% CI 1.384-3.236] times more likely to consider it as important for their decision). (6) 1.773 (95% CI 1.127-2.786) times more likely to consider statement 6 (being convinced that my participation will be free of any financial cost) as important for their decision, (7) 2.470 (95% CI 1.444-4.226) times more likely to consider statement 7 (the attitude of the researchers/physicians) as important for their decision (people younger than 70 years were 3.481 [95% CI 1.586-7.642] times more likely to consider this statement as important for their decision). Respondents younger than 70 years were (8) 3.33 (95% CI 1.35-8.20) times more likely to consider statement 8 (getting to know/meet others that will take part in the same trial) as important for their decision. Respondents from Southern European countries were (9) 2.96 (95% CI 1.90-4.63) times more likely to consider statement 9 (having family or friends who have previously taken part in a vaccine trial) as important for their decision.

**VACCELERATE Volunteer Registry**

The score for a willingness to participate in the Volunteer Registry was 4 “Positive” for 25.6% (133/520) of the participants and 5 “Very positive” for 9% (47/520) of the participants (Table 4). The highest score for a willingness to participate was 3.24 for those aged 60 years to 69 years. The perspectives of participants regarding registration (per country) in the Volunteer Registry is presented in Table 5, while motives for participating in the Volunteer Registry did not vary among the sexes (Table 6).

Countries in which participants were more willing to join the Volunteer Registry were Ireland (3.67/5.00), Sweden (3.47/5.00), and France (3.38/5.00; Table 5). The respondents who were both “positive” and “very positive” were then directed to a supplementary question to select a reason for choosing to join the Volunteer Registry. The most widely held reason was to “Help advance medical research” (155/180, 86.1%), and the greatest proportion of this response came from individuals aged <29 years or ≥70 years. The second most popular response, at 72.8% (131/180), was “As a patient, I believe science would be greatly supported to enrich their data by my participation.”

An additional point of interest was the option to “Receive payment upon my participation,” which was recorded by 18.8% (24/128) of those aged 18 years to 59 years, whereas for those ≥60 years of age, the percentage was significantly lower, at only 3.9% (2/52).

The 104 survey participants who were unwilling to register in the Volunteer Registry were asked for justification. The 2 most frequently reported reasons across all countries for refusing were “Do not trust pharmaceutical companies/medical researchers/private or public companies” (27/104, 26%).
Trial investigators should prioritize the incorporation of benefits; factors a trial team should be able to deliver [9]. procedures to be carried out, and volunteer support are all key medication or vaccine, description of any symptoms and Communication regarding any concerns a potential volunteer confidence in and attract the attention of potential volunteers. and accurately training the medical team to execute all aspects and stages of a clinical trial are also of high importance to instill and properly training the medical team to execute all aspects and stages of a clinical trial are also of high importance to instill

Discussion

Principal Findings

The COVID-19 pandemic has shown the significance and importance of having people voluntarily participating in the development of new vaccines. The objectives of this effort were to approach PAG members across Europe through an online survey to assess their perspectives related to participation in vaccine trials despite their diagnoses. This study was also an opportunity to promote the Volunteer Registry to more diverse communities and measure patients’ willingness to register in the registry. VACCELERATE intends to approach individuals with morbidities or comorbidities with an objective to ensure inclusiveness and research equity as well as increase literacy about vaccine and clinical trials. Ultimately, VACCELERATE hopes to make participation in well-designed clinical trials a normal part of the scientific progress that leads to better medical care for all [21].

At the time of questionnaire preparation, only 3 COVID-19 vaccination doses were advocated across Europe; however, upon survey launch, a fourth dose had been introduced, which may explain the low percentage of the later dose recorded in the survey. The survey results also demonstrate that members of all educational backgrounds seek health advice from a doctor, emphasizing the importance of communicating with and training doctors on innovative medicine and clinical trials. Recruiting and accurately training the medical team to execute all aspects and stages of a clinical trial are also of high importance to instill confidence in and attract the attention of potential volunteers. Communication regarding any concerns a potential volunteer may have, a clear breakdown of all information regarding the medication or vaccine, description of any symptoms and procedures to be carried out, and volunteer support are all key factors a trial team should be able to deliver [9].

Trial investigators should prioritize the incorporation of benefits; communicate trial benefits (access to new drugs and vaccines) to potential volunteers; and ensure patients feel safe, supported, and, above all, well informed throughout the whole duration of a trial. This can be achieved by establishing trust and addressing knowledge deficits (eg, provide informative material in the patient’s native language and using simple terms) to prevent misinformation and uphold transparency. Communicating this information and establishing a network of active participants in clinical trials may be facilitated via collaboration with PAGs [22]. Furthermore, educating potential volunteers on the value of their participation and input in vaccine trials and how the pandemic’s impact on the community can be minimized may inspire further volunteering [23,24].

The most popular reason for opting to participate in the Volunteer Registry is to help advance medical research, an opinion that has been recorded in the past as a motivating factor for participation [23]. Potential volunteers may also be driven by the offer of potential personal benefit, a view which was not strongly supported by the PAG members of this study [24]. On the other hand, unwillingness to join the registry was attributable to participants’ mistrust in pharmaceutical companies, medical researchers, private or public companies, and governmental agencies [12]. Volunteering may also be affected by personal ideologies, past experiences, ethnicity, and religion, among other factors. Based on this study’s results, a significant difference in the willingness to participate in the registry has been observed between Northern and Southern European respondents. This observation needs to be further evaluated in the future.

Feedback on past participation in clinical trials involving a certain medicine showed that PAG members had an overall positive experience. Participants reported that, in terms of the quality and quantity, the information they received about the level of risk they were taking while participating in the trial was good overall. Still, 2 important aspects were lacking: offering volunteers the opportunity to provide feedback regarding their experience in the trial and providing opportunities for regular communication with the medical team. Both of these aspects may prevent participants from joining vaccine trial registries or participating in clinical trials, as these outcomes may affect the security and trust one feels in partaking in clinical trials. Therefore, the participants’ reactions indicate there is still room for improvement when designing and developing clinical trials in which support, inclusiveness, and safety of volunteers are prioritized.

Limitations

Limitations were recognized during the execution of the study. The number of responses from women was significantly greater than that from men, raising concerns of gender disparities as well as limited generalizability. An additional factor that may have shaped these results is that a greater number of respondents had a higher level of education (38% of them had a postgraduate or doctorate degree). Finally, as most responses were collected from Germany, Greece, and Cyprus (Figure 1), there was deliberation as to whether the results can be considered representative of PAGs across Europe.
Conclusions
This study exhibited and analyzed data from a Pan-European, online survey targeting adult individuals with chronic underlying conditions (patients) from the European region who are members of PAGs.

Despite the high percentage of participants acknowledging awareness of the term “clinical trials,” few individuals affirmed they were willing to participate in the Volunteer Registry due to a lack of trust in certain bodies involved in clinical trial conduct, concerns involving safety, or even religious beliefs. The results of this online survey represent only an initial indication of patient willingness to register in the Volunteer Registry and support that PAG members value advancements in medical research and clinical trials.

The information presented aids in interpreting issues and setbacks in existing registrations so that a plan may be constructed to improve future promotion, campaigns, and approach schemes for vaccine trials, in particular for PAG members. Overall, raising public awareness of the benefits of clinical trials and improving health literacy may increase participation in vaccine clinical trials. Careful planning and more thought need to be invested in designing trials to guarantee inclusiveness, equality, and strong support networks for groups such as PAGs.

Acknowledgments
This work was supported by the European Union’s Horizon 2020 research and innovation program under grant agreement number 101037867 (VACCELERATE). We would like to express our sincere gratitude to all European Patient Advocacy Groups for their work and assistance with disseminating this survey. The survey was designed and developed in collaboration with Conread Research Bureau Ltd, Nicosia, Cyprus. The research leading to these results was conducted as part of the VACCELERATE consortium. For further information, please refer to the official website of the VACCELERATE network [24].

Abstract

Background: A comprehensive description of the combined effect of SARS-CoV-2 and respiratory viruses other than SARS-CoV-2 (ORVs) on acute respiratory infection (ARI) hospitalizations is lacking.

Objective: This study aimed to compare the viral etiology of ARI hospitalizations before the pandemic (8 prepandemic influenza seasons, 2012-13 to 2019-20) and during 3 pandemic years (periods of increased SARS-CoV-2 and ORV circulation in 2020-21, 2021-22, and 2022-23) from an active hospital-based surveillance network in Quebec, Canada.

Methods: We compared the detection of ORVs and SARS-CoV-2 during 3 pandemic years to that in 8 prepandemic influenza seasons among patients hospitalized with ARI who were tested systematically by the same multiplex polymerase chain reaction (PCR) assay during periods of intense respiratory virus (RV) circulation. The proportions of infections between prepandemic and pandemic years were compared by using appropriate statistical tests.

Results: During prepandemic influenza seasons, overall RV detection was 92.7% (1384/1493) (respiratory syncytial virus [RSV]: 721/1493, 48.3%; coinfections: 456/1493, 30.5%) in children (<18 years) and 62.8% (2723/4339) (influenza: 1742/4339, 40.1%; coinfections: 264/4339, 6.1%) in adults. Overall RV detection in children was lower during pandemic years but increased from 58.6% (17/29) in 2020-21 (all ORVs; coinfections: 7/29, 24.1%) to 90.3% (308/341) in 2021-22 (ORVs: 278/341, 82%; SARS-CoV-2: 30/341, 8.8%; coinfections: 110/341, 32.3%) and 88.9% (361/406) in 2022-23 (ORVs: 339/406, 84%; SARS-CoV-2: 22/406, 5.4%; coinfections: 128/406, 31.5%). In adults, overall RV detection was also lower during pandemic years but increased from 43.7% (333/762) in 2020-21 (ORVs: 26/762, 3.4%; SARS-CoV-2: 307/762, 40.3%; coinfections: 7/762, 0.9%) to 57.8% (731/1265) in 2021-22 (ORVs: 179/1265, 14.2%; SARS-CoV-2: 552/1265, 43.6%; coinfections: 42/1265, 3.3%) and 50.1% (746/1488) in 2022-23 (ORVs: 409/1488, 27.5%; SARS-CoV-2: 337/1488, 22.6%; coinfections: 36/1488, 2.4%). No influenza or RSV was detected in 2020-21; however, their detection increased in the 2 subsequent years but did not reach prepandemic levels. Compared to the prepandemic period, the peaks of RSV hospitalization shifted in 2021-22 (16 weeks earlier) and 2022-23 (15 weeks earlier). Moreover, the peaks of influenza hospitalization shifted in 2021-22 (17 weeks later) and 2022-23 (4 weeks earlier). Age distribution was different compared to the prepandemic period, especially during the first pandemic year.

Conclusions: Significant shifts in viral etiology, seasonality, and age distribution of ARI hospitalizations occurred during the 3 pandemic years. Changes in age distribution observed in our study may reflect modifications in the landscape of circulating respiratory viruses during the COVID-19 pandemic.
RVs and their contribution to ARI hospitalizations. During the pandemic period, SARS-CoV-2 had a low contribution to pediatric ARI hospitalizations, while it was the main contributor to adult ARI hospitalizations during the first 2 seasons and dropped below ORVs during the third pandemic season. Evolving RVs epidemiology underscores the need for increased scrutiny of ARI hospitalization etiology to inform tailored public health recommendations.

Introduction

Stringent mitigation efforts, such as border closures, travel restrictions, lockdowns, social distancing, use of masks in public spaces, school and business closures, and remote work, had been implemented worldwide to reduce the transmission of SARS-CoV-2 and its impact on hospital bed capacity [1]. While the first weeks of 2020 in the Northern Hemisphere were dominated by respiratory viruses other than SARS-CoV-2 (ORVs), SARS-CoV-2 almost completely replaced seasonally circulating ORVs within several weeks [2-4]. Public health measures in response to the pandemic altered traditional seasonality of some respiratory viruses (RVs), with virtual disappearance of others during extended periods of time in different parts of the world [5-10]. Among children, mitigation efforts led to a decrease in pediatric visits and hospitalizations overall and especially in those having acute respiratory infections (ARIs) [11,12], bronchiolitis [13,14], and pediatric asthma exacerbations associated with ARIs [15]. Easing of public health measures was accompanied by a subsequent surge of ORV circulation [16-18] and gradual return to usual seasonal patterns [19,20]. An interseasonal surge in RSV hospitalizations occurred in 2021 in winter instead of the usual summer season in Australia [16] and during the summer-fall months instead of winter in Canada [20]. In 2022, an unusually late influenza season was observed in the Northern Hemisphere [20] and an earlier than usual RSV hospitalization peak occurred between October and December [19,21].

The pandemic had an impact on laboratory resources, with lower volumes of performed tests and changes in the propensity to test for ORVs, especially during the first months, as well as on health-seeking behaviors, which may complicate the interpretation of ORV surveillance. Detection of ORVs in hospitalized patients may be more informative since admission requires a certain degree of severity and the propensity to be tested for a larger panel of RVs is higher. However, because of the high demand of SARS-CoV-2 tests in hospital laboratories, testing for ORVs was reduced even in hospitalized patients during the first stages of the pandemic.

A number of reports described detection of ORVs in patients hospitalized with ARI or COVID-19 during the pandemic [9,22-26]. However, to our knowledge, no report has described the results of the systematic detection of both ORVs and SARS-CoV-2 (not only at the physician request) using a panel of multiple RVs in a multicenter network including both pandemic years and comparing them with as long as 8 prepandemic years. The characterization of the combined impact of both SARS-CoV-2 and ORVs on ARI hospitalizations during the 3 pandemic years and its comparison with prepandemic seasons may provide insightful information on the postpandemic period when SARS-CoV-2 is expected to cocirculate along with ORVs.

In Quebec, Canada, a prospective hospital-based surveillance network with systematic testing for a panel of 17 RVs in pediatric and adult patients admitted for ARI has been in place since 2012-2013 during periods with high influenza circulation [27-30]. The same network was used for surveillance during the pandemic by adding SARS-CoV-2 to the panel and by extending surveillance periods to intense RV circulation. We report here the results of the comparison of RV contribution to hospitalization during 3 pandemic seasons (2020-21 to 2022-23) and 8 prepandemic seasons.

Methods

Population and Study Design

The characteristics of the Quebec prospective hospital-based surveillance network during the prepandemic years have been described in detail elsewhere [27-30]. In brief, 4 regional hospitals (2 community and 2 academic or tertiary; all of them serving both children and adults) with a catchment area of nearly 10% of the Quebec population (approximately 8.8 million in 2023) participated in the surveillance during 8 influenza seasons since 2012-13. One of the 4 hospitals (approximately 15% of the population included in previous years) was not able to participate in 2020-21 because of challenges with hospital resources during the pandemic, and it rejoined the network in 2021-22. Two additional tertiary hospitals, 1 adult and 1 pediatric hospital, joined the network in 2021-22, for a total of 6 hospitals (approximately 15% of the Quebec population). Results from these 2 hospitals are included only in the description of virus detection per week and are not used for comparison with the prepandemic period. All patients presenting to the emergency department with ARI were systematically swabbed during high influenza activity weeks of prepandemic years or during periods with increased hospitalizations due to SARS-CoV-2 or ORVs during the pandemic (Figure 1).
Figure 1. Weekly number of patients hospitalized for acute respiratory infection (ARI) included in active hospital-based prospective surveillance during the prepandemic (2012-20) and pandemic (2020-23) seasons in Quebec, Canada. Four hospitals participated in the prepandemic period. Three hospitals participated in 2020-21 with periodic sampling by day of the week. Four hospitals participated in 2021-22 and 2022-23 with periodic sampling by day of the week. Two additional hospitals that joined in 2021-22 are not presented.

Inclusion and Exclusion Criteria

Eligible patients were those who were admitted for ≥24 hours and who met a standardized ARI definition (fever or feverishness not attributed to another illness or cough or sore throat) that was expanded in 2020-21 to include symptoms specific for COVID-19 (adjusted from the Canadian Nosocomial Infection Surveillance Program [CNISP] [31]; fever or history of fever not attributed to another illness, or cough [or exacerbation of cough] or difficulty breathing [or exacerbation of difficulty breathing], or sudden extreme fatigue, or at least two of the following symptoms: rhinorrhea or nasal congestion, sore throat, myalgia or arthralgia, or sudden anosmia or ageusia). Nurses collected demographic and clinical details from the patient or legal representative on a standardized questionnaire and reviewed patients’ charts at discharge for additional clinical information. Patients with onset of ARI symptoms after admission, those who refused to consent or were unable to consent (during the period before the ethics committee exemption), those who did not meet the ARI definition, and those who were admitted for less than 24 hours were excluded from this analysis.

Surveillance Period

For the prepandemic years, the surveillance period started when the positivity rate for influenza in respiratory specimens from the provincial sentinel laboratory surveillance was ≥15% for 2 consecutive weeks and stopped the week after this rate dropped below 15% or when the planned sample size for the season was achieved (800-1000 specimens depending on the season). The provincial laboratory surveillance included >40 laboratories across the province of Quebec with >100,000 respiratory specimens per year. Surveillance lasted from 7 to 12 weeks per season (median of 8.5 weeks) between epi-weeks 49 (earliest) and 14 (latest) (Figure 1). In 2020-21, the surveillance period (September 27, 2020 [epi-week 40] to May 29, 2021 [epi-week 21]; overall duration of 35 weeks) coincided with Québec’s second and third COVID-19 waves (caused by ancestral and Alpha SARS-CoV-2 variants) [32] (Figure 2; Multimedia Appendix 1). In 2021-22, the surveillance period (October 04, 2021 [epi-week 40] to June 18, 2022 [epi-week 24]; duration of 34 weeks) captured an unexpected interseasonal RSV surge along with the descending and ascending phases of the fourth (Delta variant), fifth (Omicron BA.1 variant), and sixth (Omicron BA.2 variant) waves. The 2 additional hospitals joined the surveillance in 2021, with the adult hospital starting at epi-week 43 and the pediatric hospital starting at epi-week 46. During 2022-23, the surveillance period lasted 32 epi-weeks (from October 02, 2022 [epi-week 40] to May 20, 2023 [epi-week 20]). Details of the epidemiologic situation in Quebec are presented in Multimedia Appendix 1. Because of challenges with hospital resources during periods of high SARS-CoV-2 circulation, the surveillance was paused during some weeks and sampling of enrollment during predetermined days of the week was adopted by some hospitals (Figure 1).
Figure 2. Proportion of respiratory virus detection among patients hospitalized for acute respiratory infection by epi-week in the hospital-based prospective surveillance network during the prepandemic (2012-20) and pandemic (2020-23) seasons in Québec, Canada. All participating hospitals are included (4 hospitals from 2012-13 to 2019-20, 3 hospitals in 2020-21, and 6 hospitals in 2021-22 and 2022-23). In order to simplify the presentation, epi-week 53 (2014-15 and 2019-20) is excluded. Weeks 40 to 20 are presented. The apparent increase in the proportion of hospitalizations due to influenza during epi-week 14 is due to the small number of hospitalized patients since only 1 season (2015-16) contributed. For consistency with other seasons, data for epi-weeks 40 to 20 during the pandemic seasons are presented, although the surveillance period was longer for some pandemic years.

hCoV: common human coronavirus; hMPV: human metapneumovirus; hPIV: human parainfluenza virus; RSV: respiratory syncytial virus.

Laboratory Analysis
Nasal specimens collected on flocked swabs from eligible patients were sent to the provincial public health laboratory (Laboratoire de Santé Publique du Québec [LSPQ]) and tested using the Luminex NxTAG Respiratory Pathogen Panel assay that detects influenza A (subtypes H3 and H1); influenza B; respiratory syncytial virus (RSV) (A and B differentiated starting in 2016-17); human parainfluenza viruses (hPIVs) 1, 2, 3, and 4; human metapneumovirus (hMPV); common human coronaviruses (hCoVs) NL63, HKU1, 229E, and OC43; enteroviruses/rhinoviruses (not differentiated); adenovirus; bocavirus; and 3 bacteria (Mycoplasma pneumoniae, Chlamydia pneumoniae, and Legionella pneumophila). Nucleic acids were purified using the bioMerieux eMAG platform, and polymerase chain reaction (PCR) products were analyzed on a Luminex Magpix system, as prescribed by the manufacturer. NxTAG assays were approved for diagnosis by Health Canada.

This assay was systematically used during all prepandemic years and during all pandemic years in the hospitals included in the main analysis (comparison between prepandemic and pandemic seasons). Additional assays used by hospitals and contributing only to descriptive results (Figure 2) were as follows: (1) BioFire Respiratory Panel 2.1 (RP2.1) used for ORV testing by local laboratories (considered in the descriptive analysis for patients for whom specimens were not available to be tested by Luminex NxTAG); (2) in-house multiplex reverse transcription PCR (MRVP) detecting influenza A and B; hPIVs 1, 2, and 3; adenovirus; rhinovirus; enterovirus; hCoVs 229E and OC43; RSV; and hMPV (used by the adult center added to the surveillance starting at epi-week 43 in 2021) [33]; and (3) in-house PCR using LightMix Modular Assays according to the manufacturer’s recommendations [34] to detect influenza A and B, RSV, hCoV (not differentiated), hMPV, adenovirus, hPIV (not differentiated), enteroviruses/rhinoviruses (not differentiated), and SARS-CoV-2 (used by the pediatric center added to the surveillance starting at epi-week 46 in 2021). Throughout the pandemic years, SARS-CoV-2 was detected at local laboratories by using commercially available diagnostic tests.

Statistical Analysis
Proportions were compared by using the chi-square or Fisher exact test when appropriate. Mean values were compared by using the Wilcoxon test. The Cochran-Armitage trend test was used to assess the linear trend of proportions across age categories. Statistical significance was set at \( P < .05 \). Statistical analyses were conducted using SAS version 9.4 (SAS Institute). A similar hospitalization rate and viral etiology distribution was assumed for days with and without enrollment during weeks with only 3 enrollment days.

Ethical Considerations
Institutional Review Board approval was obtained from all participating hospitals (Hôpital régional de Rimouski [number: CCER 11-12-13], Hôpital de Chicoutimi [number: 2011-032], Hôpital de la Cité-de-la-Santé – Laval [number: 06.02.02/2011-2012], and Centre hospitalier universitaire...
régional de Trois-Rivières [number: 2011-016-00]) for the first 3 years, and a signed informed consent form, including the possibility of a secondary analysis, was used. A waiver was obtained for the following years when the project was conducted as sentinel surveillance mandated by the Ministry of Health from the Research Ethics Board of the Centre hospitalier universitaire de Québec-Université Laval (2019-4455), and it was considered exempt from the requirement for ethics approval. During pandemic years, surveillance was performed within the legal mandate of the National Director of Public Health of Quebec under the Public Health Act and did not require research ethics committee review. This retrospective analysis used deidentified data. No compensation was provided to patients.

**Results**

**Surveillance Participants**

Overall, 15,199 patients potentially eligible for surveillance were approached (6412 during the prepandemic period, 1454 in 2020-21, 3124 in 2021-22, and 4209 in 2022-23) (Multimedia Appendix 2). Patients missed by nurses (n=25) or those with samples not received by LSPQ or samples of insufficient volume (n=1213) were comparable to those included in the main analysis with respect to age (mean age 61 vs 62 years; \( P=.97 \)) and sex (47% vs 49% female; \( P=.17 \)). A total of 10,550 patients hospitalized for community-acquired ARI were included in the analysis: 5832 (1493 children aged 0-17 years and 4339 adults) during the 8 prepandemic influenza seasons, 791 (29 children and 762 adults) during the 2020-21 season, 1606 (341 children and 1265 adults) during the 2021-22 season, and 1894 (406 children and 1488 adults) during the 2022-23 season (Table 1).

When comparing the age distribution of hospitalized patients from the hospitals that participated in the surveillance since the beginning, the proportion of children was significantly lower in 2020-21 compared to prepandemic seasons (29/791, 3.7% vs 1493/5832, 25.6%; \( P<.001 \)), and it increased and almost reached the levels observed during prepandemic seasons in the following 2 pandemic years (around 21% in both the second [341/1606, 21.2%] and third [406/1894, 21.4%] pandemic years; \( P<.001 \)). During both prepandemic and pandemic seasons, the proportion of young adults among patients hospitalized with ARI was very low (1%-2% for those aged 18-29 years and those aged 30-39 years), and there was a subsequent gradual increase with age to 2%-4% in those aged 40-49 years, 4%-7% in those aged 50-59 years, 13%-19% in those aged 60-69 years, 19%-25% in those aged 70-79 years, and 29%-39% in those aged \( \geq 80 \) years (\( P<.001 \) for the increase in the proportion for both prepandemic and pandemic seasons) (Figure 3). Compared to the prepandemic period, the proportion of patients aged \( \geq 60 \) years was significantly higher during the first pandemic year (653/791, 82.6% vs 3561/5832, 61.1%; \( P<.001 \)) and then decreased to varying degrees during the subsequent years (approximately 70% in 2021-22 [1123/1606, 69.9%] and 2022-23 [1341/1894, 70.8%]) but remained higher than that during the prepandemic period (\( P<.001 \)), mirroring the decrease in pediatric hospitalizations but likely also associated with age-dependent SARS-CoV-2 severity (Figure 3).
Table 1. Number and proportion of patients hospitalized for acute respiratory infection by age group and detected respiratory virus in Quebec, Canada, during prepandemic (2012-20) and pandemic (2020-23) seasons.

aP<.05 for comparison with 2012-20; Fisher exact test.
bP<.05 for comparison between the first pandemic year (2020-21) and each of the subsequent years (2021-22 and 2022-23).

Figure 3. Age distribution of patients hospitalized for acute respiratory infection in the hospital-based prospective surveillance network in the prepandemic period (peaks of influenza seasons from 2012-13 to 2019-20) and 3 pandemic years (2020-21, 2021-22, and 2022-23) in Quebec, Canada.
Viral Etiology

Overall Hospitalizations

During the prepandemic seasons, at least one respiratory virus was detected in 70.4% (4107/5832) of the patients hospitalized for ARI (Table 1). The most frequently detected viruses across all age groups were influenza (2107/5832, 36.1%), RSV (1080/5832, 18.5%), hMPV (475/5832, 8.1%), enteroviruses/rhinoviruses (465/5832, 7.9%), and hCoV (376/5832, 6.4%). Coinfections were detected in 12.3% (720/5832) of patients.

In 2020-21, the most frequently detected virus was SARS-CoV-2 (307/791, 38.8%). ORVs were detected in 5.4% (43/791) of patients, and the most frequent were enteroviruses/rhinoviruses (26/791, 3.3%), hMPV (11/791, 1.4%), and adenoviruses (10/791, 1.3%). No influenza or RSV was detected. Coinfections were detected in 1.8% (14/791) of patients; 1.0% (8/791) involved a combination of ORVs without SARS-CoV-2 and 0.8% (6/791) involved SARS-CoV-2 with ORVs.

In 2021-22, the most frequently detected viruses were SARS-CoV-2 (582/1606, 36.2%), RSV (162/1606, 10.1%), enteroviruses/rhinoviruses (153/1606, 9.5%), influenza viruses (61/1606, 3.8%; all being influenza A [H3N2]), adenoviruses (59/1606, 3.7%), and bocaviruses (55/1606, 3.4%). ORVs (excluding those with SARS-CoV-2 coinfection) were detected in 28.5% (457/1606) of patients. Coinfections were detected in 9.5% (152/1606) of patients: 7.3% (118/1606) involved a combination of ORVs without SARS-CoV-2 and 2.1% (34/1606) involved SARS-CoV-2 with ORVs. The peak of hospitalization due to RSV was detected 16 weeks earlier (epi-week 40) compared to prepandemic seasons (on average, epi-week 4) (Figure 2). The peak of hospitalization due to influenza occurred 17 weeks later in 2021-22 (epi-week 17) than the average peak at epi-week 52 during prepandemic seasons (Figure 2).

In 2022-23, the most frequently detected viruses were SARS-CoV-2 (359/1894, 19.0%), RSV (215/1894, 11.4%), influenza viruses (134/1894, 7.1%; mostly influenza A [H3N2] at 88.8% [119/134]), and enteroviruses/rhinoviruses (213/1894, 11.2%). ORVs without SARS-CoV-2 were detected in 39.5% (748/1894) of patients. Coinfections were detected in 8.7% (164/1894) of patients: 6.9% (130/1894) involved a combination of ORVs without SARS-CoV-2 and 1.8% (34/1894) involved SARS-CoV-2 with ORVs. The timing of influenza and RSV hospitalization was more aligned with historical time frames, although differences still occurred (influenza peaked 4 weeks earlier [epi-week 48 vs epi-week 52]; RSV peaked 15 weeks earlier [epi-week 41 vs epi-week 4]) (Figure 2).

Pediatric Hospitalizations

During the prepandemic period, at least one RV was detected in 92.7% (1384/1493) of children, including 30.5% (456/1493) coinfections. Pediatric hospitalizations due to RVs sharply decreased during the first pandemic year. The detection rate decreased to 58.6% (17/29) in 2020-21 (7/29, 24.1% being coinfections) and reverted to a rate comparable to that in the prepandemic period in 2021-22 (308/341, 90.3%) and 2022-23 (361/406, 88.9%). A similar trend was observed for coinfections, with a decrease to 24.1% (7/29) in 2020-21 and an increase to a rate closer to that in the prepandemic years during the 2 subsequent years (110/341, 32.3% in 2021-22 and 128/406, 31.5% in 2022-23).

Prior to the COVID-19 pandemic, the most frequently detected viruses in hospitalized children were RSV (721/1493, 48.3%) and influenza (365/1493, 24.4%) (Table 2). In 2020-21, SARS-CoV-2, RSV, and influenza were not detected in any hospitalized child, and hospitalizations with an identified virus in children were due to enteroviruses/rhinoviruses (8/29, 27.6%), adenoviruses (7/29, 24.1%), and bocaviruses (6/29, 20.7%). The proportions of detected adenoviruses and bocaviruses were significantly higher than those reported during the prepandemic seasons (Table 2), and no significant differences were detected for the rest of the viruses. In the 2 subsequent pandemic years, RSV was again the most frequently detected virus in children, while influenza and SARS-CoV-2 had a low etiological contribution to pediatric ARI hospitalizations. In 2022-23, most of the hospitalizations in children were due to ORVs without SARS-CoV-2 (278/341, 81.5%), and only 8.8% (30/341) were due to SARS-CoV-2 (including 10 coinfections with ORVs). The predominant virus was RSV (115/341, 33.7%), followed by enteroviruses/rhinoviruses (110/341, 32.3%) and bocaviruses (49/341, 14.4%). Compared to prepandemic seasons, the contribution was significantly higher for enteroviruses/rhinoviruses, hPIV 1-4, and bocaviruses, and lower for RSV, influenza, and hCoV (Table 2). In 2022-23, most of the hospitalizations were due to ORVs (339/406, 83.5%), and 5.4% (22/406) were due to SARS-CoV-2 (including 13 coinfections with ORVs). The predominant virus was again RSV (158/406, 38.9%), followed by enteroviruses/rhinoviruses (114/406, 28.1%), bocaviruses (53/406, 13.1%), hMPV (39/406, 9.6%), hCoV (38/406, 9.4%), adenoviruses (35/406, 8.6%), influenza (29/406, 7.1%), and hPIV (26/406, 6.4%). Compared to prepandemic seasons, significantly less cases of RSV and influenza and more cases of enteroviruses/rhinoviruses, bocaviruses, and hPIV were detected.

Some differences in the age distribution of children hospitalized before or during the pandemic were observed regarding some etiological viruses. For example, the average age among children hospitalized with RSV was 16 months in 2022-23, which was higher than in the prepandemic period (8 months) and in 2021-22 (7 months; P<.001). Differences in the average age of children hospitalized with enteroviruses/rhinoviruses were also observed but to a lower degree. It was higher in 2022-23 (21 months) and 2021-22 (20 months) than in the prepandemic period (17 months; P<.001).

**Adult Hospitalizations**

During the prepandemic seasons, at least one RV was detected in 62.8% (2723/4339) of adults (264/4339, 6.1% co-infections), and influenza was the most predominant virus (1742/4339, 40.1% globally and 1742/2723, 63.9% of all detected viruses). During all pandemic years, significantly fewer adults (1810/3515, 51.5%) were positive for at least one RV (including SARS-CoV-2 and ORVs) in comparison to the prepandemic...
period (2723/4339, 62.8%). With a few exceptions, the detection rate was comparable to prepandemic years in the younger age groups (18-59 years) and was lower in those aged ≥60 years (Table 1). SARS-CoV-2 was the most frequently identified virus during all 3 pandemic years among adults hospitalized for ARI (2020-21: 307/762, 40.3%; 2021-22: 552/1265, 43.6%; and 2022-23: 337/1488, 22.6%) (Tables 1 and 3). At least one ORV was detected in 3.4% (26/762), 14.2% (179/1265), and 27.5% (409/1488) of adults in 2020-21, 2021-22, and 2022-23, respectively. Except for enteroviruses/rhinoviruses and hPIV in 2022-23, all individual viruses were detected in lower proportions during the pandemic period compared to the prepandemic period, although differences did not always reach statistical significance owing to low numbers (Table 3).

A sensitivity analysis, which excluded comparisons of the hospital that did not participate during the first pandemic year, did not reveal differences in detected trends (data not presented).

The results of viral detection in the 2 additional hospitals in 2021-22 and 2022-23 compared to the 4 hospitals included in the main analysis are presented in Multimedia Appendix 3. Differences might be explained by the different assays used for laboratory analyses, the populations (only pediatric patients in one hospital and only adults in the other hospital), and the time spans. While comparisons with prepandemic seasons are not appropriate in this context, we included results from the additional hospitals in the presentation of viral etiology by week in order to illustrate a more comprehensive impact of RVs on hospitalization (Figure 2).

Discussion

Principal Findings

Our report, based on the systematic detection of RVs, describes changes in the etiology of pediatric and adult ARI hospitalizations during 3 pandemic years compared with 8 prepandemic winter seasons in the same population. To our knowledge, this is the longest time span of follow-up during both pandemic and prepandemic periods in both pediatric and adult hospitalized patients. We detected continuing changes in viral etiology and age distribution during the 3 pandemic years compared to the prepandemic period. While SARS-CoV-2 was the most frequent viral etiology of ARI hospitalizations during the 3 pandemic years, it was absent among children during the first year and scarcely detected during the second and third years. ORVs were the most important contributors to pediatric ARI hospitalization during all 3 pandemic years. In adults, SARS-CoV-2 was the most important contributor to ARI hospitalization during the first 2 pandemic years, but its relative importance gradually decreased, mirroring the increasing role of ORVs, and dropped below ORVs’ detection during the third pandemic year. The most striking differences in age distribution were detected during the first pandemic year, mainly due to a remarkable decrease in pediatric ARI hospitalization.

Interpretation of the Findings

The differences in the etiology and age distribution of ARI hospitalizations were a consequence of changes in both ORV and SARS-CoV-2 circulation and their impacts on hospitalizations, reflecting the intensity of mitigation measures and the resulting modification of immunity in the population following extended periods of the absence of some viruses (such as RSV). For instance, the circulation of ORVs was very low in 2020-21 when more stringent measures were implemented, increased during autumn 2021 following the easing of some measures, declined in December 2021 following the tightening of the measures in response to the Omicron wave, and increased again in February-March 2022 following broader travelling and school opening in Quebec (Multimedia Appendix 1) [35]. The increase in the average age of children hospitalized with RSV and enteroviruses/rhinoviruses during the pandemic period suggests that younger children had less exposure to these viruses due to the mitigation measures deployed in 2020-21. Another potential contributing factor was the evolution of SARS-CoV-2 variants. For example, during the 2020-21 season when ancestral and Alpha SARS-CoV-2 variants (affecting mostly adults) circulated, the pediatric population was spared, while during the autumn and winter of 2021-22 when Delta and then Omicron variants predominated [32], the pediatric population was more affected. Finally, COVID-19 vaccine uptake and effectiveness, and outpatient antiviral availability, which had an impact on preventing hospitalizations, varied by age group. During the second pandemic year, older patients were prioritized in the COVID-19 vaccination campaigns, and more patients with comorbidities were offered outpatient antiviral treatment. For children, however, COVID-19 vaccines were available later, and in young adults, vaccine uptake was lower than in the older population [36]. Therefore, the impact on SARS-CoV-2 hospitalizations varied by age and time period. The effectiveness of COVID-19 vaccines and their impact on the SARS-CoV-2 portion of ARI hospitalizations varied depending on the type of vaccine, the frequency of doses and delays between dose administrations, and the proportion of the population with prior COVID-19 infection, which steadily increased with the unfolding of the pandemic, allowing the development of hybrid immunity [37].

Overall, during the prepandemic influenza seasons, the 2 most frequently detected viruses among patients hospitalized with ARI were influenza and RSV. SARS-CoV-2 was the most important respiratory virus during the first pandemic year. In 2021-22 and 2022-23, its contribution decreased, while the contribution of ORVs increased. However, there were differences between the pediatric and adult populations. RVs (mostly RSV) affected more children than adults during the prepandemic winter seasons. Although the overall impact of ORVs was lower during the pandemic period, children remained mostly affected by ORVs and not by SARS-CoV-2 during all pandemic years. In adults, influenza was the most important virus during the prepandemic years, whereas SARS-CoV-2 was more important than ORVs during the first 2 pandemic years, while their roles reversed during the third pandemic year. It is of note that with the addition of the contribution of SARS-CoV-2 to ARI hospitalizations, the relative role of ORVs decreased during the pandemic years compared to the prepandemic period both in children and adults [38,39], with some minor exceptions (eg, enteroviruses/rhinoviruses) [40,41].

Nonenveloped viruses (rhinoviruses and adenoviruses) were less impacted by preventive measures aiming to halt SARS-CoV-2 transmission [40-42]. Their detection has been reported in hospitalized patients during periods of decreased detection of other RVs [43,44]. In our study, among children, the proportion of adenoviruses and enteroviruses/rhinoviruses was higher during the first pandemic year compared to the prepandemic period, and the proportion of enteroviruses/rhinoviruses remained higher during the second and third pandemic years. Among adults, the proportion of enteroviruses/rhinoviruses was higher during the third pandemic year. Since our study did not include less severe infections not leading to hospitalization, our findings reflect not only the circulation of these viruses, but also their virulence that may vary by age and season. It is of note that the proportion of enteroviruses/rhinoviruses might have been underestimated in the prepandemic period of our study because it was conducted only during the peaks of influenza circulation, and the weeks of the most intense circulation of enteroviruses/rhinoviruses may not have been captured.

The important reduction of pediatric respiratory hospitalization, virtual absence of influenza and RSV during the first pandemic year, and increased role of COVID-19 and ORVs, especially RSV, in hospitalized children during the second and third pandemic years in our study are in line with reports from some other countries and other Canadian provinces [14,23,24,45,46]. Of note, the timing of the unusual surge of RSV varied by region of the world. In Europe, Israel, and the United States, increases were reported in the Spring-Summer of 2021 [14,23,24,45]. Major shifts in the epidemiology of RSV with large-scale outbreaks were reported in New Zealand (corresponding to the
usual season) [47] and Australia (out of season) [16]. In Canada, the first province to report a surge of RSV was Quebec in August 2021, while the other provinces followed with a delay of 2 to 3 months [46]. In 2022, an earlier than usual start of the RSV season was reported in the Northern Hemisphere [17,21], with a peak of RSV-related hospitalizations between October and December [19,21]. The surge in RSV hospitalizations and the shift in the average age of children hospitalized with RSV (older in 2021-22) observed in our study are consistent with the results of other studies [48,49], and the findings might be attributable to the “immunity debt” that occurred because of the lack of exposure during the first pandemic year. However, it is not clear why important variability in the increase of the RSV hospitalization rate occurred globally, for example, it was relatively comparable to the prepandemic period in Germany but higher in the United States [19,21]. After a prolonged absence, the influenza season of 2021-22 occurred later than during prepandemic years in the Northern Hemisphere and affected mostly adults [20,50,51]. A shorter season than the typical prepandemic season was reported in Canada and Europe [51], while a longer season occurred in the United States [52]. During the third pandemic year (2022-23), an unusually early influenza season was reported in other Canadian provinces [20], Europe [53], and the United States [54], which is similar to our findings.

Evidence from across the world suggests that RV-specific seasonality is being progressively re-established [17,20,53,55]. However, it is yet unclear how the co-circulation of different viruses, now with the addition of SARS-CoV-2, will impact the occurrence and severity of ARI hospitalizations. Systematic testing for a panel of RVs allowed us to detect a high proportion of coinfection (>30%, including both SARS-CoV-2 and ORVs) in children during both the prepandemic and pandemic periods (with the exception of a somewhat lower proportion in the first pandemic year) and <10% coinfection in adults. However, our analysis did not aim to study the severity of coinfection or potential viral interference since we did not assess the expected coinfection rate, which requires additional epidemiological data. Viral interference between RVs (positive [additive or synergistic] or negative [antagonistic]) has been demonstrated at the cellular, host, and population levels before the pandemic [56]. SARS-CoV-2 could also interact with existing RVs. For example, it has been reported in a retrospective population-based cohort study that children with prior SARS-CoV-2 infection are more likely to have an RSV infection [57]. Moreover, rhinovirus infection may reduce the likelihood of SARS-CoV-2 infection according to in vitro assays [56].

Study Limitations

This study had some limitations. First, the prepandemic surveillance occurred during the peaks of influenza activity, and therefore, the relative contribution of other RVs may be underestimated as compared to the entire winter season. Surveillance periods during the pandemic years were mostly tailored to the increase in respiratory hospitalizations following increased SARS-CoV-2 or ORV circulation and were much longer. However, we believe that the comparison is still valid because it includes periods with the most strain on hospital capacity due to intensive circulation of ORVs, SARS-CoV-2, or both. Second, the ARI definition used during the pandemic years was broader and less specific for some RVs than during the prepandemic years and may have contributed to lower detection of RVs. In addition, it may have contributed to an increase in older age groups in which symptoms, such as exacerbation of difficulty breathing and sudden extreme fatigue, may be associated with other nonrespiratory conditions. On the other hand, this broad definition may have decreased the probability of missing patients in whom RVs may have contributed to the deterioration of their condition. Third, the first pandemic year was limited to only 3 hospitals, and periodic pauses and sampling of enrollment during the 2 pandemic years were necessary given the stretched resources, which limited the sample size. However, this should not have influenced the relative contribution of RVs and global comparisons, as the surveillance period during pandemic years was much longer than prepandemic seasons and sensitivity analysis did not reveal differences in trends when excluding the hospital not included in the first pandemic year. In addition, this approach allowed the maintenance of surveillance in the context of resource challenges during the pandemic. Fourth, 19% of eligible patients hospitalized for ARI were excluded from the main analysis. However, we do not believe that this impacted the validity of comparisons made in this study given that age was the main factor driving differences in RV detection and there was no difference by age and gender in missed eligible patients compared to those included in the study. Finally, our results may not necessarily be extrapolated to other regions or periods of time because of temporal and geographical differences in ORVs and SARS-CoV-2 epidemiology.

Study Strengths

The main strength of this study was the systematic testing for a broad panel of RVs for all admitted patients with symptoms of ARI during surveillance periods, by using the same diagnostic assay during all study periods. Moreover, it included both pediatric and adult populations during a total of 11 years, with the participation of at least three hospitals from different Quebec regions in each year, a broad case definition, a comprehensive detection of 17 RVs and SARS-CoV-2 potentially contributing to ARI hospitalizations, and a possibility to distinguish community-acquired infections from health care–acquired infections.

Conclusion

Important shifts in viral etiology, seasonality, and age distribution of ARI hospitalizations in children and adults were observed during the 3 pandemic years compared to the prepandemic period. While the first pandemic season was significantly different from the prepandemic winter seasons, the second and third years were more comparable in terms of both RV contribution and age distribution. The complex interplay among mitigation measures, intrinsic seasonality and secular trends of ORVs, changes in circulating SARS-CoV-2 variants and their virulence, COVID-19 vaccine uptake and effectiveness, outpatient antiviral treatments, and potential viral interference may have played roles in the differential contribution of ORVs and SARS-CoV-2 to ARI hospitalizations. Our study underscores the importance of surveillance in
understanding altered seasonal patterns of RVs and shows that the role of SARS-CoV-2 relative to ORVs is continually changing. The current situation may reflect a transition period until SARS-CoV-2 finds its ecological niche in the human population and ORVs re-establish their usual seasonal patterns. Although new SARS-CoV-2 variants may emerge and cause occasional increases in hospitalizations, in the long run, it may establish itself as another usual respiratory virus. At this point, it is difficult to foresee its role compared to ORVs; however, our study suggests that SARS-CoV-2 may continue to be the most important contributor to ARI hospitalizations in adults. Increased scrutiny of continuing changes in the etiology of ARI hospitalizations by using systematic multiplex testing approaches that allow valid comparisons, including assessment of observed and expected coinfections, is needed to inform mathematical modeling and appropriate public health recommendations.

Acknowledgments
We acknowledge France Bouchard who coordinated the surveillance and Sophie Auger who entered and cleaned the collected data throughout the years. We are extremely grateful to the front-line surveillance staff from the participating hospitals who collected and provided data in challenging circumstances during the pandemic period: Ménard Francois, Gagnon Maude, Desbiens Karine, Tremblay Chantale, Simard Patricia, Murry Carole, and Rhainds Jennifer from Chicoutimi Hospital; Estel Debois, Alexandra Bouffard, Alexandra Fortier, Alexandra Mondor, Rosalie Beaudoin, Kristina Boucher, Mélyna Carrier, Brigitte Dion, Marie-Ève Chamberland, and Lise Anne Paradis from Hôtel-Dieu de Lévis Hospital; Dolcé Patrick, Gagnon Isabelle, Lévesques Julie, Bernatchez Isabelle, and Lévesques Janie from Rimouski Hospital; Poirier André, Danylo Alexis, Tapps Danielle, Loranger Josée, and Toupin Guylaine from Trois-Rivières Hospital; Wadas Katerin, Lafleur Caroline, Ane Tres Silicia, and Tomas Fernanda from Centre universitaire de santé McGill; and Thibeault Roseline, Jacob-Wagner Marieve, Hamelin Marie-Eve, Theriault Ariane, Pelletier-Bélanger Joannie, and Côté Claudia from Centre hospitalier de l’Université Laval. We also thank Desautels Lyne, Martinneau Christine, and Ménard Joël from Laboratoire de Santé Publique du Québec who supported the surveillance despite the exponentially increasing demand on laboratories during the pandemic. We also acknowledge the support of Hany Geagea and Lauriane Padet for revising the literature. This work was supported by the Ministère de la Santé et des Services sociaux du Québec. The sponsor was not involved in the study design, data collection, result interpretation, and drafting of the manuscript.

Data Availability
The data collected in this surveillance study are the property of the Quebec Ministry of Health (Ministère de la Santé et des Services sociaux du Québec) and have been shared with the research group under the legal mandate of the National Director of Public Health of Quebec under the Public Health Act precluding data sharing with a third party. Aggregate data are available within the manuscript and the multimedia appendix files. Real-time surveillance data from HospiVir are available online [58].

Authors’ Contributions
RG, RA, and SC conceived and designed the study. RA, CF, GB, and JD collected the data. RA, SC, HC, CF, GB, and JD contributed to the data or analysis tools. RD added the results of the third year to the revised version of the manuscript and updated the literature search included in the revised version. RA, SC, and HC performed the statistical (RA and SC) and laboratory (HC) analyses. All authors contributed to the interpretation of the results. RG drafted the manuscript. All authors revised the paper and approved the final version.

Conflicts of Interest
RG, RA, and SC report that the Ministère de la Santé et des Services sociaux du Québec provided financial support to their institution for this work. RG reports personal fees from Abbie (honorary for a conference on respiratory syncytial virus burden in children unrelated to this work). The other authors have nothing to disclose.

Abstract

Background: In May 2020, the World Health Organization (WHO) declared Latin America and the Caribbean (LAC) the epicenter of the COVID-19 pandemic, with over 40% of worldwide COVID-19–related deaths at the time. This high disease burden was a result of the unique circumstances in LAC.

Objective: This study aimed to (1) measure whether the pandemic was expanding or contracting in LAC when the WHO declared the end of COVID-19 as a public health emergency of international concern on May 5, 2023; (2) use dynamic and genomic surveillance methods to describe the history of the pandemic in the region and situate the window of the WHO declaration within the broader history; and (3) provide, with a focus on prevention policies, a historical context for the course of the pandemic in the region.

Methods: In addition to updates of traditional surveillance data and dynamic panel estimates from the original study, we used data on sequenced SARS-CoV-2 variants from the Global Initiative on Sharing All Influenza Data (GISAID) to identify the appearance and duration of variants of concern (VOCs). We used Nextclade nomenclature to collect clade designations from sequences and Pangolin nomenclature for lineage designations of SARS-CoV-2. Additionally, we conducted a 1-sided t test for whether the regional weekly speed (rate of novel COVID-19 transmission) was greater than an outbreak threshold of 10. We ran the test iteratively with 6 months of data across the period from August 2020 to May 2023.

Results: The speed of pandemic spread for the region had remained below the outbreak threshold for 6 months by the time of the WHO declaration. Acceleration and jerk were also low and stable. Although the 1- and 7-day persistence coefficients remained statistically significant for the 120-day period ending on the week of May 5, 2023, the coefficients were relatively modest in
magnitude (0.457 and 0.491, respectively). Furthermore, the shift parameters for either of the 2 most recent weeks around May 5, 2023, did not indicate any change in this clustering effect of cases on future cases. From December 2021 onward, Omicron was the predominant VOC in sequenced viral samples. The rolling \( t \) test of speed=10 became entirely insignificant from January 2023 onward.

**Conclusions:** Although COVID-19 continues to circulate in LAC, surveillance data suggest COVID-19 is endemic in the region and no longer reaches the threshold of the pandemic definition. However, the region experienced a high COVID-19 burden in the early stages of the pandemic, and prevention policies should be an immediate focus in future pandemics. Ahead of vaccination development, these policies can include widespread testing of individuals and an epidemiological task force with a contact-tracing system.

**Introduction**

**Background**

COVID-19, the disease caused by the virus SARS-CoV-2, was first detected in Wuhan, China, in the fall of 2019 [1-5]. The first case of COVID-19 in Latin America and the Caribbean (LAC) [6] occurred in São Paulo, Brazil, and involved a Brazilian national traveling home from Northern Italy [7]. Our research team conducted an analysis of the pandemic in LAC 1 year into the pandemic [8]. This study provides 2 additional years of updated surveillance and epidemiological analysis for the region.

We have adopted the World Bank’s definition of LAC, which is based on economic development and geographical proximity, encompassing Argentina, Belize, Bolivia, Brazil, Colombia, Chile, Costa Rica, Ecuador, El Salvador, Guatemala, Guyana, Honduras, Mexico, Nicaragua, Panama, Paraguay, Peru, Suriname, Uruguay, and Venezuela in the Latin America region and Antigua and Barbuda, Aruba, the Bahamas, Barbados, Bermuda, the British Virgin Islands, the Cayman Islands, Cuba, Curacao, Dominica, the Dominican Republic, Grenada, Haiti, Jamaica, Puerto Rico (the United States), St Barthelemy, St Kitts and Nevis, St Lucia, St Vincent and the Grenadines, Sint Maarten (the Netherlands), Trinidad and Tobago, Turks and Caicos Islands, and the US Virgin Islands in the Caribbean region [6].

The World Health Organization (WHO) and Director-General Ghebreyesus declared the end of COVID-19 as a public health emergency of international concern on May 5, 2023 [9-11], based on the recommendation of the COVID-19 Emergency Committee [11]. To that end, we compare how the pandemic was progressing before and after the declaration. The “public health emergency of international concern” status is not a definitive statement of whether a pandemic exists or whether one has ended. The aim of this study was to provide a statistical context to determine whether COVID-19 had transitioned from pandemic to endemic status in LAC at the point of the declaration, a time when many governments worldwide had dropped emergency policy responses around COVID-19.

Epidemiological terms, such as “pandemic,” “epidemic,” “outbreak,” and “endemic,” are used to describe the occurrence and spread of diseases [2,12]. The distinctions between these terms lie in their scope and geographic extent. The terms “pandemic,” “epidemic,” “outbreak,” and “endemic” do not describe the severity of a disease; instead, they describe its prevalence [13]. An epidemic refers to a sudden increase in the number of disease cases in a specific population or region. If the epidemic spreads across several countries or continents, it becomes a pandemic. An outbreak, in contrast, describes a sudden increase in a concentrated setting, usually involving a more limited geographic area than an epidemic. The word “endemic” refers to the constant presence of a disease in a particular geographic region or population, with no sudden increases in case volume [14-16].

Public health surveillance is the “ongoing, systematic collection, analysis, and interpretation of health-related data essential to planning and evaluation of public health practice” [17]. Surveillance not only explains the burden due to a disease but also generates research questions and guides researchers on topics that require further investigation [18-32]. Surveillance allows us to compare the burden of a disease between geographical regions and to understand which regions are most impacted. The impact can be measured through absolute numbers and rates of how many people contract a disease, how many die, and what the affiliated costs are.

However, traditional public health surveillance has inherent limitations, which this study addresses. For example, surveillance predominantly offers a retrospective view, presenting a static snapshot of past events [18-32]. In the middle of a burgeoning pandemic, policy makers and public health practitioners also need to understand what is about to happen. For example, forward-looking metrics are helpful to understand the trajectory of an outbreak’s growth, the shift from linear to exponential expansion, or disparities in the impact across regions. To that end, we have developed enhanced surveillance metrics that capture the dynamic nature of a pandemic and identify imminent growth, notably pinpointing a region’s position along the epidemiological outbreak curve. Although many large cities, states, and countries conducted helpful COVID-19 disease projection models to inform leaders how to
“flatten the curve” so as not to overwhelm health systems, these one-off studies cost millions and only gave projections for a relatively short time frame [33-49]. Moreover, these studies were outdated by the time of their publication and were not relevant to future variants of concern (VOCs) with varied rates of transmission, severe disease, and reproduction. Our enhanced surveillance metrics provide predictive models in an ongoing systematic fashion consistent with surveillance systems. Our enhanced metrics also incorporate dynamic indicators of the pandemic speed at national, regional, and worldwide levels. These metrics gauge the acceleration of the speed from 1 week to the next and predict new cases based on prior dynamic panels across months of daily infections, effectively forecasting the progression of the outbreak. This predictive ability identifies the “echoing forward” of cases. Our metrics have undergone rigorous testing and validation in prior publications that this study updates [8,50-57].

For purposes of this study, standard surveillance metrics explain what has already happened in LAC, while enhanced surveillance metrics show what is about to happen by predicting new cases based on past infections or where along an epidemiological curve a country may sit. We use both types of metrics to inform the possible declaration of the end of the pandemic.

Objectives

This study had 3 objectives. First, we aimed to measure whether there was an expansion or contraction in the pandemic in LAC when the WHO declared the end of the COVID-19 public health emergency of international concern on May 5, 2023. At both the region and country level, we used advanced surveillance and analytical techniques to describe the status of the pandemic in a 2-week window around the WHO declaration. From a public health perspective, we needed to know whether the rate of new COVID-19 cases was increasing, decreasing, or stable from week to week and whether any changes in the transmission rate indicated an acceleration or deceleration of the pandemic. Statistical insignificance represents a significant finding, as this can signal the epidemiological “end” to the pandemic if the rate of new cases is 0 (or extremely low) and stable, meaning that the number of new cases is neither accelerating nor decelerating.

Second, we used dynamic and genomic surveillance methods to describe the history of the pandemic in the region and situate the time window around the WHO declaration within the broader history. We included the ratio of COVID-19 deaths to the number of transmissions as a proxy for the mortality risk from infection at the population level. We also included a historical record of genomic surveillance from sequenced viral specimens to identify the appearance and spread of VOCs in the region.

Third, we aimed to provide a historical context for the course of the pandemic in LAC. We addressed several questions: How did countries respond to the pandemic? How did the region fare in terms of the disease burden? What social, economic, and political factors shaped the course of COVID-19 in the region? This context can provide important lessons for disease prevention and mitigation in future pandemics.

Regional analyses are valuable because multiple factors, not limited to climate change, governance, economic trade routes, public health infrastructure, and human migration, can all shape the risk profile of COVID-19 transmissions [58-62]. In this study, we discussed the role of these factors in the course of the pandemic in LAC. In May 2020, the WHO declared LAC the epicenter of the pandemic, accounting for over 40% of all worldwide COVID-19 deaths at the time [63]. This high disease burden was a result of the unique circumstances in LAC, and these circumstances can inform preparedness for future pandemics and waves of transmissions.

Methods

Study Design and Data Collection

We conducted trend analyses with longitudinal COVID-19 data from Our World in Data (OWID) [64] to provide updates of traditional surveillance data and dynamic panel estimates from the original studies by Post and colleagues [8,55,56,65-67]. For the LAC region, the data comprised an unbalanced panel of 43 countries and territories, from August 21, 2020, to May 12, 2023. Please see the Introduction section for the complete list of countries. Since several countries worldwide switched from daily to weekly reports at various points in 2023, so we used a cubic spline to interpolate daily new cases and deaths if any country had 4 consecutive periods of nonzero new cases interspersed by 6 days of 0 new cases.

Additionally, we used data on sequenced SARS-CoV-2 variants from the Global Initiative on Sharing All Influenza Data (GISAID) to identify the appearance and duration of VOCs [68-72]. We used Nextclade nomenclature [73] to collect clade designations from sequences and Pangolin nomenclature for lineage designations of SARS-CoV-2 [74,75]. Metadata for the study period were collected on June 22, 2023. To avoid a low frequency or potentially erroneous samples, the data set was further filtered to exclude months with fewer than 100 available samples, variant groups with fewer than 5 samples in a month, and variant groups representing less than 0.5% of the total samples in a month. The final data set consisted of 184,386 total samples available on GISAID [69-72].

Traditional surveillance metrics include the speed of spread of the pandemic, defined as the rate of new COVID-19 cases per 100,000 people. Enhanced metrics add acceleration, jerk, and 1- and 7-day persistence measures. Acceleration is the change in speed from one unit of time to the next. This measure can identify whether the rate of transmission is increasing (positive acceleration), decreasing (negative), or stable (0). Jerk is the change in acceleration from one time unit to the next. Its name is lifted from physics nomenclature. A large jerk can signal explosive growth in transmission rates. The 1- and 7-day persistence measures provide the impact of the 1- and 7-day lag speed on the current speed. Thus, these measures capture how COVID-19 cases echo-forward to cases either 1 or 7 days later. They are derived from an Arellano-Bond dynamic panel data model [76], which follows the form

\[ y_{it} = \beta y_{it-1} + \beta X_{it} + \alpha_i + u_{it}, \]

where the dependent variable is speed, the independent variables include weekend and recent week indicators, \( \alpha_i \) is a country
fixed effect, and $u_i$ is the idiosyncratic error term. See the initial study for details [8].

**Statistical Analysis**

Lastly, we analyzed the potential “statistical end” to the pandemic with (1) dynamic panel estimates for shifts in the pandemic [40,42] and (2) a 1-sided $t$ test for whether the mean speed was equal to or greater than the outbreak threshold of 10 [77]. We ran the latter test on a rolling 6-month window of the weekly regional speed, and we plotted the $P$ values from the $t$ test over time. All statistical analyses were conducted in R version 4.2.1 (R Foundation for Statistical Computing) with the plm package (version 2.6-2) [65,66].

**Ethical Considerations**

All data used in this study are publicly available and contain no identifiable, private information. Therefore, the study does not constitute research with human subjects, as defined by 45CFR46:102, and Institutional Review Board review was unsolicited. However, the authors note that anonymized COVID-19 data surveillance systems can generate local and global ethical questions beyond the scope of this study [78].

**Results**

**Dynamic Panel Estimates**

Table 1 presents dynamic panel estimates for the most recent time window. The Wald test for regression was significant ($P<.001$), and the Sargan test failed to reject the validity of the overidentification restrictions ($P=.99$). Although the 1- and 7-day lag coefficients were statistically significant as a function of the large sample size, suggesting a cluster effect in which cases on a given day impacted cases 1 and 7 days later, the coefficients were modest in magnitude (0.457 and 0.491, respectively). Furthermore, the shift parameters for the most recent week were significant and negative, meaning the clustering effect had become smaller in the week after the WHO declaration (but the shift parameter was positive and similar in magnitude for the prior week).

**Static Surveillance Metrics**

Static surveillance metrics for the week of April 28, 2023, are provided in Table 2. The same metrics for the week of May 5, 2023, are provided in Table S1 in Multimedia Appendix 1. Most countries had a small number of new COVID-19 cases. The exceptions were Brazil, Costa Rica, Panama, Puerto Rico, and Uruguay. By far, the highest transmission rate was observed in Puerto Rico, where the speed was 144 in the week of April 28 and 182 in the following week. The next highest speed over the 2 weeks was just under 19 in Brazil, and the speed for the country dipped to 12 in the following week. For all other countries and territories, the speed was below the threshold considered a low transmission rate by the Centers for Disease Control and Prevention (CDC) [79]. Most rates fell well below the informal threshold of 10 cases per week per 100,000 population [8,50-57]. Specifically, low transmission is considered no more than 10 cases per 100,000 people per week, moderate transmission is 10-50 cases per 100,000 people per week, and substantial transmission is 50-100 cases per 100,000 people per week [79,80].

</table>
We noted, however, some sparsity in data reports. To temper the episodic reporting that became more frequent in 2023, we shifted from daily transmission rates and daily speed to weekly transmission rates and weekly speed in contrast to our initial study. A second benefit of shifting from daily to weekly reporting was that the CDC established weekly thresholds of what constitutes a low, moderate, and substantial outbreak, as noted earlier. For example, having 0 new cases in Argentina over the 2 weeks is clearly a product of a failure to report data. Although Puerto Rico appears to have been in a large outbreak around the WHO declaration, island territories often vacillate between high and low transmission rates [81]. The outbreaks in the other 4 countries were relatively small. Based on the definition of a pandemic or an outbreak in several countries, the data indicated a shift from pandemic to endemic COVID-19 in most of LAC, while it was an epidemic in Puerto Rico.

The surveillance metrics demonstrated little to no change before and after the WHO declaration. Without question, Brazil had the most cases of COVID-19 transmissions and deaths, but this rank is partly a function of population size. Thus, a better measure is the number of COVID-19 cases and deaths per 100,000 people. Moreover, death is often a better proxy for the state of an outbreak than transmissions because deaths are less likely to be undercounted [82]. Undercounting may be due to poor public health infrastructure, a switch to home antigen testing, or a dearth of polymerase chain reaction (PCR) testing or other resources. Although Brazil reported 0.02 deaths per confirmed infection, several countries had higher rates. Peru had the highest rate at 0.05, followed by Mexico at 0.04 and Ecuador, Haiti, and Paraguay at 0.03.

Table 3 and Table S2 in Multimedia Appendix 1 contain enhanced dynamic surveillance metrics for the 2 weeks before and after May 5, 2023. Again, the speed was low for every country except Brazil, Costa Rica, Panama, Puerto Rico, and Uruguay. Acceleration and jerk were both either small or negative for every country and territory. The 7-day persistence effect on the speed was also small except for the countries in outbreak status. These metrics suggest the pandemic may have indeed ended for the region. Only a single territory was in a substantial outbreak and 4 others in relatively modest outbreaks; thus, epidemiologically, COVID-19 would be considered an epidemic in Puerto Rico and an end-stage epidemic in Brazil, Costa Rica, Panama, and Uruguay, with mild outbreaks in these countries. The average speed for the LAC region was below the outbreak threshold. Since COVID-19 cases in LAC have leveled off, with the exception of Puerto Rico, indicating that the disease is stable or constant in the region, it is more accurate to say that COVID-19 in LAC has shifted to being endemic [13,83,84]. Note that the numbers in Table 3 and Table S2 in Multimedia Appendix 1 are not calculated as day-over-day averages across the week, as they are in Table 2 and Table S1 in Multimedia Appendix 1. Thus, the magnitudes of the speed are consistent but not identical to those matched across tables.

Table 4 compares the 7-day persistence effect on the speed for the top 5 countries around the 2 weeks of the WHO declaration. These ranks largely reflect the speed in the countries with outbreaks in the prior tables. However, Chile appeared at rank 5 in the week of April 28, 2023. This level of persistence would be cause for alarm if Chile did not see a substantial drop, as it did, in the subsequent week.

<sup>a</sup>LAC: Latin America and the Caribbean.

Figure 1 plots the regional speed, acceleration, jerk, and 7-day persistence metrics from August 21, 2020, to May 12, 2023. The dashed gray line denotes the informal CDC outbreak threshold speed of 10. The region was in a nearly continuous state of outbreak until September 2021. Several months later, the Omicron variant drove a substantial outbreak, culminating in a speed of 66 novel cases per week per 100,000 population. A second, smaller wave followed, which brought a peak speed of 20 in July 2022. A final outbreak barely eclipsed the outbreak threshold speed of 10 in December 2023. The region has seen the speed decrease, stabilize, and remain well below the outbreak threshold ever since.

Figure 1. Timeline of speed, acceleration, jerk, and 7-day persistence in LAC from 2020-2023. LAC: Latin America and the Caribbean.

Figure 2 plots variant groups as a proportion of all viral specimens collected and sequenced in the region (and made available through GISAID) each month. The early, nearly continuous state of outbreak in the region spanned the ancestral variant through the temporary dominance of the Delta variant. Interestingly, the region also had a period in which the majority of viral specimens returned as the Gamma variant. Compared to other worldwide regions, LAC had a greater diversity of variants. Later outbreaks were driven by the Omicron variant. LAC, like much of the rest of the world, saw a surge in cases amid the heightened transmissibility of Omicron [85]. Another potential indication of the end to the pandemic is the continued dominance of the Omicron variant. Although the region saw a mixture of variants prior to the arrival of Omicron in November 2021, viral sequences have almost exclusively returned as Omicron and its subvariants ever since.

Figure 2 plots variant groups as a proportion of all viral specimens collected and sequenced in the region (and made available through GISAID) each month. The early, nearly continuous state of outbreak in the region spanned the ancestral variant through the temporary dominance of the Delta variant. Interestingly, the region also had a period in which the majority of viral specimens returned as the Gamma variant. Compared to other worldwide regions, LAC had a greater diversity of variants. Later outbreaks were driven by the Omicron variant. LAC, like much of the rest of the world, saw a surge in cases amid the heightened transmissibility of Omicron [85]. Another potential indication of the end to the pandemic is the continued dominance of the Omicron variant. Although the region saw a mixture of variants prior to the arrival of Omicron in November 2021, viral sequences have almost exclusively returned as Omicron and its subvariants ever since.
Figure 2. VOC groups as a proportion of all sequenced SARS-CoV-2 specimens over time in LAC from March 2020 to May 2023. LAC: Latin America and the Caribbean; VOC: variant of concern.

Figure 3 plots $P$ values from a series of 1-sided $t$ tests of whether the speed for the region was equal to or greater than the outbreak threshold of 10. These tests were conducted on a rolling 6-month window of the weekly regional speed. The dashed gray line denotes the least restrictive conventional significance level threshold of $\alpha=0.10$. The test immediately rejected the null hypothesis in favor of the alternative and continued to so until the end of 2021. The test statistic became totally insignificant for a brief period in December 2021, before regaining significance in February 2022. This second period of significance was driven by the large Omicron outbreak. The test lost significance again in August 2022 and has been totally insignificant from December 2022 onward. This more recent lack of statistical significance is consistent with the end to the pandemic in the region, as the test clearly failed to reject the null hypothesis of the outbreak threshold speed.

Figure 4 provides a timeline of the onset of COVID-19 in LAC, as well as vaccination programs and major events that shaped the course of the pandemic in the region, such as economic, educational, and political impacts.
Discussion

Principal Findings

The results indicate that COVID-19 was well contained in LAC at the time of the WHO declaration. Both traditional and enhanced surveillance metrics indicated low and stable transmission rates around the time of the declaration. Nearly every SARS-CoV-2 test specimen returned as the Omicron variant from November 2021 onward. Finally, the rolling $t$ test for regional outbreak status was entirely insignificant from December 2022 onward. Collectively, these results suggest a transition from pandemic to endemic in the region. However, these more recent trends do not reflect the full history of COVID-19 in LAC. The region had a unique set of risk factors and responses to COVID-19, which shaped the trajectory of transmission rates, especially in the early stages of the pandemic.
Although many countries in LAC reacted swiftly and preemptively to protect citizens and contain the spread of COVID-19, the region struggled to contain the levels of infection, mainly due to the prevalence of informal economies and the limitations of health infrastructure and social protection systems [86-90]. The informal sector of the economy refers to unrecorded economic activity, which would contribute to the gross domestic product (GDP) and tax revenue, if recorded. The sector contributes around a third of all economic activity in low-to-middle-income countries, but the sector poses a challenge for public health prevention efforts because its workers are often unknown and unregulated by governments [91]. LAC also faces an elevated risk profile for pandemics because of several factors, including climate change and human migration [92,93]. (We note, however, that the relationship between weather and COVID-19 transmissions can be complex, and not every product of climate change necessarily raises the risk of transmission [58]. Recent work indicates prevention strategies should be instituted in the summer and fully implemented in the winter [59].)

In May 2020, LAC was declared the epicenter of the pandemic by the WHO, with over 40% of the world’s COVID-19 deaths and more than 6.5 million confirmed cases at the time [63]. Just 1 year later, in May 2021, the region recorded its one-millionth COVID-19 death, with almost 90% of the deaths occurring in 5 countries: Brazil (44.3%), Mexico (22.1%), Colombia (8.3%), Argentina (7.3%), and Peru (6.7%) [94]. At that time, of the 153.5 million COVID-19 vaccines administered in the Americas, only 21.6% came through LAC [94,95]. Through 2022 and 2023, difficulties in production, access, and equitable distribution among different countries within LAC limited COVID-19 vaccination success and exacerbated hesitancy and rejection [96]. Despite the relatively late arrival of COVID-19 to LAC, the region suffered disproportionately. Several factors emerged as key determinants of the region’s hardship, including pandemic unpreparedness, fragile health care systems, socioeconomic inequalities, and poor governmental support [97,98]. Ultimately, LAC suffered the largest death toll from COVID-19 across developing regions and 1 of the sharpest declines in economic activity, with expected long-lasting socioeconomic consequences for the region [99].

LAC was economically vulnerable when the pandemic hit, due to limited fiscal resilience after the 2008 worldwide recession [86]. In 2020, the region experienced a historic 7% contraction in the GDP, with many countries seeing over a 10% economic decline [86,100]. This contraction was the largest in the region’s history [101]. Although modest growth was observed in 2021 and 2022 (6.9% and 3.5%, respectively), the International Monetary Fund projected a slowdown to 1.7% in 2023, largely due to inflation caused by interest rate hikes and fiscal policies [100]. Challenges included worsening inequality, higher poverty rates, and impacts on labor income, particularly among the extremely poor [102-106]. Major economic challenges anticipated for LAC in the years ahead include lingering effects of the pandemic in the setting of increased energy and food prices, which are mostly due to Russia’s invasion of Ukraine and China’s economic slowdown [100]. Even as the region rebounded, poverty rates remained high and continued to rise in 2022 [107,108]. Labor income, accounting for 68% of income among impoverished households, saw significant drops, particularly among the extremely poor [109].

LAC was especially burdened by sociopolitical unrest during the pandemic, in large part due to preexisting increases in authoritarian practices, weak democratic institutions, politicized judicial systems, and high levels of organized and unorganized crime and violence [100]. The region experienced a disproportionate number of political and public health threats, most notably the assassination of Haiti’s president in a coup d’état, followed by a devastating earthquake that effectively eliminated any remnants of the public health infrastructure [110,111]. COVID-19 was eclipsed by the outbreak of violence, cholera, and extreme poverty [112]. Other political turmoil included significant demonstrations in Brazil repeatedly protesting former President Jair Bolsonaro and his far-right administration’s handling of the pandemic, which included promotion of unscientific theories and pandemic denialism [113-116]. Intense protests also occurred in Cuba, Chile, Bolivia, and Colombia, with the average growth rate of the number of protests in LAC marked at 5.84% compared to a worldwide rate of 1.15%, according to the United Nations Development Program [97,117]. Given previously described socioeconomic issues, protests in LAC were also markedly intersectional, with examples including regular violent demonstrations in Colombia over both pandemic-related restrictions and police brutality and unpopular tax reform at the time [118]. Overall, in the region, as a result of unpopular policies and social unrest, a widespread anti-incumbent electoral trend was observed, starting in 2020 [100].

**Policies Implemented to Control and Mitigate the Transmission of COVID-19**

Much of the LAC COVID-19 response was spearheaded by the WHO’s Pan American Health Organization (PAHO). PAHO efforts included building the COVID-19 Genomic Surveillance Regional Network, which provided the region a way to track the evolution of COVID-19 and monitor new variants and pathogens with pandemic potential [119]. PAHO also deployed extra COVID-19 support personnel and equipment to weaker regional health systems, notably in Venezuela, Bolivia, Paraguay, Guyana, Nicaragua, Honduras, Guatemala, Haiti, and some of the smaller Caribbean island states [120]. Throughout the pandemic, PAHO emphasized a multisectoral approach that included school closures, teleworking, hospital readiness assessments, and increased testing capabilities [120-124].

Specific countries’ public health responses to the early pandemic included Chile implementing a nightly curfew, with many large cities soon establishing mandatory quarantine measures [125]. After the first case was reported in Costa Rica on March 6, 2020, the country’s National Emergency Commission enabled systematic and interinstitutional mobilization of resources, as well as the activation of emergency operation centers [125]. After community transmission was identified on March 26, 2020, in Mexico, the country introduced mandatory restrictions that included suspending classes in all public and private schools, enforcing stay-at-home orders, cancelling public and private events, banning meetings of more than 100 people, and...
self-quarantining among disease contacts for at least 15 days [125]. Upon the declaration of a state of national emergency in Peru on March 15, 2020, strict controls were placed on citizens’ movements, with only trips related to the purchase of food and medicines allowed and only workers from critical sectors permitted to commute [125].

The WHO encouraged countries in LAC to deploy a phased vaccine introduction that prioritized frontline and health care workers, as well as older adults and people with underlying health conditions [126]. Vaccine introduction and administration, which began in the region at the end of December 2020, varied widely by country both initially and throughout the pandemic despite various organizational efforts to ensure equitable access [126,127]. Internal vaccine research and development in LAC was minimal compared to the rest of the world, with no development spearheaded by any LAC nations [128]. The largest scientific contribution, as measured by published COVID-19 vaccine research manuscripts, was made by Brazil, which contributed one-third of the region’s papers regarding vaccine efficacy and safety [128]. Vaccination campaigns were a critical tool in the pandemic because vaccines were highly effective in reducing the probability of death, and population level fatality rates are partly a function of the percentage of the population vaccinated [62,129,130].

In October 2022, PAHO’s director reassured the region that disease trends insinuated a potential transition of the pandemic from an acute phase to a phase of sustained control [100]. Through 2022, the United States donated over 70 million COVID-19 vaccines to LAC directly and via the COVID-19 Vaccines Global Access (COVAX) partnership, with top recipients including Mexico (16.9 million doses), Guatemala (8.5 million doses), and Colombia (7 million doses) [100,131,132]. Larger agreements and agencies such as COVAX relied on a variety of vaccine types, mainly including messenger RNA (mRNA)–based vaccines (Pfizer-BioNTech, Moderna) and viral vector vaccines (Oxford University-AstraZeneca, Johnson & Johnson, Sputnik V) [133-135]. The lowest vaccine rates were observed in Haiti, with just over 2% of its population fully vaccinated by December 2022 [100]. Additional countries with vaccination rates below 40% included Grenada, Jamaica, St Lucia, and St Vincent and the Grenadines [100].

As the pandemic continued, new light was shed on the effect of LAC migrant crises on public health and vaccination policies [136]. Venezuela was deeply impacted [137,138]. By August 2022, more than 6.8 million Venezuelans fled the country due to political, social, and economic turmoil in what is now considered the largest international displacement in LAC in contemporary history [136]. Most Venezuelan refugees remained in LAC, with Argentina, Brazil, Chile, Colombia, Ecuador, and Peru having absorbed 75% of the migrants [139]. In addition to placing severe socioeconomic strain on recipient countries, the massive refugee influx also increased communicable disease spread and created new public health obstacles. For COVID-19, these challenges included ensuring access to vaccinations [136]. For example, most countries required government-issued identification to access COVID-19 vaccinations, which almost no refugees possessed upon arrival [136,140]. Colombia was 1 of few countries to eventually extend COVID-19 vaccine access to migrants with irregular immigration status, including those without documentation, and did so in October 2021 [136]. Meanwhile, many LAC leaders, including Colombian President Iván Duque Márquez and Venezuelan President Nicolás Maduro, blamed the constant flux of migrants throughout LAC for upsurges in COVID-19 cases [137]. In addition to questionable vaccine access, 75% of displaced Venezuelans in Peru and 39% in Colombia believed they would not be able to access health care if they became ill with COVID-19 [136].

At the end of the pandemic, to the best of our knowledge, barring Haiti due to the paucity of testing and reporting [141,142], the highest COVID-19 mortality rate in the region was in Peru, followed by Chile, Brazil, Trinidad and Tobago, and Argentina [100]. Despite accounting for just 25% of the world’s total COVID-19 case volume, LAC accounted for 43% of total deaths [119]. Major gaps in technical capacity, medical care coordination, and information technology infrastructure (many areas do not have infrastructure to support digital health systems and still rely on a pen-and-paper medical record system) were retrospectively highlighted as key reasons why LAC experienced such catastrophic spread and burden of COVID-19 [143,144]. In addition to these improvements, the region will focus on comprehensive disease surveillance strategies and methods to mitigate collateral damage on public health and social services during similar future crises [98].

**Limitations**

COVID-19 data had become less frequently reported around the world by the time the WHO declared an end to the pandemic [145]. Additionally, more people began to use at-home tests as the pandemic evolved [146]. Some countries, such as Argentina, appear to have stopped reporting novel COVID-19 cases altogether. Viral specimen tests for VOCs in GISAID are also dependent on testing and sequencing capacity, which varied by country across the region. Because the enhanced surveillance metrics of the speed, acceleration, jerk, and 7-day persistence are based on rates, not total counts, statistical bias caused by countries dropping in or out of the sample is mitigated, but to the extent that a nonincluded country is unrepresentative of the region in the disease burden, the omission of a country or territory can still influence historical data comparisons. The dynamic panel estimates are based on a 120-day window, which further limits intertemporal biases caused by changes in reporting. Still, data availability is always a limitation. Continued reports on COVID-19 transmissions after mid-May 2023 would provide additional insight to whether COVID-19 had by then truly shifted from pandemic to endemic status. This team did not believe transmissions data were sufficiently available to draw firm conclusions beyond that time point.

**Conclusion**

The concern about potential resurgence of the virus is valid. As long as COVID-19 continues to spread and mutate, the possibility of new variants emerging remains. Variants could potentially be more transmissible, resistant to vaccines, or cause more severe illness. This underlines the importance of continued vigilance, vaccination efforts, and worldwide cooperation to control the spread of the virus [54].
LAC experienced a high COVID-19 disease burden in the early stages of the pandemic. To prepare for future pandemics, one of the most important lessons from across the world may lie in the ways to reduce the disease burden ahead of the dissemination of vaccines and treatment modalities [147]. On that front, rapid and widespread testing of individuals, coupled with an epidemiological task force and contact-tracing system, is an effective first line of defense [148]. Lockdown policies have also proven effective [149], perhaps in part because international trade is positively associated with COVID-19 transmissions [61]. (As with climate change and transmissions, the relationship between containment policies and transmissions can be complex, and stricter containment may not always imply fewer transmissions [150,151].) Finally, new technologies will always renew the potential to improve early surveillance methods [152-154].

One bright point for LAC and other regions has been an advance in regional cooperation to tackle the public health threat posed by novel pathogens [155,156]. Novel indicators of pandemic preparedness at the regional level might further identify countries in relative need of support [157]. Measures of general governance, for example, are positively correlated with vaccination rates [60]. Recent work also suggests ways to reduce not only the death caused by novel pathogens but also the likelihood of their appearance, such as better surveillance of human and wildlife interaction and reductions in air pollution [158,159]. Continued cooperation will be necessary to reduce both the likelihood and impact of future pandemics [160,161].

Abstract

Background: Wireless emergency alerts (WEAs), which deliver disaster information directly to individuals’ mobile phones, have been widely used to provide information related to COVID-19 and to encourage compliance with social distancing guidelines during the COVID-19 pandemic. The floating population refers to the number of people temporarily staying in a specific area, and this demographic data can be a useful indicator to understand the level of social distancing people are complying with during the COVID-19 pandemic.

Objective: This study aimed to empirically analyze the impact of WEAs on the floating population where WEAs were transmitted in the early stages of the COVID-19 pandemic. As most WEA messages focus on compliance with the government’s social distancing guidelines, one of the goals of transmitting WEAs during the COVID-19 pandemic is to control the floating population at an appropriate level.

Methods: We investigated the empirical impact of WEAs on the floating population across 25 districts in Seoul by estimating a panel regression model at the district-hour level with a series of fixed effects. The main independent variables were the number of instant WEAs, the daily cumulative number of WEAs, the total cumulative number of WEAs, and information extracted from WEAs by natural language processing at the district-hour level. The data set provided a highly informative empirical setting as WEAs were sent by different local governments with various identifiable district-hour-level data.

Results: The estimates of the impact of WEAs on the floating population were significantly negative (−0.013, P=.02 to −0.014, P=.01) across all specifications, implying that an additional WEA issuance reduced the floating population by 1.3% (=100(1−e−0.013)) to 1.4% (=100(1−e−0.014)). Although the coefficients of DCN (the daily cumulative number of WEAs) were also negative (−0.0034, P=.34 to −0.0052, P=.15) across all models, they were not significant. The impact of WEAs on the floating population doubled (−0.025, P=.02 to −0.033, P=.005) when the first 82 days of observations were used as subsamples to reduce the possibility of people blocking WEAs.

Conclusions: Our results suggest that issuing WEAs and distributing information related to COVID-19 to a specific district was associated with a decrease in the floating population of that district. Furthermore, among the various types of information in the WEAs, location information was the only significant type of information that was related to a decrease in the floating population. This study makes important contributions. First, this study measured the impact of WEAs in a highly informative empirical setting. Second, this study adds to the existing literature on the mechanisms by which WEAs can affect public response. Lastly, this study has important implications for making optimal WEAs and suggests that location information should be included.

Introduction

The frequency of disasters and the scale of the damage have increased dramatically over the decades. Natural disasters related to climate, weather, or water hazards have increased more than 5-fold over the past 50 years. Such incidents have resulted in approximately 115 casualties and US $202 million in damage per day [1]. Likewise, man-made disasters, including criminal attacks (eg, shooter incidents and terrorist attacks), human-based technological incidents (eg, building or bridge collapses), and events related to the manufacture, transportation, storage, and use of hazardous materials, have also increased significantly over the past 50 years. Moreover, the number of occurrences was estimated to have increased 6-fold or more, whereas the amount of damage increased by approximately 189 times [2].

Along with a significant number of disasters, the importance of wireless emergency alerts (WEAs) to rapidly deliver disaster information is emphasized. Many countries, including the United States, Japan, and South Korea, have adopted WEAs as a disaster information delivery system channel. This is because WEAs operate as a cell broadcast service (CBS) system that can send messages to multiple mobile phone users in a defined area simultaneously. Information is delivered directly to an individual’s cell phone; hence, it can be easily accessed through an individual’s mobile phone without the hassle of searching.

WEAs have been actively used to prevent the spread of COVID-19 since early 2020 [3]. In the United States, Utah and Massachusetts have issued WEAs reminding the populace of safety rules related to COVID-19 [4,5]. In New Zealand, WEAs were sent to mobile phone users across the country in the name of the National Emergency Management Agency [6]. Taiwan also used a cell-based mass texting system known as the Public Warning CBS to share information on COVID-19 [7].

One of the most efficient ways to respond to a disaster situation is to evacuate people from the danger zone to a safer location. Therefore, it is necessary to monitor changes in the flow of public movement, including the floating population, among the various public responses that occur during such disasters. Along with the growing frequency of disasters, there is increasing demand for countries or local governments to examine the impact of WEAs, as it could be one of the solutions to prevent severe damage from emergent events. WEAs are an information delivery channel optimized for this purpose, enabling people in a specific area to receive disaster notifications on their cell phones and prompting them to evacuate. Therefore, analyzing the relationship between the issuance of WEAs and the size of the floating population in a given area is the most intuitive and effective way to measure the policy performance of sending WEAs, which provides important implications for developing future policies. However, little is known about the impact of WEAs on people’s behavior because granular data sets of the focal outcome variable at various regions and short-time levels are unlikely to be available (eg, the real-time population at a specific time in a particular region). Only a few studies have examined the impact of WEAs, and they focused on either the impact of a single region [8] or simply compared the delivering and nondelivering regions [3].

We empirically investigated the associations between WEAs and the floating population in 25 districts in Seoul, the largest metropolis in South Korea, in the early stages of the COVID-19 pandemic for 13 months, from January 2020 to January 2021. The floating population denotes the transient influx of individuals within a defined area, and this metric serves as a pivotal indicator, offering perspectives on the adherence to social distancing protocols during the COVID-19 pandemic. As most WEA messages focus on compliance with the government’s social distancing guidelines, we can safely say that the goal of transmitting WEAs during the COVID-19 pandemic is to control the floating population at an appropriate level.

Methods

Data Set

In May 2005, the South Korean government established a nationwide WEA transmission system for the first time in the world, and since 2013, the WEA reception function has been mandatory for all mobile phones. WEAs operate as a CBS system, a method of simultaneously sending messages to multiple mobile phone users in a defined area. CBS is a one-to-many geo-targeted and geo-fenced messaging service, unlike SMS.

Since the establishment of the WEA transmission system, only the central government has had the authority to send WEAs, but this authority was extended to local governments in 2019 with an amendment to the relevant law. Since then, local governments have sent WEAs related to natural disasters, such as storms, floods, conflagrations, and other issues in their jurisdictions. WEA sending standards and the composition of contents are the subjects of the authority’s autonomy. Unlike WEAs sent by the central government, those from the local governments are sent only to their jurisdictional areas.

We have collected 6442 WEAs sent by each local government in the designated district (Gu—administrative district in Seoul, and there are 25 of them) in Seoul for 13 months from January 2020 to January 2021. Detailed WEAs were extracted from the “Public Data Portal” built by the Ministry of the Interior and Safety of the South Korean government. The empirical period covers the early stage of the COVID-19 pandemic in South Korea.

To investigate what kind of information should be included in the WEAs, we extracted information from the WEAs using natural language processing. The first information extracted from WEAs was whether or not the WEAs contained location information. The second indicated whether the WEAs had up-to-date information. The third indicated whether the WEAs had information on hand (eg, number of confirmed cases). The
final one indicated whether the WEAs had disease information (eg, detailed information on COVID-19).

For the dependent variable, we used the estimated floating population provided by SK Telecom, which has the largest number of subscribers in South Korea, at the district-hour level during the same period. We summarized the materials that aid in the understanding of our dependent and independent variables in Multimedia Appendix 1.

**Empirical Model**

We specified our empirical model at the region-hour level as follows:

\[
\text{Dependent variable} = \beta_0 + \beta_1 N_{it} + \beta_2 DCN_{it} + \beta_3 TCN_{it} + \beta_4 X_{it} + \sum \gamma_j \text{Fixed effects} + \epsilon_{it}
\]

where \( \text{Dependent variable} \) denotes the dependent variable in district \( i \) at time \( t \); \( N_{it} \) indicates the number of WEAs in district \( i \) at time \( t \); \( DCN_{it} \) indicates the daily cumulative number of WEAs in district \( i \) until time \( t \) (excluding the number of WEAs at time \( t \)); \( TCN_{it} \) indicates the total cumulative number of WEAs in district \( i \) until time \( t \) since January 1, 2020; \( X_{it} \) indicates the information extracted from WEAs with natural language processing; and \( \sum \gamma_j \) indicates the group of fixed effects that includes district-fixed effects, time-fixed effects, and joint district and time-fixed effects. To control the effect of unobservable factors (eg, daily work commute), we included these granular factors, weekday, and hour-fixed effects. This specification alleviated the concern about controlling unobservable factors that could affect the floating population.

The dependent variable was the floating population at time \( t \) in district \( i \). We specified continuous variables in logarithms since they have a skewed distribution (eg, \( \ln N_{it} \) and \( \ln TCN_{it} \)). As appropriate, we added 1 to the variables to avoid logarithms of 0. Table 1 shows the distribution of \( N \) and \( DCN \) during the day. The first column represents 24 hours. For instance, 0 indicates a period from midnight to 1 AM. The second and third columns represent the average \( N \) (in gray) and \( DCN \) (in light gray) across 25 districts. As shown in Table 1, \( DCN \) increased over time during a day as \( N \) accumulated. On average, people received 0.65 WEAs daily, and the peak time was 6 PM. Tables 2 and 3 report the summary statistics and correlations of the variables. Most of the correlations are significant (\( P<.001 \)) except for a correlation between floating population and number of WEAs with order information, as shown in Table 3. The correlations between each variable were mostly at a modest level, and considering our sample size (the number of observations in the analysis is 236,775), we concluded that each variable had different variations. We used the ordinary least squares method to estimate the unknown parameters of our empirical model.

Various types of information were sent through WEAs, and natural language processing techniques were used to extract and identify them. Sentences in WEAs were stemmed through a morphology analyzer named “Mecab” and “Okt tagger” in KoNLPY, an open-source Korean language processing package. After classifying common nouns, proper nouns, adjectives, and verbs through the morphology analyzer, informative words were extracted by specifying a list for the exclusion of stopwords and out-of-vocabulary words in advance. The type of information included in the WEAs was identified by classifying the extracted words according to a predetermined semantic standard (named entity recognition; NER). We used the NER application programming interface (API) of the AI API/Data service provided by the Electronics and Telecommunications Research Institute, Korea; this API is known to have a high performance of 89.4% in Korean NER [9].

f TCN: the total cumulative number of WEAs in a specific district since January 1, 2020, the beginning of the observation period.

Ethical Considerations

To compile the data set used in this study, publicly available information was collected through the Ministry of the Interior and Safety of the Republic of Korea. We received confirmation of exemption from the Public Institutional Bioethics Committee designated by the Ministry of Health and Welfare of the Republic of Korea (P01-202309-01-043).

Results

Parameter estimates of our empirical model are shown in Table 4. We included district, weekday, hour, and joint district-hour fixed effects in all regressions.

As shown in the first row of Table 4 (N), the estimates were significantly negative across all models, implying that when people received WEAs, the floating population decreased. Based on the estimate in column 2, one increase in WEA was related to a reduction of the floating population by 1.3% (100(1 – e−0.013)). Other specifications yielded similar results, ranging from 1.3% (100(1 – e−0.013)) to 1.4% (100(1 – e−0.014)). Although the coefficients of DCN were also negative across all models and related to a reduction of the floating population from 0.34% (100(1 – e−0.0034)) to 0.52% (100(1 – e−0.0052)), they were insignificant. To check the impact of cumulative WEAs, we incorporated the TCN into the main specification, as shown in column 2 of Table 4. The results show that cumulative WEAs were also negatively correlated with the floating population. We replaced TCN with TCC (total number of confirmed cases of COVID-19) and Day (daily time trend) to check the robustness and summarize the results in columns 3 and 4 of Table 4, respectively. We used the variables related to TCN, TCC, and Day separately due to their high correlation (0.963 between log (TCN) and log (TCC); 0.902 between log (TCN) and log (Day); and 0.899 between log (TCC) and log (Day)). As shown in columns 3 and 4, TCC and Day had negative impacts on the floating population, like TCN.

We conducted several robustness checks with subsamples and different specifications. The results of the robustness checks were consistent with our main findings. Subsequently, we performed 2 falsification tests, and we found that our results did not hold when using incorrect variables in terms of district and timing. Detailed information and results of the robustness checks and falsification tests are summarized in Multimedia Appendix 2.
Table 4. Parameter estimates of the main empirical model: panel regression model using wireless emergency alerts (WEAs) and the floating population at the district-hour level with a series of fixed effects.

Discussion

Principal Results

This study empirically measured the association between the details of issuing WEAs and the granular region-hour-level estimated floating population changes in 25 districts in Seoul, South Korea. We used variations in the number and content of WEAs independently managed by local authorities to empirically measure the WEAs’ impact. By estimating a panel-data model with a series of fixed effects, we found robust evidence that issuing WEAs was related to the reduction of the floating population in districts of Seoul. A collection of robustness and falsification tests showed that our findings were robust. Furthermore, we found that location was the only significant type of information among various types extracted from WEAs that was associated with a decrease in the floating population.

The information necessary for disaster response must be delivered promptly and accurately to overcome disaster situations. WEAs, which deliver disaster information directly to the recipients’ mobile phones, have become a major means of providing disaster information. One of the most efficient ways to respond to a disaster situation is to evacuate people from dangerous areas to safe locations. Therefore, a major objective of issuing WEAs is to control or reduce the floating population in hazardous areas to an appropriate level. These policy objectives gained further prominence during the COVID-19 pandemic, as the primary content of WEAs at the peak of the pandemic emphasized practicing social distancing and avoiding densely populated areas. Hence, an intuitive approach to measuring the impact of WEAs is to examine the relationship between the number of WEAs sent and the size of the floating population in a given area. Our empirical data set was ideal for this study due to the following reasons: (1) The data set provided a highly informative empirical setting to measure the impact of WEAs, as different local governments sent WEAs with various region-hour-level data in districts of Seoul, which are identifiable; (2) The data set contained granular information on floating populations with various region-hour–level data, which were compatible with the WEA data set; (3) WEAs are mandatory for mobile users; and lastly, (4) the empirical data set fully covered the COVID-19 pandemic in South Korea after the first confirmed case was reported, which provides us with a clear impact in a long-enough range. Overall, our empirical data were ideal for studying our research question.

This study makes several contributions. First, this study offers new empirical evidence on the impact of WEAs, advancing previous research that mainly relied on hypothetical scenario surveys due to limited WEAs and challenges in identifying key variables [10-12]. Earlier studies, particularly those examining COVID-19, faced difficulties in robust statistical analysis and data collection reflecting public responses [3,13]. Unlike previous work that focused on a few regions or solely on the...
number of WEAs, this study stands out by analyzing variations in the number and content of WEAs across different regions due to the regions’ independent authorities issuing them [8].

Second, this study provides a plausible mechanism for how WEAs can reduce other focal outcomes, such as the numbers of infections and deaths [3], which remain unclear. Previous studies revealed that population density has a strong correlation with the number of infections and deaths from COVID-19 [14-17]. Transmitting WEAs reduces the floating population in the area where WEAs are sent and consequently reduces the confirmed COVID-19 cases and deaths.

Lastly, this study provides important implications for developing a policy on making optimal WEAs to prevent national disasters or pandemics, which suggests that location information should be highlighted rather than other information (eg, date and general information).

Limitations
This study has some limitations due to technical issues with the WEA system and the difficulty in obtaining data sets. This study observed the relationship between the transmission history of WEAs in districts and the change in the floating population. However, we could not confirm whether the people who received WEAs moved to a safe place, which makes it hard to argue for a causal relationship. To supplement this limitation, we require an additional data set that can check the WEA confirmation time and movement history through personal-level mobile phone log records.

We used the estimated floating population provided by SK Telecom as a dependent variable. However, it is worth noting that while SK Telecom has the largest number of subscribers, with a market share of 44.3% as of 2021 [18], the floating population they estimated and provided may have differed from the actual floating population. We conducted an additional analysis using the floating population provided by the Seoul local government as the dependent variable, and the results are summarized in Multimedia Appendix 2. The implications of this study remained consistent even when analyzed with an additional data set.

This study focused on WEAs and the floating population of 25 districts in Seoul, the capital and largest city of South Korea. For a more generalized conclusion about the effectiveness of WEAs, it is necessary to expand and analyze the data set to include more regions in future studies.

WEAs can be blocked by changing mobile phone settings; in that case, the impact of transmitting WEAs on behavioral responses may vary. Nevertheless, due to technical constraints, the government cannot collect data on the rate of WEA blocking. The WEA sending system should be developed so that the WEA reception or blocking rate can be aggregated and used for policy formulation.

Conclusions
This study analyzed the impact of WEAs sent in the 25 districts of Seoul on changes in the floating population in those areas, using the fact that the content of the WEAs sent during the COVID-19 pandemic was focused on compliance with social distancing guidelines. The results showed that issuing WEAs and distributing information related to COVID-19 to a specific district in Seoul, South Korea, was related to the reduction of the floating population of that district. Furthermore, among the 4 types of information (location, date, order, and disease) in the WEAs, location information was the only significant type that was associated with a decrease in the floating population. Contrasting with previous studies that could not generalize findings by using hypothetical survey results or analyzing WEAs and the floating population in a single region, this study empirically elucidates the impact of WEAs on public behavior by examining the number and content of region-hour–level messages sent by 25 districts with independent dispatch authority, along with the corresponding changes in the floating population.

Our findings provided a plausible mechanism by which WEAs could effectively suppress infectious diseases by providing clues that transmitting WEAs was related to the reduction of the floating population during the COVID-19 pandemic. Our findings focused on a correlational relationship rather than a causal one, as we were unable to observe whether people who received WEAs moved to safer places.

We hope that this research will spur further investigation into the sophisticated measurement of WEA impact and the establishment of disaster response systems.

Abstract

Background: Healthy Davis Together was a program launched in September 2020 in the city of Davis, California, to mitigate the spread of COVID-19 and facilitate the return to normalcy. The program involved multiple interventions, including free saliva-based asymptomatic testing, targeted communication campaigns, education efforts, and distribution of personal protective equipment, community partnerships, and investments in the local economy.

Objective: This study identified demographic characteristics of individuals that underwent testing and assessed adherence to testing over time in a community pandemic-response program launched in a college town in California, United States.

Methods: This study outlines overall testing engagement, identifies demographic characteristics of participants, and evaluates testing participation changes over 4 periods of the COVID-19 pandemic, distinguished by the dominant variants Delta and Omicron. Additionally, a recurrent model is employed to explore testing patterns based on the participants’ frequency, timing, and demographic characteristics.

Results: A total of 770,165 tests were performed between November 18, 2020, and June 30, 2022, among 89,924 (41.1% of total population) residents of Yolo County, with significant participation from racially or ethnically diverse participants and across age groups. Most positive cases (6351 of total) and highest daily participation (895 per 100,000 population) were during the Omicron period. There were some gender and age-related differences in the pattern of recurrent COVID-19 testing. Men were slightly less likely (hazard ratio [HR] 0.969, 95% CI 0.943-0.996) to be retested and more likely (HR 1.104, 95% CI 1.075-1.134) to stop testing altogether than women. People aged between 20 and 34 years were less likely to be retested (HR 0.861, 95% CI 0.828-0.895) and more likely to stop testing altogether (HR 2.617, 95% CI 2.538-2.699). However, older age groups were less likely to stop testing, especially those aged between 65-74 years and 75-84 years, than those aged between 0 and 19 years. The likelihood of stopping testing was lower (HR 0.93, 95% CI 0.889-0.976) for the Asian group and higher for the Hispanic or Latino (HR 1.185, 95% CI 1.148-1.223) and Black or African American (HR 1.198, 95% CI 1.054-1.350) groups than the White group.

Conclusions: The unique features of a pandemic response program that supported community-wide access to free asymptomatic testing provide a unique opportunity to evaluate adherence to testing recommendations and testing trends over time. Identification of individual and group-level factors associated with testing behaviors can provide insights for identifying potential areas of improvement in future testing initiatives.

**Introduction**

The COVID-19 pandemic presented major challenges and demanded effective public health responses involving sustained behavior change, stay-at-home restrictions, face coverings, testing, and vaccination. Public health guidelines are a critical first line of a pandemic response but rely on compliance with evolving recommendations and restrictions. Trust and compliance are driven by complex factors, including individuals’ beliefs [1], risk perception [2,3], trust in government [4], and demographic factors [5-7] that may vary throughout a pandemic, making containment particularly challenging.

Widespread testing and timely diagnosis are critical for pandemic control and preparedness. The deployment of clinical testing on a massive scale (“mass testing” [8]) was one of the essential control measures for curtailing the burden of the COVID-19 pandemic, particularly during its early phases [9]. Early detection of cases can limit viral transmission by isolation, quarantine, and contact tracing [10-12]. New preventive and surveillance mechanisms emerged throughout the pandemic, including vaccine programs, wastewater surveillance [13], and at-home COVID-19 tests [14]. Both the virus itself and protective behaviors changed throughout the waves of the pandemic [1], complicating long-term interventions. Government and public health officials implemented health contingencies that were adaptable and flexible to reduce socioeconomic and long-term health burden fatigue [15,16].

Understanding how people’s adherence to preventive measures changes over time can guide policy makers as they amend strategies to revitalize public health strategies in future outbreaks. Studies of previous natural disasters suggest that people’s perceptions of risk and their responses to such risk may vary between individuals. Gender, age, socioeconomic status, personal experience of a natural hazard, and trust in authorities affect people’s responses to catastrophic events [6,17,18]. For the COVID-19 pandemic, a growing body of research reported factors associated with adherence and nonadherence to COVID-19 preventive measures [1,19-21]. Specifically, age [5], gender [6,7], higher education level [22], marital status, and having children [23] are all associated with adherence measures.

Healthy Davis Together (HDT) [24] was a program implemented in the city of Davis, California, as an effort to mitigate the spread of COVID-19 and facilitate the return to normalcy. Launched in September 2020, HDT focused on curtailing the pandemic burden among Davis residents and workers. In July of 2021, the program was expanded to support residents of the wider Yolo County in a rebranded effort, Healthy Yolo Together (HYT). It employed a multipronged approach, including engaging the community, implementing effective testing and contact tracing measures, promoting health education, and fostering collaboration with stakeholders.

HDT implemented comprehensive interventions that combined disease control measures and the promotion of health-conscious behaviors. Polymerase chain reaction (PCR) testing accessibility was enhanced with the establishment of new testing locations offering voluntary and complimentary SARS-CoV-2 testing. HDT engaged over 200 public health ambassador students dedicated to advocating for healthy behaviors. Mass communication campaigns were promoted across diverse media platforms to encourage testing and the adoption of health-promoting behavior. The program provided incentives to promote health-promoting behaviors. Collaborations were established with local businesses to implement and adjust safety protocols. The program fostered stronger partnerships among the university, city, county, and private and community organizations. In addition, HDT implemented citywide subsewer shed–level wastewater monitoring for early detection. The program maintained an analytical team tasked with real-time data analysis to pinpoint communities or specific locations requiring increased testing implementation. This analytical approach complemented the program’s health behavior strategies.

In this study, we thoroughly examine testing behavior within the HDT program, emphasizing patterns of testing throughout. We use regression modeling for recurrent events to characterize testing behavior within the HDT program. This method enables us to examine individual testing events and current testing over time, providing insights about the participants’ testing patterns and testing adherence throughout the program’s duration.

**Methods**

**Data Description**

Testing participation was aggregated and subdivided into distinct periods according to the dominant variants Delta and Omicron: pre-Delta (November 18, 2020, to June 13, 2021), Delta (June 14, 2021, to December 20, 2021), Omicron (December 21, 2021, to March 15, 2022), and post-Omicron (March 16, 2022, to June 30, 2022). These periods were based on the most common disease control measures and the promotion of health-conscious behaviors. Polymerase chain reaction (PCR) testing accessibility was enhanced with the establishment of new testing locations offering voluntary and complimentary SARS-CoV-2 testing. HDT engaged over 200 public health ambassador students dedicated to advocating for healthy behaviors. Mass communication campaigns were promoted across diverse media platforms to encourage testing and the adoption of health-promoting behavior. The program provided incentives to promote health-promoting behaviors. Collaborations were established with local businesses to implement and adjust safety protocols. The program fostered stronger partnerships among the university, city, county, and private and community organizations. In addition, HDT implemented citywide subsewer shed–level wastewater monitoring for early detection. The program maintained an analytical team tasked with real-time data analysis to pinpoint communities or specific locations requiring increased testing implementation. This analytical approach complemented the program’s health behavior strategies.

In this study, we thoroughly examine testing behavior within the HDT program, emphasizing patterns of testing throughout. We use regression modeling for recurrent events to characterize testing behavior within the HDT program. This method enables us to examine individual testing events and current testing over time, providing insights about the participants’ testing patterns and testing adherence throughout the program’s duration.

**Methods**

**Data Description**

Testing participation was aggregated and subdivided into distinct periods according to the dominant variants Delta and Omicron: pre-Delta (November 18, 2020, to June 13, 2021), Delta (June 14, 2021, to December 20, 2021), Omicron (December 21, 2021, to March 15, 2022), and post-Omicron (March 16, 2022, to June 30, 2022). These periods were based on the most common variant reported by the California Department of Public Health [25] (Figure 1). Hereafter, the Delta B.1.617.2, Omicron B.1.1.529, and subsequent Omicron BA.2, BA.3, BA.4,266, and BA.5 variants will be referred to as Delta, Omicron, and post-Omicron, respectively. During the pre-Delta period, HDT primarily served the city of Davis. Subsequently, at the onset of the Delta variant in July 2021, testing access was extended to encompass Yolo County as a whole.
Figure 1. Tests performed per 100,000 population (light blue) and positive test rates (dark blue) daily from November 18, 2020, to June 30, 2022. Free asymptomatic testing was accessible to Yolo County residents in July 2021. Vertical lines mark 4 distinct periods characterized by dominant SARS-CoV-2 variants.

Yolo County has an estimated population of 218,774 individuals, with 106,002 males and 112,772 females. Among them, approximately 68,640 reside in the city of Davis. Throughout the program, 770,165 tests were administered to 89,924 unique individuals, including 53,869 residents of the city of Davis. A significant number of participants in Davis were linked to the University of California, Davis. The university enforced weekly testing mandates starting in the fall of 2020 for those who were physically present on campus.

HDT program participants were given a unique ID, which allowed us to distinguish between new and returning individuals. An individual can be classified as a unique participant for a specific period (eg, Delta) if they underwent testing at least once during that period, regardless of whether they were also tested during another period. However, for the overall program analysis, each participant was counted only once, regardless of how many times they were tested across multiple periods. New participants are individuals who underwent testing for the first time. Total tests refer to the overall number of tests conducted within a specific period or in total. Positive tests denote the total count of tests yielding a positive result, distinct from participants with a positive result, which indicates the number of individuals who had at least one positive test during a specified period.

Ethical Considerations
This study used deidentified data and received an exemption from institutional review by the University of California Davis Office of Research.

Diagnostic Tests
Saliva tests were conducted using an innovative high-throughput quantitative reverse transcriptase–PCR method [24]. Most tests (98.4%) comprised of saliva tests while the remaining 1.6% consisted of BinaxNOW (Abbott) rapid antigen tests administered to symptomatic individuals. Employing saliva samples for quantitative reverse transcription PCR tests enhances the feasibility of widespread asymptomatic testing in the community, as it incurs lower monetary and labor costs with only a slight decrease in sensitivity [26].

Statistical Models
We used regression modeling for recurrent events to analyze testing behavior, given that participants underwent multiple tests at irregular intervals. This modeling framework facilitates the analysis and interpretation of testing recurrence, providing insights into factors influencing testing adherence, frequency, and consistency among participants. Additionally, trends, fluctuations, and potential predictors of testing behavior can be identified, offering insights for optimizing testing strategies, resource allocation, and public health interventions to promote regular and sustained testing participation. The reReg library in R (R Foundation for Statistical Computing) was used to analyze the temporal dynamics of testing behavior [27,28].

The regression Cox model for recurrent events extends the traditional Cox proportional hazards model, which is commonly used for analyzing time-to-event data in survival analysis, to handle recurrent event data. Additionally, this modeling framework enables the examination of covariate effects on the rate of event occurrence while properly addressing the correlation among recurrent events within the same individual. This model, also known as the Andersen-Gill model, can be represented as follows:

$$\lambda_i(t) = \lambda_0(t) \times \exp (\beta_1 X_{i1} + \beta_2 X_{i2} + ... + \beta_p X_{ip}) \quad (1)$$

where $\lambda_i(t)$ represents the hazard rate for individual $i$ at time $t$. $\lambda_0(t)$ is the baseline hazard rate at time $t$. $\beta_1, \beta_2, ..., \beta_p$ are the regression coefficients associated with the covariates $X_{i1}, X_{i2}, ..., X_{ip}$.

https://publichealth.jmir.org/2024/1/e48784
of the baseline hazard rate and the covariates, with the regression coefficients determining the impact of the covariates on the hazard rate. We assumed noninformative censoring, suggesting that the reasons people decided to take part in testing during the program are not related to why they might eventually stop testing altogether.

**Mean Cumulative Function**

The Mean Cumulative Function (MCF) denotes the expected cumulative count of tests up to a specific time point, considering both the occurrence and timing of test events. The MCF was calculated by age and racial or ethnic groups. We also apply the terminal event process Cox model to examine the occurrence of complete cessation of testing while accounting for covariates.

**Data Preprocessing**

For this study, individuals who undergo COVID-19 testing at least once a week are selected. Each selected individual is treated as a single event, even if they receive multiple tests within the same week. This study includes 61,363 participants who have undergone testing on at least 2 occasions (2 different weeks). The event for each participant begins with their first test and ends during the subsequent week of another test. A test occurrence is marked as 1, while the status remains 0 to signify ongoing participation. The final testing instance for each participant is identified, and the event of the subsequent week is marked as 0 to indicate a censoring event.

**Results**

**Description of Testing Trends**

HDT conducted 770,165 tests among 89,924 residents of Yolo County (approximately 41.1% of the Yolo population, 218,793), of which 53,869 individuals reported a zip code in the city of Davis (approximately 78.4% of Davis population, 68,710). Testing coverage was most significant in the city of Davis, where the program originated, and efforts were first focused. Figure 1 illustrates the total daily tests per 100,000 population and positive test rates observed in Yolo County throughout this study. On June 28, 2021, the positivity rate surged, likely because there were fewer tests reported on that day. Overall, 12,626 tests were positive among 11,545 unique individuals, for an aggregated test positivity rate of 1.64% and a case rate of 13%. The average daily number of tests conducted per 100,000 population was 422 (SD 210) during the pre-Delta period, 746 (SD 449) during Delta, 895 (SD 518) during Omicron, and 435 (SD 254) during the post-Omicron period. A summary of tests and positive cases per study period is reported in Table 1.

**Table 1. Summary of testing participation for each period of this study and overall.**

</table>

Total tests conducted, participation, recruitment, and positive test tallies across pandemic periods are displayed in Table 1. For instance, during pre-Delta, 191,904 tests were conducted, which corresponds to 24.9% (n=770,165) of the total tests conducted in the entire program. During Delta, 2570 positive cases were detected in new participants, corresponding to 22.3% (n=11,545) of the total of unique people who resulted as positive.

Changes in policy at the state and local level, social expectations and behavior, the emergence of new strains, and differences in the intensity of testing lead to differing participation rates across pandemic periods. In total, HDT or HYT served 89,924 unique individuals across the entire program. A total of 39,819 (44.3%) participated in testing during pre-Delta, 58,920 (65.5%) during Delta, 46,545 (51.8%) during Omicron, and 23,566 (26.2%) during the post-Omicron period. Further, 61,363 individuals, equivalent to 68.2% of all participants, took part in the testing process multiple times. A longer period of days did not mean a higher number of participants. The highest participation of people was during the Delta period.

Omicron had the highest number of positive cases despite being the shortest period in the program. Out of all positive cases,
6351 (50.3%) were observed during Omicron. On average, 1958 (SD 1333; \( \sim 895, \text{SD 518, tests per 100,000} \)) daily tests were performed at a test positivity rate of 3.81% (Table 1). The enrollment of new participants decreased with each subsequent period: 39,819 individuals were engaged in the first stage of the program (pre-Delta), 33,814 during Delta, 13,503 during Omicron, and 2788 during post-Omicron. Most positive tests (a total of 2080, 97.1%) were from new participants (Table 1).

HDT or HYT collaborated with multiple school districts in Yolo County to provide free weekly testing to students. Excluding participants under 19, there were 67,083 participants from the community; among them, 8774 (13%) individuals tested positive, and 422 (4.8%) had positive results in two or more weeks. Further, 265,000 (34.4%) underwent testing once, while participation ranged from 1 to 83 weeks, with a median of 7.5 (IQR 7) weeks. Figure 2A illustrates uptake in testing by individuals, showing the weeks they underwent testing and information on when everyone was initially tested. It is noticeable that at the beginning of each testing wave, there is typically a higher flux of new participants signing up each week. It also enables the observation of participants’ ongoing engagement throughout the program. Figure 2B illustrates the weeks in which an individual received at least one positive test result, showing a notable increase in positive cases during the Omicron wave. Figure 2C describes key measures implemented during the Healthy Davis Program, with color bars representing the seasons: winter (blue), spring (green), summer (yellow), and fall (orange).

Testing rates between male and female residents varied across 4 distinct periods and overall. Female participants underwent more testing compared to males. Participants aged 18 or younger were less involved in testing during the pre-Delta period but increased their participation during the Delta period. Individuals aged 19-34 years underwent more testing in the pre-Delta period when compared to the Delta and post-Omicron periods. Participants who identified as Hispanics or Latinos had lower participation rates in post-Omicron (Table S1 in Multimedia Appendix 1 [29]).
Demographic Characteristics of Test Participants

A total of 48,670 participants identified as female, making up 45.9% of the 106,034 estimated female population in Yolo County. Meanwhile, 39,524 were male, representing 35% of the 112,759 estimated male population in the county. Testing in all race or ethnic groups and age groups younger than 85 years exceeded 54,698 (25%) of Yolo County’s population (Figure 3). The lowest testing participation rate was observed among individuals aged older than 85 years. This is not unexpected, given that testing for participants aged 85 years and older was compulsory at congregate living facilities funded by Medicare or Medicaid, as part of several state-level testing initiatives. The highest overall test positivity rates were observed among individuals of American Indian or Alaska Native descent (7.6%), Native Hawaiian or Other Pacific Islander (5.6%), Latinos (4.5%), and people aged 20-44 years (20-34 years, 6.5%; 35-44 years, 6.9%).

Figure 3. Rates of tests conducted and positive cases by race or ethnicity and age in years for Yolo County. The light-blue bars represent the total population size for each group based on the Census Bureau 2020 data. Dark-blue bars correspond to the proportion of participants within each demographic group. Red bars correspond to participants with a positive test result.

Adherence to Testing

In a sample of 61,363 participants that tested during this study period, there were 652,232 tests, with an average number of 10.62 (SD 13) tests per individual, in a median follow-up time of 40 (IQR 41.5) weeks. The average number of tests observed per week (MCF) by age and racial or ethnic groups is described in Figure 4A. Participants between the ages of 0 and 19 years demonstrated more consistent engagement in testing compared to other age groups, maintaining a higher level of involvement throughout this study’s period. Participants identifying as multiracial exhibited higher levels of engagement in testing compared to those identifying as Hispanic, Latino, American Indian, or Alaska Native (Figure 4B). Throughout this study period, the average testing patterns remained consistent across various age and racial or ethnic groups.

Figure 4 illustrates the baseline cumulative rate function as the expected number of tests conducted up to a particular time point, independent of any covariates included in the model (Figure 5A). We also describe the baseline cumulative hazard function in recurrent tests, representing the expected cumulative number of tests occurring up to a specific time point, without considering any covariates or risk factors (Figure 5B). It provides a baseline estimate of testing occurrence over time.
Figure 5. Baseline cumulative hazard function ((A) expected cumulative tests occurring up to a specific time) and baseline cumulative rate function ((B) expected tests up to a specific time).

**Adherence to Testing**

The recurrent event analysis showed that male participants (HR 0.969, 95% CI 0.943-0.996) and individuals 85 years and older (HR 0.781, 95% CI 0.598-1.020) experienced lower adherence to testing compared to females and younger age groups (0-19 years), respectively (Table 2). Hispanic or Latino participants (HR 0.741, 95% CI 0.712-0.772) and American Indian or Alaska Native individuals (HR 0.735, 95% CI 0.567-0.953) experienced lower testing rates compared to individuals from other racial or ethnic groups.

**Discontinuation in Testing Participation**

Male participants showed a significantly higher risk of discontinuing testing compared to females (HR 1.10, 95% CI 1.08-1.13), see Table 3. Individuals aged 20-34 years (HR 2.62, 95% CI 2.54-2.70) exhibited the highest hazard of discontinuing testing, followed by those aged 35-44 years (HR 1.51, 95% CI 1.47-1.56) and 45-54 years (HR 1.31, 95% CI 1.27-1.35), compared to those aged 0-19 years. Participants identifying as multiracial (HR 1.52, 95% CI 1.20-1.94), American Indian or Alaska Native (HR 1.20, 95% CI 1.05-1.36), and Hispanic or Latino (HR 1.19, 95% CI 1.15-1.22) were more prone to discontinuing testing compared to White participants. These findings underscore the importance of targeted outreach strategies tailored to engage and retain the demographic groups at risk of stopping testing. Addressing barriers such as accessibility, convenience, and perceived need for testing among younger age groups and specific racial or ethnic groups may help mitigate the discontinuation of testing and continue surveillance of SARS-CoV-2 transmission within communities.

### Discussion

HDT, and later HYT, was a community COVID-19 surveillance program that focused on free asymptomatic and symptomatic testing to catch cases early and provide resources and information for transmission reduction strategies. The primary focus of this study was to assess how well the program reached and maintained coverage and equity goals by tallying the demographic characteristics of participants and changes in testing participation. The HDT or HYT program used a high-throughput method to administer and process large volumes of tests, which allowed it to reach a substantial portion of the city of Davis and Yolo County’s population, covering all who willingly underwent testing. Extra testing campaigns and expanded access to free testing were adapted over time to ensure they reached the most vulnerable and underserved populations.

Although men typically face higher vulnerability to the health impacts of COVID-19 [30,31], the testing program saw a higher participation rate among women across all adult age groups except those aged 85 years or older. Additionally, men showed a slightly lower likelihood of retesting and a higher tendency to discontinue testing altogether compared to women. These results are consistent with research from prior infectious disease outbreaks indicating that women tend to be more cautious than men in the context of an epidemic [32,33] and more likely to adopt preventive behaviors and adhere to public health guidelines [34-36]. Additionally, studies have shown that women reported higher levels of fear regarding the coronavirus than men during the periods that HDT or HYT was active [7,37]. Gender differences in risk perception may stem from deeply ingrained gender roles or disparities in trust toward authority figures and institutions [2,38].

COVID-19 testing adherence varies across different age groups. Younger individuals (20-34 years) are less likely to retest and more likely to stop testing, while those aged 35-64 years have a higher probability of discontinuing testing. However, older age groups (65-74 years and 75-84 years) are less likely to stop testing compared to those aged 0-19 years. This pattern may be influenced by the free weekly testing provided to students aged 0-19 years by HDT or HYT in collaboration with multiple Yolo County school districts, and the mandatory testing for Medicare or Medicaid-funded congregate living facility residents supported by state-level testing programs.

The adherence to and cessation of testing also exhibit variations among various ethnic groups. Communities such as Hispanic or Latino and American Indian or Alaska Native tend to test less frequently compared to the White demographic. On the other hand, the Native Hawaiian or Other Pacific Islander group tends to test more frequently. There are also disparities in stopping testing, with Hispanic or Latino and Black or African American individuals more likely to cease testing compared to White individuals, while Asian individuals are less likely to do so. American Indian or Alaska Native and Multiracial groups show no significant difference. These variations could be due to differences in testing behaviors, access to testing facilities, or other community-specific factors. It is noteworthy that HDT or HYT has been conducting targeted outreach to heavily impacted communities and using data analysis to strategically allocate resources where increased testing is needed.

Monitoring the spread of a disease and accurately identifying its burden through a voluntary surveillance program relies heavily on maintaining consistent user cooperation and continuing recruitment of new users. However, disaster fatigue is a natural response during extended public health crises such
as the COVID-19 pandemic that can reduce participation over time and stymy new recruitment efforts [15]. Nonetheless, HDT or HYT demonstrated the program’s effectiveness in retaining participants across a broad spectrum of age and race or ethnic demographics through and engaging new individuals in testing throughout its duration. The highest burden of infection arrived with the dominance of the Omicron variant in California, during which the testing program accelerated testing and outreach efforts to achieve the highest daily testing rate of the surveillance program. An overall increase in positive cases from Omicron is consistent with the drastic increase in virulence and avoidance of both immunity and contemporary prophylaxis [39-41]. Individuals who were already experienced with the system may have perceived increasing risk with the new variant, and opted for more testing; additionally, many workplaces and schools were requesting negative COVID-19 tests or proof of vaccination to return to the facility for a return to a sense of normalcy.

There was a significant decline in testing participation following the Omicron period. Motivation to engage in preventive behaviors against COVID-19 may have decreased because people became fatigued or burned out due to excessive and repeated exposure to similar messages about COVID-19 over time [15,16,21]. The increased availability, credibility, and convenience of other surveillance methods such as at-home COVID-19 tests [14], coupled with the impact of vaccines on risk perception [21], may have reduced the desire to continue with centralized surveillance testing. Lack of trust in government, misinformation, resistance, and conspiracy theories continue to pose a challenge for health authorities in maintaining or revitalizing public support for community-level surveillance of COVID-19, though it is unclear how this has affected participation in HDT or HYT.

In long-term crises such as the COVID-19 pandemic, public health authorities may constantly face new challenges in maintaining preventive strategies due to changes in the virus and social behavior. The comprehensive data collected during COVID-19 testing campaigns offers an opportunity to gain insight into people’s adherence and practices toward public health measures, which can inform the design of future strategies to educate communities about the benefits of engaging in preventive practices during new emerging infectious disease outbreaks.

The HDT or HYT program provides a unique setting to analyze people’s behavior since noncompliance with prevention measures may be due to reasons other than limitations in access or availability of tests. However, the nature of this data does not allow us to conclude the reasons for the observed differences. Nonetheless, the patterns observed in this analysis are consistent with findings reported in previous studies using different data sources, such as survey information.

The pandemic has highlighted the significance of social dynamics in disease control. Mathematical models played a crucial role in monitoring the behavior of SARS-CoV-2. However, access to information that accounts for social behavior and people’s adherence to health policies was extremely limited as was access to granular population-based incidence data. Analysis of acceptance and response is a starting point not only to improve future public health interventions but also to generate information that may be useful for the designing of statistical and mathematical models to study the dynamics of infectious diseases.

This analysis examines what factors affect acceptance to testing, using data from large-scale community PCR testing. While this type of data provides valuable insights, it falls short in capturing individual-level behavioral characteristics that may have affected the uptake of testing or vaccination resources. Collecting such data in future studies is crucial to optimizing the effectiveness of population-based interventions like testing, as it can help us identify the specific factors that influence people’s decisions to participate and inform the design of targeted interventions to improve uptake.

Abstract
During public health crises, the significance of rapid data sharing cannot be overstated. In attempts to accelerate COVID-19 pandemic responses, discussions within society and scholarly research have focused on data sharing among health care providers, across government departments at different levels, and on an international scale. A lesser-addressed yet equally important approach to sharing data during the COVID-19 pandemic and other crises involves cross-sector collaboration between government entities and academic researchers. Specifically, this refers to dedicated projects in which a government entity shares public health data with an academic research team for data analysis to receive data insights to inform policy. In this viewpoint, we identify and outline documented data sharing challenges in the context of COVID-19 and other public health crises, as well as broader crisis scenarios encompassing natural disasters and humanitarian emergencies. We then argue that government-academic data collaborations have the potential to alleviate these challenges, which should place them at the forefront of future research attention. In particular, for researchers, data collaborations with government entities should be considered part of the social infrastructure that bolsters their research efforts toward public health crisis response. Looking ahead, we propose a shift from ad hoc, intermittent collaborations to cultivating robust and enduring partnerships. Thus, we need to move beyond viewing government-academic data interactions as 1-time sharing events. Additionally, given the scarcity of scholarly exploration in this domain, we advocate for further investigation into the real-world practices and experiences related to sharing data from government sources with researchers during public health crises.

KEYWORDS
COVID-19; crisis response; cross-sector collaboration; data infrastructures; data science; data sharing; pandemic; public health

Introduction
Although the world appears to be recovering from the intense impact of the COVID-19 pandemic, it is imperative to recognize that the far-reaching effects of this disease continue to endure across the globe. Its significant ramifications, such as economic fallout, disruptions in education, mental health challenges, and racial and socioeconomic health inequities, have left indelible marks on humanity, showcasing the vulnerabilities of human society when confronted with a global public health crisis.

Looking back, we should now ask: “What actions could have been done better to save more lives and reduce the aforementioned negative effects?” Moving forward, it is crucial to reflect on the valuable lessons that appear when we pose this question. Such reflection may prepare us better for future public health crises.

Among any effort to effectively manage the spread of the COVID-19 pandemic, the rapid sharing of data stands out as a key strategy. However, instances of failure have been exposed, signaling opportunities for improvement in this critical facet of
the pandemic response. Just 1 year into the COVID-19 outbreak, the British Medical Association’s chair of council voiced criticism, suggesting that “our devastating mortality figures could in part be a result of the failure of the government to properly and openly share data, communicate accurately, and act swiftly” [1]. He stressed the problematic absence of transparency concerning the actual availability of personal protective equipment supplies and the formulation of decisions on restrictions and tiers (ie, a classification system indicating local COVID-19 alert levels adopted in the United Kingdom) without also revealing the underlying statistics that supported them [1]. The US Centers for Disease Control and Prevention (CDC) itself faced criticism for its perceived “slow and siloed approach to sharing data,” which resulted in overly optimistic evaluations of the evolving vaccine effectiveness against the delta variant and contributed to the country’s falling behind in addressing that new viral mutation [2].

Government entities, a primary source of public health data, bear the responsibility for ensuring timely availability and facilitating the subsequent use of such data. To expedite the pandemic response efforts, social debates and academic studies have centered on enhancing data sharing among health care providers [3], across government departments at different levels [4], and on an international scale [5]. However, a data sharing approach that receives less attention but carries equal significance during public health crises is cross-sector data sharing collaborations between government entities and academic researchers. Specifically, this involves dedicated projects wherein a government entity shares the public health data it aggregates with an academic research team for further data analysis. The resulting data insights are then leveraged to inform policy making.

In this viewpoint, we outline the common challenges in data sharing during COVID-19, as well as other public health and general crises such as natural disasters and humanitarian emergencies. We then argue that government-academic data collaboration has the potential to alleviate these challenges, making it a topic worthy of deeper scholarly exploration. We aim to initiate a constructive discussion on effective strategies to foster this kind of cross-sector collaboration, thus paving the way for more robust and resilient responses to future public health crises.

The Significance of Data Sharing During Crises Cannot Be Overstated

In times of crisis, the saying “speed is everything” resonates more profoundly than ever. The landscape of a crisis is defined by difficulties related to uncertainty, urgency, and the relentless pursuit of solutions. Among these difficulties, data emerge as a beacon of understanding—a key resource that can illuminate facts, accelerate actions, and prevent unnecessary public panic. The significance of data sharing cannot be overstated during such moments when rapid access to comprehensive, accurate, and timely data becomes the linchpin of effective crisis management. The lessons learned from previous natural disasters and humanitarian crises have reinforced the importance of rapid data sharing [6-8]. This demand originated from not only frontline responders, decision makers, and those directly impacted but also those capable of and willing to contribute to crisis resolution, such as academic researchers. Similarly, even before the arrival of the unprecedented COVID-19 pandemic, a collection of public health crises highlighted the critical role of sharing data to safeguard global well-being. The outcomes of not sharing data or failing to integrate and coordinate data access during public health emergencies were studied, as seen during the 2003 outbreak of SARS [9,10]. In the past, data sharing was limited by technological constraints or underdeveloped legal frameworks. However, the necessity of data exchange was evident. Today, with advancements in data science knowledge and techniques, data sharing holds the potential for even greater advances that may improve the responses to public health crises.

Several characteristics collectively set COVID-19 apart from preceding crisis events: its expansive geographical reach, rapid transmission, prolonged duration, and far-reaching socioeconomic consequences. Moreover, the exceptional need for rapid data dissemination across jurisdictional and organizational boundaries during this crisis also added to its distinctiveness [11]. As stated by epidemiologist Dr Maria van Kerkhove, the COVID-19 technical lead at the World Health Organization (WHO), “When there’s so little information on a novel pathogen, any information that you can get your hands on is absolutely critical” [12]. During the COVID-19 pandemic, data sharing has played a crucial role in enhancing decision makers’ contextual understanding of the pandemic, which was deemed a key aspect of “public health situational awareness” by the US government during the pandemic [13]. Ideally, such heightened awareness would have facilitated more rapid responses, thus enabling the implementation of appropriate measures, such as resource allocation and public health interventions. When successful, data sharing also enables the examination of health disparities by providing access to demographic data, which was particularly significant in COVID-19 due to the disproportionate impact on marginalized socioeconomic, racial, and ethnic groups worldwide [14,15].

During the early stages of COVID-19, we did witness efforts to share data, such as information about potential treatments and disease spread. However, in many instances, the underlying data were of varying or low quality, as evidenced by the pandemic-related preprints that emerged [16]. In addition, considering the unpredictability of the COVID-19 pandemic, rapid data exchange necessitated effective coordination particularly among various stakeholders engaged in the “learning health system” cycle [17], which involved assembling, analyzing, and transforming data into knowledge and then performance, all within a limited time frame. Different actors’ data needs also varied across pandemic phases, such as whether a situation occurred suddenly or insidiously or whether consequences rapidly abated or lingered. Given the complexity of crisis data–sharing relationships, in the next section, we examine documented challenges in data sharing during crises that provide us with a better understanding of this issue.
Data Sharing Challenges During Public Health Crises

Public health crises have the potential for global ramifications; however, addressing them necessitates a localized approach [18]. During the COVID-19 outbreak, there existed attempts to share key data points (eg, viral genomes and methods of transmission) at the international, national, and local levels [19]. However, a difficulty lay in effectively acquiring public health insights due to the complexity of integrating disparate data across geopolitical boundaries and jurisdictional levels.

In the United States, the COVID-19 response was impaired due to the public health data infrastructures' inability to effectively share data across and within jurisdictions. As widely reported, the efficiency and timeliness of data sharing, supported by these data infrastructures, have not always been satisfactory. The desired data are “scattered” across unconnected or proprietary databases, exist in incompatible formats, or are of dubious quality and provenance [20]. Present methods of collecting public health data primarily depend on manual processes for reporting instances of certain communicable diseases and outbreaks of new diseases. Using the data accessible in electronic health record systems is not often done, even when possible. This disconnect impedes the effective use of available data. Unsurprisingly, secondary use of clinical data for public health purposes is usually insufficient [21]. Furthermore, many researchers were and still are unable to swiftly integrate with existing public health data infrastructures and “find the right antidote” for research demands when facing unforeseen public health crises [22].

The long-standing underinvestment in the maturity and agility of US public health data infrastructures has been frequently emphasized at the federal as well as state and local levels [23]. This gap became particularly problematic during the COVID-19 pandemic. From a broader perspective, neither early legislative efforts, such as the HITECH Act of 2009, nor more recent programs dedicated to COVID-19, such as the CDC’s Data Modernization Initiative, have successfully addressed the country’s fragilities in constructing critical infrastructures to meet the ongoing public health surveillance needs [21]. Admittedly, modern data-driven technologies have been widely implemented in both research and clinical contexts. Nevertheless, the aforementioned deficiencies hindered not only comprehensive real-time data analyses at the technical level [24] but also large-scale coordination between data holders and requesters at the social and organizational levels [25]. For example, in response to COVID-19, a plethora of data aggregation initiatives emerged, involving key actors, such as academic medical center networks as data holders and public health departments as data consumers. Subsequently, data requests from these federal- or state-level public health departments turned out to impose a substantial burden on academic medical centers’ reporting mechanisms [25].

While measures taken in response to the COVID-19 pandemic brought some data sharing challenges into sharp relief, the challenges arising at that time have a long history. A succession of diverse crises exposed the challenges that responders encountered when aiming to achieve rapid data sharing. By mapping the nature of different types of crises alongside their documented challenges, we can enhance our understanding of the most important data sharing approaches to study and maintain during such crises. In Table 1 [25-97], based on the extant research literature, we summarize 5 categories and 20 subcategories of common data sharing challenges during COVID-19, other public health crises, as well as other natural disasters and humanitarian crises.

After conducting a comprehensive search of scholarly literature in various fields such as public health, biomedicine, crisis informatics, and broader information science, we developed a corpus of papers relevant to data sharing challenges. Starting from this corpus, the aforementioned categories and subcategories were developed through an iterative qualitative analysis process to describe, conceptually order, and classify the bodies of text [98] as follows. First, we discerned challenges documented in the literature. Identifiable patterns then emerged, leading to the inductive grouping of specific challenges into common broad categories. These categories were further refined into their respective subcategories, taking into account the nuances of specific challenges and whether they were experienced during the COVID-19 pandemic, other public health crises, or additional types of crises (ie, natural disasters and humanitarian crises). Given the vast volume of publications discussing data sharing challenges, the categories and subcategories we developed are not meant to be exhaustive. Rather, they function as a starting framework for an interpretive critique of existing research gaps.

In all, the 5 categories of data sharing challenges we have identified are (1) data availability and quality, (2) data management and sharing, (3) information systems and data interoperability, (4) resource limitations, and (5) multiparty collaboration and coordination. In Table 1, we use omnibus terms, such as “stakeholders” and “data sharing entities,” to encompass a diverse range of individuals (eg, researchers, clinicians, and first responders) and organizations (eg, government agencies, health care providers, and humanitarian groups) actively involved in data exchange during crises. In the next section, we describe government-academic data collaborations—an often-underexplored type of data interaction during public health crises—and how to mitigate the challenges outlined below in these collaborations.
Table 1. Common data sharing challenges among stakeholders and example references by type of crises.

Navigating Challenges: Government-Academic Collaboration as Part of the Social Infrastructure for Public Health Crisis Response

Data collected, aggregated, or provided by government entities have been observed to play a key part in managing the COVID-19 crisis. As an example that involves government data for internal use, in the United States, the city government of Boston used its preexisting data warehouse, aggregating data from 31 departments, to rapidly develop a public dashboard at the outset of the pandemic [99].

Simultaneously, there were instances globally where academia has engaged in using government data to understand the pandemic, with various forms of such cross-sector initiatives. For example, the Israeli government orchestrated a “datathon” competition—an event uniting participants from diverse sectors, including academic scientists, to devise practical, data-driven models and insights [100]. Another approach to effectively leveraging government data is by directly making them available to citizens, including academic researchers. The term “open government data” (OGD) refers to government-held data made accessible to the public to enhance transparency regarding government operations [101]. One common method for obtaining OGD is through government agencies’ open data portals [102]. This method has enabled various stakeholders to engage in data analysis before and during the COVID-19 period [103,104].

Nonetheless, there are limitations to the aforementioned data interactions between government entities and academia. Specifically, short-term data analysis competitions may not adequately support the relatively medium to long-term needs for pandemic response policy planning by government entities. Participants from various sectors are unlikely to sustainably remain within the government’s data collaboration network after the competition ends. On the other hand, in relation to OGD, there is a critical aspect of their availability—when accessing OGD, users download data independently without direct interactions with government agencies as data providers. Such a relatively unilateral data access approach may give rise to issues related to data quality and usability (eg, data integrity, granularity, and timeliness [105]), potentially impeding users’ understanding and appropriate interpretation of OGD and in turn undermining the data’s overall effectiveness to be used accurately, appropriately, and efficiently.

Consequently, there is a growing demand for enhanced “direct” collaboration between government entities and researchers on
Despite this limited information, these additional cases make applications to track the pandemic within the state [114]. Of data-driven tools (eg, symptom and vaccination monitoring), the Michigan program, attempting to connect essential workers with available health and Human Services Agency and the University of Michigan, partnered with the Michigan Department of Health and Human Services Agency and the University of Michigan, to develop a series of data-driven tools (eg, symptom and vaccination monitoring applications) to track the pandemic within the state [114]. Despite this limited information, these additional cases make it clear that such collaborations exist more broadly, and that they potentially hold value in responding to public health crises.

Our call for research into government-academic collaborations is vital given the history of previous efforts. For example, between 2005 and 2011, the CDC launched the Centers of Excellence in Public Health Informatics program. This initiative shared similarities with the form of government-academic collaboration we are advocating as it aimed to bridge the gap between public health research and practice through collaborations among academia, local or state public health departments, and other health informatics professionals [115]. The program financially supported academic institutions, such as Harvard University and Indiana University [116], to establish research centers that would translate research outcomes into public health practice. Data sharing and information exchange were integral components as well, though primarily from clinical sources to public health information systems [117]. However, after the funding concluded, the infrastructures of the research centers necessitated institutional or external backing for sustainability. This indicates the difficulty in maintaining the long-term viability of such short- or medium-term programs.

Up to this point, we have outlined several forms of government-academic data interactions and their limitations in terms of effectiveness, efficiency, and sustainability. In the following subsection, we elaborate on an alternative collaborative form that may function better during public health crises than the other aforementioned government-academic data interactions.

**Government-Academic Collaborations as a Promising Solution to Data Sharing Challenges**

**Overview**

A public health data infrastructure can be defined as “an ecosystem composed of the people, processes, procedures, tools, facilities, and technologies, which supports the capture, storage, management, exchange, and creation of data and information to support individual patient care and population health” [118]. Nonetheless, it is notable that existing discussions around these kinds of infrastructures mostly center on technological aspects, such as health information systems and their data standards for interoperability. At the same time, other key components involving people, processes, and norms have received less attention [119]. In fact, for researchers, we contend that data collaborations with government entities should be considered part of the social infrastructure that supports their research efforts toward public health crisis response. Specifically, as we argue below, many of the data sharing challenges displayed in Table 1 may be effectively mitigated through well-planned government-academic collaborations. In the upcoming sections, we explain how the 5 types of challenges (data availability and quality, data management and sharing, information systems and data interoperability, resource limitation, and multiparty collaboration and coordination) can be navigated by developing partnerships between government entities and academia, particularly during public health emergencies.
Data Availability and Quality

Government-academic data collaborations are goal oriented and usually provide researchers with prepared data sources, alleviating concerns about data location and the identification of relevant information from the vast pool of available data “outside,” which are often collected by researchers themselves. In the exemplar case described above, the IDM researchers highlighted that during their collaboration with the Washington State DOH, the COVID-19 data shared by the government was of high quality, which significantly expedited their work, enabling them to deliver outputs swiftly [111]. Furthermore, this collaborative model often implies prioritized communication channels, facilitating prompt resolution of data quality issues by both parties.

Data Management and Sharing

Intentionally built collaborations often smooth data exchange activities by facilitating the creation of a preestablished data sharing framework, which comprises agreements on data management and use, as well as clearly defined obligations and codes of conduct for both parties involved [120]. For example, in response to the external demands for Zika-related research projects, Brazil’s Secretariat of Health took a proactive approach by initiating collaboration protocols with researchers [74]. These data-related agreements clearly regulated the conditions for accessing data and thus laid the foundations for project execution at maximum speed [74]. Besides, such data sharing frameworks function as a common space where collaborators can fine-tune their collective data activities based on project performance.

Information Systems and Data Interoperability

As government entities and researchers work together around data resources, potential issues, such as inadequate technical infrastructures and inconsistent data standards, may come to light during the early stages [121]. Nonetheless, such a collaboration also presents an opportunity for both parties to acknowledge these problems and proactively work toward resolving them. To illustrate, although not identical to the collaborative model we advocate, the well-known National COVID Cohort Collaborative initiative aimed to overcome interoperability barriers. Ultimately, it managed to build a scalable data analytics infrastructure by uniting US federal agencies, health care providers, and research leaders to harmonize pandemic data across different organizations [122]. Notably, there remains much to investigate regarding the implementation of data standardization within collaborative efforts on a smaller scale, specifically between government entities and researchers.

Resource Limitations

Government-academic collaborations make dedicated investments, including workforce and funding, in their data projects. This commitment enables the efficient integration of complementary resources from both sectors, facilitating a synergistic approach to data-driven initiatives. In particular, public health and biomedical informatics experts recently stressed the need to build “a public health workforce that is skilled in informatics and data science...to meet 21st century health threats” [21]. Nonetheless, they simultaneously pointed out the challenges in recruiting incoming talent as well as in training this workforce, an ongoing problem that state and local public health departments have historically faced [21]. This further highlights the value of government-academic collaborations, in which public health authorities can borrow well-established expertise from academics in “rapid response data science” [107].

Multiparty Collaboration and Coordination

Previous ongoing collaborative relationships help to build trust in advance, eliminating the need for a cumbersome initiation period characterized by misaligned organizational priorities and conflicting power dynamics that impede the rapid circulation of data assets. In the case of the Washington State DOH and IDM described above, the IDM researchers achieved favorable outcomes in their collaboration with DOH employees by recognizing the significance of building trust [111]. Based on their accounts, the crucial element that contributed to the success of the collaboration was the ability to align needs and tasks at an early stage of the partnership [111]. In addition, such early coordination efforts may also help data holders preempt the challenges posed by the previously discussed scenario of receiving a sudden surge in requests from data consumers [25].

To summarize, we contend that placing sole emphasis on the exchange of data through technological infrastructures falls short when confronted with the challenges of a public health crisis. Government-academic data collaborations, as essential social infrastructures, encompass not only people, processes, and norms but also rely on trusting relationships within the larger legal and political context. These elements are all integral and indispensable components for the success of the data sharing enterprise. Ultimately, sharing data is not just a technical process—it should be a collaborative endeavor that transcends boundaries. Thus, we should study and implement such collaborations now, before the next public health crisis is on us. Doing so may help to establish greater readiness and more rapid responses in the future. We now outline recommendations that, if implemented, may assist in developing this crucial sociotechnical infrastructure.

Conclusion and Recommendations

In this viewpoint paper, we investigate the challenges associated with sharing data in public health crises, many of which stem from the long-standing inadequacy in the US public health data infrastructures. In particular, we have witnessed repeated appeals for increased data sharing endeavors spanning various sectors and extending in multiple directions, such as data scientists in the health care industry stressing that “sharing data should not just be a one-way street from the clinician to the researcher” [123]. However, the factors for successful collaborative data sharing across sectors in public health crises—in which government entities share data with academic researchers for effective use—need further attention. Therefore, resulting from a synthesis of extant research and our arguments, we call for more effort to be invested in building data sharing infrastructures capable of bridging and leveraging the respective strengths of government entities and academic researchers. Such infrastructures need to be established within an ecosystem that
incorporates not only technologies but also policies, processes, and personnel. This holistic framework is ideally designed to facilitate researchers in seamlessly accessing and employing data aggregated and managed by government entities for their mutual benefit.

The COVID-19 pandemic has taught us a valuable lesson, which surpasses those gained from any previous public health emergencies: that the aforementioned infrastructure for rapid and effective data sharing should be established well in advance of a crisis. Particularly, we argue that government-academic data interactions should not be thought about as only 1-time data sharing. Instead, we recommend that emphasis should be placed on the construction of robust and enduring collaborative infrastructure that not only outlasts a specific public health crisis but also is in place to respond to the next one. Ideally, these data collaborations should not be confined to emergencies or a small number of high-priority threats [51]. After all, data sharing practices both during and between crises affect crisis response efforts, albeit potentially in distinct manners. To be specific, routine data sharing practices in scientific research and the availability of preexisting baseline data before a crisis can play a crucial role in facilitating prompt planning for health relief activities [32,55]. In addition, even before implementing crisis response measures, persistent data partnerships may hold the potential to enhance the detection and early characterization of issues arising during a crisis, facilitated by the accelerated exchange of information between government entities and academics.

As of May 2023, the WHO and the US government declassified COVID-19 as a public health emergency. While most individuals have moved on, for those who have compromised immune systems or are otherwise at greater risk for negative outcomes from the virus, exchanging data to facilitate accurate disease-level reporting remains crucial for evaluating their safety. However, the termination of certain data sharing mandates and data-collection initiatives could hinder government bodies and research institutions from maintaining uninterrupted access to vital disease-related metrics [124]. With the resurgence of COVID-19 hospital admissions since July 2023 in the United States [125] and the possibility of “a new norm of summer surges” [126], it is worth considering whether we want to revert to a just-in-time approach to data sharing practices or if we should be proactive and build just-in-case resilient, long-term data infrastructures for forthcoming public health scenarios. We strongly assert that our choice should be the latter.

**Future Research Agenda**

As mentioned, it is critical to begin now to establish more effective government-academic collaborative infrastructures for public health crisis response. To do so, we must develop more systematic research on the facilitating and impeding factors for such data collaborations. In this viewpoint paper, we reviewed existing research literature and summarized data sharing challenges during different crisis scenarios (Table 1). Significantly, we conclude from the literature review that there is a conspicuous scarcity of scholarship addressing the practices and experiences related to disseminating data from government sources to researchers throughout extended or ongoing crisis response situations, including instances of global health crises. In particular, in terms of data-exchange partnerships during public health crises, the public health and biomedical informatics literature often enumerates a wide range of stakeholders [21,127] but generally lacks a specialized focus on the connections between government entities and researchers. On the other hand, literature within the realm of crisis informatics more often addresses the circulation of information and data among the public, frontline responders, and governmental bodies in natural disaster scenarios (eg, earthquakes [88], hurricanes [128], and wildfires [129]).

While government-academic collaborations that allow data exchange did exist at different administrative levels during COVID-19, there is a notable dearth of research studying these relationships. To initiate further discussions, we draw on the data sharing challenges outlined earlier and propose 3 key research questions, to foster more substantive dialogues and shape the future research agenda: (1) What types of government-academic collaborative infrastructures should we be developing? How can these infrastructures be best sustained? (2) Considering the unique characteristics of public health crises, what are the best practices for implementing data sharing and data collaborations? and (3) From the respective views of government entities and researchers, what are the incentives and disincentives that influence their willingness and capacity to engage in developing and sustaining collaborative data infrastructures?

In conclusion, the COVID-19 pandemic has emphasized the imperative for robust and durable government-academic partnerships in public health crises. As we transition beyond the pandemic, it is crucial to develop systematic research on the factors influencing these collaborations. Before the next public health crisis arises, we invite decision makers, researchers, and practitioners across government entities, academia, and various sectors to leverage the collective knowledge and expertise of diverse stakeholders, strengthening existing and building new government-academic data collaborative infrastructures. The time to act is now, and the path to a more resilient future begins with our commitment to addressing these critical challenges.

Abstract

Background: Beyond the direct effect of COVID-19 infection on young people, the wider impact of the pandemic on other infectious diseases remains unknown.

Objective: This study aims to assess changes in the incidence and mortality of 42 notifiable infectious diseases during the pandemic among children and adolescents in China, compared with prepandemic levels.

Methods: The Notifiable Infectious Disease Surveillance System of China was used to detect new cases and fatalities among individuals aged 5-22 years across 42 notifiable infectious diseases spanning from 2018 to 2021. These infectious diseases were categorized into 5 groups: respiratory, gastrointestinal and enterovirus, sexually transmitted and blood-borne, zoonotic, and vector-borne diseases. Each year (2018-2021) was segmented into 4 phases: phase 1 (January 1-22), phase 2 (January 23-April 7), phase 3 (April 8-August 31), and phase 4 (September 1-December 31) according to the varying intensities of pandemic restrictive measures in 2020. Generalized linear models were applied to assess the change in the incidence and mortality within each disease category, using 2018 and 2019 as the reference.

Results: A total of 4,898,260 incident cases and 3701 deaths were included. The overall incidence of notifiable infectious diseases decreased sharply during the first year of the COVID-19 pandemic (2020) compared with prepandemic levels (2018 and 2019), and then rebounded in 2021, particularly in South China. Across the past 4 years, the number of deaths steadily decreased. The incidence of diseases rebounded differentially by the pandemic phase. For instance, although seasonal influenza dominated respiratory diseases in 2019, it showed a substantial decline during the pandemic (percent change in phase 2 2020: 0.21, 95% CI 0.09-0.50), which persisted until 2021 (percent change in phase 4 2021: 1.02, 95% CI 0.74-1.41). The incidence of gastrointestinal
and enterovirus diseases decreased by 33.6% during 2020 but rebounded by 56.9% in 2021, mainly driven by hand, foot, and mouth disease (percent change in phase 3 2021: 1.28, 95% CI 1.17-1.41) and infectious diarrhea (percent change in phase 3 2020: 1.22, 95% CI 1.17-1.28). Sexually transmitted and blood-borne diseases were restrained during the first year of 2021 but rebounded quickly in 2021, mainly driven by syphilis (percent change in phase 3 2020: 1.31, 95% CI 1.23-1.40) and gonorrhea (percent change in phase 3 2020: 1.10, 95% CI 1.05-1.16). Zoonotic diseases were not dampened by the pandemic but continued to increase across the study period, mainly due to brucellosis (percent change in phase 2 2020: 0.94, 95% CI 0.75-1.16). Vector-borne diseases showed a continuous decline during 2020, dominated by hemorrhagic fever (percent change in phase 2 2020: 0.68, 95% CI 0.53-0.87), but rebounded in 2021.

Conclusions: The COVID-19 pandemic was associated with a marked decline in notifiable infectious diseases in Chinese children and adolescents. These effects were not sustained, with evidence of a rebound to prepandemic levels by late 2021. To effectively address the postpandemic resurgence of infectious diseases in children and adolescents, it will be essential to maintain disease surveillance and strengthen the implementation of various initiatives. These include extending immunization programs, prioritizing the management of sexually transmitted infections, continuing feasible nonpharmaceutical intervention projects, and effectively managing imported infections.

KEYWORDS
children and adolescents; COVID-19; notifiable infectious diseases

Introduction

Globally, the nearly 1.9 billion children and adolescents younger than 20 years, who account for approximately 26% of the world’s population, are particularly vulnerable to infectious diseases [12]. Yet, previous research has suggested that compared with adults, children and adolescents are more likely to be asymptomatic or have milder symptoms of COVID-19, experience a shorter course of illness, and have a lower risk of developing severe disease [3,4]. They are also less likely to experience multisystem inflammatory syndrome [5]. In China, there has been relatively limited epidemiological research on COVID-19 infections among children and adolescents and the bulk of studies have focused on the original virus strains from the early stages of the outbreak. For instance, the largest published Chinese population study included only 2135 children and adolescents infected with COVID-19 from January to February 2020 [6]. With the easing of COVID-19–related restrictions worldwide, there has been a sharp increase in the number of children and adolescents infected with the virus [3,4].

In the early response to the COVID-19 pandemic, countries variably introduced a series of social and behavioral measures (eg, border closures, quarantine, lockdowns, school closures, travel restrictions, and face masks) to reduce viral transmission. These approaches are relatively effective [5,7-11]. For example, short-term prospective observational research has indicated that school closures and restricted social distancing were associated with a 38% reduction in the incidence of COVID-19 [12]. Another study conducted in 11 countries demonstrated a 15% reduction in the incidence of COVID-19 associated with multiple social restrictions; additionally, it found that earlier implementation of lockdown measures was associated with a larger reduction in the incidence of COVID-19 [13]. Social restrictions aimed at limiting the transmission of COVID-19 have also had an indirect effect on the incidence of a wide range of other infectious diseases, likely reflecting the interruption of the transmission chain [14]. Respiratory diseases have been particularly affected [14-17]. Chinese surveillance indicates that during the early stages of the COVID-19 pandemic in 2020, the rates of positive tests for all respiratory viruses declined. Reductions varied from 17.2% for respiratory syncytial virus to 87.6% for influenza virus [16]. These patterns were also evident in countries with a low prevalence of COVID-19, such as Australia, which experienced a 36% reduction in antibiotic dispensing for respiratory tract infections in the first year of the pandemic [18]. In England, in the first 12 months after the onset of the COVID-19 pandemic, large and sustained reductions were found in the rates of hospital admissions for respiratory infections as well as for a spectrum of other severe and vaccine-preventable childhood infections, such as meningitis [16].

In any country, it is apparent that a balance of factors has affected the transmission and severity of COVID-19, including the timing and intensity of lockdowns and their subsequent lightening, evolving virus strains, and access to vaccines. What is less clear is how these dynamic changes have impacted other infectious diseases. For instance, in China, hand, foot, and mouth disease (HFMD) surged following the gradual lightening of COVID-19 restrictions, distinct from scarlet fever or seasonal influenza, both of which remained at lower levels [19]. Although several studies have investigated the impacts of COVID-19–related restrictions early in the pandemic, there has been less attention to children and adolescents. To date, there has been a lack of systematic exploration in children and adolescents regarding the impacts of the COVID-19 pandemic and the associated social restrictions on the spectrum of infectious diseases. In addition, little attention has been paid to the effects following the lifting of these restrictions [15-17,19]. This study analyzed data for 42 notifiable infectious diseases in children and adolescents in mainland China from 2018 to 2021 to investigate the indirect effect of COVID-19 restrictions on a wide spectrum of infectious diseases. Specifically, we aimed to determine the variability and persistence of this indirect effect across age, sex, time, region, and disease category, with the expectation that this information can inform the nature of
protective strategies for children and adolescents within subsequent pandemics.

**Methods**

**Data Collection**

Using the China Information System for Disease Control and Prevention (CISDCP), we identified data on daily new cases and deaths for 42 notifiable infectious diseases reported in children and adolescents aged 5-22 years between 2018 and 2021. For each case, we recorded the date and location of disease onset and death, diagnosed disease, age, and sex. The CISDCP covers 55,077 national health facilities in 397 cities across all 31 provinces of mainland China and maintains a detailed surveillance protocol [20]. The CISDCP had a national average coverage rate that remained stable and exceeded 95% for all health facilities at or above the county level during the study period, and in 2017, web-based reporting was available for 87.2% of national health facilities [20]. In this analysis, we only included children and adolescents with a confirmed diagnosis of any of the 42 notifiable infectious diseases. Cases from Hong Kong and Macao were excluded. Demographic information at the city level was provided by the National Bureau of Statistics of China [21].

**Ethical Considerations**

Ethical approval was not required for this study because it exclusively used data that were deidentified and publicly available, making it exempt from review by an institutional review board or ethics committee.

**Classification**

In this study, we focused on 42 notifiable infectious diseases that are captured within the CISDCP. To classify these diseases, we revised our previous approach to categorization [20], classifying vaccine-preventable infectious diseases and bacterial infections based on their respective modes of transmission. These 42 infectious diseases were grouped into 5 categories: (1) respiratory diseases, (2) gastrointestinal and enterovirus diseases, (3) sexually transmitted and blood-borne diseases, (4) zoonotic diseases, and (5) vector-borne diseases. Respiratory diseases included 10 diseases: seasonal influenza, mumps, tuberculosis, scarlet fever, rubella, pertussis, measles, meningococcal meningitis, leprosy, and diphtheria. Gastrointestinal and enterovirus diseases included 8 diseases: HFMD, infectious diarrhea, dysentery (amoebic dysentery and bacterial dysentery), acute hemorrhagic conjunctivitis, typhoid and paratyphoid, hepatitis A, cholera, and poliomyelitis. Sexually transmitted and blood-borne diseases included 6 diseases: syphilis, gonorrhea, HIV/AIDS, hepatitis B, hepatitis C, and hepatitis D. Vector-borne diseases include 9 diseases: hemorrhagic fever, dengue, Japanese encephalitis, typhus, malaria, kala-azar, schistosomiasis, filariasis, and plague. Zoonotic diseases included 9 diseases: brucellosis, hepatitis E, hydatid disease, rabies, anthrax, leptospirosis, H5N1, H7N9, and severe acute respiratory syndrome.

**Epidemic Stages and Phases**

As shown in Figure 1, we divided the 4-year study period into 3 stages of the COVID-19 pandemic based on the timing of the major restrictions that were implemented in response to the pandemic [19]: 2018 and 2019 were considered pre–COVID-19 pandemic years, 2020 was categorized as COVID-19 year 1, and 2021 as COVID-19 year 2.

Because of the different intensities of COVID-19–related restrictive measures taken to prevent and control COVID-19, we further divided 2020 into 4 phases: phase 1 (January 1-22), phase 2 (January 23-April 7), phase 3 (April 8-August 31), and phase 4 (September 1-December 31). In phase 1, COVID-19 had just broken out and no specific interventions or COVID-19–related restrictions were implemented in mainland China. In phase 2, the most intense COVID-19 restrictions were implemented, including school closures and travel restrictions, routine temperature monitoring, mask wearing and social distancing, and isolation of high-risk groups and those with COVID-19. In phase 3, marked by the lifting of the lockdown in Wuhan (April 8, 2020), all provinces of mainland China downgraded their response to the public health emergency, and there was a return to regular education, work, and public transit in cities without major COVID-19 outbreaks. During this phase, a variety of COVID-19–related restrictions remained in practice, including social distancing, mask wearing, routine temperature monitoring, school closures, and capping the number of meetings. Phase 4 began on September 1, signaling the return of businesses, recreational activities, and school reopenings across the nation. However, routine temperature monitoring and mask wearing were still widely practiced. To mitigate the influence of seasonal characteristics on infectious diseases, we applied these same 4 phases, identified in 2020, to each of the study years, which resulted in each year, from 2018 to 2021, being divided into 4 phases. During all epidemic phases in 2021, routine temperature monitoring and mask wearing were still practiced, as described in Figure 1. In China, widespread vaccination against COVID-19 began in 2021.
Figure 1. Categorization of the 3 stages (pre–COVID-19 (2018 and 2019), year 1 (2020), and year 2 (2021)) of the pandemic and 4 phases of the first year of the pandemic in China (2020) by intensity of COVID-19 restrictions.

Statistical Analysis
Incidence and mortality were used to present trends by year from 2018 to 2021. Incidence (per 100,000) was calculated by the number of incident cases divided by the number of the population aged 5-22 years. Mortality (per 100,000) was calculated by the number of deaths divided by the number of the population aged 5-22 years (per 100,000). To assess changes in the 4 epidemic phases, the percent change (PC) for “during versus pre” was calculated using the following formula: \[
\frac{\text{incidence (2020)} - \text{incidence (2018-2019)}}{\text{incidence (2018-2019)}} \times 100\%
\]
and the PC for “COVID-19 year 2 versus COVID-19 year 1” was assessed using the following formula:
\[
\frac{\text{incidence (2021)} - \text{incidence (2020)}}{\text{incidence (2020)}} \times 100\%.
\]
Heat maps were used to show the characteristics of each disease for incidence, number of cases, and number of deaths. Stacked plots were used to visualize the proportion of each infectious disease. To illustrate the trends in infectious diseases from 2018 to 2021, the spiral visualization was used to represent the daily number of incident cases.

To assess the changes in the epidemic phases, the PC in the incidence of each category was calculated at the city level as follows:
\[
\frac{\text{incidence (phase x in 2020-2021)} - \text{incidence (phase x in 2018-2019)}}{\text{incidence (phase x in 2018-2019)}} \times 100\%,
\]
where incidence (phase x in 2020-2021) indicated the average incidence in the corresponding phase in 2021 or 2020 and incidence (phase x in 2018-2019) indicated the average incidence in the specific phase during 2018-2019. The PC in specific phases was calculated by disease, disease category, year, and prefecture-level city. To eliminate the impact of season and quantify the impact of different COVID-19–related restrictions in the epidemic phases on the incidence of infectious diseases, multivariable generalized linear models were applied and used to compare changes in regional variation and specific categories of infectious disease changes by epidemic phases in pandemic years compared with the pre–COVID-19 years of the pandemic in 2018 and 2019. A quasi-Poisson model was fitted for prediction using the indicators as follows: phase category for 2020 and 2021, with number of person-days (population size times the number of days in the month) as an offset. All models were fitted for the daily number of cases. Incidence rate ratios (IRRs) associated with the phase indicators estimated reflect the effects of COVID-19 restrictions on the incidence of each notifiable disease in the pandemic years. IRRs associated with the disease categories were also estimated to assess the impact of COVID-19–related restrictions on various disease categories. All statistical analyses were performed using the R program (version 4.1.1; R Foundation).

Role of the Funding Source
The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the report. The authors from Peking University had full access to the data in the study.

Results
Changes in the Incidence and Mortality of Notifiable Infectious Diseases, 2018-2021
Between 2018 and 2021, nearly 5 million Chinese children and adolescents between the ages of 5 and 22 years (2,818,718 males and 2,079,542 females) were diagnosed with 1 of 42 notifiable infectious diseases. A total of 3701 deaths were reported during this period (2530 in males and 1171 in females). As depicted in Figure 2, the number of reported cases of notifiable infectious diseases fluctuated throughout the study period. In 2018, 911,522 cases were reported, which rose to 2,268,809 in 2019 and declined to 813,635 in 2020, before increasing again to 904,294 in 2021. From 2018 to 2021, the overall incidence of notifiable infectious diseases was 248.848, 738.338, 266.051, and 281.664 per 100,000, respectively. During the first year of the COVID-19 pandemic in 2020, the incidence of notifiable infectious diseases dropped by 46.1% but then rebounded by 5.9% in 2021. Nevertheless, the total mortality and number of deaths decreased steadily over the 4-year period, with rates of 0.304 (n=1112 cases), 0.340 (n=1045 cases), 0.286 (n=869 cases), and 0.210 (n=675 cases) per 100,000 over each year, respectively (Multimedia Appendices 1 and 2).
Trends of Notifiable Infectious Diseases, by Category, 2018-2021

Table 1 and Figure 3 present the overall and temporal trends across the 5 categories of infectious diseases, before and during the COVID-19 pandemic. Among the 5 categories, respiratory, sexually transmitted and blood-borne, and gastrointestinal and enterovirus diseases were the most commonly reported notifiable infectious diseases in those aged 5-22 years (Multimedia Appendix 3). Although the overall incidence of notifiable infectious diseases in children and adolescents declined during the first year of the COVID-19 pandemic and then increased during COVID-19 year 2, the different categories of infectious diseases exhibited diverse temporal changes. Generally, the peak of infectious diseases was reached from December 2019 to January 2020, attributed to a seasonal influenza outbreak. The incidence of notifiable infectious diseases in the first year of the COVID-19 pandemic (2020) was higher than that in the prepandemic years, but then dropped dramatically from February 2020 to March 2021, before rising at the end of the reporting period in the last quarter of 2021 (Figure 4).

The seasonality of respiratory diseases is generally pronounced in winter in China. This was not experienced in the first year of the COVID-19 pandemic, with the fourth quarter of 2020 and the first quarter of 2021 presenting a low incidence of respiratory diseases. This appeared to rebound the following year, with much higher levels in the fourth quarter of 2021. Seasonal influenza dominated these trends; before the pandemic, the incidence of influenza in 2019 was 8 times more common than in 2018 (incidence rate of 480.541 vs 52.858, respectively), and remained elevated compared with 2018 throughout 2020 and 2021. Excluding seasonal influenza, the incidence of all other respiratory diseases continued to decline during the COVID-19 pandemic (50.768 and 43.241 per 100,000 in 2020 and 2021, respectively), compared with pre–COVID-19 levels (average 106.735 per 100,000), especially for mumps, tuberculosis, scarlet fever, and rubella. The 1 exception was pertussis. The leading causes of respiratory deaths were tuberculosis and seasonal influenza. The number of deaths decreased steadily during these 4 years (Multimedia Appendix 4).

Generally in China, gastrointestinal and enterovirus diseases peak in incidence from April to July. However, this peak was not experienced during the COVID-19 pandemic in 2020. Compared with the 2 pre–COVID-19 years, the incidence of gastrointestinal and enterovirus diseases decreased by 33.6% in 2020, but rebounded by 56.9% in 2021. HFMD and infectious diarrhea were the main contributors to this rebound of
gastrointestinal and enterovirus diseases. Infectious diarrhea surpassed HFMD as the most common notifiable infectious disease among the gastrointestinal and enterovirus diseases category in 2020.

Different trends were apparent in the sexually transmitted and blood-borne diseases category. In the initial year of the COVID-19 pandemic, the previous upward trend in incidence observed in the prepandemic years was halted (32.133 and 39.336 per 100,000 in 2018 and 2019, respectively, vs 35.562 per 100,000 in 2020). However, this was succeeded by a noticeable rebound in the second year of the pandemic (38.753 per 100,000 in 2021), representing a 9.0% increase from 2020. The incidence of hepatitis B, C, and D and HIV/AIDS remained stable or declined slightly during the COVID-19 pandemic; however, the incidence of syphilis and gonorrhea increased in both years of the pandemic. In 2018, the disease with the highest incidence within the sexually transmitted and blood-borne diseases category was hepatitis B. Hepatitis B was overtaken by syphilis from 2019 to 2021, particularly in adolescents aged 15-19 years (Figure 5). Across the 4 years, HIV/AIDS remained the major cause of death from any infectious disease in children and adolescents, although the mortality rate decreased by 26.6% over this period, from 0.267 per 100,000 in 2018 to 0.196 per 100,000 in 2021.

In China, zoonotic diseases typically show a seasonal pattern with the highest incidence in summer. Zoonotic diseases seemed less affected by COVID-19, with the incidence continuing to increase from 0.660 per 100,000 in 2018 to 0.982 per 100,000 in 2021, an increase of 18.2%. While this was mainly attributed to brucellosis, which has the highest incidence among zoonotic diseases, the previous growth trends of other zoonotic diseases such as hepatitis E and hydatid disease were also constrained. The incidence and mortality of rabies continued to decline during the study period, although it remained the third leading cause of death from any notifiable infectious disease in children and adolescents in China (followed by HIV/AIDS and tuberculosis).

There was a substantial prepandemic increase in the incidence of vector-borne disease from 2018 to 2019 (from 0.542 to 1.175 per 100,000 in 2018 and 2019, respectively), which remained low during 2020 and 2021. The observed trend was attributed to dengue, Japanese encephalitis, typhus, malaria, and kala-azar, which exhibited significant declines in 2020 (0.335 per 100,000) and remained at low levels in 2021 (0.344 per 100,000). Conversely, hemorrhagic fever seemed to experience a resurgence during the COVID-19 pandemic, increasing by 26.8%.
Table 1. Incidence (per 100,000) and mortality (per 100,000) for 42 notifiable infectious diseases among 5-22-year olds, by year.

AHC: acute hemorrhagic conjunctivitis; HD: hydatid disease; HF: hemorrhagic fever; HFMD: hand, foot, and mouth disease; ID: infectious diarrhea; JE: Japanese encephalitis; MM: meningococcal meningitis; SF: scarlet fever; SI: seasonal influenza; SM: schistosomiasis; T/P: typhoid and paratyphoid; TB: tuberculosis.
Figure 4. Temporal changes in the incidence of infectious diseases by disease category and day, from 2018 and 2019 (pre–COVID-19), year 1 (2020), and year 2 (2021) of the COVID-19 pandemic. (A) Overall infectious diseases; (B) Gastrointestinal and enterovirus; (C) Respiratory diseases; (D) Sexually transmitted and bloodborne; (E) Vector borne; (F) Zoonotic.

Figure 5. The leading infectious diseases by incidence by disease category and across age, from 2018 to 2021. HF: hemorrhagic fever; HFMD: hand, foot, and mouth disease; ID: infectious diarrhea; JE: Japanese encephalitis; NA: not applicable; SI: seasonal influenza; TB: tuberculosis.

Regional Variations in Infectious Disease Changes by Epidemic Phase

In the pre-pandemic years, there was evidence of a geographic North-South demarcation (the “Qinling-Huaihe River”), which separates China into 2 regions with varying incidences of notifiable infectious diseases. Compared with North China, South China has a more serious burden of infectious diseases, a pattern that remained evident in 2020 and 2021 (Figure 6 and Multimedia Appendix 5).

We then proceeded to compare changes in regional variation using the categories from 2018, 2019, and 2021, which were delineated based on the 4 phases of the pandemic in 2020.
comparison with the corresponding time phases in 2018 and 2019, the overall incidence of infectious diseases among children and adolescents was greater in each region during phase 1 of 2020. In phase 2, the overall incidence of infectious diseases among children and adolescents markedly declined across the country, and the incidence of notifiable infectious diseases was also lower in almost all regions of China than in the same phase in 2018 and 2019 (Multimedia Appendix 6). This pattern continued to be evident in phase 3 and phase 4 in 2020. However, in 2021, the incidence of infectious diseases among children and adolescents began to markedly recover, with even higher levels than in the prepandemic years in some regions. Considering the magnitude of the seasonal influenza outbreak from 2019 to 2021, we conducted sensitivity analyses by excluding seasonal influenza, and the results remained consistent (Multimedia Appendix 7).

Figure 6. (A) Regional variation in infectious diseases incidence by year and (B) percent change of incidence in each epidemic phase during COVID-year 1 in 2020 and COVID-year 2 in 2021 compared with the average pre–COVID-19 levels for 2018-2019 at the city level.

Persistence and Variability of the COVID-19 Pandemic by Notifiable Disease Category

Overview
As shown in Figure 7 and Multimedia Appendix 8, an indirect effect of the COVID-19 pandemic was evident on infectious diseases, characterized by a significant decrease in overall incidence during the initial year of the pandemic (2020), succeeded by a resurgence toward pre–COVID-19 pandemic levels for certain diseases. However, the degree of this phenomenon varied across the phases depending on the disease category.
**Respiratory Diseases**

The indirect impact of COVID-19 on respiratory diseases among Chinese children and adolescents appeared to be relatively consistent, as evidenced by a reduced incidence of each respiratory disease during the 2 pandemic years compared with the 2 prepandemic years. A rebound in the incidence rate of respiratory diseases was observed only during phase 4 in 2021, coinciding with a return to prepandemic rates. COVID-19–related restrictions appeared to impact the incidence of seasonal influenza, mumps, tuberculosis, scarlet fever, rubella, pertussis, and measles, as their incident IRRs were always lower during the 2 pandemic years than in the corresponding phases before the COVID-19 pandemic. The overall rebound in phase 4 of 2021 was driven mainly by seasonal influenza, pertussis, and meningococcal meningitis with larger IRRs of 1.02 (95% CI 0.74-1.41), 2.83 (95% CI 2.51-3.18), and 1.21 (95% CI 1.02-1.43) in phase 4 of 2021, respectively.

**Gastrointestinal and Enterovirus Diseases**

The incidence rebound started from phase 3 of 2020 and reached a similar level to prepandemic years in phase 4 of 2020, which was maintained during 2021. The rebound of gastrointestinal and enterovirus diseases was primarily led by infectious diarrhea, with incident IRRs in phases 2, 3, and 4 of 2020 being 0.45 (95% CI 0.41-0.50), 1.22 (95% CI 1.17-1.28), and 1.48 (95% CI 1.41-1.55), respectively. A similar pattern was observed in other gastrointestinal and enterovirus diseases, which exhibited varying degrees of rebound from phase 3 of 2020 onward, although they did not fully return to the levels seen before the COVID-19 pandemic in 2018 and 2019.

**Sexually Transmitted and Blood-Borne Diseases**

The indirect impact of COVID-19 on reducing sexually transmitted and blood-borne diseases was not sustained, as there was a rapid rebound starting from phase 3 of 2020 when China relaxed its most stringent prevention measures. Subsequently, the incidence of these diseases returned to pre–COVID-19 levels.
levels. This rapid rebound, particularly notable in South China, was largely driven by increases in the incident IRRs for syphilis and gonorrhea during phase 3 of 2020, reaching 1.31 (95% CI 1.23-1.40) for syphilis and 1.10 (95% CI 1.05-1.16) for gonorrhea (see Multimedia Appendices 9 and 10).

**Zoonotic Diseases**

The indirect impact of COVID-19 on zoonotic diseases appeared to be weak, as there was a rapid rebound observed after phase 3 of 2020, with the incidence levels remaining similar to each phase of the pre–COVID-19 years. Brucellosis stood out as the most pronounced rebound point, showing an incident IRR of 2.08 (95% CI 1.86-2.33) in phase 3 of 2020, especially notable in North China.

**Vector-Borne Diseases**

The indirect impact of COVID-19 on vector-borne diseases appeared to be relatively enduring, as the incidence during the COVID-19 pandemic years consistently remained lower than the levels observed before the pandemic. Despite rebounds in incidence for diseases such as hemorrhagic fever and typhus, these were insufficient to alter the overall trend for this group of diseases.

**Discussion**

**Principal Findings**

This examination of the incidence and mortality of 42 notifiable infectious diseases among Chinese children and adolescents aged 5-22 years in the period immediately preceding and the 2 years following the COVID-19 pandemic reveals that initially, the pandemic had a significant indirect effect, leading to notable decreases in all infectious diseases. However, this effect was not sustained, and the incidence of infectious diseases rebounded to previous levels during the second year of the pandemic, especially in southern China, where COVID-19 restrictions were largely lifted by 2021. The indirect effect of the pandemic varied by disease category, region, and time, with sexually transmitted and blood-borne diseases rebounding first, followed by gastrointestinal and enterovirus, and zoonotic diseases. By contrast, the indirect effect of the COVID-19 pandemic seemed to have a more continuous impact on vector-borne and respiratory diseases. Vector-borne diseases remained below prepandemic levels throughout the study period, while respiratory diseases only rebounded toward the end of the study period.

**Comparison With Other Studies**

Numerous studies have demonstrated a decrease in the incidence of infectious diseases during the initial phases of the COVID-19 pandemic, coinciding with the implementation of strict COVID-19–related restrictions [16,22-27]. For instance, hospital admission data from England revealed reductions in various infectious diseases during the pandemic, with the most significant decline observed in the incidence of seasonal influenza [16]. Other data from China indicated reductions in all infectious diseases, with respiratory diseases experiencing the most substantial declines [19,22,24]. However, a research study in Australia suggested that while various vaccine-preventable infectious diseases declined, the incidence of sexually transmitted and blood-borne diseases increased during the pandemic [26]. We demonstrated that while the incidence of hepatitis B, C, and D, as well as HIV/AIDS, remained stable or experienced slight declines during the COVID-19 pandemic, cases of syphilis and gonorrhea increased. Our study provides new evidence indicating that the implementation of national restrictions in response to the COVID-19 pandemic did not consistently or uniformly reduce the incidence of infectious diseases. This emphasizes the significance of public health professionals collaborating with governments to formulate comprehensive prevention and control policies addressing a broader spectrum of infectious diseases, beyond solely focusing on pandemic measures. This effort needs to encompass various aspects, ranging from health education to immunization, and from individuals to institutions, with a focus on both children and adolescents as well as their parents. A key finding from this study was the significant geographic disparities in infectious disease distribution observed both before and during the COVID-19 pandemic years. For instance, zoonotic diseases primarily affected western regions, whereas vector-borne diseases were mostly concentrated in coastal zones. While reflecting prepandemic patterns, these disparities stem from various factors including economic, geographic, climatic, and social differences. Urbanization, for example, aggregates populations and potentially increases the risk of disease transmission [28-35]. The complexity of these regional distribution patterns highlights the importance of conducting in-depth research and disease surveillance to unravel the nuanced relationships between environmental factors and socioeconomic determinants of health.

The resurgence in respiratory diseases observed in the last quarter of 2021 was primarily fueled by upticks in seasonal influenza, pertussis, and meningococcal meningitis. Interestingly, these conditions also demonstrated the most pronounced sustained decline in incidence. This indicates that the most significant indirect effect of COVID-19 restrictions was observed in other respiratory infections, likely reflecting the impact of sociobehavioral restrictions on the transmission of respiratory diseases [36,37]. The persistent behavioral restrictions aimed at reducing COVID-19 transmission, which remained in place even after school reopenings, might have contributed to the relative delay observed in returning to pre–COVID-19 levels of seasonal influenza, mumps, scarlet fever, rubella, and measles. The rebound in the incidence of seasonal influenza, pertussis, and meningococcal meningitis coincided with the peak season for these infectious diseases, which also aligned with the lifting of restrictions. During the pandemic, the decreased incidence of respiratory infectious diseases resulted in lower viral exposure and reduced immunization rates, leading to an “immunity debt.” This phenomenon increases the proportion of individuals susceptible to infection while gradually reducing herd immunity in the population [38]. In addition to immunization against influenza, pertussis, meningococcal meningitis, and COVID-19, wearing masks during the peak season for infectious respiratory diseases may represent an effective response to mitigate the scale of rebound in respiratory infections, as evidenced by ongoing efforts in Europe [38].
During the COVID-19 pandemic, there was a notable decrease in the incidence of gastrointestinal and enterovirus diseases among Chinese children and adolescents, which gradually increased as COVID-19 restrictions loosened, eventually returning to average levels. This pattern aligns with the impact of COVID-19 restrictions on social contact. In line with previous research, the most significant decline in gastrointestinal and enterovirus diseases was observed for HFMD, a seasonal virus that frequently affects children in school settings [19,22,25]. We demonstrated that infectious diarrhea and dysentery rebounded initially, followed by HFMD. However, acute hemorrhagic conjunctivitis, typhoid and paratyphoid, and hepatitis A exhibited persistently lower levels during the monitoring period. Understanding these nuances is crucial. For instance, 2 rounds of rebound have been described for HFMD: the first coinciding with the reopening of schools and the second corresponding to the seasonal increases experienced in spring and early summer [39].

During the initial phase of the COVID-19 pandemic, the incidence of sexually transmitted and blood-borne diseases decreased but rebounded to prerestriction levels when COVID-19–related restrictions were partially lifted. Gonorrhea and HIV/AIDS rebounded to average levels observed across 2018 and 2019, while syphilis rebounded to a higher incidence during the second year of the pandemic. Research conducted in the United States [40] and Germany [41] has indicated a positive correlation between sexually transmitted diseases and population mobility, implying that the COVID-19 restrictions effectively curbed population movement. While restrictions on population mobility might have reduced access to sexual partners and decreased high-risk sexual behavior and injecting drug use, the inability to attend hospitals for screening might have also contributed to the reduction of these infections during the pandemic [42]. As restrictions on population mobility were lifted before the reopening of schools, the rise in the incidence of gonorrhea and HIV/AIDS to levels exceeding historical norms is potentially driven by out-of-school adolescents. Previous research has also indicated that restrictions implemented to reduce COVID-19 transmission were ineffective in stemming the spread of syphilis [43]. In the United States, syphilis is more prevalent among individuals engaging in unprotected sex or having multiple partners, those who are HIV positive, and those who engage in sexual activity with peers, with recent significant increases observed among women [44]. One possible factor during the pandemic was the reduced access to condoms, which may have led to an increase in unprotected intercourse [45]. These findings underscore the importance that, during any pandemic, efforts to ensure the preservation of programs and interventions aimed at identifying and treating sexually transmitted infections are critical, alongside specific responsive measures.

Vector-borne diseases, along with respiratory infectious diseases, were the conditions that experienced the most pronounced benefits from COVID-19 pandemic measures, with incidence levels remaining lower for an extended period, despite some rebound observed in hemorrhagic fever and typhus. The restrictions on population mobility and the stringent control of students’ mobility during the pandemic seem to have substantially reduced opportunities for children and adolescents to come into contact with vectors and animal reservoirs of vector-borne and zoonotic diseases. This has led to a decreased incidence of both types of infectious diseases, consistent with evidence observed in adults [19]. While the highly cautious approach by the Chinese government to international travel may have contributed to this phenomenon, a resurgence of vector-borne diseases is anticipated once international travel resumes [46], as evidenced in Italy [47]. International travel has minimal impact on zoonoses, diseases that appear to be more prevalent in rural areas where children and adolescents have increased interaction with animals. School closures in these areas may elevate the risk of exposure to diseases such as brucellosis for students residing in rural areas [48].

Implications

Human civilization has encountered numerous pandemics throughout history. Interventions implemented during the COVID-19 pandemic have proven effective in “buying time” for vaccine development and reducing human mortality. However, there has been considerably less focus on measures to control the rebound in the incidence of common infectious diseases that often resurge during the later phases of any epidemic. In formulating strategies to address future pandemics, public health policy makers and governments are urged to consider approaches aimed at limiting the anticipated rebound in the incidence of other infectious diseases, particularly for disease categories where the rebound is projected to surpass prepandemic levels. Priority infectious diseases should be selected based on regional monitoring data, and comprehensive strategies should be developed for all categories of infectious diseases. Implementing interventions in schools may prove effective in preventing the rebound of gastrointestinal and enterovirus diseases while expanding vaccination programs can help address the immunization deficit resulting from limited exposure to respiratory infectious viruses or vaccine shortages during the pandemic. Maintaining testing and treatment services for sexually transmitted diseases is crucial across any pandemic while developing response strategies for imported vector-borne illnesses is imperative in any postpandemic phase.

Strengths and Limitations

This study possesses several notable strengths. First, we used data from the CISDCP, a long-term, systematic surveillance system covering over 85% of health facilities in China [20,49]. In China, health monitoring is largely conducted within schools. However, the utilization of the CISDCP allowed us to access data for out-of-school children and adolescents as well, thereby further increasing the representativeness of our study. While the CISDCP encompasses suspected cases, carriers of pathogens, and confirmed cases, we specifically included only patients with diagnoses supported by both uniform clinical standards and laboratory tests. This approach undoubtedly enhanced the accuracy of our results. Several potential limitations should be noted as well. The incidence of infectious diseases is influenced by multiple factors during the COVID-19 pandemic, and this study solely analyzed the impact of COVID-19–related restrictions, without considering specific meteorological, travel, and human mobility factors. Furthermore, the collective nature...
of COVID-19–related restrictions poses challenges in assessing the effects of individual restrictions. In addition, the variability in COVID-19 policy responses across Chinese provinces in 2021, such as fluctuating lockdowns and reopening, as well as variations in policy enforcement, complicates the distinction between affected and unaffected areas within these analyses. Indeed, the variability in policy implementation could potentially result in an underestimation of the impact of 2021 policies on the incidence rates of infectious diseases.

Conclusions
This study has unveiled the indirect impact of COVID-19–related restrictions on the incidence of infectious diseases among 5-22-year-old children and adolescents in China. Throughout the COVID-19 pandemic, there was a notable reduction in the incidence of the majority of infectious diseases, particularly respiratory and vector-borne diseases. However, the lifting of national COVID-19–related restrictions led to a rapid rebound in gastrointestinal and enterovirus diseases, sexually transmitted and blood-borne diseases, and zoonotic diseases, particularly in southern China. The overall resurgence of infectious diseases was primarily driven by respiratory diseases such as seasonal influenza, pertussis, and meningococcal meningitis, as well as gastrointestinal and enterovirus diseases such as HFMD and infectious diarrhea. Some sexually transmitted and blood-borne diseases, such as syphilis and gonorrhea, did not exhibit any reductions and instead showed persistently rising levels over the pandemic years. Planning for future pandemics must acknowledge that while mitigating strategies for the specific infectious agent are crucial, investment in broader efforts must also continue to protect children and adolescents. Beyond health education and access to routine immunizations, strategies should encompass precise approaches for different infectious diseases; strengthening disease surveillance; and ensuring access to prevention, diagnosis, and treatment services for sexually transmitted infections.

Acknowledgments
This study was supported by the National Natural Science Foundation (grant 82103865 to YD and grant 82273654 to YS) and Beijing Natural Science Foundation (grant 7222244 to YD and grant 7222247 to YS). We acknowledge Professor David Burgner (Murdoch Children’s Research Institute, Royal Children’s Hospital) for helpful preliminary discussions and suggestions.

Data Availability
All of the data (deidentified) collected in the surveillance system can be shared with investigators whose proposed use of the data has been approved by an independent review committee identified for this purpose by contacting the corresponding author. The study protocol and statistical analysis plan must be approved by the committee. Proposals should be directed to dongyanhui@bjmu.edu.cn, songyi@bjmu.edu.cn, or majunt@bjmu.edu.cn.

Authors’ Contributions
YD and YS have equal contributions to this study. LC, LW, and YX conceptualized and designed the study, completed the statistical analyses, drafted the initial manuscript, and reviewed and revised the manuscript. YD, JEM, and YS contributed to the conceptualization and design of the study; supervised the data collection, statistical analyses, and initial drafting of the manuscript; and reviewed and revised the manuscript. SS and JM contributed to the interpretation of the data, and critically reviewed and revised the manuscript. All authors approved the final manuscript as submitted and agreed to be accountable for all aspects of the work.

Conflicts of Interest
None declared.

Abstract

Background: Structural racism produces mental health disparities. While studies have examined the impact of individual factors such as poverty and education, the collective contribution of these elements, as manifestations of structural racism, has been less explored. Milwaukee County, Wisconsin, with its racial and socioeconomic diversity, provides a unique context for this multifactorial investigation.

Objective: This research aimed to delineate the association between structural racism and mental health disparities in Milwaukee County, using a combination of geospatial and deep learning techniques. We used secondary data sets where all data were aggregated and anonymized before being released by federal agencies.

Methods: We compiled 217 georeferenced explanatory variables across domains, initially deliberately excluding race-based factors to focus on nonracial determinants. This approach was designed to reveal the underlying patterns of risk factors contributing to poor mental health, subsequently reintegrating race to assess the effects of racism quantitatively. The variable selection combined tree-based methods (random forest) and conventional techniques, supported by variance inflation factor and Pearson correlation analysis for multicollinearity mitigation. The geographically weighted random forest model was used to investigate spatial heterogeneity and dependence. Self-organizing maps, combined with K-means clustering, were used to analyze data from Milwaukee communities, focusing on quantifying the impact of structural racism on the prevalence of poor mental health.

Results: While 12 influential factors collectively accounted for 95.11% of the variability in mental health across communities, the top 6 factors—smoking, poverty, insufficient sleep, lack of health insurance, employment, and age—were particularly impactful. Predominantly, African American neighborhoods were disproportionately affected, which is 2.23 times more likely to encounter high-risk clusters for poor mental health.

Conclusions: The findings demonstrate that structural racism shapes mental health disparities, with Black community members disproportionately impacted. The multifaceted methodological approach underscores the value of integrating geospatial analysis and deep learning to understand complex social determinants of mental health. These insights highlight the need for targeted interventions, addressing both individual and systemic factors to mitigate mental health disparities rooted in structural racism.

Introduction

Structural Racism and Discrimination (SRD) is a fundamental determinant of health disparities and poor health outcomes among historically marginalized communities in the United States [1]. SRD refers to systemic or institutional racism and societal norms that constrain the chances, resources, influence, and welfare of people and communities due to their racial and ethnic background and other characteristics. Racial segregation in urban centers is an outcome of SRD-driven policy inequalities such as discriminatory mortgage lending practices (redlining), confining Black Americans to central city neighborhoods, which became sites of concentrated poverty and heightened inequities. Residents of segregated neighborhoods experience disproportionate exposure, susceptibility, and vulnerability to economic and social inequality, environmental pollution, toxic substances, and unsafe conditions, thereby affecting individual health conditions, health practices, and access to health care services [2]. Further, neighborhood-level racial and ethnic segregation determines and limits access to educational, employment, and health-related resources [1]. Studies have emphasized the significance of neighborhood segregation on health inequity [3].

Past research has focused on the relationship between interpersonal discrimination and health; however, SRD is likely to have broad downstream effects on psychological, biological, physiological, and behavioral processes [4]. Mental health is of particular importance, especially since the start of the COVID-19 pandemic, where estimates of pooled prevalence of depression are 7 times higher than expected [5], with minority Americans experiencing more severe and chronic symptoms across time [6]. As individuals are embedded within larger systems of influence, it is essential to understand the relationship between SRD and mental health at a community level [5]. The socioecological model of health provides a framework to examine how individual health and behavior are impacted by interpersonal, neighborhood, and societal factors [7]. The National Institute on Minority Health and Health Disparities (NIMHD) has encouraged a place-based approach, as “relationships between SRD and physical/mental health are influenced by numerous place-based factors… individual-level factors (i.e., health-related behaviors, ways of coping) are understood best within the context of the lived environment and structural policies that perpetuate inequities” [1].

To examine the contribution of SRD to inequalities, various measures have been used including racial residential segregation [8]. However, no domain of structural racism operates in isolation, multiple index measures of SRD have been created and applied. Dougherty et al [9] developed a structural racism index measure by combining 7 measures of SRD: housing dissimilarity index, school dissimilarity index, high school graduation ratio, incarceration ratio, poverty ratio, primary care ratio, and ambulatory care ratio. Still, there are no consistent, agreed-upon relevant content domains of structural racism [10].

Instead of selecting 1 approach or developing yet another index, we examined mental health disparities without reference to race to determine whether communities experiencing SRD can be identified using an unsupervised retrospective approach.

This study used the NIMHD framework to explore the relationship between SRD and mental health. By using machine learning algorithms with geodata science, we conducted spatial modeling and geovisualization to investigate how location-based factors, indicative of SRD, impact mental and physical health. This approach allows for a statistical analysis of these dynamics over time and space, offering a comprehensive analysis of the effects of place on health outcomes [11]. Data were analyzed at multiple geographic scales—county, city, and census tracts. Understanding mental health at the community level is important, given the complex intersectionality of factors that promote or hinder health in the United States [12].

Our study site is Milwaukee County (population of 918,661), the most populous county in Wisconsin, with a racially diverse population of Black (n=241,608, 26.3%), Hispanic or Latino (n=143,311, 15.6%), and White origin (n=541,091, 58.9%) [13]. The county includes the hypersegregated city of Milwaukee (population 636,305), where redlining confined the African American population to its central city neighborhoods. Devastated by deindustrialization and disinvestments, these neighborhoods exhibit concentrated urban poverty, heightened spatial inequalities, and dramatic health disparities [14], where Black residents experience a poverty rate 5 times higher than that of White residents and White residents outlive Black residents by almost 14 years [13]. Acknowledging the damaging legacy of SRD on health, Milwaukee County was among the first jurisdictions in the United States to declare racism as a public health crisis in 2019, with 170 jurisdictions following its suit.

Methods

Overview

To identify geospatial determinants of health across behavioral indicators, built environment, sociocultural environment, and health care (based on the NIMHD framework), georeferenced data sets were acquired from the United States Census Bureau. The United States Census Bureau anonymizes and deidentifies data before releasing them to the public. Detailed demographic data can be obtained only at the Census Tract level (each tract comprises 4000 residents) and not at an individual level. In accordance with census policies, we analyzed all data at the census tract level, and no individual-level data have been obtained or used. Selected variables (eg, age, gender, population, race, ethnicity, marital status, educational attainment, educational enrollment, employment, neighborhood stability, and poverty) were compiled into a data set of 217 explanatory variables. Notably, race-based factors were deliberately withheld during the initial stages of our unsupervised machine learning analysis. This approach allowed the model to operate without
the assumption that racial disparities significantly influence mental health outcomes. It was only in the final stage of the analysis that race and ethnicity variables were incorporated, providing an opportunity to observe whether the emerging patterns of poor mental health prevalence correlated with racial factors. All variables were joined to the administrative boundary shapefile of Milwaukee County census tracts collected from the TIGER/Line database11 (using ArcGIS Desktop 10.7; Environmental Systems Research Institute).

**Variable Selection Procedure**

**Overview**

Variable selection minimizes the number of predictors in quantitative models to improve efficiency and reduce complexity. Public health research commonly uses conventional techniques such as subject matter expert selection and regression-based stepwise selection. However, tree-based methods such as random forest can handle nonlinear, nonparametric relationships and provide more robust results [15].

Extreme multicollinearity can cause parameter estimate instability, unintuitive parameter signs, high $R^2$ diagnostics despite few or no significant parameters, and inflated standard errors of the parameter estimates [16]. To avoid this, variance inflation factor (VIF) and Pearson correlation analysis are used to detect multicollinearity and select the most uncorrelated variables for the random forest variable selection model. The variable selection method [17] implemented in the Variable Selection Using Random Forest (VSURF) R package (R Foundation for Statistical Computing) yields the best results compared with other variable selection and baseline methods [18]. The method ranks variables by their importance, eliminating the least important ones and constructing a sequence of random forest models. Eventually, variables of the most optimized model are selected.

**Geographically Weighted Random Forest**

Spatial modeling enables the examination of how variables behave across geographical space to identify spatial heterogeneity and dependence. Local spatial modeling offers a more informed approach to understanding complex phenomena compared with conventional global approaches [19]. The geographically weighted random forest (GWRF), a localized model, is ideal for conducting public health research. However, GWRF has not been used to examine the variability in relationships between place-based risk factors and the prevalence of poor mental health. This study used GWRF to investigate nonstationarity and localized associations between risk factors and the prevalence of poor mental health.

Local feature importance in GWRF measures how much each feature contributes to the accuracy of the model within a specific region, calculated by the increase in mean squared error or the decrease in node impurities averaged over all trees in the model. These measures are derived from the out-of-bag (OOB) error, which is a measure of the model’s performance on data not used during training [20].

**Self-Organizing Maps**

Self-organizing maps (SOMs) are unsupervised artificial “neural” networks that create a 2D space topographic map of a data set. “Neurons,” or relational clusters, are organized to preserve their context or neighborhood, and SOMs use closeness or neighborhood function to display input space properties. We implemented a SOM model to explore a data set containing 296 census tracts in Milwaukee County×12 determinant factors of poor mental health. The SOM was trained on this data set using a 5×5 hexagonal grid, selected for its ability to create a more comprehensive and representative map of the data. After training the SOM, we delved deeper into the clusters formed on the map by combining the SOM with k-means clustering, an algorithm known for its efficiency in partitioning data into distinct groups or clusters. We determined the optimal number of clusters for our data set by evaluating the “within-cluster sums of squares” and the “average silhouette” statistics [21].

**Ethical Considerations**

This study uses anonymized and deidentified publicly available data sets that were released by federal or state agencies for public consumption. All publicly available government data are aggregated at the census tract level, where each tract is composed of 4000 individuals. We received full approval from the Medical College of Wisconsin institutional review board with exemption from oversight by Code of Federal Regulations 46.104 (d) 4, as we conducted secondary analyses of publicly available anonymized and deidentified data sets that do not contain any personally identifiable information and do not pose any risk to ethical violations. Given that the project did not involve direct contact with subjects, an informed consent process was not required and no compensation was provided. Moreover, the project did not require a waiver of HIPAA (Health Insurance Portability and Accountability Act) authorization as outlined in 45 Code of Federal Regulations 164.514(e) because it used a Limited Data Set.

**Results**

**Input Factor Selection**

We compiled a database of 217 geospatial determinants of health across behavioral indicators, built environment, sociocultural environment, and health care to analyze the relationship between place-based factors and mental health. Next, we excluded all race-based factors and used the remaining 184 variables to identify highly colinear variables, VIF, and Pearson correlation analysis was applied (VIF threshold=7.5; Pearson correlation threshold=0.75). As a result, 105 uncorrelated factors were selected to be used as the input for the variable selection (VSURF) procedure.

**User Statistics**

The VSURF procedure was applied to the 105 place-based factors to find a sufficiently parsimonious set of significant indicators of poor community mental health (ie, the percentage of adults who stated that their mental health was not good 14 or more days in the past month) and measures of SRD. The VSURF selected 98 variables at the thresholding step, then 24 variables at the interpretation step, and 12 variables at the
prediction step. The most important place-based factors of mental health were adults who smoke, insufficient sleep, adults without health insurance, adults who are obese, adults who are sedentary, marriage rate, people living below the poverty level, childhood opportunity index score, median age, homeownership, full-time employment, and educational attainment (all variables are percentages except for Age and Childhood Opportunity Index score). These variables account for 95.11% of the variability in poor mental health in communities, with a mean of squared residuals of 0.74.

Partial dependence plots depicting the relationship of each of the 12 predictive variables for poor mental health were constructed. Figure 1 illustrates the correlation between the selected 12 variables and poor mental health. The results of the partial dependence plot approach showed that the relationship among the prevalence of smoking, poverty, insufficient sleep, lack of health insurance, single households, sedentariness, and poor mental health was positive. In contrast, the childhood opportunity index, median age, homeownership, and employment rate exhibit negative relationships with poor mental health. Notably, obesity and educational attainment did not follow linear trends in relation to poor mental health, illustrating the complexity of these factors. The largest difference makers were the prevalence of smoking, lack of insurance, poverty, insufficient sleep, employment, and age.

Figure 1. Partial dependence plots illustrate the marginal effect of each of the 12 selected predictor variables on the prevalence of poor mental health. The Y-axis in each plot indicates the prevalence of poor mental health outcomes, quantified as a percentage, and the X-axes represent the value of each predictive variable. The curve in each partial dependence plot shows the relationship between the predictor variable and the prevalence of poor mental health outcomes. An ascending curve implies that an increase in the predictor variable corresponds with an increase in poor mental health outcomes, while a descending curve implies the opposite.

GWRF Implementation
Next, we used GWRF to investigate and visualize local associations between poor mental health prevalence and the 12 identified place-based risk factors at multiple scales—the county, the city, and census tract levels. Six place-based risk factors (prevalence of smoking, lack of insurance, poverty, insufficient sleep, employment, and age) were identified as having a spatially heterogeneous impact. We trained the GWRF with 45 nearest neighbors (census tracts) with bootstrapped 5000 “ntrees” and 4 “mtry” in each tree. It yielded a local model with an $R^2$ square (OOB) of 94.91%, mean squared error (OOB) of 0.051, and Akaike Information Criterion (OOB) of –856.447. Spatial variation of the local contribution of the 6 risk factors to the prediction of poor mental health is shown in Figure 2.
Figure 2. Geographic variation in place-based risk factors impacting mental health. Maps represent a visualization of the localized influences of 6 place-based risk factors—prevalence of smoking, lack of health insurance, poverty level, insufficient sleep, employment status, and median age—on predictions of poor mental health. Visualization is based on the findings of the GWRF model. Each risk factor is represented in a separate map, with color gradients signifying areas of varying impact on mental health. Darker shades indicate regions where a risk factor significantly correlates with poor mental health, while lighter shades correspond to weaker correlations. These visual representations underscore the spatial heterogeneity of mental health determinants and the significance of targeted interventions. GWRF: geographically weighted random forest. For a higher-resolution version of this figure, see Multimedia Appendix 1.

SOMs Implementation

A SOM approach was used to determine impactful clusters of the 12 most significant place-based factors related to mental health. Census tracts were grouped based on similarities in these mental health–related factors. The SOM was integrated with k-means clustering to further delineate and group census tracts based on their similarity. The original 25 SOM grid codes were condensed into 3 clusters, depicted in Figure 3. Each cluster represents a collection of census tracts displaying similar patterns or characteristics across the 12 mental health–related factors. Clusters 1, 2, and 3 differ markedly in their composition, each corresponding to varying levels of mental health risk. Although a more detailed understanding of each cluster necessitates additional data, particularly in terms of specific demographic, socioeconomic, and environmental variables that may influence these risk levels, these clusters can be generally categorized as representing high (cluster 3), moderate (cluster 2), and low (cluster 1) risk for poor mental health. This categorization is based on the aggregated mental health factors within each cluster. Deeper analysis with more comprehensive data could reveal more nuanced distinctions and cluster-specific contributing factors.

Figure 4 represents the geospatial distribution of the 3 mental health risk clusters across Milwaukee County. Classification into low-, moderate-, and high-risk labels refers to the collective intensity of the 12 key place-based mental health factors within each cluster. For instance, the “high-risk” label indicates the prevalence of higher levels of risk factors (ie, smoking prevalence, lack of health insurance, and poverty) known to contribute to poor mental health but does not necessarily mean that all individuals in this cluster have poor mental health.
To examine racial disparities within community clusters, we calculated a disproportionality index, the ratio of the percentage of a specific racial demographic within each cluster compared with that within a base population. Within the low-risk group (cluster 1), the disproportionality index is 1.5 for the White population, indicating an overrepresentation; the Black and Hispanic populations are underrepresented with indices of 0.21 and 0.6, respectively.

In the moderate risk group (cluster 2), the White population is underrepresented, with an index of 0.6; the Black and Hispanic populations are overrepresented, with indices of 1.52 and 1.51, respectively. The most significant disparity was found in the high-risk group (cluster 3), where the Black population’s disproportionality index was 2.23, and the White and Hispanic populations were underrepresented with indices of 0.34 and 0.51, respectively.

The findings of our unsupervised approach demonstrate significant mental health disparities that align with the racial demographics in Milwaukee County, despite our exclusion of race-related factors. The overrepresentation of Black populations in the high-risk cluster combined with the overrepresentation of the White population in the low-risk cluster indicates that disparities observed across clusters are not isolated occurrences but rather are indicative of underlying socioeconomic disparities likely caused by structural racism and discrimination. Notably, while Hispanic community members were underrepresented in the low-risk cluster 1 and overrepresented in the moderate-risk cluster 2, they were underrepresented in the high-risk cluster 3. This highlights that there are differences across racial minority demographics that influence mental health. For example, differences in upward financial mobility have been identified between Black and Hispanic communities [22].

The spatial dependency of risk areas was investigated to discover the locationality of poor mental health areas. To examine the degree of similarity, the Global Moran I index was calculated to measure the degree of similarity between an area and its neighboring areas. The calculated Moran Index is 0.53 with a z score of 21.63, indicating that there is <1% likelihood that the clustering of poor mental health risk was the result of random chance. The findings, displayed in Figure 4, show that clusters 2 and 3 are primarily located in central city neighborhoods of Milwaukee County, aligning with predominantly Black communities in the central and north side of the city and with the Hispanic community in Milwaukee’s south side.

Although generated without incorporating location as a factor, Figure 4 demonstrates spatial autocorrelation, signifying the presence of spatial dependency in mental health outcomes. This suggests that mental health issues are not randomly distributed but rather display geographically linked patterns. Spatial dependency confirms the influence of location or spatial context on mental health. Our results align with previous findings, further demonstrating that mental health outcomes are partly a product of spatially located phenomena such as socioeconomic conditions, access to health care, environmental factors, and SRD. The observations reinforce the assertion that conventional global models are not ideal for examining complex phenomena such as community mental health or SRD [19,23]. Local spatial modeling offers more precise outcomes when processes are affected by both their geographical location and the fluctuating conditions of underlying variables across different times and locations.

Figure 3. Integrated self-organizing map and k-means showing the 3 clusters of census tracts in Milwaukee County based on similarities among the 12 mental health risk factors. The differences between clusters are maximized and within clusters are minimized. The size or area of each wedge reflects its proportional “influence” on mental health in the corresponding census track grouping.
Discussion

Principal Findings

To address the complex issue of SRD and its impact on mental health disparities, our study used a 5-step process. First, we compiled a comprehensive database of place-based explanatory factors, also known as “geospatial determinants of health,” at the census tract scale [24]. Second, we deliberately eliminated all race-based factors, an unprecedented approach to assess whether SRD effects on mental health disparities could be examined without directly referencing race. Third, we conducted a variable selection process, identifying the most defining place-based characteristics that shape the mental health conditions of an affected community. Fourth, using SOMs, we clustered census tracts based on mental health risk factor similarity. Finally, we investigated the racial composition, demographic characteristics, and spatial dependency of risk areas to shed light on racial disparities, confirmed SRD, and illuminated the locationality of mental health and SRD (Table 1).

Our study introduces a novel approach to analyzing mental health disparities and their structural underpinnings, diverging from traditional models. By integrating advanced geospatial and machine learning techniques, it provides a more granular, community-specific insight into these disparities. This method contrasts with conventional approaches that may not fully capture the intricate, locality-specific interactions of factors impacting mental health [8]. In line with the study by Groos et al [8] based on the exploration of structural racism quantification methods, this study exemplifies the shift toward more sophisticated, nuanced methodologies in understanding the complex effects of SRD on health outcomes.
poor mental health in both the central city neighborhoods and the affluent shoreline areas of Milwaukee County.

Age is a determinant of mental health. Adult mental health diagnoses often begin in adolescence, with approximately half of all adult mental health disorders emerging in the teenage years [33]. The median onset age ranges from 8 to 35 years, and increased age is associated with better mental health [34]. Chen et al [35] found that the relationship between census tracts’ median age and prevalence of poor mental health follows a negative curvilinear trend, consistent with a large-scale meta-analysis of 192 epidemiological studies. Our results demonstrate that poor mental health in the central city neighborhoods of Milwaukee County is more significantly associated with age than in other parts of the county, indicating that the influence of age on mental health varies locally.

Although high-risk clusters showed high spatial alignment with socioeconomically disadvantaged communities in Milwaukee, several individual factors were strong predictors of mental health in more affluent and socioeconomically secure areas (eg, in Milwaukee’s lakefront communities). These include unemployment, lack of insurance, sleep deprivation, and smoking. These observations suggest that while these communities are not locations of high-risk clusters, mental health associations are evident in subgroups of community members.

### Geographical Disparities in Mental Health Challenges

Insights gained from the disproportionality indices reveal the need for targeted interventions and policy adjustments in Milwaukee communities. These indices do not only demonstrate disparities but are also critical for guiding approaches that can address racial imbalances in mental health, steering toward a more equitable health care system. Our findings align with research demonstrating that mental health outcomes are the products of spatially located phenomena, including socioeconomic conditions, access to health care, environmental factors, and deeply rooted SRD [36]. This confluence of factors reinforces the assertion that conventional global “one-size-fits-all” approaches fall short of understanding complex phenomena such as community mental health or the intricacies of structural racism and discrimination [19,23]. *With the exception of median household income, all data represent a percentage of the population in the census tracts that comprise each cluster. Data sets were sourced from the Centers for Disease Control and Prevention’s 500 Cities Project and the United States Census Bureau.*
processes are governed by their location and by conditions that fluctuate over time, the use of localized spatial modeling approaches offers a more realistic alignment, yielding more accurate and nuanced results. This perspective challenges traditional frameworks and calls for a tailored approach that considers the unique characteristics of each community, reflecting a more comprehensive understanding of mental health disparities (Table 1) [37-39].

While our approach introduces innovative methods for analyzing mental health disparities, it is crucial to acknowledge the inherent limitations of observational studies. Such limitations highlight the need for caution in interpreting causality from our findings. Our study’s results, therefore, should be considered indicative of associations rather than definitive causal relationships. For example, the relationships of several factors with mental health (eg, smoking, sleep deprivation, and unemployment) are likely bidirectional. This acknowledgment is vital in guiding future research and formulating public health policies that are based on a comprehensive understanding of mental health determinants.

Finally, while our study demonstrates that Black residents are overrepresented in neighborhoods where high-risk factors for poor mental health are localized, our approach does not address risk for Black community members who live in non-Black majority communities. Moreover, our classification of communities as Black, Hispanic, and White does not recognize diversity within these racial demographics (eg, Puerto Rican vs Mexican heritage) [40].

Conclusions
Understanding the complex interplay between SRD and mental health is vital to informing public health policies and interventions. For example, acknowledging that SRD places additional burdens on an individual’s ability to cope with life’s demands calls for targeted support in areas such as mental health services, education, employment, and community infrastructure. Our study, deploying advanced Geographic Information System and unsupervised machine learning analyses, unravels complex spatiotemporal relationships predicting poor mental health while excluding explicit race-related variables. The findings highlight that the risk for poor mental health is intertwined with structural and spatially localized factors that correspond with disproportional racial representation within communities. These insights illustrate a need for reinvestment strategies that recognize, protect, and promote mental health, with a focus on communities disproportionately affected by SRD. Such strategies must be implemented in a manner that considers the multifaceted risks and includes protections against further exacerbating disparities. In an era where mental health disparities persist, our research emphasizes the importance of a targeted and localized approach, prioritizing communities with historical burdens of discrimination, ensuring equitable access to resources, and ultimately fostering a more resilient and inclusive mental health care system.

Multimedia Appendix 1
Geographic variation in place-based risk factors impacting mental health. Maps represent a visualization of the localized influences of 6 place-based risk factors—prevalence of smoking, lack of health insurance, poverty level, insufficient sleep, employment status, and median age—on predictions of poor mental health. Visualization is based on the findings of the GWRF model. Each risk factor is represented in a separate map, with color gradients signifying areas of varying impact on mental health. Darker shades indicate regions where a risk factor significantly correlates with poor mental health, while lighter shades correspond to weaker correlations. These visual representations underscore the spatial heterogeneity of mental health determinants and the significance of targeted interventions. GWRF: geographically weighted random forest.

Abstract

Background: The COVID-19 pandemic and related control measures affected the mental health of all populations. Particular subgroups are underrepresented in mainstream surveys because they are hard to reach, and study measurements are not adapted to their skills. These subgroups include people with lower cognitive and literacy skills, such as people with mild intellectual disability (MID), who were considered vulnerable during the COVID-19 pandemic given their low socioeconomic status, small social networks, increased risks of health problems, and difficulties understanding health-related information.

Objective: This study examines the impact of the COVID-19 pandemic on mental health among people with MID or low literacy skills compared with those predominantly represented in national surveys.

Methods: A repeated cross-sectional study of people with MID or low literacy skills and a general population sample was conducted in the Netherlands. An easy-read web-based survey was co-designed with, and tested among, people with MID or low literacy skills and conducted in 3 rounds within 1 year of the COVID-19 pandemic (T1: November to December 2020, T2: March to April 2021, and T3: September to October 2021). The survey contained questions about demographics and 6 aspects of mental health: feeling happy, feeling energized, feeling stressed, worry, feeling lonely, and sleeping problems.

Results: Our adapted survey and recruitment procedure enabled 1059 persons with MID or low literacy skills to participate (T1: n=412, 38.9%; T2: n=351, 33.1%; and T3: n=296, 28%). They were significantly younger, had a lower level of education, and more often than not were born outside the Netherlands compared to the general population sample (P<.001). Approximately half of them (604/1059, 57.03%) received professional care. They displayed poorer mental health scores than the general population sample. The percentages of people with MID or low literacy skills who reported more negative feelings in T1 ranged from 20.6% (85/412) reporting feeling lonely often or almost always to 57.8% (238/412) reporting feeling happy almost never or sometimes. The general population sample’s percentages were 5.4% (160/2930) and 32.2% (941/2918), respectively. Although scores improved over time in both populations, the disproportional effects remained.

Conclusions: General COVID-19–related restrictions for the entire Dutch population affected people with MID or low literacy skills more negatively than the general population. Our study underscores the relevance of including these subpopulations in public health research because they are often overlooked in regular health data. An accessible web-based survey particularly targeted at this population enabled us to do so, and we reached a group of respondents significantly different from regular survey
participants. This survey’s results provided insights into the health of people with MID or low literacy skills and gained knowledge to be used by care organizations and policy makers to reduce health disparities during a pandemic and in general.

**Introduction**

Studying COVID-19–Related Impact

The COVID-19 pandemic and related disease control measures affected the entire world. People were advised to adhere to strict hygiene measures and to work from home (if possible), and public places and nonessential shops were closed. In addition, social distancing and visiting restrictions were in place during lockdowns. In general, these restrictions had a major impact on daily routines, social contacts, and mental health [1-3], affecting some individuals more than others [4]. In the Netherlands, the *Rijksinstituut voor Volksgezondheid en Milieu* (RIVM; National Institute for Public Health and the Environment) started conducting a national longitudinal survey to monitor the impact of COVID-19 and related measures on Dutch citizens [5,6]. The monitor is informative regarding disease control strategies and policy making [7]; however, there is an external validity bias because participant characteristics show that a majority of the participants have a high educational level and are middle-aged or older and women [6,8,9]. Indeed, studies have demonstrated that particular subgroups are often underrepresented and excluded from mainstream surveys because general recruitment strategies are unsuitable for reaching them, and study measurements are not adapted to their cognitive level or literacy skills [10-12]. These groups often comprise people with lower socioeconomic status and higher risks of health problems, and, in the case of the COVID-19 pandemic, more difficulties complying with preventive measures [13-15], given their housing or work situation.

This study examines the impact of the COVID-19 pandemic and related restrictions on mental health and well-being among people with lower cognitive and literacy skills in addition to those who are predominantly represented in the national survey. An accessible survey based on the national survey was developed, and alternative recruitment techniques were used to specifically include these underrepresented subgroups.

**Subpopulations at Risk for Greater COVID-19–Related Impact**

In the Netherlands, approximately 19% of the adult population (ie, 2.5 million adults) have limited reading, writing, or numeracy skills [16]. These limitations have various causes, such as a low level of educational attainment, migrant background, parents’ level of education and literacy, or low information-processing skills [17]. The last item plays an important role in people with mild intellectual disability (MID), who experience considerable limitations in both intellectual functioning and adaptive behavior and often need support in their daily life [18]. It is estimated that 4% to 8% of the Dutch population have an MID [19]. People with low literacy skills or MID often have limited work and income, poor health, and small social networks [20-24]. In general, studies have shown that people with low education and health literacy as well as those without social support, a stable income, a daily routine, and access to services are more at risk of mental health problems such as anxiety, general distress, and loneliness arising from the COVID-19 pandemic [1,3,5,14,25,26]. Therefore, it is likely that the COVID-19 pandemic had a higher impact on the mental health of people with MID or low literacy skills compared with the general population. However, during the first months of the pandemic, very limited knowledge was available about the impact on this subpopulation, and our study was set up to provide both these essential insights and practical recommendations for policy makers and care providers.

During the COVID-19 pandemic, studies on mental health specifically aimed at people with mild or more severe intellectual disability (ID) showed negative impacts as a result of social isolation or a lack of social support, the rapid changes in COVID-19–related measures and difficulty understanding these measures, difficulty accessing services, and disruption of daily routines [27-29]. Two European surveys among people with ID found that more than half reported stress or anxiety [30,31] or felt more anxious than usual because of the pandemic and subsequent lockdown [31]. A US survey found that 41% of the participants with ID had experienced more mental health problems or symptoms since the pandemic began; worry and stress were most often mentioned [32]. Similarly, people with low health literacy experienced more anxiety disorders, bouts of depression, and sleeping disorders during the COVID-19 pandemic than those showing sufficient health literacy [14]. Altogether, these studies—primarily conducted during the first lockdown periods—showed a great impact on the mental health of people with MID or low literacy skills, which contributed to an increase in preexisting inequalities in health and well-being [24,33].

The current underrepresentation in national surveillance and surveys of people with MID or low literacy skills, as well as the consequent lack of information about them, adds to existing health disparities. To better understand the impact of the COVID-19 pandemic on people with MID or low literacy skills, the specific factors driving this impact, and their specific needs, more information is urgently needed. Knowledge acquired through monitoring population health in its local context can provide a basis for government and health organizations to develop appropriate strategies to reduce this impact accordingly. In addition, the course of the pandemic and the ever-changing COVID-19 disease control strategies over time are important aspects regarding the context in which people were affected. Due to the rapidly changing situation and regulations during the pandemic (eg, when vaccinations were offered or restrictions

https://publichealth.jmir.org/2024/1/e44827
were lifted), a dynamic impact on mental health was expected, and more insight is needed into how people responded to this unpredictable course.

**Objectives**

This study examines the impact of the COVID-19 pandemic on people with MID or low literacy skills in direct comparison with the general population and over the course of the pandemic at 3 different time points. A unique survey study was set up that complemented the RIVM national survey. This study developed an accessible version of the web-based survey together with representatives of the target population and used suitable techniques to reach people with MID or low literacy skills.

**Methods**

**Study Design**

A repeated cross-sectional study of people with MID or low literacy skills and a general population sample was conducted during the COVID-19 pandemic in the Netherlands. The inclusion criteria were people with reading and writing difficulties, aged ≥16 years, living in the Netherlands, and completion of the survey. No exclusion criteria were used. A control question to assess participants on literacy skills or intellectual ability was not included because this was expected to be too sensitive for the participants. For reasons of comparison, the same survey was presented to 2 panels used to represent the general Dutch population.

The survey was administered 3 times in a 1-year period between November 2020 and November 2021. The first survey (T1) was distributed during a nationwide second lockdown (November to December 2020), the second survey (T2) was administered after the second lockdown and when the Dutch vaccination program had started (April to May 2021), and the third survey (T3) was distributed after the summer when most COVID-19–related restrictions had been lifted (September to October 2021). Figure 1 shows the timeline and the severity of the COVID-19 pandemic in the Netherlands by means of excess mortality rates. Data were derived from Statistics Netherlands [34].

**Study Population and Recruitment**

The surveys were disseminated via organizations working with people with MID or low literacy skills, such as advocacy organizations, care facilities for people with MID, language education organizations and libraries supporting and educating people with no or low literacy skills, social workplaces, the Dutch center of expertise on health disparities Pharos, Special Olympics, and a website offering accessible web-based information and programs for people with limited digital or literacy skills [35]. The surveys were open for between 4 and 6 weeks, giving the organizations time to distribute them within their network. Support was available to allow people who were anxious or unable to complete the survey independently to participate in this study. At the end of each survey, participants were asked to participate in future research, resulting in a panel of participants who could be contacted directly for the subsequent survey rounds.

Our easy-read survey was also distributed within the same time period to 2 municipal health service (MHS) panels: GGD Gelderland-Zuid (n=approximately 2500) and GGD Gelderland-Midden (n=approximately 7000). Each MHS panel consisted of residents in its service area who are regularly asked to complete health surveys. There is a known bias to these panels, in that they generally consist of older and more highly
educated residents, with an overrepresentation of women [36]. We particularly used these panels in our study to obtain comparative data from a Dutch population sample and because these panels were also invited to participate in the national RIVM survey.

All participants received the same survey. Participation was voluntary, and participants could stop completing the survey at any time. Completion of a prior survey was not mandatory for participation in the next round. Data were obtained anonymously; therefore, matching between surveys and paired within-group analysis over time were not possible.

Web-Based Survey Development

The RIVM survey on Dutch citizens’ perception of the COVID-19-related measures, their impact on well-being, and whether people were complying formed the basis of this monitor but was adapted to provide an easy-read version for this study [6]. The national survey consisted of >100 questions (eg, about participants’ well-being, trust in the government, adherence to COVID-19–related measures, the risk of COVID-19 infection, and the understanding of COVID-19 information). Over time, new topics such as willingness to receive COVID-19 vaccinations and vaccine hesitancy were added to the survey. To create an easy-read version, we adapted the national survey in three steps by (1) shortening the survey (ie, we selected only a limited number of relevant topics), (2) reducing the number of response categories, and (3) adjusting the language level. This procedure was based on literature insights [37] and carried out in collaboration with professionals (researchers: n=2, care providers: n=3, and policy makers: n=2 working with people with MID or low literacy skills regarding health-related issues) as well as 2 experiential experts with MID or low literacy skills trained to advise, and experienced in advising, research projects. First, to shorten the survey, we discussed, prioritized, and selected the most relevant topics in light of our research objective to measure mental health, relevance to the target population, and the target population’s cognitive capacity to answer the questions. Second, we reduced the number of response categories, in terms of Likert-scale options [38,39], by verifying the distinctiveness between the response categories and checking the relevance of the categories [40]. During the third and final step, abstract concepts, time references, and the language level were adjusted [41].

The easy-read survey consisted of 40 to 60 questions, with the length depending on the answers given to previous questions. The survey was pilot-tested with people with MID or low literacy skills (n=6) using the think-aloud methodology in cognitive interviews [42]. We used this method to verify the intended constructions of the questions and to assess the language level and the fit of the questions and response categories. Next, a web-based version of the survey was created on a web-based platform (called I Coresearch) designed with and for people with MID [43]. The platform has a clear layout, the possibility to enlarge font size, icons that can be added to response categories, and a speech-to-text and text-to-speech function. Additional pilot tests were carried out in which we observed participants (n=4–7 in each wave) while they were completing the survey to evaluate and improve the usability of the platform. The observation sessions were followed by retrospective interviews. The tests resulted in minor adjustments to the questions, the response categories, and the web-based platform. This procedure resulted in a final short easy-read web-based survey.

These same steps were followed to modify and revise the survey for the second and third rounds. After each survey round, the findings were discussed in 4 to 5 focus groups with either people with MID or low literacy skills or care and support professionals and policy makers concerned with these subgroups. This not only led to a quick dissemination of our findings accompanied by solutions or practical tips to put into practice, but the group discussions also provided input for the subsequent survey rounds in which questions that became less relevant over time (eg, adherence to specific measures and difficulty coping with changes in specific daily activities) were replaced by new questions (eg, about vaccination).

Measures

The easy-read survey consisted of various topics, and we report the measures used for this specific study only (for details, refer to Multimedia Appendix 1).

Demographics and Contextual Factors

Similar to the national survey, an extensive section on demographics was included, such as age, gender, educational level, country of birth, and living situation. Furthermore, contextual factors known to have a potential influence on mental well-being were selected from the national survey and included, such as health status (eg, a rating of physical health and whether the participant had experienced COVID-19 infection), having social contacts, and socioeconomic status (eg, work status and the cessation of main activities because of COVID-19–related restrictions) [24,25]. To fit our target group’s everyday experience, work status included paid work, volunteer work, school, and day care. In addition to the national survey questions, we included receiving professional care because this is an important characteristic describing the support needs of our target population, as well as survey completion methods (alone or with help), about which participants with MID or low literacy skills were asked (refer to Multimedia Appendix 1 for all questions listed in the easy-read questionnaire).

Mental Health

To gain a better understanding of the impact of the COVID-19 pandemic on mental health, a final set of 6 outcome measures regarding mental health were defined. The RIVM survey incorporated a mix of newly developed and existing validated scales or items in its well-being module, including psychological well-being (the 5-item Mental Health Inventory [44]), loneliness (the 6-item De Jong Gierveld Loneliness Scale [45]), life satisfaction, resilience, positive and negative effects experienced due to the COVID-19 pandemic, and emotional response (ie, the extent of worry, stress, or fear people experience) to monitor various aspects of mental health during the COVID-19 pandemic [6]. The most relevant items for our target group and research aim were selected from this set in the first developmental step of item generation. Subsequently, the response format was evaluated. For reasons of uniformity, the response categories...
in this series of questions were all adapted to a 4-point Likert scale. All questions had to be revised in accordance with the language level and understanding of the target group, and we ensured that overlapping concepts were avoided. These steps resulted in the following questions: (1) “Did you feel happy in the last couple of days?” (2) “Did you feel full of energy in the last couple of days?” (3) “Did you worry in the last couple of days?” (4) “Did you feel stressed in the last couple of days?” (5) “Did you feel lonely in the last couple of days?” and (6) “Did you have problems falling asleep in the last couple of days?” The outcomes were measured on a 4-point Likert scale: 1=yes, almost always; 2=yes, often; 3=yes, sometimes; and 4=no, almost never (Multimedia Appendix 1).

Statistical Analyses

Mental health was measured at 3 time points over a 1-year period among people with MID or low literacy skills (referred to as the target panel) as well as among members of the MHS panels. First, we calculated the frequencies and medians of the descriptive and contextual measures at each time point for the target panel and the MHS panels. To assess differences between the panels, in each round, Pearson chi-square tests were conducted for nominal or ordinal variables, and nonparametric t tests (2-tailed) were performed for age. Second, we calculated the differences in frequencies of mental health scores using Pearson chi-square tests between survey rounds within each panel and between panels for each survey round. Third, we analyzed the impact of the group differences on mental health using linear regression analyses, while controlling for gender- and age-related differences. Given the large number of participants in each round and the multitude of comparisons made in analysis, differences and associations were considered statistically significant if P values were <.01 [46]. Statistical analyses were conducted in SPSS (version 25.0; IBM Corp).

Ethical Considerations

The study was reviewed by the medical research ethics committee of Radboud University Medical Center, which ruled that this study did not fall under the Medical Research Involving Human Subjects Act and was therefore exempt from formal ethical review (2020-7033). We conducted the study in accordance with the General Data Protection Regulation and standard operating procedures of our research center.

All participants received the survey after they had been fully informed, in plain language, about the purpose of this study. All participants provided web-based written informed consent regarding participation and the use of their data for this study and for future purposes before filling out each questionnaire. For each survey, 20 vouchers worth €50 (US $53.9) each were raffled among people with MID or low literacy skills as motivation for participation.

Contact information used for the purpose of this raffle or future research was obtained and saved in a separate environment so that survey data could be obtained anonymously. Therefore, matching between surveys and paired within-group analysis over time was not possible.

Results

Participant Characteristics

Our web-based survey and adapted recruitment procedure enabled 1059 persons with MID or low literacy skills to participate (T1: n=412, 38.9%; T2: n=351, 33.1%; and T3: n=296, 28%). Background and contextual characteristics per survey round for the target panel and the MHS panels are presented in Table 1. Over the 3 time periods, 46.6% (138/296) to 53.2% (219/412) of the participants with MID or low literacy skills were women, with median ages ranging from 42 (IQR at T1: 27-57; IQR at T3: 28-54) to 45 (IQR 30-57 at T2) years and >70% (T1: 292/412, 70.9%; T2: 253/351, 72.1% and T3: 221/296, 74.7%) reporting no education or a low educational level. The majority (299/412, 72.6% at T1; 295/351, 84% at T2 and to 253/296, 85.5% at T3) were born in the Netherlands, 49.5% (204/412) to 62.2% (184/296) received professional care, and 22.6% (93/412) to 31.8% (94/296) reported living in a residential setting. Approximately half of the respondents (217/412, 52.7% at T1; 164/351, 46.7% at T2 and 170/296, 57.4% at T3) in each round reported very good or good physical health.

A total of 9305 MHS panel members completed our survey (T1: n=2930, 31.49%; T2: n=3213, 34.53%; and T3: n=3162, 33.98%). On the MHS panels over the 3 survey rounds, 55.85% (1766/3162) to 62.53% (1832/2930) of the participants were women, with median ages ranging from 52 to 62 years, and 12.73% (373/2930 at T1) to 17.08% (540/3162 at T3) had no education or a low educational level (ie, >70% had an intermediate or advanced educational level). The majority (2790/2930, 95.22% at T1; 3073/3213, 95.64% at T2 and 3023/3162, 95.6% at T3) were born in the Netherlands, only 3.28% (96/2930 at T1; 92/3213, 2.86% at T2 and 105/3162, 3.32% at T3) received professional care, and <1% (6/2930, 0.2% at T1; 6/3213, 0.19% at T2 and 3/3162, 0.1% at T3) lived in a residential setting. In addition, 77.12% (2478/3213 at T2 and 2435/3162, 77% at T3) to 79.39% (2326/2930 at T1) reported having very good or good physical health.

Altogether, this suggests that we successfully included a sample that represented our target population (ie, people with MID or low literacy skills). In addition, the characteristics of the MHS panels resemble those of the national sample, which is often used to represent the general Dutch population [9,36].

Value for the target panel is not significantly different from that for the regional panel ($P=.01$).

This variable is constructed concerning the daily activities of paid work, volunteer work, and day care.

Value for the target panel is not significantly different from that for the regional panel ($P=.02$).

Mental Health

The analyses of the distributions of the frequencies of mental health scores within the target panel show no differences between T1 and T2. There are significant differences between T1 and T3 regarding feeling happy, feeling energized, feeling stressed, worry, feeling lonely, and sleeping problems among people with MID or low literacy skills (Figure 2) and between T2 and T3 for these aspects, except for worry and feeling lonely; the percentage of people reporting positive feelings often or almost always increased, and the percentage of people reporting negative feelings often or almost always decreased over time. There were no differences observed regarding sleeping problems.

Regarding the MHS panels, there were significant differences between each survey round for feeling happy, feeling energized, and feeling stressed. For worry and feeling lonely, significant differences were observed only between T3 and the 2 previous rounds. The direction of the differences is similar to that observed in the target panels. Similar to the target panels, the MHS panels did not report differences regarding sleeping problems.

The analyses between the different panels within the survey rounds show that the percentage of participants in the target panel reporting negative feelings on mental health outcomes was significantly higher compared with the members of the MHS panels, especially within T1 and T2 (Figure 2); for example, looking at the 6 outcome measures within T1, the percentages of people who reported more negative feelings range from 20.8% (85/408) feeling lonely often or almost always to 58.3% (238/408) feeling happy almost never or only sometimes. The MHS panels show a different and more positive distribution on all outcome measures. The percentages of people on the MHS panels who reported more negative feelings range from 5.5% (160/2904) feeling lonely often or almost always to 32.2% (941/2918) feeling happy almost never or only sometimes. Figure 2 presents more details on the distribution of all mental health outcomes for the target panel and the MHS panels.
Figure 2. Distribution of mental health outcomes for participants in the target panels and members of the municipal health service (MHS) panels at 3 different time periods. T1: first survey; T2: second survey; T3: third survey. a) Difference between groups within each round ($P<.001$), b) Difference between rounds within target group (T1 vs T3: $P<.001$), c) Difference between rounds within panel (T1 vs T2, T2 vs T3, and T1 vs T3: $P<.001$), d) Difference between rounds within target group (T2 vs T3, and T1 vs T3: $P<.001$), e) Difference between rounds within target group (T1 vs T3: $P=.005$), f) Difference between rounds within panel (T1 vs T2, and T1 vs T3: $P<.001$ and T2 vs T3 $P=.01$).

Impact of Literacy Skills on Mental Health

Regression analyses adjusted for age and gender by using them as covariates show that the differences found between the 2 panels exist for almost all mental health outcomes in each survey round, except feeling stressed in T3 ($P=.07$). In addition, the differences between the panels during T1 (age- and gender-adjusted $\beta$ ranging from $-0.376$ to $0.525$) are larger than...
those observed in T3 (age- and gender-adjusted β ranging from −0.257 to 0.509), except for sleeping problems. Table 2 presents details for all time periods and outcome measures.

Table 2. Results for each survey round with panel as independent variable, mental health measures as dependent variables, and gender and age as covariates.

Discussion

Principal Findings

This is the first study to monitor the mental health and well-being of people with MID or low literacy skills and a general population sample over the course of 1 year during the COVID-19 pandemic. With our adapted web-based survey co-designed with representatives from our target population, we were able to reach subgroups that are usually underrepresented in surveys. Our study showed that feelings of happiness, energy, worry, stress, and loneliness improved in both populations over the course of the pandemic. However, the COVID-19 pandemic and related restrictions had a much bigger impact on the mental health of people with MID or low literacy skills than on that of the general population.

In general, our findings show that, during the second lockdown in the Netherlands (ie, at the time of the first survey round), people with MID or low literacy skills as well as the general population sample reported poorer mental well-being than 1 year later when all restrictions were lifted, and the COVID-19 infections became less severe (ie, at the time of the third survey round). These findings are in line with research on people in vulnerable positions [1] as well as the general population who experienced fewer negative feelings over the course of the COVID-19 pandemic [5]. Previous literature has shown that the impact on mental health and well-being is correlated to the...
stringency of disease control measures [25, 47]; for example, the closure of social care services, workplaces, and day care activities negatively influenced daily structure and social interactions [29-31, 48, 49], thereby increasing stress and anxiety [50], and quarantines and social isolation were found to have an effect on loneliness, fear, and boredom [27, 28, 51]. When these measures were relaxed, there was a partial improvement in mental health [47]. Although our study was not designed to prove any causation between the stringency of disease control measures and mental health impact, our findings show a similar pattern of decreasing worries, stress, and loneliness whereas feelings of happiness and energy increased over time. Notably, this was also the case in our general population sample [1, 3, 5, 14, 25, 26]; however, the pandemic disproportionately impacted people with MID or low literacy skills, who reported more negative mental health outcomes in all survey rounds.

Qualitative studies among people with MID show that long-term social restrictions in particular had an extensive impact on their daily life by limiting social connections and work activities [27, 29]. Our target population reported these limitations in daytime activities to a greater extent than the general population sample. Interviews by Voermans et al [29] provide more in-depth assessment of the consequences of these limitations for people with MID, showing a major impact in terms of social isolation, difficulties coping with negative thoughts, struggles with autonomy in society, stigmatization, a lack of routine and purpose, boredom, and lower self-worth. As awareness is raised about the significant value of meaningful social contacts and daytime activities, professionals and policy makers should provide tailored policies that consider both health risks and the risks of social isolation. Societal participation initiatives should be organized and sustained for people with MID or low literacy skills, both during and outside of a pandemic.

Besides the disruptive impact of disease control measures on the target population’s daily routines and social contacts, the high levels of confusion and uncertainty that resulted from the rapidly changing measures as well as fear and loss of control may have played a role in their reduced mental health [32] in periods of both stringent measures and relaxation of control measures [14]. In addition, people with lower health literacy skills are known to have less resilience, which affects their feelings of anxiety, stress, or worry [52, 53], thereby putting them at greater risk of mental health problems. Ongoing support should be provided to enhance resources of resilience and coping strategies in people with MID or low literacy skills through either formal or informal caregivers.

Our findings highlight the need to prioritize the mental health consequences of the pandemic and the disease control measures for people with MID or low literacy skills [1, 54, 55]. The majority of our sample received support from formal and informal caregivers, who are an important source of support. Studies have shown detrimental effects on the mental health of these caregivers as well [28, 56]. Therefore, we suggest tailoring generic disease control measures to the specific situations of groups considered vulnerable and their support system, instead of widely implementing measures such as social distancing, visiting restrictions, and closure of schools or day care facilities (e.g., by developing strategies to maintain social inclusion during pandemic challenges through a combination of supportive carers, assisted digital communication technologies, and safe social activities) [57, 58]. Hence, engaging groups considered vulnerable and their support system in policy making and decision-making is essential in the tailoring process [59].

This study underscores the relevance of including people with MID or low literacy skills in health research and therefore endorses current calls to action in practice and science [60]. Health information systems are crucial for providing data for policy making and decision-making, but the underrepresentation of people with MID or low literacy skills in health data may lead to biased policy decisions, with adverse and detrimental effects on existing health disparities [13, 33]. Previous research has suggested that, to reduce disparities and guide policy, researchers should evaluate how health outcomes are distributed among specific demographic groups and compare these distributions with those of the overall population [61], as was done in our study. Collecting information about people with MID or low literacy skills should become routine in demographic and public health data collection. We have shown that, by co-designing an adapted survey and using an accessible web-based platform and specific recruitment procedures, it is possible to collect information among people with MID or low literacy skills, even during lockdown periods; for example, the sample characteristics showed that participants with MID or low literacy skills differed from the general population in educational level, country of birth, and daily activities. With our adjusted approach to data collection, we were quickly able to obtain relevant information about people with MID or low literacy skills and disseminate our findings and recommendations, thereby facilitating policy makers to guide disease control measures and health promotion activities that address the immediate as well as longer-term health needs of people with MID or low literacy skills or other populations considered vulnerable.

**Limitations of the Study**

Executing a repeated cross-sectional survey among people with MID or low literacy skills during a pandemic is fraught with challenges. Therefore, our study has some limitations. First, we did not collect longitudinal data because we wanted to lower the threshold for participation by choosing an anonymous design. In addition, people were not obliged to complete all 3 surveys. As a result, it was impossible to track individual participants over time. Second, inevitably, the validated questions had to be revised to include people with MID or low literacy skills in our survey. However, we tested the questions in cognitive interviews, and the project team worked as inclusively as possible together with the target population to create a valid survey to obtain reliable data. More than half of the participants over all survey rounds (558/1059, 52.69%) were able to complete the web-based survey themselves, and support was arranged for the remaining group of respondents (497/1059, 46.93%). This should encourage future researchers to consider easy-read web-based surveys among people with MID or low literacy skills as long as target group representatives are closely involved in designing and testing these surveys. Third, our study started after the onset of the COVID-19 pandemic and lacks a baseline measurement of mental health before the pandemic.
Therefore, it remains inconclusive as to whether people with MID or low literacy skills experienced greater mental health problems during the COVID-19 pandemic than before the pandemic. Fourth, we relied mostly on organizations in our network (eg, health care organizations and public libraries with special literacy programs) to contact and recruit people with MID or low literacy skills. Besides the possible sampling bias that this may have caused, we could not track how many people were approached to take part in the survey. Therefore, we were unable to report information about response rates. Fifth, because the survey was conducted on the web, those without access to the internet or sufficient digital literacy skills may have been excluded. Sixth and last, there was also a bias in our general population sample. However, although the sample was not representative of the Dutch general population in terms of age, gender, and educational level, it allowed us to contextualize our findings and gain a deeper understanding of the challenges faced by people with MID or low literacy skills compared with the general population sample, while controlling for differences in gender and age. We were able to do so because we used the same easy-read questionnaire in both groups to prevent survey bias. An open-ended question about the experience of members of the MHS panels with this type of questionnaire at T3 revealed that the majority of participants (1829/2337, 78.26%) appreciated this approach, given that a broader population was enabled to participate. Although this may indicate that easy-read questionnaires can be used for broader purposes and other populations, rather than being aimed specifically at people with low literacy skills alone, this single question does not provide sufficient information regarding a broad survey approach, and more research is required.

Conclusions

In conclusion, our study enabled insight into the impact of the COVID-19 pandemic and related control measures on the mental health of people with MID or low literacy skills. General disease control measures for the entire Dutch population had a more negative impact on people with MID or low literacy skills than on the general population. Although mental health improved over the course of the pandemic in both populations as the COVID-19–related restrictions were gradually lifted, and the severity of the disease decreased over time, the disproportional effect remained. Professionals should be aware of this and pay attention to the needs of people with MID or low literacy skills in research, practice, and policy by tailoring measures that consider physical, social, and mental health effects and providing support to overcome such effects.

This study underscores the relevance of including people with MID or low literacy skills in public health research because they are often overlooked in regular health data. An accessible and structural web-based monitor for people with MID or low literacy skills enabled us to do so and provides better knowledge for care providers and policy makers to react to unexpected events such as a pandemic. To prevent existing health disparities from increasing, greater account should be taken of the impact of control measures on people who are relatively more vulnerable.

Acknowledgments

The authors offer grateful thanks to their coresearchers Anneke van der Cruijsen and Paméla Melkert who were involved during all steps of the study as well as to all experts by experience who participated in the development, testing, or evaluation of the web-based survey and supported survey completion or the discussion of the survey results. The authors thank all organizations that participated in the recruitment of participants and, in particular, MEE Gelderse Poort, GGD Gelderland-Zuid, GGD Gelderland-Midden, and Pharos for their valuable contributions and cooperation during the execution of the study. This study was supported by a grant from the Netherlands Organization for Health Research and Development (ZonMw; grant 1043002201000). The funder had no role in study design, data collection, data analysis, data interpretation, the writing of the manuscript, and the decision to publish.

Data Availability

The data sets generated and analyzed during this study are available in the Radboud Data Repository.

Authors’ Contributions

MCJKL, FR, and GAJFK participated in the study conception and design. AM and MCJKL conducted the literature search and coordinated survey development and participant recruitment. KEB, AM, and MCJKL performed survey development, AM was involved in survey programming, and KEB facilitated the implementation of the survey on the web-based platform. AM, FR, and MCJKL contributed to the acquisition of data. AM accessed and verified the data; and KEB, AM, and MCJKL analyzed the data and plotted the tables and figures. AM and MCJKL drafted the manuscript. All authors participated in interpreting the data and study findings, critically reviewing and contributing to the revision of the manuscript, and approving the final version.

Abstract

Background: With the emergence of SARS-CoV-2 variants that have eluded immunity from vaccines and prior infections, vaccine shortages and vaccine effectiveness pose unprecedented challenges for governments in expanding booster vaccination programs. The fractionation of vaccine doses might be an effective strategy for helping society to face these challenges, as fractional doses may have efficacies comparable with those of the standard doses.

Objective: This study aims to investigate the relationship between vaccine immunogenicity and protection and to project efficacies of fractional doses of vaccines for COVID-19 by using neutralizing antibody levels.

Methods: In this study, we analyzed the relationship between in vitro neutralization levels and the observed efficacies against both asymptomatic infection and symptomatic infection, using data from 13 studies of 10 COVID-19 vaccines and from convalescent cohorts. We further projected efficacies for fractional doses, using neutralization as an intermediate variable, based on immunogenicity data from 51 studies included in our systematic review.

Results: In comparisons with the convalescent level, vaccine efficacy against asymptomatic infection and symptomatic infection increased from 8.8% (95% CI 1.4%-16.1%) to 71.8% (95% CI 63%-80.7%) and from 33.6% (95% CI 23.6%-43.6%) to 98.6% (95% CI 97.6%-99.7%), respectively, as the mean neutralization level increased from 0.1 to 10 folds of the convalescent level. Additionally, mRNA vaccines provided the strongest protection, which decreased slowly for fractional dosing with dosages between 50% and 100% of the standard dose. We also observed that although vaccine efficacy increased with the mean neutralization level, the rate of this increase was slower for vaccine efficacy against asymptomatic infection than for vaccine efficacy against symptomatic infection.

Conclusions: Our results are consistent with studies on immune protection from SARS-CoV-2 infection. Based on our study, we expect that fractional-dose vaccination could provide partial immunity against SARS-CoV-2 and its variants. Our findings provide a theoretical basis for the efficacy of fractional-dose vaccines, serving as reference evidence for implementing fractional dosing vaccine policies in areas facing vaccine shortages and thereby mitigating disease burden. Fractional-dose vaccination could be a viable vaccination strategy comparable to full-dose vaccination and deserves further exploration.

Introduction

COVID-19 continues to threaten fragile health care and socioeconomic systems, exacting a devastating human and economic toll around the world. The primary means of COVID-19 control are the widespread implementation of vaccination and the preservation of public health and social measures. Worldwide, 123 vaccine candidates have been tested in humans as of August 31, 2022, with 52 in the final phases of clinical trials [1]. Although 68% of the world population has received at least one dose of the COVID-19 vaccine as of October 1, 2022 [2], global vaccine shortages and inequities persist [3], with only 18.55% and 1.27% of people in low-income countries being fully vaccinated or receiving booster doses, respectively [2].
As of October 2022, the Omicron subvariant BA.5 has displaced BA.2 as the predominant strain of SARS-CoV-2 in countries around the world. The timely achievement of administering the optimal threshold of doses to the population was critical to preventing a new mutation of the virus, thereby averting accelerated transmission dynamics in society and mitigating consequential socioeconomic issues [4-6]. Although vaccine effectiveness is expected to wane quickly, a booster shot can restore the protection against infection by both Omicron subvariants to 30% - 60% and increase protection against severe disease from a high level to a very high level [7]. A highly vaccinated population is still not enough to combat Omicron’s spread due to immune escape and the waning of vaccine-derived immunity against the ancestral SARS-CoV-2 strain [8]. Countries should time the ramp-up of their booster doses to account for the risks of waning vaccine effectiveness against infection, disease, and death. Mass vaccination with fractional doses of COVID-19 vaccines to boost immunity in a vaccinated population could be a cost-effective strategy for mitigating the public health costs of resurgences caused by vaccine-evasive variants [9].

Given accelerating vaccination, expanding booster programs, and concerns about vaccine safety, the fractional dosing of vaccines could help by providing partial protection for a significant number of people [10]. In the clinical trial of the mRNA-1273 vaccine, 2 fractional doses (half of the full dose) gave geometric mean plaque reduction neutralization test (PRNT) titers that, after 2 weeks, were comparable with those of 2 standard doses [11]. Further, the model-predicted efficacy of the half dose and the measured efficacy of the standard dose were nearly 95% for symptomatic disease [12]. Fractional-dose vaccination has also successfully addressed vaccine shortages in outbreak events [13]. For example, Angola and the Democratic Republic of the Congo adopted fractional doses (one-fifth of the standard dose) of the 17DD yellow fever vaccine to accelerate vaccine rollout during their 2016 yellow fever outbreaks and finally won the war against yellow fever [14,15]. During the mpox (monkeypox) outbreaks in 2022, the US Food and Drug Administration (FDA) issued an emergency use authorization on August 9, 2022, for the JYNNEOS vaccine to prevent mpox infections by administering intradermal injections with a lower volume (one-fifth) to adults aged ≥18 years [16]. During the COVID-19 pandemic period, fractional dosing for young people was approved in some countries, considering that young adults have a robust immune response to vaccines, and lower doses may also be linked with fewer side effects. For example, the FDA approved the use of one-third of the standard doses of the Pfizer-BioNTech COVID-19 vaccine (10 μg) for 5- to 11-year-old children, and one-tenth doses (3 μg) are used for children aged <5 years [17-19].

Fractional-dose vaccination could be an effective strategy for mitigating the epidemic risks of COVID-19 (eg, it allows for the deployment of more vaccines to reach more individuals in settings with limited health care budgets [12,20]) and reducing its disease burden, and this strategy’s effectiveness may be comparable to that of the full-dose strategy [21,22]. However, vaccine efficacy has mainly been tested for standard doses (ie, via clinical trials) [23] rather than for fractional doses, of which the efficacies are measured via phase 1 and 2 clinical trials. These trials involve various vaccines, with immune response being measured based on neutralizing antibody titers. Więcek et al [12] derived the efficacy of fractional doses against symptomatic infection by using its relationship with neutralizing antibody titers in standard doses [23]. However, other clinical outcomes of COVID-19 (eg, asymptomatic infection) are related to measured immunity and how vaccine efficacies can be predicted by using dose fractions based on corresponding immunity levels remain unclear. In this study, we first investigated the relationship between neutralizing antibody titers and vaccine efficacies against SARS-CoV-2 infection. We then predicted vaccine efficacies for fractional doses by using real-world data obtained through a systematic review of neutralizing antibody levels induced by fractional doses of vaccines.

**Methods**

**Sample and Data**

To collect the neutralization data of COVID-19 vaccines that were reported in phase 1 and 2 clinical trial studies, we performed a systematic review of peer-reviewed studies in PubMed on March 15, 2022. We searched for studies in PubMed by using a combination of the following search terms, with no restriction on publication language: (1) “COVID-19” OR “SARS-CoV-2” OR “2019-nCoV” OR “coronavirus”; (2) “vaccin*”; (3) “fractiona*” OR “dose”; and (4) “efficacy” OR “effectiveness” OR “neutralizing antibody” OR “neutralising antibody” OR “neutralization titer” OR “neutralization level” OR “antibody titer” OR “immune response” OR “immune protection” OR “immunogenicity” OR “reactogenicity” OR “safety” OR “adverse event” OR “adverse reaction” OR “adverse effect”; the final search term included search terms 1 to 4, which were combined by using the Boolean operator AND. The searched studies were published between January 1, 2020, and March 15, 2022. The inclusion and exclusion criteria are summarized in **Table 1**. Studies were excluded if they were duplicate publications, preliminary animal studies, preprints, reviews, or commentaries. We reported studies in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines.
We performed a systematic review of peer-reviewed studies that reported on the neutralization of COVID-19 vaccines in phase 1 and 2 clinical trials and were published in PubMed between January 1, 2020, and March 15, 2022. We excluded studies, based on the full-text assessment, if they (1) lacked original neutralizing antibody data; (2) reported vaccines that were no longer being processed; or (3) reported vaccines for which standard dosages were not determined.

### Measures of Variables
We calculated the dose fraction for each sample as the fraction of the dose tested in the group divided by the corresponding standard dose. The mean neutralization level was defined as the ratio of the vaccine-induced neutralizing antibody level to the number of neutralizing antibodies in convalescent sera (ie, those measured in the same study). By doing so, we standardized the neutralizing antibody level and enabled the comparison of neutralization titers across studies that used different assays. The $\log_{10}$ transformation of the mean neutralization level was assumed to be normally distributed [23]. This $\log_{10}$-transformed mean neutralization level was the key variable in the models and data analyses reported in the Results section.

### Results
We identified 2811 studies, through the electronic search on PubMed, that were published between January 1, 2020, and March 15, 2022. A total of 2777 studies were left after excluding duplicates. After 2694 studies were excluded based on the title and abstract screening, we retrieved 83 studies eligible for the full-text screening. After we excluded 32 studies based on the full-text screening, 51 studies met the inclusion criteria and were included in the systematic review (Figure 1, Multimedia Appendix 1, and Figure S1 in Multimedia Appendix 3).
Alongside the published studies included in the systematic review, we collected 13 records of the efficacy of 10 vaccines (eg, BNT162b2, ChAdOx1 nCoV-19, and CoronaVac) against asymptomatic and symptomatic infections for 11 COVID-19 variants (eg, Alpha, Beta, and Delta) from PubMed (Multimedia Appendix 2). Informed by the information on standard-dose vaccines, the nonlinear relationship between the standardized mean neutralization level and vaccine efficacies (which were stratified into 4 dosage groups) was fitted by using a logistic model (Figure S3 in Multimedia Appendix 3); the parameter estimates and root mean square deviations of the asymptomatic and symptomatic infection models are shown in Table 2. The slope parameter \( k \) for the asymptomatic infection model was estimated to be 1.84 and was smaller than that for the symptomatic infection model (3.10), reflecting that although vaccine efficacy increased with the mean neutralization level, the rate of this increase was slower for vaccine efficacy against asymptomatic infection than for vaccine efficacy against symptomatic infection (Figure 2). We estimated the mean neutralization level for 50% protection (10n50) against asymptomatic and symptomatic infections to be 262% (95% CI 190% - 361%) of the mean convalescent level and 20% (95% CI 14% - 28%) of the mean convalescent level, respectively. We predicted the vaccine efficacy of fractional doses against infection outcomes based on the established model (Figure 2). As the mean neutralization level increased from 0.1 to 10 folds
of the convalescent level, the predicted vaccine efficacy against asymptomatic and symptomatic infections increased from 8.8% (95% CI 1.4%-16.1%) to 71.8% (95% CI 63%-80.7%) and from 33.6% (95% CI 23.6%-43.6%) to 98.6% (95% CI 97.6%-99.7%), respectively (Figure 2). mRNA vaccines provided the strongest protection, which decreased slowly for fractional dosing with dosages between 50% and 100% of the standard dose.

Table. Model parameter estimates for the logistic function of vaccine efficacy against asymptomatic and symptomatic infections. We fit the nonlinear relationship between the standardized mean neutralization level and vaccine efficacies (which were stratified into 4 dosage groups) by using a logistic model that was informed by the information on standard-dose COVID-19 vaccines (Figure S3 in Multimedia Appendix 3). The parameter estimates and root mean square deviations (RMSDs) of the asymptomatic and symptomatic infection models are shown in this table.

*aParameter estimates and CIs for the logistic function (Equation 1 in Multimedia Appendix 3) describe the protective efficacy experienced by individuals with a given log_{10}-transformed neutralization level.

*bThe 50% protective neutralization values reported here have been converted from the log_{10} scale back to the linear scale (as reported in the main text).
Figure 2. Estimating vaccine efficacy by using neutralizing antibody levels. Estimated vaccine efficacy against (A) asymptomatic infection and (B) symptomatic infection. The x-axis and y-axis denote the reported mean neutralization levels from phase 1 and 2 trials and the predicted protective efficacies for vaccines or the convalescent cohort, respectively. The gray solid line and shading indicate the best fit and the 95% CIs of the logistic model, respectively. Each dot indicates the predicted efficacy for vaccines (eg, mRNA, protein subunit, viral vector, inactivated, and DNA) or convalescent individuals.

The results of fitting the generalized additive model on dose fractions and mean neutralization levels are presented in Table S1 in Multimedia Appendix 3. The estimated coefficients of the \( \log_{10} \) of the dose fractions were 0.746 (\( P = .02 \)), 0.803 (\( P = .002 \)), and 0.543 (\( P = .02 \)) for mRNA, protein subunit, and nonreplicating viral vector vaccines, respectively. The fitted models showed that the efficacies of mRNA (\( P = .02 \)) and protein subunit (\( P = .002 \)) vaccines significantly increased as the dose fraction increased (Figure S4 in Multimedia Appendix 3). The predicted efficacies of dose fractions for different vaccine types are presented in Figures 2-4. For example, the mRNA vaccine efficacy against asymptomatic and symptomatic infections increased from 12.1% (95% CI 7.2%-19.7%) to 74.8% (95% CI 64.6%-82.9%) and from 52.9% (95% CI 29.8%-74.8%) to 99.5% (95% CI 98.9%-99.8%), respectively, for dose fractions ranging from 0.03 to 5. The protein subunit vaccines had efficacies of 5.2% (95% CI 2.1%-12.2%) to 59.6% (95% CI 46.5%-71.4%) against asymptomatic infection and 19.4% (95% CI 4.8%-53.2%) to 98.4% (95% CI 96.2%-99.3%) against symptomatic infection for dose fractions in the study range of 0.03 to 5. The nonreplicating viral vector vaccines had efficacies of 6% (95% CI 3.3%-10.9%) to 37.1% (95% CI 31.2%-43.4%).
against asymptomatic infection and 23.6% (95% CI 9.5%-47.7%) to 92.9% (95% CI 89.3%-95.3%) against symptomatic infection for dose fractions in the study range of 0.03 to 5.

**Figure 3.** Estimating vaccine efficacy against asymptomatic infection by using neutralizing antibody levels of vaccines. The x-axis and y-axis denote the fraction of dose and the estimated protective efficacy for 3 types of vaccines (e.g., mRNA, protein subunit, and NR viral vector), respectively. The solid line and shading indicate the best fit and the 95% CIs of the logistic model, respectively. NR: nonreplicating.
Figure 4. Estimating vaccine efficacy against symptomatic infection by using neutralizing antibody levels of vaccines. The x-axis and y-axis denote the fraction of dose and the estimated protective efficacy for 3 types of vaccines (eg, mRNA, protein subunit, and NR viral vector), respectively. The solid line and shading indicate the best fit and the 95% CIs of the logistic model, respectively. NR: nonreplicating.

Discussion

This review revealed the immunogenicity, efficacy, and safety of fractional doses as of December 2021, indicating that they would be safe and comparably effective to the standard doses. The included articles predominantly focused on 10 vaccines (eg, BNT162b2, ChAdOx1 nCoV-19, and CoronaVac) for 11 COVID-19 variants (eg, Alpha, Beta, and Delta). Informed by available data from published studies of immune responses for both standard doses and fractional doses, we predicted vaccine efficacies by using neutralizing antibody levels for both standard-dose vaccines and fractional-dose vaccines.

We investigated the relationship between neutralizing antibody titers and the vaccine efficacies against infection for standard doses and derived vaccine efficacies for fractional doses. This study contributes further evidence supporting the use of neutralization titers as significant predictors of vaccine efficacy against asymptomatic infections, symptomatic infections, and severe diseases, in line with previous studies [23,24]. We additionally explored the relationship between dose fractions and vaccine efficacy, using neutralization titers as intermediate variables and accounting for vaccine type.

There would be public health and economic advantages to using a dose-sparing strategy to increase vaccine supply and
vaccination coverage around the world [12,20]. According to the World Health Organization, fractional dosing strategies have the potential to save lives, but only after a thorough review of immunogenicity data [25]. Using untested fractionated vaccine doses in a low-resource setting should also be considered, that is, in cases where higher-resource settings have access to the full vaccine doses and ethics and politics have been taken into account [20]. Further, fractional-dose vaccination could help to optimize the availability of vaccine doses during vaccine shortages, and even in cases where the vaccine supply is increasing, this strategy would still have a high value for vulnerable individuals, as lower doses may also be linked with fewer side effects [17-19].

The following five vaccine types were included in the final analysis: mRNA, protein subunit, nonreplicating viral vector, inactivated, and DNA vaccines. Other vaccine types and mix-and-match vaccine regimens have been used in the rollout of booster programs. For example, previous studies showed that the mix-and-match CoronaVac/BNT162b2 vaccination regimen was superior when compared to the CoronaVac/CoronaVac regimen in terms of immunogenicity [26]. As more studies are conducted and evidence accumulates, our model can be expanded to incorporate combinations of vaccines, thereby enhancing its robustness and utility. Given that the immunity and efficacy data we used were all from the general population, our results may not apply to specific groups, such as individuals who are immunocompromised or high-risk occupational populations, since neutralization levels and efficacies in these groups can be different [27,28].

Despite the vital role of a timely vaccination plan for reducing negative pandemic impacts in society [29,30], studies have suggested that manifold factors (eg, psychological, sociodemographic, cultural, institutional, environmental, and economic factors) in society that drive infections and numbers of deaths should also be considered and emphasized in plans for facing the next pandemic crisis [31-33].

Despite the robustness of our qualitative results, we identified certain limitations. First, our study does not explicitly include age groups, across which levels of vaccine efficacy and safety may differ [34]. Second, our study does not include the waning rate of vaccine-derived immunity for fractional-dose vaccination, which may vary with respect to dose size [12]. Third, the neutralizing antibody data were extracted for ancestral strains, but data on efficacy against asymptomatic infection were collected for different variants. Ideally, we should have used the neutralizing antibody and efficacy data of the same strains, but the neutralizing antibody data of the different variants were limited, and the neutralizing antibody levels of the different variants may have differed from those of the ancestral strains [35-37]. Hence, our prediction of efficacy against COVID-19 variants was based on neutralization levels specific to ancestral strains. Caution is advised when applying the model; however, it remains valid if neutralization levels of ancestral strains are tested and used as the predictor. Our findings provide a theoretical basis for the efficacy of fractional-dose vaccines, serving as reference evidence for implementing fractional dosing vaccine policies in areas with vaccine shortages to reduce disease burden. Effective governance would facilitate the implementation of fractional dosing strategies at the early phase of the next pandemic, thereby providing time for vaccine production to increase and meet supply and demand requirements [6].

To summarize, our results are consistent with studies on predicting immune protection against symptomatic SARS-CoV-2 infection [23], and we further projected vaccine protection against asymptomatic infection. We expect that fractional-dose vaccination could provide partial immunity against, for example, SARS-CoV-2 infection. This strategy would be cost-effective in curbing the COVID-19 outbreak, as it balances the lower efficacy of smaller doses with faster vaccine coverage and lower side effects, especially if global vaccine shortage issues persist.

Abstract

Background: Racialized populations in the United States, Canada, and the United Kingdom have been disproportionately affected by COVID-19. Higher vaccine hesitancy has been reported among racial and ethnic minorities in some of these countries. In the United Kingdom, for example, higher vaccine hesitancy has been observed among the South Asian population and Black compared with the White population, and this has been attributed to lack of trust in government due to historical and ongoing racism and discrimination.

Objective: This study aimed to assess vaccine receipt by ethnicity and its relationship with mistrust among ethnic groups in British Columbia (BC), Canada.

Methods: We included adults ≥18 years of age who participated in the BC COVID-19 Population Mixing Patterns Survey (BC-Mix) from March 8, 2021, to August 8, 2022. The survey included questions about vaccine receipt and beliefs based on a behavioral framework. Multivariable logistic regression was used to assess the association between mistrust in vaccines and vaccine receipt among ethnic groups.

Results: The analysis included 25,640 adults. Overall, 76.7% (22,010/28,696) of respondents reported having received at least 1 dose of COVID-19 vaccines (Chinese=86.1%, South Asian=79.6%, White=75.5%, and other ethnicity=73.2%). Overall, 13.7% (3513/25,640) of respondents reported mistrust of COVID-19 vaccines (Chinese=7.1%, South Asian=8.2%, White=15.4%, and other ethnicity=15.2%). In the multivariable model (adjusting for age, sex, ethnicity, educational attainment, and household size), mistrust was associated with a 93% reduced odds of vaccine receipt (adjusted odds ratio 0.07, 95% CI 0.06-0.08). In the models stratified by ethnicity, mistrust was associated with 81%, 92%, 94%, and 95% reduced odds of vaccine receipt among South Asian, Chinese, White, and other ethnicities, respectively. Indecision, whether to trust the vaccine or not, was significantly associated with a 70% and 78% reduced odds of vaccine receipt among those who identified as White and of other ethnic groups, respectively.

Conclusions: Vaccine receipt among those who identified as South Asian and Chinese in BC was higher than that among the White population. Vaccine mistrust was associated with a lower odds of vaccine receipt in all ethnicities, but it had a lower effect on vaccine receipt among the South Asian and Chinese populations. Future research needs to focus on sources of mistrust to better understand its potential influence on vaccine receipt among visible minorities in Canada.

Introduction

Vaccines are a successful, evidence-based measure against many infectious diseases and a key response to contain the spread of SARS-CoV-2 and prevent severe outcomes such as hospitalizations and death. Soon after the approval of COVID-19 vaccines by Health Canada, nationwide vaccination began on December 14, 2020. As of March 2023, approximately 87.1% of the Canadian population (aged 5 years and older) had received at least 1 dose of COVID-19 vaccines, and 84.5% had completed the 2-dose primary series of vaccination [1]. Although these numbers are impressive, vaccine receipt in Canada has varied by subgroups with some expressing more resistance or hesitancy [2]. Vaccine hesitancy, characterized as a “delay in acceptance or refusal of vaccines despite availability of vaccination services” [3], is a major barrier to prevent severe outcomes for SARS-CoV-2 infection.

The analysis of COVID-19 cases and mortality rates shows disproportionate infections and deaths across various racial and ethnic populations in many countries, including the United Kingdom, the United States, and Canada [4-6]. In the United Kingdom, despite an attenuation of the elevated risk of COVID-19 mortality after adjusting for sociodemographic characteristics and health status, risk remained substantially higher among South Asian people from Bangladeshi and Pakistani background in both the first and the second waves of the pandemic [5]. Similarly, in the United States, the African American or Black and Hispanic populations experienced disproportionately higher rates of SARS-CoV-2 infection and COVID-19–related mortality [4]. In Canada, the South Asian population, one of the fastest growing ethnic minorities [7], has been disproportionately impacted by the pandemic with an increased risk of both infection and mortality from COVID-19 [6]. Age-standardized mortality rates among the South Asian population (31 deaths per 100,000 population) were second to Black (49 deaths per 100,000 population), followed by Chinese (22 deaths per 100,000 population) [6]. Studies from the United Kingdom have also identified the South Asian population as one of the most affected groups with a 10%-50% higher risk of death related to COVID-19 compared with the White British population [8]. However, despite this elevated risk, studies have reported significantly low levels of vaccine acceptance among this group in the United Kingdom [9,10]. Gauging current levels of vaccine acceptance across various population groups (specifically those at higher risk of infection and severe outcomes) and identifying modifiable factors to increase vaccine receipt are important considerations to control COVID-19 [11] and reduce mortality and morbidity. Numerous studies have evaluated COVID-19 vaccine hesitancy among the general population. These studies have attributed various factors to low acceptance of vaccine including concerns around safety and effectiveness of the vaccine [12], potential side effects, and short duration of immunity [13]. Other factors include a low socioeconomic status, identifying as a member of a marginalized population (such as Black, Hispanic, Indigenous, or other person of color), and dissatisfaction or mistrust of the system based on past experiences of discrimination and systematic racism [14,15].

The rapid development of COVID-19 vaccines has been possible due to substantial public funding and unprecedented levels of scientific collaboration and innovation to address global public needs. However, building trust in the vaccine to encourage its receipt has been an uphill task for many governments and public health agencies [16]. Trust is defined as one’s belief that another person or institution will act in accordance with one’s expectations of positive behavior by others [17], and institutional trust is recognized as a key measure of government performance [18]. Some early studies on vaccine hesitancy implicated a general mistrust in the benefits and safety of vaccines and concerns about their unforeseen effect [19,20]. Medical mistrust is a key factor that underlies general health inequities [21] and pertains to both the absence of trust and a sense that someone or something is acting against one’s best interests; this can include health care providers, systems, and government [22,23]. A study investigating the role of medical mistrust in receipt of vaccines among ethnically diverse communities in the United Kingdom found medical mistrust to be associated with COVID-19 vaccine hesitancy and lower intention to vaccinate. Suspicion related to the benefits and safety of vaccines and concerns about their unforeseen effect were the main contributor to this relationship [21].

In this study, we investigated COVID-19 vaccine receipt and its relationship with mistrust in vaccines by ethnicity in British Columbia (BC), Canada.

Methods

Design

We used data from the BC COVID-19 Population Mixing Patterns Survey (BC-Mix), a repeated web-based survey, designed and launched to assess population mixing patterns in BC during the COVID-19 pandemic [24]. To capture participants from a broad demographic range, the survey invitation was disseminated through Instagram, Facebook, YouTube, WhatsApp, Twitter, and Google search engine results pages. The Google Ads Audience manager and Facebook Ads manager allow for paid advertisements to be targeted at specific audiences. We used these tools to target the survey advertisement campaigns to only residents of BC who are 18 years and older. To help capture underrepresented groups, we promoted the survey to various ethnic populations. For instance, a South Asian community organization promoted the survey on their social media pages and also sent the survey to individuals on their mailing address. Although the survey was in English, it was also promoted in different languages (specifically, Korean and Farsi) to members of minority community groups in BC on their social media pages. Flyers
were also distributed at grocery stores and restaurants particularly including those frequented by minority groups.

As of August 30, 2022, over 94,000 participants had participated in the survey since its launch in September 2020. We have described the survey development, design, and domains in detail elsewhere [24,25].

**Measures**

Participants were asked about their receipt of at least 1 dose of any of the approved COVID-19 vaccines in Canada and were also assessed for their level of mistrust in the COVID-19 vaccines.

Responses were rated on a 5-point scale ranging from 1 to 5, with 1 being “strongly disagree” and 5 being “strongly agree.” For the purpose of analyses, the responses were recoded, with those who responded “strongly disagree” or “disagree” coded as “trust” and those who responded “agree” and “strongly agree” coded as “mistrust.” Individuals who chose “neutral” were considered “undecided.”

We assessed sex, age, ethnicity, educational attainment, occupation, and household size based on self-reported data. Those who identified as First Nations, Inuit, Metis, Black (African or Caribbean), Filipino, Latin American or Hispanic, Southeast Asian (eg, Vietnamese, Cambodian, Malaysian, and Laotian), Arab, West Asian (eg, Iranian and Afghan), Korean, Japanese, and other prefer to self-describe, and prefer not to answer, were grouped under “other” due to their small sample sizes. Survey questions and response categories for the BC-Mix baseline and the follow-up survey are provided in Multimedia Appendices 1 and 2, respectively.

**Statistical Analyses**

The domain on COVID-19 vaccine hesitancy and receipt was added to the survey on March 8, 2021. The analysis for this study was restricted to survey responses collected between March 8, 2021, and August 8, 2022. The survey data were weighted using 2016 Census data (Statistics Canada [26]) as the reference population. Employing Bethlehem’s weighting adjustment technique [27], age, sex, geography (Health Authority region), and ethnicity were used as auxiliary variables for weighting.

Participant characteristics were summarized using weighted frequencies and percentages, stratified by ethnicity. The distribution of mistrust in COVID-19 vaccines was examined for each ethnicity. We examined the distribution of vaccine receipt by mistrust status for each ethnicity. Logistic regression was used to examine the unadjusted and adjusted association between mistrust and vaccine receipt stratified by ethnicity. Confounders included ethnicity, sex, age, educational attainment, and household size while accounting for sampling design.

Data preparation, descriptive analyses, and all other analyses were performed in SAS software version 9.4 (SAS Institute Inc).

**Ethical Considerations**

Informed consent was obtained from all participants. Ethical approval for this study was provided by the University of British Columbia Behavioral Research Ethics Board (H20-01785).

**Results**

**Participant Profile**

The analysis included 25,640 individuals. Overall, 55% (15,787/28,694) of the participants were male, and 41.7% (11,967/28,694) were older than 55 years. A total of 10.1% of participants identified as South Asian, 11% as Chinese, 62.7% as White, and 16.1% as of “other” ethnicity. Overall, 7.5% (2140/28,694) lived in a household size of >6, and this proportion was highest among those who identified as South Asian (17.2%, 499/2905) and “other” ethnicities (13.7%, 634/4641) compared with White (4.8%, 872/17,993) and Chinese (4.3%, 135/3156); see Table 1.
Table 1. Participant profile: comparison of characteristics by ethnicity (N=25,640).

**Vaccine Receipt by Ethnicity and Trust**

Overall, 76.7% (22,010/28,696) of respondents reported having received at least 1 dose of the COVID-19 vaccines. Vaccine receipt was highest among individuals who identified as Chinese (2718/3156, 86.1%) followed by South Asian (2312/2905, 79.6%), White (13,583/17,991, 75.5%), and those belonging to the “other” ethnicity (3398/4642, 73.2%); see Table 2.

COVID-19 vaccine receipt by vaccine mistrust differed by ethnicity. Overall, 13.7% of the respondents reported mistrust of COVID-19 vaccines (Multimedia Appendix 3). There was a difference by ethnicity in the proportion of people who mistrusted the vaccine but still received it. This proportion was 50.6% among those who identified as South Asian, compared with 40.5% among Chinese, 26.9% among White, and 25.1% among individuals of “other” ethnicities (Table 3).

Association Between Mistrust and Vaccine Receipt

In the unadjusted logistic regression model, those who identified as Chinese were significantly more likely to have received the vaccine (odds ratio [OR] 2.01, 95% CI 1.55-2.62) compared with those who identified as White. Although those who identified as South Asians were also more likely to have received the vaccine, this effect was not significant. Individuals who mistrusted COVID-19 vaccines had 94% reduced odds of vaccine receipt (OR 0.06, 95% CI 0.05-0.07) compared with those who trusted vaccines. In the models stratified by ethnicity, mistrust was associated with 81% (OR 0.19, 95% CI 0.09-0.43), 92% (OR 0.08, 95% CI 0.03-0.18), 94% (OR 0.06, 95% CI 0.05-0.07), and 95% (OR 0.05, 95% CI 0.03-0.07) reduced odds of vaccine receipt among those who identified as South Asian, Chinese, White, and those of other ethnicities, respectively. Individuals who were undecided or neutral regarding whether they trusted or mistrusted the vaccine had 70% reduced odds of receiving the vaccine. Among undecided South Asians, reduced odds of receiving the vaccine were 54% (OR 0.46, 95% CI 0.22-0.94) compared with 71% in the White (OR 0.29, 95% CI 0.24-0.34) and 78% in the “other” (OR 0.22, 95% CI 0.16-0.30). In those identifying as Chinese, the reduction in odds was not significant (Table 4).

After adjusting for age, sex, educational attainment, and household size, mistrust was associated with a 93% reduced odds of vaccine receipt (adjusted OR [aOR] 0.07, 95% CI 0.06-0.08). There was some attenuation of the effect of ethnicity, but results were similar for those who identified as Chinese (aOR 1.63, 95% CI 1.20-2.20), those who identified as South Asian (aOR 1.08, 95% CI 0.93-1.25), and those of “other” ethnicities (aOR 1.17, 95% CI 0.86-1.61).

The adjusted magnitude of association between mistrust and vaccine receipt was greatest among individuals of “other” ethnicities (aOR 0.05, 95% CI 0.03-0.07), followed by those who identified as White (aOR 0.06, 95% CI 0.05-0.07), those who identified as Chinese (aOR 0.08, 95% CI 0.03-0.20), and those who identified as South Asian (aOR 0.17, 95% CI 0.07-0.38). A significant association was observed between those who were undecided and those who received the vaccine among individuals identifying as White (OR 0.30, 95% CI 0.25-0.36) and of “other” ethnicity (OR 0.22, 95% CI 0.16-0.31; Table 5).

Other covariates associated with vaccine receipt included female sex (OR 1.59, 95% CI 1.45-1.75), age >55 years compared with 18-34 years (OR 1.88, 95% CI 1.64-2.15), and a university education compared with below high school education (OR 1.71, 95% CI 1.22-2.38; Table 5).

**Discussion**

This study assessed the role of self-reported mistrust of COVID-19 vaccines in vaccine receipt among different ethnic groups in BC, Canada. We found that mistrust was lower among individuals who identified as Chinese and South Asian. Vaccine uptake was higher among people identifying as Chinese compared with people identifying as White. Among those who identified as South Asian, vaccine receipt was higher than the White population, but this difference was not statistically significant. Mistrust of the vaccine was significantly associated with a reduced odds of vaccine receipt, regardless of race and ethnicity. However, the magnitude of association between mistrust and vaccine receipt differed by ethnicity, with vaccine trust playing the least important role in vaccine receipt among those who identified as South Asian. Only 8.2% of those who identified as South Asian reported mistrust (Multimedia Appendix 3), and despite that, vaccine receipt among this group was still the highest (50.6%) compared with 40.5% among those who identified as Chinese, 26.9% among White, and 25.1% among individuals of “other” ethnicities. Indecisiveness about whether the vaccine was to be trusted or not also had a significant association with vaccine receipt. In the “undecided” group, those who identified as Chinese and South Asians had the highest proportion of vaccine receipt (88% and 71%, respectively) compared with White (66%) and those identifying as of “other” ethnicities (61%).
Our results contrast with findings from other studies that have reported a higher prevalence of vaccine hesitancy and lower vaccine receipt in racialized groups. For instance, although the United Kingdom became the first country to approve COVID-19 vaccines for emergency use in December 2020 and took the lead in vaccinating its population, it faced elevated vaccine hesitancy among Black, South Asian, and other ethnic minorities [9,28-31]. Similarly, US-based studies reported greater vaccine hesitancy and lower vaccine receipt among African Americans and Hispanics compared with the White American population [32-34].

Several reasons have been cited for this widespread hesitancy and lower vaccine receipt among ethnic groups. Unknown future effects, side effects of vaccines, a lack of trust in government and pharmaceutical industry, and historical inequities and racism have been implicated in vaccine hesitancy among people of color in both the United Kingdom and United States [9,32,34,35]. Contrary to this, overall vaccine acceptance among people designated as a visible minority in Canada has been relatively high with 74.8% reporting being “very” or “somewhat willing” to receive COVID-19 vaccines [2]. Of the 11 distinct ethnic groups surveyed in Canada, the South Asian group had one of the highest proportions of vaccine acceptance (82.5%) third in line to Japanese at 87.6% and Koreans at 85.5% compared with 77.7% in those who were not a visible minority [2].

In our study, mistrust of the vaccine as well as indecisiveness whether to trust the vaccine or not was significantly associated with a reduced odds of vaccine receipt regardless of race and ethnicity. The timing of our survey may explain some of these trends. The BC-Mix survey was launched in September 2020, with the vaccine questionnaire being added in March 2021—approximately 3 months after nationwide vaccination in Canada began. Limited information about the novel SARS-CoV-2 virus and concerns over safety and efficacy of a vaccine developed in a very short time may have generated a considerable number of people indicating reluctance to get vaccinated as reported in studies from the United States and France [36-38]. This may, to some degree, also explain a high prevalence of indecisiveness in our study, which, as our results demonstrate, had a significant association with willingness to get vaccinated. Dearth of accurate information, misinformation or mixed messages coupled with lack of culturally tailored, and targeted messaging in the early months of the pandemic may have further fueled skepticism or indecisiveness among various population groups—specifically the already racialized and marginalized communities. However, despite this, mistrust and indecisiveness appeared to have less of an impact on vaccine receipt among those who identified as Chinese (88%) and South Asian (70%).

There may be several potential explanatory factors for why people who identified as South Asian received a vaccine despite reporting vaccine mistrust. First, the decision to get vaccinated despite mistrust may be due to targeted interventions by BC Health Authorities to increase vaccine uptake within the South Asian community. These interventions may have, to some degree, overridden the initial fears and mistrust at the individual level. Second, a higher risk perception of COVID-19 severe outcomes, perhaps from having witnessed the high burden of disease and mortality among community members in both BC and Ontario [39] coupled with messaging from primary care physicians and community-based health workers framing vaccines as a “lifesaver,” may have driven many to opt for the vaccine despite their initial mistrust [40]. Third, subjective norms could be another explanation whereby members of the South Asian community, mistrustful of the vaccines, felt pressured to “give in” as other members of the family or one’s social circle appeared to be strongly supportive of vaccination [40]. Fourth, South Asian grandparents are 8 times more likely to live with their grandchildren (National Household Survey 2011) [41], and this seems to be reflected in our sample, where 17.2% of South Asian individuals (highest compared with any other ethnic group) lived in a household size of 6 or greater. Fear of exposing the older adult in the family to COVID-19 may have been another factor pushing those who were mistrustful of the vaccine to get vaccinated. Lastly, fear of consequences for not following government regulations, such as those related to international travel or accessing public facilities, may have convinced some to get vaccinated despite mistrust [40]. Future research should focus on some of these psychosocial and behavioral factors that could explain greater acceptance and receipt of COVID-19 vaccines among the South Asian population.

Contrasting findings have been observed in UK and US studies. In the UK Household Longitudinal Study, higher vaccine hesitancy (among those who had not yet received a vaccine) was seen in most minority ethnic groups compared with the White British or Irish group. The highest odds were seen in the Black or Black British group (OR 13.42, 95% CI 6.86-26.24) and the Pakistani and Bangladeshi South Asian subgroups (OR 2.54, 95% CI 1.19-5.44), and adjustment for covariates made relatively little difference to these associations [29]. In the United States, Wu et al [35] examined the mechanisms behind COVID-19 vaccine acceptance in 3 Asian American ethnic groups (East Asian, Southeast Asian, and South Asian), including how sociodemographic characteristics and racism predicted COVID-19 vaccine perceptions. Trustworthiness of public health agency’s recommendation for COVID-19 vaccines was not associated with ethnicity. When predicting COVID-19 vaccine safety concerns, the South Asian group (compared with non-Asian) reported significantly higher safety concerns, which was mediated by racism [35].

Despite some methodological differences, contrasting findings of vaccine hesitancy and receipt among the South Asian population in Canada compared with the United Kingdom raises thought-provoking questions as to why the Canadian South Asian population might be more accepting and trusting of COVID-19 vaccines than their British counterparts. This finding may partly be explained by subgroup differences that exist among South Asian diaspora. It is important to note that South Asians (people originating from or having ancestry in India, Pakistan, Bangladesh, Nepal, Sri Lanka, Maldives, and Bhutan) are not a monolithic group but have considerable heterogeneity based on country of origin, religion, culture, and language. In the United Kingdom, while Indians comprise the biggest South Asian subgroup (similar to Canada), people of Pakistani and
Bangladeshi origin also have a significant presence. In fact, when put together, the group comprising people with Pakistani and Bangladeshi origins surpass Indians in numbers [42]. Significant differences in health behaviors and health outcomes for chronic diseases have been reported among various South Asian subgroups based on religion and country of origin [43]. Research exploring vaccine receipt and hesitancy among various subgroups of ethnic denominations in the United Kingdom reveals greater hesitancy and mistrust among the South Asian population originating from predominantly Muslim countries such as Bangladesh and Pakistan compared with India [29,44].

In the province of BC, Indians, and specifically Indians of Punjabi origin who are settled in the province of Punjab and identify predominantly with Sikh religion, constitute the largest South Asian subgroup, whereas the number of Pakistanis and, especially, Bangladeshis is relatively small [45]. Although we do not have a subgroup breakdown of the South Asian sample, it is possible that our study sample predominantly constitutes South Asian individuals originating from India, and thus our findings may be reflective of the subgroup differences highlighted by UK-based studies where South Asians of Indian origin are more accepting of the vaccine than Pakistanis or Bangladeshis [29,44]. Vaccine acceptance has been a challenge in many Muslim countries where rejection of immunization is widely prevalent on the grounds that the vaccine contains animal byproducts that are not halal (kosher) or unfounded claims that it may cause infertility [46-48]. Subgroup differences based on country of origin and religion require further investigations to understand vaccine receipt and hesitancy among the South Asian population, which may inform effective vaccine receipt strategies for COVID-19 and other vaccines in future.

Another plausible explanation for the difference in vaccination receipt between the South Asian population in the United Kingdom compared with Canada could be greater anti-Muslim sentiment and social exclusion experienced by the Muslim community in the United Kingdom [49]. This may therefore result in greater mistrust between political leadership and Muslims. The South Asian population in the United Kingdom, specifically Muslims, have been targets of increased hate crimes associated with the war on terror after the events of September 11, 2001, and high-profile police action after the 2005 London bombings, which resulted in alienation of the Muslim community and greater distrust of the government [50]. Although anti-Muslim sentiment in Canada has also increased, a 2016 national survey examining the relationship between Canadian Muslims and Canadian society at large revealed that Muslims, nearly 7 in 10 of whom are immigrants, were generally happy to be in Canada and 84% of Muslims surveyed believed that they were treated better in Canada than their coreligionists in other Western countries, a number that has increased since 2006 [51]. The majority also expressed optimism regarding their relationship with the government. In contrast, a 2016 British examination about the state of Muslim citizens’ opinions on a broad range of topics revealed that relations between Britain’s political establishment and the leadership of the Muslim community are at a nadir [50]. Higher vaccine acceptance among the South Asian population in Canada may thus partly be explained by a higher degree of social inclusion experienced by one of the major subgroups (ie, Muslims) within the South Asian diaspora compared with Muslims in the United Kingdom. This however is speculative and needs to be investigated in future research as an understanding of the contexts and fluidities underlying the knowledge and beliefs and lived experiences about health and immunization in diverse communities is critical for designing effective interventions [52].

Higher vaccine receipt among the South Asian population in Canada could also be related to potential differences in vaccine program administration. For instance, ethnic minorities in the United Kingdom were more likely to receive an influenza vaccine administered by general practitioners in communities with whom they may have a trusting relationship, while COVID-19 vaccines were administered through mass vaccination centers or hospital hub [53]. Moreover, residential segregation driven by systemic racism may have resulted in additional barriers in terms of travel time and transport-related costs to accessing centralized vaccination sites for some communities in the United Kingdom [53]. Although a somewhat similar vaccination setup was rolled out in BC, working at a grassroots level to get the populations most impacted by the pandemic onboard may explain lower resistance and higher levels of vaccine receipt among these groups. For instance, in BC, the greatest concentration of the South Asian population is in the Fraser Health region where they make up almost 15% of the population [54]. The South Asian Health Institute was established in 2013 to improve health for South Asian people and reduce chronic disease burden. This institute works closely with Fraser Health Authority (a regional health authority), community leaders and stakeholders to promote health and well-being and has ongoing programs targeting lifestyle behaviors like diet, physical activity as well as mental health, and drug toxicity. During the pandemic, South Asian Health Institute and several South Asian community volunteer groups and clinic partners were able to leverage their pre-pandemic established relationships and networks within the South Asian community and were at the forefront in reaching out to the community via “in-reach” clinics set up in community centers and places of worship [55]. These clinics were staffed with South Asian team members providing support for registration with the provincial COVID-19 vaccination program. Moreover, translation services for COVID-19 information were available in 145 languages including Hindi, Urdu, Punjabi, Tamil, and Chinese [55]. These measures removed many barriers around language, transportation, technological issues, health system navigation, and vaccine hesitancy. This may partly explain high vaccine receipt even among groups that were mistrustful of the vaccine.

Limitations

This study has some limitations. Because this was a web-based survey in English, it may have excluded many South Asians and Chinese with limited digital literacy and fluency in English. Thus, the findings cannot be generalized to these population groups. The findings of our survey may be subject to social desirability bias; given the self-reported nature of the data, it is possible that participants responded in ways that they deemed socially acceptable. We were also unable to provide further
disaggregation of ethnicity to examine differences among certain ethnic groups and subgroups (eg, Indian, Pakistani, and Bangladeshi groups in the South Asian diaspora). Additionally, we did not investigate the source or cause of mistrust that limits our ability to identify modifiable factors for future vaccination strategies. Despite these limitations, this is one of the largest surveys examining vaccine receipt and mistrust among South Asians in Canada.

Conclusions
Factors that influence vaccine acceptance are multifaceted and often, as research shows, shaped by complex, sociocultural, historical, institutional, clinical, community, and governmental levels [56]. In contrast to findings among South Asians in the United Kingdom, our study found higher levels of vaccine acceptance, and similar levels of vaccine uptake, compared with individuals identifying as White. We also found high vaccine receipt among those South Asians who mistrusted the vaccine. The contrasting results may have a range of explanations—including important differences between the South Asian populations in the United Kingdom and Canada in terms of country of origin, religion, racism, social exclusion, alienation, and consequent mistrust in the government and systems—all of which have an impact on vaccination uptake. Future research needs to focus on disentangling the potential influence of these factors on vaccine receipt. An understanding of factors that facilitate vaccine receipt among the South Asian population residing in Canada will enable researchers and health professionals to tailor this information and use it for developing targeted interventions and informed national vaccination programs for South Asians residing in regions with elevated vaccine hesitancy.

Abstract

Background: The durability of heterologous COVID-19 vaccine effectiveness (VE) has been primarily studied in high-income countries, while evaluation of heterologous vaccine policies in low- and middle-income countries remains limited.

Objective: We aimed to evaluate the duration during which the VE of heterologous COVID-19 vaccine regimens in mitigating serious outcomes, specifically severe COVID-19 and death following hospitalization with COVID-19, remains over 50%.

Methods: We formed a dynamic cohort by linking records of Thai citizens aged ≥18 years from citizen vital, COVID-19 vaccine, and COVID-19 cases registry databases between May 2021 and July 2022. Encrypted citizen identification numbers were used to merge the data between the databases. This study focuses on 8 common heterologous vaccine sequences: CoronaVac/ChAdOx1, ChAdOx1/BNT162b2, CoronaVac/ChAdOx1/ChAdOx1, CoronaVac/ChAdOx1/BNT162b2, BBIBP-CorV/BBIBP-CorV/BNT162b2, ChAdOx1/ChAdOx1/BNT162b2, and ChAdOx1/mRNA-1273. Nonimmunized individuals were considered for comparisons. The cohort was stratified according to the vaccination status, age, sex, province location, month of vaccination, and outcome. Data analysis employed logistic regression to determine the VE, accounting for potential confounders and durability over time, with data observed over a follow-up period of 7 months.

Results: This study includes 52,580,841 individuals, with approximately 17,907,215 and 17,190,975 receiving 2- and 3-dose common heterologous vaccines (not mutually exclusive), respectively. The 2-dose heterologous vaccinations offered approximately 50% VE against severe COVID-19 and death following hospitalization with COVID-19 for 2 months; however, the protection significantly declined over time. The 3-dose heterologous vaccinations sustained over 50% VE against both outcomes for at least 8 months, as determined by logistic regression with durability time-interaction modeling. The vaccine sequence consisting of CoronaVac/CoronaVac/ChAdOx1 demonstrated >80% VE against both outcomes, with no evidence of VE waning. The final monthly measured VE of CoronaVac/CoronaVac/ChAdOx1 against severe COVID-19 and death following hospitalization at 7 months after the last dose was 82% (95% CI 80.3%-84%) and 86.3% (95% CI 83.6%-84%), respectively.

Conclusions: In Thailand, within a 7-month observation period, the 2-dose regimens could not maintain a 50% VE against severe and fatal COVID-19 for over 2 months, but all of the 3-dose regimens did. The CoronaVac/CoronaVac/ChAdOx1 regimen
showed the best protective effect against severe and fatal COVID-19. The estimated durability of 50% VE for at least 8 months across all 3-dose heterologous COVID-19 vaccine regimens supports the adoption of heterologous prime-boost vaccination strategies, with a primary series of inactivated virus vaccine and boosting with either a viral vector or an mRNA vaccine, to prevent similar pandemics in low- and middle-income countries.

Introduction

The effectiveness of COVID-19 vaccine is typically determined through randomized controlled trials prior to market approval [1]. Most clinical trials on COVID-19 vaccines focused on homologous vaccination [2], whereas most vaccination programs in low- and middle-income countries (LMICs) use heterologous vaccination for the primary series [3-7]. Recently, evidence has consistently shown that the vaccine effectiveness (VE) of a 3-dose homologous messenger ribonucleic acid (mRNA) vaccine regimen against severe COVID-19 appears to wane at 6 months after the third dose. However, evidence regarding the durability of 3-dose heterologous vaccination regimens remains limited [8-11]. Most research on the durability of heterologous COVID-19 VE have been conducted in high-income countries [12-14]. Although real-world VE studies provide information about the protective effects of heterologous regimens, considerable variations exist across studies because of differences in the vaccine combinations used, unmeasured confounders, and differences in the vaccination eligibility criteria over time and across countries [15]. To our knowledge, no population-based studies have been conducted on the durability of VE of the heterologous prime-boost regimens primarily used in LMICs, which involve a primary series of inactivated vaccines followed by an mRNA or a viral vector vaccine.

In Thailand, a heterologous vaccination strategy was implemented without strong evidence of VE due to supply constraints [16]. The primary series of vaccinations was initially administered using inactivated virus vaccines, followed by viral vector vaccines, whereas mRNA vaccines were mainly used as a booster dose [7,17,18]. Although test-negative case-control studies have been conducted of heterologous vaccination effectiveness in Thailand [7,17,18], these studies are limited in size and follow-up period and therefore were unable to determine the temporal relationship [19]. Thailand is not unique in this regard. To the best of our knowledge, no LMIC has modeled VE durability or waning over time in population-based cohort studies.

Thailand has maintained a national citizen registry linked to national health databases since 1993 [20]. Specialized registries have been established for COVID-19 testing, COVID-19 cases, and COVID-19 vaccination [21]. By linking these records, we examined a dynamic cohort of the Thai population to assess the durability of VE of heterologous vaccine sequences, providing insights for future pandemics. This study aims to evaluate the duration during which the VE of heterologous vaccine sequences against severe COVID-19 and death following hospitalization for COVID-19 (fatal COVID-19) remains over 50%.

Methods

Study Design

This was a dynamic cohort study in which participants entered or exited the cohort at different timepoints during the study period, depending on when they met the eligibility criteria for entering or leaving the cohort [22]. The time frame of this study was from May 2021 (when the COVID-19 vaccination started in Thailand) to July 2022 (when the compulsory registration of all COVID-19 cases ended). We assumed that all individuals residing in the same province would have a similar risk of exposure to SARS-CoV-2 during the pandemic.

Setting

Figure 1A displays the time series of notified SARS-CoV-2 infection, severe COVID-19, and deaths following hospitalization with COVID-19, while Figure 1B shows the circulating variants. Figure 1A shows that the national trends in COVID-19 case notifications and COVID-19 vaccine administration from May 2021 to June 2022. In Figure 1B, from May 2021 to May 2022, B.1.1.7 (Alpha) was rapidly replaced by B.1617.2 (Delta), which caused a peak in severe and fatal COVID-19 cases. The Delta variant has since been replaced by the B.1.1.529 (Omicron) variant, which has a higher infection rate but reduced severity [23]. A marked reduction was noted in the reporting of COVID-19 cases after the reimbursement protocol for COVID-19 was integrated into the universal health coverage program [24]. Therefore, no data analysis was conducted beyond July 2022. Figure 1C shows that the first vaccine to be rolled out was CoronaVac (Sinovac [SV], Sinovac Biotech), for which the rate of uptake remained steady until the end of 2021. ChAdOx1 nCoV-19 (University of Oxford/AstraZeneca [AZ]) was rolled out in June 2021 and was the main vaccine used during the Delta variant outbreak. Simultaneously, a limited volume of BBIBP-CorV (Sinopharm [SP], National Biotech Group, Beijing Institute of Biological Products) became available via national academies and the private sector. BNT162b2 (Pfizer/BioNTech Inc [PZ]) was introduced at the end of 2021 and was expected to become the main vaccine used in 2022. The market share of mRNA-1273 (Moderna [MN]) has remained low.
**Figure 1.** The overall situation of the COVID-19 outbreak during the recruitment period of the dynamic cohort. (A) Daily number of cases of COVID-19 notified (top 2 rows) and COVID-19 deaths (bottom row). (B) SARS-CoV-2 variants circulating in Thailand (pink: Alpha; green: Delta; lilac: Omicron). (C) Daily number of vaccine doses administered by product during the study period.

**Data Sources**

Data were retrieved from national databases of the Thai Ministry of Public Health (MoPH) and the Ministry of Interior. The core data set is the civil registration database, which contains all the citizen identification records. In Thailand, citizens must show their citizen identification cards to access public services such as government-funded health care. COVID-19 vaccine procurement and delivery in both the public and private sectors were monitored by the MoPH through the Mor Prom database, which holds details, including the location of vaccination, citizen identification code, vaccine type, and vaccine batch. Another MoPH database, CO-WARD, recorded all reverse transcription polymerase chain reaction (RT-PCR) test results and clinical outcomes, including severity and death. COVID-19 testing,
quarantine, treatment, and vaccination costs were all recorded for reimbursement through national health insurance schemes. In addition, all deaths are recorded by law in a separate national Ministry of Interior (Thailand) database. All the databases were linked using encrypted citizen identification in the analysis.

Participants

In this study, the participants were all Thai citizens aged 18 years or older because the 2021 vaccination policy only included the adult population. At the start of the study period (May 1, 2021), all participants were nonimmunized, meaning that they had neither received a vaccination nor had a prior SARS-CoV-2 infection. Upon vaccination, participants moved into a group defined by the sequence of vaccines received: SV-AZ, AZ-PZ, SV-SV-AZ, SV-AZ-AZ, SV-AZ-PZ, SP-SP-PZ, AZ-AZ-PZ, and AZ-AZ-MN. Thus, the participant vaccination status could change over time sequentially from nonimmunized to 1, 2, and 3 doses. Participants were excluded from the cohort if they had evidence of SARS-CoV-2 infection (positive antigen test kit [ATK] or RT-PCR) or if they died from any cause. Otherwise, they were followed up until the end of the study period (July 31, 2022).

Exposures and Outcomes

Table 1 lists the outcomes and exposure variables. Outcomes were defined as untested/uninfected or infected (positive RT-PCR results). The infected group was further classified as nonsevere or severe (oxygen saturation ≤94% on room air or rapid progressive pneumonia based on the doctor’s decision) [25] and fatal infection (any hospitalized death with SARS-CoV-2 infection). The assessment of severity was assessed daily, without missing data [26]. We omitted the evaluation of VE in asymptomatic patients or patients with nonsevere COVID-19 because of underreporting issues. Additionally, our analysis omitted cases of severe COVID-19 that resulted in death prior to hospitalization. This decision was based on our data exploration, which showed that such scenarios accounted for less than 1% of COVID-19–related deaths. On December 1, 2021, the national policy changed such that individuals who tested positive using an ATK were defined as having SARS-CoV-2 infection, whereas previously, the case definition required confirmation using RT-PCR [27]. Owing to this change in the classification of cases during the study period, we included only severe COVID-19 cases and deaths following hospitalization for COVID-19 (fatal COVID-19) as the outcomes of interest. The primary independent variable in this study was the vaccine regimen. Due to the presence of multiple categories of vaccination sequences, our analysis focused on the 8 most prevalent heterologous sequences. Other vaccine sequences administered to an insufficient number of individuals (see Data Availability) were excluded from this report. The control group consisted of nonimmunized individuals. Additional variables for confounder adjustment encompassed age, sex, province of residence, and the calendar month of infection (a proxy for the predominant variant during each period). The results were consolidated based on the time elapsed 2 months following the receipt of the last vaccine dose, as evidence suggests that the decline in the immune response against the SARS-CoV-2 virus starts 3 months after the final dose [28].

<sup>f</sup>Month of infection is a categorical variable.
<sup>g</sup>Time elapsed since 2 months after the last dose of each vaccine sequence was treated as a categorical variable for the Mantel-Haenszel method and as a continuous variable in the logistic regression model (1 month was assumed to be 30 calendar days).

**Data Manipulation Methods**

The encrypted citizen identification is used to merge data from each database. Individuals were classified according to their vaccination sequence at the end of each month and further stratified according to sex, age group, province of residence, SARS-CoV-2 infection status, and severity of infection. Once infected (positive ATK or RT-PCR results), the participants were excluded from the analysis for subsequent months.

**Data Analysis**

**Estimation of VE Over Time**

The variables employed in our analysis (Table 1) were used in stratified cross-tabulation and logistic regression analyses. The outcome variables were severe COVID-19 (Y₁) and death following COVID-19 (Y₂). They were analyzed separately and reported. The exposure variable was the vaccine sequence, for which we included two 2-dose and five 3-dose regimens. Other vaccine sequences had small sample sizes and were omitted.
In this study, 2 analytical methods were employed to evaluate VE. The first method, the Mantel-Haenszel risk ratio [29], calculated VE\textsubscript{i} as \( VE\textsubscript{i} = 1 – aRR \), where \( aRR \) is the adjusted risk ratio, adjusted for other variables (x) and t represents a categorical time variable (2-7 months after the last dose), as indicated by data observed within 7 months since the last dose. In this study, T+2 was used as the measure of t, based on the assumption that VE begins to wane 2 months after the last dose. The second method, logistic regression, assesses VE durability using the formula: \( VE\textsubscript{i} = 1 – aOR \), where \( aOR \) is the adjusted odds ratio, adjusted for other variables (x), and t is a continuous time variable measuring the months after the last dose. This approach allows for projecting aOR to calculate \( VE\textsubscript{i} \) more than 7 months postvaccination. Given the rarity of severe and fatal COVID-19 cases (incidence less than 1 per 1000), logistic regression was used to estimate the aOR of the vaccine, and the aOR was used to estimate the VE. This is based on the assumption that the odds ratio (OR) approximates the relative risk in rare event scenarios [30-32]. The hypothesis posits that VE may either persist or wane over time. Performing both analyses over a 7-month period aims to determine the concordance between the 2 methods, particularly whether aOR aligns with adjusted risk ratio in a rare outcome situation.

**Stratified Cross-Tabulation and Pooling Effect (Mantel-Haenszel Method)**

Each outcome and exposure variable were cross-tabulated using all the stratification factors, as shown in Table 1. Eventually, 51,744 tables (2x2) per month (T) were obtained for each vaccine sequence and outcome. The Mantel-Haenszel relative risk [33] of each specific vaccine sequence was calculated using 2x2 tables. By subtracting the relative risk values of all the vaccine sequences from unity, we determined the effectiveness of the vaccine sequences for each month. All VE points were plotted against the month since the last dose of each vaccine sequence to illustrate the waning of VE\textsubscript{i} over time.

**Logistic Regression**

The primary objective of the regression analysis was to estimate the time since the last vaccination dose at which VE decreased to 50%—the minimum threshold recommended by the World Health Organization [31]. According to the variables listed in Table 1, the main independent variables of interest were vaccine sequence (V), time since 2 months after the last dose (T), and their interaction (VT). Other independent variables with their categories were all denoted as \( x \). Using the abbreviations in Table 1, we constructed the model to predict an individual’s probability of obtaining the outcome using the following formula for each vaccine sequence:

\[
\hat{\beta}_V + \hat{\beta}_X i + \hat{\beta}_0 \]

where \( i \) indexes the set of outcomes, \( \hat{\beta}_X \) is the coefficient for each category of other variables, and \( \hat{\beta}_0 \) denotes the intercept term. From the model, \( \hat{\beta}_V \) would be the natural logarithm (ln) of OR\textsubscript{i} at T=0. For each incremental month, the ln(OR\textsubscript{i}) would change by \( \hat{\beta}_VT \). Given that VE\textsubscript{i} is VE against \( Y_i \) of each vaccine sequence, the VE\textsubscript{i} for any T is A statistically significant \( \hat{\beta}_VT \) indicates a significant change in the VE\textsubscript{i} over time. A variance inflation factor of greater than 5 was considered to indicate collinearity among noninteraction variables [34]. The following formula was used to obtain the estimated time at which VE\textsubscript{i} declined to 50% (\( T_{VE=50%} \)): \( T_{VE=50%} = (\ln(0.5) – \hat{\beta}_X)/\hat{\beta}_VT \). Hence, the number of months after the last dose of each vaccine sequence at which VE\textsubscript{i} declined to 50% was \( T_{VE=50%}+2 \). Additionally, a booster dose may be required.

**Subgroup Analysis**

We conducted a subgroup analysis by age group, utilizing the logistic regression model to examine the consistency of VE durability for each age group in relation to the overall population, where \( x \) represents variables other than the age group. All analyses were performed using epiDisplay version 3.5.0.2 [35], car version 3.1 [36], and tidyverse version 1.3.1 [37] packages in R version 4.1.1 (R Core Team 2021; R: A Language and Environment for Statistical Computing, R Foundation for Statistical Computing). \( P<.05 \) was considered statistically significant.

**Ethics Approval**

This study was approved by the human research ethics committee of Songkla University (REC 65-373-18-4). The waiver of consent for accessing encrypted data was granted by the MoPH and Ministry of Interior (Thailand).

**Results**

**Participants**

A dynamic cohort of 52,580,841 individuals was established throughout the study period, beginning in May 2021. The cohort size decreased over the course of the study, as the participants exited because of SARS-CoV-2 infection (positive ATK or RT-PCR). For the 8 vaccine regimens included in our analysis, by the end of the study, 17,907,215 and 17,190,975 individuals who received 2 and 3 doses, respectively (not mutually exclusive), remained in the cohort. Thus, 45.73% (24,048,933/52,580,841) of the cohort comprised individuals who either received vaccine sequences other than the 8 primary sequences or received no vaccination at all. Table 2 describes the characteristics of individuals receiving each vaccine sequence. The columns are arranged in a chronological order based on the date on which the Thai government policy included the vaccine regimen, starting with the inactivated virus vaccine, followed by the viral vector vaccine, and finally the mRNA vaccine.
In May 2021, there were 44,424,291 nonimmunized individuals. This number decreased over time as vaccination campaigns continued. At the end of the study period, this number was reduced to 76,402. The sex distribution across all vaccine types

remained relatively balanced. The number of individuals in the 18-40 years and 40-60 years age groups differed across the vaccine regimens. The interval between doses 1 and 2 of the vaccine was approximately within 1 month if dose 1 was SV or SP and 2-3 months if dose 1 was AZ, as per national guidelines [25]. The duration between doses 2 and 3 varied between 1 and 6 months. Amid the emergence of the Omicron variant, PZ and MN were the predominant vaccines used.

Effectiveness of the Vaccines

The effectiveness of each heterologous vaccine regimen over time is shown in Figure 2, Figure 3, and Table 3. The estimated VEs over time from the logistic regression are illustrated in Figures S1-S2 of Multimedia Appendix 1. Table S1 of Multimedia Appendix 1 shows no significant collinearity (variance inflation factor<5) among the noninteraction variables in all logistic regression models. The 2-dose heterologous vaccination provided approximately 50% of the initial protection against severe and fatal COVID-19. After dose 2, protection against severe COVID-19 declined to less than 50% effectiveness at 5.9 months for SV-AZ and 4.7 months for AZ-PZ. The protective effect against death following COVID-19 was too low to compute a \( \text{TVE}=50\%+2 \).

All 3-dose heterologous vaccine sequences provided better protection than 2-dose heterologous vaccinations. SV-SV-AZ and SV-AZ-AZ provided persistent protection against both outcomes by over 80% and 60%, respectively, from the initial period to 7 months after dose 3 without evidence of waning. There was no statistical significance of the waning of VE against death between the SP-SP-PZ and AZ-AZ-MN groups. The \( \text{TVE}=50\%+2 \) protective effect against severe and fatal COVID-19 for each other 3-dose heterologous vaccine sequence varied from 8.7 to 14.6 months. Figures 2 and 3 demonstrate the concordance in estimating VE using logistic regression within 7 months following the last dose for all vaccine sequences, as illustrated in Figures S1-S2 of Multimedia Appendix 1.

Figure 2. Vaccine effectiveness of 2-dose vaccine sequences at preventing (A) severe and (B) fatal COVID-19 estimated using the Mantel-Haenszel risk ratio method with 95% CI ribbon from July 2021 to July 2022. For each month, the risk ratios of having the outcomes were stratified by the number of months after dose 2 and adjusted by sex, age group, province, and month of infection. AZ: AstraZeneca (ChAdOx1); PZ: Pfizer/BioNTech (BNT162b2); SV: Sinovac (CoronaVac).
Figure 3. Vaccine effectiveness of 3-dose vaccine sequences at preventing (A) severe and (B) fatal COVID-19 estimated using the Mantel-Haenszel risk ratio method with 95% CI ribbon from July 2021 to July 2022. For each month, the risk ratios of having the outcomes were stratified by the number of months after dose 3 and adjusted by sex, age groups, province, and month of infection. For SV-SV-AZ, SV-AZ-AZ, and SP-SP-PZ vaccine sequences, the vaccine effectiveness at 2 and 3 months after dose 3 was excluded due to an insufficient number of outcomes, resulting in CIs with an infinite range. AZ: AstraZeneca (ChAdOx1); MN: Moderna (mRNA-1273); PZ: Pfizer/BioNTech (BNT162b2); SP: Sinopharm (BBIBP-CorV); SV: Sinovac (CoronaVac).

<sup>h</sup>MN: Moderna (mRNA-1273).

### Subgroup Analysis

Figures S3-S18 of Multimedia Appendix 1 display the decline in VE over time, stratified by age group, and Table 2 provides a comprehensive summary of these figures. This table presents the effectiveness of the 2- and 3-dose COVID-19 vaccine sequences stratified by age group in relation to severe COVID-19 cases and COVID-19-related fatalities. The initial VE was compared with the VE 7 months after administration of the last dose. These findings indicate that VE is generally lower in people aged ≥80 years. The VE of distinct vaccine sequences varied based on the age group and outcome; however, the P values suggest that these differences were not statistically significant. The SV-SV-AZ regimen provided at least 6 months of durable VE against both severe and fatal COVID-19 in all age groups, including in those aged over 80 years (Figures S7-S8 of Multimedia Appendix 1). Neither of the dose regimens included in our analysis (SV-AZ and AZ-PZ) provided protective efficacy (>50% VE). Conversely, the VE of each 3-dose sequence increased (>50%) and subsequently waned over time, with a significant P value for the interaction term. Those older (age 61-80 years and ≥80 years) experienced reduction in VE to below 50% against severe or fatal COVID-19.
within 7 months of the last dose, except for the SV-SV-AZ sequence.

Discussion

Principal Findings

In Thailand, as in many other LMICs, most people receive heterologous vaccine regimens for primary series and booster doses. The main 2-dose regimens delivered in Thailand (SV-AZ and AZ-PZ) exhibited suboptimal protection against severe COVID-19, with VE decreasing to <50% after 5-7 months, as confirmed by the Mantel-Haenszel method and logistic regression. Furthermore, the initial effectiveness of these vaccines against COVID-19-related mortality was <50%. In contrast, the 3-dose regimen provided superior initial protection against both severe and fatal COVID-19, with the VE remaining >50% for at least 8 months, as determined by logistic regression with durability time-interaction modeling. However, among individuals aged ≥80 years, all vaccine combinations conferred a comparatively lower level of protection with shorter durability relative to other age groups. For the 2-dose regimen in Thailand, sequential administration of the SV-AZ vaccine was initially favored even after the availability of AZ-AZ because of a shorter recommended interdose interval based on research examining humoral immune responses [3,38]. Nevertheless, a subsequent test-negative case-control study suggested that SV-AZ was ineffective against severe COVID-19 (VE<50%) within 3 months of administering the final dose [17], which is consistent with our findings. Regarding the 3-dose regimens, other studies from Thailand similarly found heterologous vaccines to have a high VE, although they included a different set of regimens in their analysis [18].

In light of a heterologous 3-dose vaccination strategy that provides a minimum of 8 months of sustained VE against severe and fatal COVID-19 cases, the need for annual immunization has become a topic of ongoing debate [39,40], particularly given the financial burden of regular COVID-19 vaccination campaigns. Information from this study can potentially help governments identify appropriate target groups and vaccination frequencies for future COVID-19 booster vaccination policies. The durability of immunity acquired through vaccination is known to be nonuniform across different age groups due to immunosenescence [41]. Consequently, older individuals may not develop the same level of immunity against COVID-19 as younger adults, rendering vaccines less effective in preventing severe and fatal COVID-19 [42-45]. Our data show that VE for individuals aged >80 years waned after 6 months. Only the SV-SV-AZ regimen exceptionally provided more than 50% effectiveness against both severe and fatal COVID-19 over 6 months. Therefore, individuals aged >80 years receiving other regimens might need a booster dose approximately every 6 months during the pandemic era.

Limitations

This study has a few limitations that are primarily related to the use of national registry data. We were unable to identify information on unmeasured confounders such as occupations, comorbidities, and SARS-CoV-2 variants. In Thailand, health care workers were prioritized at the start of the campaign, and as it would be expected that health care workers might have different risks of developing severe COVID-19, this may have led to overestimates or underestimates of VE of the SV-AZ regimen in our study [46]. Similarly, we could not control for the comorbidities that increase the risk of developing severe COVID-19, such as diabetes and immunocompromising conditions. Individuals with these comorbidities had priority for receiving vaccination [46]. Lack of control for comorbidities may have led to an underestimation of the VE of all vaccines.

Additionally, we were unable to control for the variants of concern, which is important because there was a switch from Delta to Omicron during the study period. However, partitioning the analysis into windows for the months when Alpha and Delta variants were dominant was not possible owing to an inadequate number of cases in the vaccinated population. Most of the Thai population only received their first dose of vaccine after the Delta variant surged. Booster doses were administered mainly in 2022 during the Omicron variant–dominant period. Therefore, in this study, the evaluation of VE applies mainly to protection against the Delta variant.

Another limitation of the registry data is that it was not possible to verify whether all the individuals in the cohort were truly uninfected. Therefore, it is likely that there were many individuals with hybrid immunity and undetected natural infections in the cohort. Furthermore, this study did not account for reinfection, which might lead to a survival bias, particularly in older populations, as the remaining population is likely to be healthier [47,48]. Finally, we were unable to continue our analysis beyond July 2022 when the CO-WARD registry database ended. We also did not track individuals after any evidence of SARS-CoV-2 infection; thus, we do not have data on reinfection. The lack of reinfection data means that this study does not provide information on the protective effect of natural SARS-CoV-2 infection against subsequent infections. Given the transmissibility of the Omicron variant, which frequently causes breakthrough infections in vaccinated individuals but is less virulent [49], it is possible that by 2024, natural immunity acquired from natural infection with the Omicron variant will protect most people from reinfection. Therefore, another study is needed to clarify whether an additional booster dose is needed for individuals younger than 80 years.

Conclusion

Our findings show evidence of a significant waning of vaccine protection in Thailand, particularly for the main heterologous 2-dose regimens (SV-AZ and AZ-PZ). Overall, all 3-dose regimens demonstrated higher VE than 2-dose regimens and maintained durability of VE against severe and fatal COVID-19, with over 50% effectiveness for at least 8 months. Only the SV-SV-AZ regimen consistently showed effectiveness across all age groups. Individuals older than 80 years who received other regimens should receive a booster dose at 6 months after their last dose. Within a 7-month follow-up period, the heterologous prime-boost vaccination strategies, which involve a primary series of an inactivated virus vaccine and a booster with either a viral vector or mRNA vaccine, is proven to prevent severe and fatal COVID-19 in situations of vaccine shortages. This approach is particularly pertinent in scenarios, wherein
viral vector and mRNA vaccines are not readily available during the early stages of a pandemic. However, estimates of VE over a year are needed for vaccine regimens delivered in Thailand to inform future vaccination policies. The ongoing emergence of SARS-CoV-2 variants and the resulting herd immunity warrant the continuation of vaccine development and monitoring of VE.

Acknowledgments
The researchers would like to sincerely thank the Ministry of Public Health and the Bureau of Registration Administration, Department of Provincial Administration, Ministry of Interior for providing us with a large valuable data set. This study was partially supported by the Thailand Science Research and Innovation through the 2024 fundamental fund to the Health Intervention and Technology Assessment Program, Ministry of Public Health.

Data Availability
The aggregated data and R codes are shared by GitHub in [50]. To accommodate readers who are not familiar with R coding, we have also provided an Excel file that summarizes the results for each time period in [51].

Authors' Contributions
PK, NC, ST, and AC accessed the underlying data. PK, NC, and AC scrutinized the foundational data and took responsibility for the integrity of the data and accuracy of the data analysis. PK, YT, and VC were responsible for deciding to submit this manuscript. PK and VC conceived and designed this study. PK, NC, and AC curated the data. PK and VC designed the methods and conducted formal analyses. PK, SB, CP, YT, and VC wrote the original draft. SB, CP, NS, BL, ST, NC, AC, and YT reviewed and edited the manuscript. CP and NS were the project administrators and managed the resources. VC supervised this study. All the authors have read and approved the final manuscript.

Abstract

Background: Despite COVID-19 vaccine mandates, many chose to forgo vaccination, raising questions about the psychology underlying how judgment affects these choices. Research shows that reward and aversion judgments are important for vaccination choice; however, no studies have integrated such cognitive science with machine learning to predict COVID-19 vaccine uptake.

Objective: This study aims to determine the predictive power of a small but interpretable set of judgment variables using 3 machine learning algorithms to predict COVID-19 vaccine uptake and interpret what profile of judgment variables was important for prediction.

Methods: We surveyed 3476 adults across the United States in December 2021. Participants answered demographic, COVID-19 vaccine uptake (ie, whether participants were fully vaccinated), and COVID-19 precaution questions. Participants also completed a picture-rating task using images from the International Affective Picture System. Images were rated on a Likert-type scale to calibrate the degree of liking and disliking. Ratings were computationally modeled using relative preference theory to produce a set of graphs for each participant (minimum R²>0.8). In total, 15 judgment features were extracted from these graphs, 2 being analogous to risk and loss aversion from behavioral economics. These judgment variables, along with demographics, were compared between those who were fully vaccinated and those who were not. In total, 3 machine learning approaches (random forest, balanced random forest [BRF], and logistic regression) were used to test how well judgment, demographic, and COVID-19 precaution variables predicted vaccine uptake. Mediation and moderation were implemented to assess statistical mechanisms underlying successful prediction.

Results: Age, income, marital status, employment status, ethnicity, educational level, and sex differed by vaccine uptake (Wilcoxon rank sum and chi-square P<.001). Most judgment variables also differed by vaccine uptake (Wilcoxon rank sum P<.05). A similar area under the receiver operating characteristic curve (AUROC) was achieved by the 3 machine learning frameworks, although random forest and logistic regression produced specificities between 30% and 38% (vs 74.2% for BRF), indicating a lower performance in predicting unvaccinated participants. BRF achieved high precision (87.8%) and AUROC (79%) with moderate to high accuracy (70.8%) and balanced recall (69.6%) and specificity (74.2%). It should be noted that, for BRF,
the negative predictive value was <50% despite good specificity. For BRF and random forest, 63% to 75% of the feature importance came from the 15 judgment variables. Furthermore, age, income, and educational level mediated relationships between judgment variables and vaccine uptake.

Conclusions: The findings demonstrate the underlying importance of judgment variables for vaccine choice and uptake, suggesting that vaccine education and messaging might target varying judgment profiles to improve uptake. These methods could also be used to aid vaccine rollouts and health care preparedness by providing location-specific details (eg, identifying areas that may experience low vaccination and high hospitalization).

Introduction

Background

In early 2020, the COVID-19 pandemic wreaked havoc worldwide, triggering rapid vaccine development efforts. Despite federal, state, and workplace vaccination mandates, many individuals made judgments against COVID-19 vaccination, leading researchers to study the psychology underlying individual vaccination preferences and what might differentiate the framework for judgment between individuals who were fully vaccinated against COVID-19 and those who were not (henceforth referred to as vaccine uptake). A better understanding of these differences in judgment may highlight targets for public messaging and education to increase the incidence of choosing vaccination.

Prior Work

Multiple studies have sought to predict an individual’s intention to receive a COVID-19 vaccine or specific variables underlying vaccination choices or mitigation strategies [1-7], but few have predicted vaccine uptake. One such study used 83 sociodemographic variables (with education, ethnicity, internet access, income, longitude, and latitude being the most important predictors) to predict vaccine uptake with 62% accuracy [8], confirming both the importance and limitations of these variables in prediction models. Other studies have compared demographic groups between vaccinated and nonvaccinated persons; Bulusu et al [9] found that young adults (aged 18-35 years), women, and those with higher levels of education had higher odds of being vaccinated. In a study of >12 million persons, the largest percentage of those who initiated COVID-19 vaccination were White, non-Hispanic women between the ages of 50 and 64 years [10]. Demographic variables are known to affect how individuals judge what is rewarding or aversive [11,12] yet are not themselves variables quantifying how individuals make judgments that then frame decisions.

Judgment reflects an individual’s preferences, or the variable extent to which they approach or avoid events in the world based on the rewarding or aversive effects of these events [13-15]. The definition of preference in psychology differs from that in economics. In psychology, preferences are associated with “wanting” and “liking” and are framed by judgments that precede decisions, which can be quantified through reinforcement reward or incentive reward tasks [12,16-21]. In economics, preferences are relations derived from consumer choice data (refer to the axioms of revealed preference [22]) and reflect choices or decisions based on judgments that place value on behavioral options. Economist Paul Samuelson noted that decisions are “assumed to be correlative to desire or want” [23]. In this study, we focused on a set of variables that frame judgment, with the presumption that judgments precede choices [12,20]. Variables that frame judgment can be derived from tasks using operant key-pressing tasks that quantify “wanting” [24-33] or simple rating tasks that are analogous to “liking” [20,34]. Both operant keypress and rating tasks measure variables that quantify the average (mean) magnitude (K), variance (σ), and pattern (ie, Shannon entropy [H]) of reward and aversion judgments [35]. We refer to this methodology and the multiple relationships between these variables and features based on their graphical relationships as relative preference theory (RPT; Figure 1) [18,36]. RPT has been shown to produce discrete, recurrent, robust, and scalable relationships between judgment variables [37] that produce mechanistic models for prediction [33], and which have demonstrated relationships to brain circuitry [24-27,30] and psychiatric illness [28]. Of the graphs produced for RPT, 2 appear to resemble graphs derived with different variables in economics, namely, prospect theory [38] and the mean-variance function for portfolio theory described by Markowitz [39]. Given this graphical resemblance, it is important to note that RPT functions quantifying value are not the same as standard representations of preference in economics. Behavioral economic variables such as loss aversion and risk aversion [38,40-51] are not to be interpreted in the same context given that both reflect biases and bounds to human rationality. In psychology, they are grounded in judgments that precede decisions, whereas in economics, they are grounded in consumer decisions themselves. Going forward, we will focus on judgment-based loss aversion, representing the overweighting of negative judgments relative to positive ones, and judgment-based risk aversion, representing the preference for small but certain assessments over larger but less certain ones (ie, assessments that have more variance associated with them) [38,40-51]. Herein, loss aversion and risk aversion refer to ratings or judgments that precede decisions.

A number of studies have described how risk aversion and other judgment variables are important for individual vaccine choices and hesitancies [52-58]. Hudson and Montelpare [54] found that risk aversion may promote vaccine adherence when people
perceive contracting a disease as more dangerous or likely. Trueblood et al [52] noticed that those who were more risk seeking (as measured via a gamble ladder task) were more likely to receive the vaccine even if the vaccine was described as expedited. Wagner et al [53] described how risk misperceptions (when the actual risk does not align with the perceived risk) may result from a combination of cognitive biases, including loss aversion. A complex theoretical model using historical vaccine attitudes grounded in decision-making has also been proposed to predict COVID-19 vaccination, but this model has not yet been tested [59]. To our knowledge, no study has assessed how well a model comprising variables that reflect reward and aversion judgments predicts vaccine uptake.

Figure 1. Picture-rating task and judgment variable extraction. (A) An example picture from the picture-rating task in which participants were asked to rate how much they liked or disliked an image on a scale from −3 (dislike very much) to +3 (like very much), with 0 being neutral. (B) Visual representation of the x-y plane for relative preference theory (RPT) value function fitting and resulting features extracted. (C) Visual representation of the x-y plane for RPT limit function fitting and resulting features extracted. (D) Visual representation of the x-y plane for RPT trade-off function fitting and resulting features extracted. (E) Each of the 15 features and their abbreviated terms.

Goal of This Study

Given the many vaccine-related issues that occurred during the COVID-19 pandemic (eg, vaccine shortages, hospital overload, and vaccination resistance or hesitancy), it is critical to develop methods that might improve planning around such shortcomings. Because judgment variables are fundamental to vaccine choice, they provide a viable target for predicting vaccine uptake. In addition, the rating methodology used to quantify variables of judgment is independent of methods quantifying vaccine uptake or intent to vaccinate, limiting response biases within the study data.

In this study, we aimed to predict COVID-19 vaccine uptake using judgment, demographic, and COVID-19 precaution (ie, behaviors minimizing potential exposure to COVID-19) variables using multiple machine learning algorithms, including logistic regression, random forest, and balanced random forest (BRF). BRF was hypothesized to perform best given its potential benefits with handling class imbalances [60], balancing both recall and specificity, and producing Gini scores that provide relative variable importance to prediction. In this study, the need for data imbalance techniques was motivated by the importance of the specificity metric, which would reflect the proportion of participants who did not receive full vaccination; without balancing, the model might not achieve similar recall and specificity values. When there is a large difference between recall and specificity, specificity might instead reflect the size of the minority class (those who did not receive full vaccination). In general, random forest approaches have been reported to have benefits over other approaches such as principal component analysis and neural networks, in which the N-dimensional feature space or layers (in the case of neural networks) are complex nonlinear functions, making it difficult to interpret variable importance and relationships to the outcome variable. To provide greater certainty about these assumptions, we performed logistic regression in parallel with random forest and BRF. The 3 machine learning approaches used a small feature set (<20) with interpretable relationships to the predicted variable. Such interpretations may not be achievable in big data approaches that use hundreds to thousands of variables that seemingly add little significance to the prediction models. Interpretation was facilitated by (1) the Gini importance criterion associated with BRF and random forest, which provided a profile of the judgment variables most important for prediction; and (2) mediation and moderation analyses that offered insights into statistical mechanisms among judgment variables, demographic (contextual) variables, and vaccine uptake. Determining whether judgment variables are predictive of COVID-19 vaccine uptake and defining which demographic variables facilitate this prediction presents a number of behavioral targets for vaccine education and messaging—and
potentially identifies actionable targets for increasing vaccine uptake.

More broadly, the prediction of vaccine uptake may aid (1) vaccine supply chain and administration logistics by indicating areas that may need more or fewer vaccines, (2) targeted governmental messaging to locations with low predicted uptake, and (3) preparation of areas that may experience high cases of infection that could ultimately impact health care preparedness and infrastructure. The proposed method could also be applied to other mandated or government-recommended vaccines (eg, influenza and human papillomavirus) to facilitate the aforementioned logistics. Locally, vaccine uptake prediction could facilitate local messaging and prepare health care institutions for vaccine rollout and potential hospital overload. Nationally, prediction might inform public health officials and government communication bodies that are responsible for messaging and vaccine rollout with the goal of improving vaccine uptake and limiting infection and hospital overload.

Methods

Recruitment

Similar recruitment procedures for a smaller population-based study have been described previously [61-63]. In this study, participants were randomly sampled from the general US population using an email survey database used by Gold Research, Inc. Gold Research administered questionnaires in December 2021 using recruitment formats such as (1) customer databases from large companies that participate in revenue-sharing agreements, (2) social media, and (3) direct mail. Recruited participants followed a double opt-in consent procedure that included primary participation in the study as well as secondary use of anonymized, deidentified data (ie, all identifying information was removed by Gold Research before retrieval by the research group) in secondary analyses (refer to the Ethical Considerations section for more detail). During consent procedures, participants provided demographic information (eg, age, race, and sex) to ensure that the sampled participants adequately represented the US census at the time of the survey (December 2021). Respondents were also presented with repeated test questions to screen out those providing random and illogical responses or showing flatline or speeder behavior. Participants who provided such data were flagged, and their data were removed.

Because other components of the survey required an adequate sample of participants with mental health conditions, Gold Research oversampled 15% (60,000/400,000) of the sample for mental health conditions, and >400,000 respondents were contacted to complete the questionnaire. Gold Research estimated that, of the 400,000 participants, >300,000 (≥75%) either did not respond or declined to participate. Of the remaining 25% (100,000/400,000) who clicked on the survey link, >50% (52,000/100,000) did not fully complete the questionnaire. Of the ≥48,000 participants who completed the survey (ie, ≥48,000/400,000, ≥12% of the initial pool of queried persons), those who did not clear data integrity assessments were omitted. Participants who met quality assurance procedures (refer to the following section) were selected, with a limit of 4000 to 4050 total participants.

Eligible participants were required to be aged between 18 and 70 years at the time of the survey, comprehend the English language, and have access to an electronic device (eg, laptop or smartphone).

Ethical Considerations

All participants provided informed consent, which included their primary participation in the study as well as the secondary use of their anonymized, deidentified data (ie, all identifying information removed by Gold Research before retrieval by the research group) in secondary analyses. This study was approved by the Northwestern University institutional review board (approval STU00213665) for the initial project start and later by the University of Cincinnati institutional review board (approval 2023-0164) as some Northwestern University investigators moved to the University of Cincinnati. All study approvals were in accordance with the Declaration of Helsinki. All participants were compensated with US $10 for taking part. Detailed survey instructions have been published previously [61-63].

Quality Assurance and Data Exclusion

Three additional quality assurance measures were used to flag nonadhering participants: (1) participants who indicated that they had ≥10 clinician-diagnosed illnesses (refer to Figure S1 in Multimedia Appendix 1 [18,33,36,64-68] for a list), (2) participants who showed minimal variance in the picture-rating task (ie, all pictures were rated the same or the ratings varied only by 1 point; refer to the Picture-Rating Task section), and (3) inconsistencies between educational level and years of education and participants who completed the questionnaire in <800 seconds.

Data from 4019 participants who passed the initial data integrity assessments were anonymized and then sent to the research team. Data were further excluded if the quantitative feature set derived from the picture-rating task was incomplete or if there were extreme outliers (refer to the RPT Framework section). Using these exclusion criteria, of the 4019 participants, 3476 (86.49%) were cleared for statistical analysis, representing 0.87% (3476/400,000) of the initial recruitment pool. A flowchart of participant exclusion is shown in Figure 2.
Questionnaire
Participants were asked to report their age, sex, ethnicity, annual household income, marital status, employment status, and educational level. Participants were asked to report whether they had received the full vaccination (yes or no responses). At the time of the survey, participants were likely to have received either 2 doses of the Pfizer or Moderna vaccine or 1 dose of the Johnson & Johnson vaccine as per the Centers for Disease Control and Prevention guidelines. Participants were also asked to respond yes (they routinely followed the precaution) or no (they did not routinely follow the precaution) to 4 COVID-19 precaution behaviors: mask wearing, social distancing, washing or sanitizing hands, and not gathering in large groups (refer to Tables S1 and S2 in Multimedia Appendix 1 for the complete questions and sample sizes, respectively). In addition, participants completed a picture-rating task at 2 points during the survey (refer to the Picture-Rating Task section).

Picture-Rating Task
A picture-rating task was administered to quantify participants’ degree of liking and disliking a validated picture set using pictures calibrated over large samples for their emotional intensity and valence [69,70]. Ratings from this task have been mathematically modeled using RPT to define graphical features of reward and aversion judgments. Each feature quantifies a core aspect of judgment, including risk aversion and loss aversion. Judgment variables have been shown to meet the criteria for lawfulness [37] that produce mechanistic models for prediction [33], with published relationships to brain circuitry [24-27,30] and psychiatric illness [28]. A more complete description of these judgment variables and their computation can be found in the RPT Framework section and in Table 1.

For this task, participants were shown 48 unique color images from the International Affective Picture System [69,70]. A total of 6 picture categories were used: sports, disasters, cute animals, aggressive animals, nature (beach vs mountains), and men and women dressed minimally, with 8 pictures per category (48 pictures in total; Figure 1A). These images have been used and validated in research on human emotion, attention, and preferences [69,70]. The images were displayed on the participants’ digital devices with a maximum size of 1204 × 768 pixels. Below each picture was a rating scale from −3 (dislike very much) to +3 (like very much), where 0 indicated indifference (Figure 1A). While there was no time limit for selecting a picture rating, participants were asked to rate the images as quickly as possible and use their first impression. Once a rating was selected, the next image was displayed.
Table 1. Judgment variable descriptions. Function and curve for derivation indicates which function space was used to derive each judgment variable (refer to the work by Markowitz [39,71]; equations are also discussed in the study by Kim et al [18]).

RPT Framework

Ratings from the picture-rating task were analyzed using an RPT framework. This framework fits approach and avoidance curves and derives mathematical features from graphical plots (Figures 1B–1D). These methods have been described at length in prior work and are briefly described in this section [11,18,33,36]. More complete descriptions and quality assurance procedures can be found in Multimedia Appendix 1.

At least 15 judgment variables can be mathematically derived from this framework and are psychologically interpretable; they have been validated using both operand keypresses [9,25-27] and picture-rating tasks [11,34]. The 15 judgment variables are loss aversion, risk aversion, loss resilience, ante, insurance, peak positive risk, peak negative risk, reward tipping point, aversion tipping point, total reward risk, total aversion risk, reward-aversion trade-off, trade-off range, reward-aversion consistency, and consistency range. Loss aversion, risk aversion, loss resilience, ante, and insurance are derived from the logarithmic or power-law fit of mean picture ratings (K) versus entropy of ratings (H); this is referred to as the value function (Figure 1B). Peak positive risk, peak negative risk, reward tipping point, aversion tipping point, total reward risk, and total aversion risk are derived from the quadratic fit of K versus the SD of picture ratings (σ); this is referred to as the limit function (Figure 1C). Risk aversion trade-off, trade-off range, risk aversion consistency, and consistency range are derived from the radial fit of the pattern of avoidance judgments (H_L) versus the pattern of approach judgments (H_A); this is referred to as the trade-off function (Figure 1D). Value (Figure S2A in Multimedia Appendix 1), limit (Figure S2B in Multimedia Appendix 1), and trade-off (Figure S2C in Multimedia Appendix 1) functions were plotted for 500 randomly sampled participants, and nonlinear curve fits were assessed for goodness of fit, yielding R², adjusted R², and the associated F statistic for all participants (Figure S2D in Multimedia Appendix 1). Only the logarithmic and quadratic fits are listed in Table S3 in Multimedia Appendix 1. Each feature describes a quantitative component of a participant’s reward and aversion judgment (refer to Table 1 for abbreviated descriptions and Multimedia Appendix 1 for complete descriptions). Collectively, the 15 RPT features will be henceforth referred to as “judgment variables.” The summary statistics for these variables can be found in Table S3 in Multimedia Appendix 1.
Statistical and Machine Learning Analyses

Overview

Wilcoxon rank sum tests, chi-square tests, and Gini importance plotting were performed in Stata (version 17; StataCorp) [72]. Machine learning algorithms were run in Python (version 3.9; Python Software Foundation) [73], where the scikit-learn (version 1.2.2) [74] and imbalanced-learn (version 0.10.1) [75] libraries were used. Post hoc mediation and moderation analyses were performed in R (version 4.2.0; R Foundation for Statistical Computing) [76].

Demographic and Judgment Variable Differences by Vaccination Uptake

Each of the 7 demographic variables (age, income, marital status, employment status, ethnicity, educational level, and sex) was assessed for differences using yes or no responses to receiving the full COVID-19 vaccination (2525/3476, 72.64% yes responses and 951/3476, 27.36% no responses), henceforth referred to as vaccine uptake. Ordinal (income and educational level) and continuous (age) demographic variables were analyzed using the Wilcoxon rank sum test (α=.05). Expected and actual rank sums were reported using Wilcoxon rank sum tests. Nominal variables were analyzed using the chi-square test (α=.05). For significant chi-square results, demographic response percentages were computed to compare the fully vaccinated and not fully vaccinated groups.

Each of the 15 judgment variables was assessed for differences across yes or no responses to vaccine uptake using the Wilcoxon rank sum test (α=.05). The expected and actual rank sums were reported. Significant results (α<.05) were corrected for multiple comparisons using the Benjamini-Hochberg correction, and Q values of <0.05 (Q_{B-H}) were reported.

Prediction Analyses

Logistic regression, random forest, and BRF were used to predict vaccine uptake using judgment, demographic, and COVID-19 precaution variables. Gini plots were produced for random forest and BRF to determine the importance of the judgment variables in predicting COVID-19 vaccination. The BRF algorithm balances the samples by randomly downsampling the majority class at each bootstrapped iteration to match the number of samples in the minority class. To provide greater certainty about the results, random forest and logistic regression were performed to compare with BRF results.

Two sets of BRF, random forest, and logistic regression analyses were run: (1) with the 7 demographic variables and 15 judgment variables included as predictors and (2) with the 7 demographic variables, 15 judgment variables, and 4 COVID-19 precaution behaviors included as predictors. COVID-19 precaution behaviors included yes or no responses to wearing a mask, social distancing, washing hands, and avoiding large gatherings (refer to Table S1 in Multimedia Appendix 1 for more details). The sample sizes for yes or no responses to the COVID-19 precaution behavior questions are provided in Table S2 in Multimedia Appendix 1. For all 3 models, 10-fold cross-validation was repeated 100 times to obtain performance metrics, where data were split for training (90%) and testing (10%) for each of the 10 iterations in cross-validation. The averages of the performance metrics were reported across 100 repeats of 10-fold cross-validation for the test sets. The reported metrics included accuracy, recall, specificity, negative predictive value (NPV), precision, and area under the receiver operating characteristic curve (AUROC). For BRF, the Python toolbox imbalanced-learn was used to build the classifier, where the training set for each iteration of cross-validation was downsamplt but the testing set was unchanged (ie, imbalanced). That is, downsampling only occurred with the bootstrapped samples for training the model, and balancing was not performed on the testing set. The default number of estimators was 100, and the default number of tree splits was 10; the splits were created using the Gini criterion. In separate analyses, estimators were increased to 300, and splits were increased to 15 to test model performance. Using the scikit-learn library, the same procedures used for BRF were followed for logistic regression without downsampling. Logistic regression without downsampling was implemented with a maximum of 100 iterations and optimization using a limited-memory Broyden-Fletcher-Goldfarb-Shanno solver. For logistic regression, model coefficients with respective SEs, z statistics, P values, and 95% CIs were reported.

Relative feature importance based on the Gini criterion (henceforth referred to as Gini importance) was determined from BRF and random forest using the .feature_importances_ attribute from scikit-learn, and results were reported as the mean decrease in the Gini score and plotted in Stata. To test model performance using only the top predictors, two additional sets of BRF analyses were run: (1) with the top 3 features as predictors and (2) with the top 3 features and 15 judgment variables as predictors.

Post Hoc Mediation and Moderation

Given the importance of both judgment variables and demographic variables (refer to the Results section), we evaluated post hoc how age, income, and educational level (ie, the top 3 predictors) might statistically influence the relationship between the 15 judgment variables and COVID-19 vaccine uptake. To identify statistical mechanisms influencing our prediction results, we used mediation and moderation, which can (1) determine the directionality between variables and (2) assess variable influence in statistical relationships. Mediation is used to determine whether one variable, the mediator, statistically improves the relationship between 2 other variables (independent variables [IVs] and dependent variables [DVs]) [77-80]. When mediating variables improve a relationship, the mediator is said to sit in the statistical pathway between the IVs and DVs [77,80,81]. Moderation is used to test whether the interaction between an IV and a moderating variable predicts a DV [81,82].

For mediation, primary and secondary mediations were performed. Primary mediations included each of the 15 judgment behaviors as the IV, each of the 3 demographic variables (age, income, and educational level) as the mediator, and vaccine uptake as the DV. Secondary mediations held the 15 judgment behaviors as the mediator, the 3 demographic variables as the IV, and vaccine uptake as the DV. For moderation, the
moderating variable was each of the 3 demographic variables (age, income, and educational level), the IV was each of the 15 judgment behaviors, and the DV was vaccine uptake. The mathematical procedures for mediation and moderation can be found in Multimedia Appendix 1.

Results

Demographic Assessment

Of the 400,000 persons queried by Gold Research, Inc, 48,000 (12%) completed the survey, and 3476 (0.87%) survived all quality assurance procedures. Participants were predominately female, married, and White individuals; employed full time with some college education; and middle-aged (mean age 51.40, SD 14.92 years; Table 2). Of the 3476 participants, 2525 (72.64%) reported receiving a full dose of a COVID-19 vaccine, and 951 (27.36%) reported not receiving a full dose. Participants who indicated full vaccination were predominately female, married, White individuals, and retired; had some college education; and were older on average (mean age 54.19, SD 14.13 years) when compared to the total cohort. Participants who indicated that they did not receive the full vaccine were also predominately female, married, and White individuals. In contrast to those who received the full vaccination, those not fully vaccinated were predominately employed full time, high school graduates, and of average age (mean age 43.98, SD 14.45 years; median age 45, IQR 32-56 years) when compared to the total cohort. Table 2 summarizes the demographic group sample size percentages for the total cohort, those fully vaccinated, and those not fully vaccinated.

When comparing percentages between vaccination groups, a higher percentage of male individuals were fully vaccinated, and a higher percentage of female individuals were not fully vaccinated (Table 2). In addition, a higher percentage of married, White and Asian or Pacific Islander, and retired individuals indicated receiving the full vaccine when compared to the percentages of those who did not receive the vaccine (Table 2). Conversely, a higher percentage of single, African American, and unemployed individuals indicated not receiving the full vaccine (Table 2).

Analysis of Machine Learning Features

**Demographic Variable Differences by Vaccine Uptake**

Age, income level, and educational level significantly differed between those who did and did not receive the vaccine (Wilcoxon rank sum test $\alpha<.05$; Table 3). Those who indicated full vaccination were, on average, older (median age 59 y), had a higher annual household income (median reported income level US $50,000-$75,000), and had higher levels of education (the median reported educational level was a bachelor’s degree). Chi-square tests revealed that marital status, employment status, sex, and ethnicity also varied by full vaccine uptake (chi-square $\alpha<.05$; Table 3).

Table 3. Wilcoxon rank sum and chi-square test results ($\alpha=.05$). Expected and actual rank sums for each vaccine uptake group are reported. “Higher” indicates that the actual rank sum was higher than expected, and “lower” indicates that the actual rank sum was lower than expected.

**Judgment Variable Differences by Vaccine Uptake**

In total, 10 of the 15 judgment variables showed nominal rank differences ($\alpha<.05$), and 9 showed significant rank differences after correction for multiple comparisons ($Q_{Hoch}<0.05$) between those who indicated full vaccination and those who indicated that they did not receive the full vaccination (Table 4). The 10 features included loss aversion, risk aversion, loss resilience, ante, insurance, peak positive risk, peak negative risk, total reward risk, total aversion risk, and trade-off range. Those who indicated full vaccination exhibited lower loss aversion, ante, peak positive risk, peak negative risk, total reward risk, and total aversion risk as well as higher risk aversion, loss resilience, insurance, and trade-off range when compared to the expected rank sum. Those who did not receive the full vaccination exhibited lower risk aversion, loss resilience, insurance, and trade-off range and higher loss aversion, ante, peak positive risk, peak negative risk, total reward risk, and total aversion risk when compared to the expected rank sum.
Table 4. Judgment variable differences by vaccine uptake (yes vs no responses to the full vaccination question). Expected and actual rank sums for each vaccine uptake group are reported from Wilcoxon rank sum tests ($\alpha=.05$). “Higher” indicates that the actual rank sum was higher than expected, and “lower” indicates that the actual rank sum was lower than expected.

Machine Learning Results: Predicting Vaccination Uptake

**Prediction Results**

With the inclusion of demographic and judgment variables, the BRF classifier with the highest accuracy (68.9%) and precision (86.7%) in predicting vaccine uptake resulted when the number of estimators was set to 300 and the number of splits was set to 10. With the addition of 4 COVID-19 precaution behaviors, the BRF classifier with the highest accuracy (70.8%) and precision (87.8%) to predict vaccine uptake occurred when the number of estimators was set to 300 and the number of splits was set to 10. It is notable that specificity was consistently >72%, precision was >86%, and the AUROC was >75% but the NPV was consistently <50%. For random forest and logistic regression, recall and accuracy values were higher than those for BRF, but specificity was always <39%, indicating a lower performance in predicting those who did not receive the vaccine. Precision was also lower, yet the AUROC was consistent with that of the BRF results.

⁵A total of 15 judgment variables (Table 4), 7 demographic variables (Table 3), and 4 COVID-19 precaution behavior (covid_beh) variables (Table S1 in Multimedia Appendix 1) were included in balanced random forest, random forest, and logistic regression models to predict COVID-19 vaccine uptake. We used 10-fold cross-validation, where the data were split 90-10 for each of the 10 iterations.

⁶NPV: negative predictive value.

⁷AUROC: area under the receiver operating characteristic curve.

Feature Importance for BRF and Random Forest

Regarding BRF, Gini importance was highest for age, educational level, and income in both BRF classifiers (both without [Figures 3A and 3B] and with [Figures 3C and 3D] inclusion of the COVID-19 precaution behaviors; refer to the clusters outlined in red in Figures 3B and 3D). For both BRF classifiers, the top 3 predictors (age, income, and educational level) had a combined effect of 23.4% on the Gini importance for prediction. Following these predictors, the 15 judgment variables had similar importance scores for both BRF classifiers (range 0.037-0.049; refer to the clusters outlined in black in Figures 3B and 3D). Regarding BRF, Gini importance was highest for age, educational level, and income in both BRF classifiers (both without [Figures 3A and 3B] and with [Figures 3C and 3D] inclusion of the COVID-19 precaution behaviors; refer to the clusters outlined in red in Figures 3B and 3D). For both BRF classifiers, the top 3 predictors (age, income, and educational level) had a combined effect of 23.4% on the Gini importance for prediction. Following these predictors, the 15 judgment variables had similar importance scores for both BRF classifiers (range 0.037-0.049; refer to the clusters outlined in black in Figures 3B and 3D). These 15 predictors had a combined effect of 62.9% to 68.7% on the Gini importance for prediction, indicating that judgment variables were collectively the most important for prediction outcomes. The least important features for predicting vaccination status were demographic variables regarding employment status, marital status, ethnicity, sex, and the 4 COVID-19 precaution behaviors. These predictors only contributed 7.3% to the Gini importance for prediction. As a follow-up analysis, BRF analyses were run using the top 3 features from both the Gini importance plots (age, educational level, and income; Table S4 in Multimedia Appendix 1) and the top 3 features plus 15 judgment variables (Table S5 in Multimedia Appendix 1). The results did not outperform those presented in Table 5. For random forest, the Gini importance was highest for age and educational level (Figure 4). These top 2 predictors had a combined effect of 16.5% to 16.8% for the 2 models (Figures 4A and 4C). Following these predictors, the 15 judgment variables and the income variable had similar Gini importance, with a combined effect of 69.4% to 75.5% for Gini importance. The least important predictors mirrored those of the BRF results.

Logistic Regression Model Statistics

Both model 1 (demographic and judgment variables) and model 2 (demographic, judgment, and COVID-19 precaution behavior variables) were significant ($P<.001$). The model statistics are provided in Tables 6 (model 1) and 7 (model 2). In model 1, age, income, marital status, employment status, sex, educational level, ante, aversion tipping point, reward-aversion consistency, and consistency range were significant ($\alpha<.05$). In model 2, age, income, marital status, employment status, sex, educational level, risk aversion, ante, peak negative risk, mask wearing, and not gathering in large groups were significant ($\alpha<.05$).

**Post Hoc Mediation and Moderation**

Because judgment variables and demographic variables (age, income, and educational level) were important predictors, we evaluated post hoc whether demographics statistically mediated or moderated the relationship between each of the 15 judgment variables and binary responses to COVID-19 vaccination.

For primary mediations, age significantly mediated the statistical relationship between 11 judgment variables and vaccine uptake (α<.05; Table 8), income mediated 8 relationships α< <.05; Table 8), and educational level mediated 9 relationships (α<.05; Table 8). In total, 7 judgment variables overlapped across the 3 models: loss resilience, ante, insurance, peak positive risk, peak negative risk, risk aversion trade-off, and consistency range. Of these, 5 significantly differed between vaccine uptake (those fully vaccinated and those not): loss resilience, ante, insurance, peak positive risk, and peak negative risk (Table 3). Thus, 2 judgment features did not differ by vaccine uptake but were connected with uptake by significant mediation.

For the secondary mediation analyses, 5 judgment variables mediated the statistical relationship between age and vaccine uptake; these variables overlapped with the 11 findings of the primary mediation analyses. Furthermore, 4 judgment variables mediated the statistical relationship between income and vaccine uptake; these variables overlapped with the 8 findings of the primary mediation analyses. Finally, 4 judgment variables mediated the statistical relationship between educational level and vaccine uptake; these variables overlapped with the 9 findings of the primary mediation analyses. In all secondary analyses, approximately half of the judgment variables were involved in mediation as compared to the doubling of judgment variable numbers observed in the primary mediation analyses. In the secondary mediation analyses, the same 4 judgment variables were found in both primary and secondary mediation results, indicating a mixed mediation framework.
Table 8. Mediation and moderation results ($\alpha=.05$). Mediator and moderator variables appear in boldface.

</table>
From the moderation analyses, only 2 interactions out of a potential 45 were observed. Age interacted with risk aversion trade-off, and income interacted with loss resilience to statistically predict vaccine uptake ($\alpha < .05$; Table 8). The 2 moderation results overlapped with the mediation results, indicating mixed mediation-moderation relationships [78,80,81].

**Discussion**

**Principal Findings**

Relatively few studies have sought to predict COVID-19 vaccine uptake using machine learning approaches [8,59]. Given that a small set of studies has assessed the psychological basis that may underlie vaccine uptake and choices [6,52,53,56,58,59,83], but none have used computational cognition variables based on reward and aversion judgment to predict vaccine uptake, we sought to assess whether variables quantifying human judgment predicted vaccine uptake. This study found that 7 demographic and 15 judgment variables predicted vaccine uptake. Other machine learning approaches (random forest and logistic regression) produced higher accuracies but lower specificities, indicating a lower prediction of those who did not receive the vaccine. The BRF also had challenges predicting the negative class, as demonstrated by the relatively low NPV despite having higher specificity than random forest and logistic regression. Feature importance analyses from both BRF and random forest showed that the judgment variables collectively dominated the Gini importance scores. Furthermore, demographic variables acted as statistical mediators in the relationship between judgment variables and vaccine uptake. These mediation findings support the interpretation of the machine learning results that demographic factors, together with judgment variables, predict COVID-19 vaccine uptake.

**Interpretation of Judgment Differences Between Vaccinated and Nonvaccinated Individuals**

Those who were fully vaccinated had lower values for loss aversion, ante, peak positive risk, peak negative risk, total reward risk, and total aversion risk, along with higher values for risk aversion, loss resilience, insurance, and trade-off range (refer to Table 1 for variable descriptions). Lower loss aversion corresponds to less overweighting of bad outcomes relative to good ones [84] and a potential willingness to obtain a vaccine with uncertain outcomes. A lower ante suggests that individuals are less willing to engage in risky behaviors surrounding potential infection, which is also consistent with the 4 other judgment variables that define relationships between risk and value (peak positive risk, peak negative risk, total reward risk, and total aversion risk). In participants who indicated full vaccination, lower peak positive risk and peak negative risk were related to individuals having a lower risk that they must overcome to make a choice to either approach or avoid, as per the decision utility equation by Markowitz [39,71]. The lower total reward risk and total aversion risk indicate that the interactions between reward, aversion, and the risks associated with them did not scale significantly; namely, higher reward was not associated with higher risk, and higher negative outcomes were not associated with the uncertainty of them. For these participants, the ability of the vaccine to increase the probability of health and reduce the probability of harm from illness did not have to overcome high obstacles in their vaccine choice. Higher risk aversion in vaccinated participants suggests that these participants viewed contracting COVID-19 as a larger risk and, therefore, were more likely to receive the full dose. These findings are consistent with those of a study by Lepinteur et al [58], who found that risk-averse individuals were more likely to accept the COVID-19 vaccination, indicating that the perceived risk of contracting COVID-19 was greater than any risk from the vaccine. Hudson and Montelpare [54] also found that risk aversion may promote vaccine adherence when people perceive contracting a disease as more dangerous or likely. Higher loss resilience in the vaccinated group was also consistent with the perspective that vaccination would improve...
their resilience and act as a form of insurance against negative consequences. The higher trade-off range suggests that vaccinated individuals have a broader portfolio of preferences and are more adaptive to bad things occurring, whereas a lower trade-off indicates a restriction in preferences and less adaptability in those who did not receive the vaccine.

**Comparison of Prediction Algorithms**

When testing these judgment variables (with demographic and COVID-19 precaution behavior variables) in a BRF framework to predict vaccine uptake, we observed a high AUROC of 0.79, where an AUROC of 0.8 is often the threshold for excellent model performance in machine learning [85,86]. The similarity of our reported recall and specificity values with the BRF suggests a balance between predicting true positives and true negatives. The high precision indicates a high certainty in predicting those who were fully vaccinated. The BRF model was successful in identifying those who received the full vaccine (positive cases; indicated by high precision and moderate recall) and those who did not (negative cases; indicated by the specificity). However, NPV was low, indicating a higher rate of false prediction of those who did not receive a full dose counterbalanced by a higher specificity that reflects a higher rate of predicting true negatives. These observations are reflected in the moderate accuracy, which measures the number of correct predictions. A comparison of random forest, logistic regression, and BRF revealed that random forest and logistic regression models produced less balance between recall (high) and specificity (low), which could be interpreted as a bias toward predicting the majority class (ie, those who received the vaccine). That being said, the NPV for BRF was lower than that for random forest and logistic regression, where a low NPV indicates a low probability that those predicted to have not received the vaccine truly did not receive the vaccine when taking both classes into account. Together, the results from all 3 machine learning approaches reveal challenges in predicting the negative class (ie, those who did not receive the vaccine).

Overall, the 3 models achieved high accuracy, recall, precision, and AUROC. BRF produced a greater balance between recall and specificity, and the outcome of the worst-performing metric (ie, NPV) was still higher than the specificities for the random forest and logistic regression models.

**Feature Importance**

Of the 3 prediction algorithms, random forest and BRF had very similar Gini importance results, whereas logistic regression elevated most demographic variables and a minority of judgment variables. This observation could be due to the large variance in each of the judgment variables, which could present challenges for achieving a good fit with logistic regression. In contrast, the demographic and COVID-19 precaution variables had low variance and could be more easily fit in a linear model, hence their significance in the logistic regression results. In comparison to logistic regression, decision trees (eg, BRF and random forest) use variable variance as additional information to optimize classification, potentially leading to a higher importance of judgment variables over most demographic and all COVID-19 precaution variables.

Focusing on the model with balanced recall and specificity (ie, the BRF classifiers [with and without COVID-19 precaution behaviors]), the top predictors were 3 demographic variables (age, income, and educational level), with distributions that varied by vaccine uptake in manners consistent with those of other reports. Namely, older individuals, those identifying as male and White individuals, and those who indicated a higher income and educational level corresponded to those who were or intended to be vaccinated [2,5,87]. Despite their saliency, these 3 variables together only contributed 23% to the prediction, corresponding to approximately one-third of the contribution from the 15 judgment variables (63%-69%). The individual Gini importance scores for the 15 judgment variables only ranged from 0.039 to 0.049 but were the dominant set of features behind the moderate accuracy, high precision, and high AUROC. The 18% difference between the accuracy and precision measures suggests that variables other than those used in this study may improve prediction, including contextual variables that may influence vaccine choices. Variables may include political affiliation [7], longitude and latitude [8], access to the internet [8], health literacy [54], and presence of underlying conditions [9]. Future work should seek to include these types of variables.

In the second BRF classifier, the 4 COVID-19 precaution behaviors only contributed 6.6% to the prediction. This low contribution could be due to these variables being binary, unlike the other demographic variables, which included a range of categories. In addition, COVID-19 precaution behaviors are specific to the context of the COVID-19 pandemic and do not promote interpretation beyond their specific context. The 15 judgment variables represent a contrast to this as they are empirically computed from a set of functions across many picture categories. An individual with higher risk aversion will generally tolerate higher amounts of uncertainty regarding a potential upside or gain as opposed to settling for what they have. This does not depend on what stimulus category they observe or the stimulus-response condition. Instead, it is a general feature of the bounds to their judgment and is part of what behavioral economists such as Kahneman consider as bounds to human rationality [84].

**Mechanistic Relationships Between Judgment and Demographic Variables**

The Gini score plots were clear sigmoid-like graphs (Figure 3), with only 3 of the 7 demographic variables ranking above the judgment variables. This observation was consistent in both BRF classifiers (with and without COVID-19 precaution behaviors), raising the possibility of a statistically mechanistic relationship among the top 3 demographic variables, the 15 judgment variables, and vaccine uptake. Indeed, we observed 28 primary mediation effects and 13 secondary mediation effects in contrast to 2 moderation relationships, which also happened to overlap with mediation findings, suggesting mixed mediation-moderation relationships [81,88]. The observation that most judgment variables were significant in mediation relationships but not in moderation relationships argues that prediction depended on the directional relationship between judgment and demographic variables to predict vaccine uptake. Furthermore, there were more significant primary mediations

https://publichealth.jmir.org/2024/1/e47979
(when judgment variables were the IVs) compared to secondary mediations, suggesting the importance of judgment variables as IVs and demographic variables as mediators. Mathematically, judgment variables (IVs) influenced vaccine uptake (DV), and this relationship was stronger when demographic variables were added to the equation. The 13 secondary mediations all overlapped with the 28 primary mediations, where demographic variables were IVs and judgment variables were mediators, suggesting that demographic variables influenced vaccine uptake (DV) and that this relationship became stronger with the addition of judgment variables. This overlap of primary and secondary mediations for 4 of the judgment variables suggests that both judgment and demographic variables influenced the choice of being vaccinated within a mixed mediation framework because adding either one of them to the mediation model regressions made the relationships stronger [49]. The lack of moderation results and a considerable number of overlapping primary and secondary mediation results imply that the relationship between judgment variables and vaccine uptake did not depend purely on their interaction with age, income, or educational level (ie, moderation) but, instead, depended on the direct effects of these 3 demographic variables to strengthen the relationship between judgment variables and vaccine uptake. This type of analysis of statistical mechanisms is helpful for understanding contextual effects on our biases and might be important for considering how best to target or message those with higher loss aversion, ante, peak positive risk, peak negative risk, total reward risk, and total aversion risk (ie, in those who were not fully vaccinated).

**Model Utility**

The developed model is automatable and may have applications in public health. The picture-rating task can be deployed on any smart device or computer, making it accessible to much of the US population or regional populations. The ratings from this task can be automatically processed, and the results can be stored in local or national databases. This method of data collection is novel in that persons cannot bias their responses as the rating task can be automatically processed, and the results can be stored in a general population sample to verify these findings. Government and public health bodies can access these data to determine predicted vaccine uptake rates locally or nationally, which can be used to (1) prepare vaccine rollouts and supply chain demand, (2) prepare health care institutions in areas that may experience low vaccine adherence and potentially higher infection rates, and (3) determine which areas may need more targeted messaging to appeal to specific judgment profiles. For use case 3, messaging about infection risks or precaution behaviors could be framed to address those with lower risk aversion, who, in this study, tended to forgo vaccination. Given that such individualized data would not be available a priori, it would be more plausible to collect data from similarly sized cohorts in geographic regions of concern to obtain regional judgment behavior profiles and, thus, target use cases 1 to 3. Further development of this model with different population samples might also improve our understanding of how certain judgment variables may be targeted with different types of messaging, offering a means to potentially improve vaccine uptake. This model might also be applied to other mandated or recommended vaccines such as those for influenza or human papillomavirus, ultimately improving preparation and messaging efforts. However, future work would be needed to model these varying vaccine choices.

Given the use of demographic variables in the proposed model, specific demographic populations could be assessed or considered for messaging. If particular demographic groups are predicted to have a low vaccine uptake rate, messaging can be targeted to those specific groups. For example, we observed that a higher percentage of female individuals were not fully vaccinated when compared to male individuals. This could be related to concerns about the COVID-19 vaccine affecting fertility or pregnancy. To improve uptake in this population, scientifically backed messaging could be used to confirm the safety of the vaccine in this context. Lower rates of vaccination have been reported in Black communities, which was also observed in this study. Researchers have identified targetable issues related to this observation, which include engagement of Black faith leaders and accessibility of vaccination clinics in Black communities, to name a few [89].

In summary, this model could be used to predict vaccine uptake at the local and national levels and further assess the demographic and judgment features that may underlie these choices.

**Limitations**

This study has a number of limitations that should be considered. First, there are the inherent limitations of using an internet survey—namely, the uncontrolled environment in which participants provide responses. Gold Research, Inc, and the research team applied stringent exclusion criteria, including the evaluation of the judgment graphs given that random responses produce graphs with extremely low $R^2$ fits (eg, <0.1). This was not the case in our cohort of 3476 participants, but this cannot perfectly exclude random or erroneous responses to other questionnaire components. Second, participants with mental health conditions were oversampled to meet the criteria for other survey components not discussed in this paper. This oversampling could potentially bias the results, and future work should use a general population sample to verify these findings. Third, demographic variability and the resulting confounds are inherent in population surveys, and other demographic factors not collected in this study may be important for prediction (eg, religion and family size). Future work might consider collecting a broader array of demographic factors to investigate and include in predictive modeling. Fourth, we used a limited set of 7 demographic variables and 15 judgment variables; however, a larger set of judgment variables is potentially computable and could be considered for future studies. There is also little information on how post–COVID-19 effects, including socioeconomic effects, affect COVID-19 vaccination choices.

**Conclusions**

To our knowledge, there has been minimal research on how biases in human judgment might contribute to the psychology underlying individual vaccination preferences and what differentiates individuals who were fully vaccinated against COVID-19 from those who were not. This population study of several thousand participants demonstrated that a small set of
demographic variables and 15 judgment variables predicted vaccine uptake with moderate to high accuracy and high precision and AUROC, although a large range of specificities was achieved depending on the classification method used. In an age of big data machine learning approaches, this study provides an option for using fewer but more interpretable variables. Age, income, and educational level were independently the most important predictors of vaccine uptake, but judgment variables collectively dominated the importance rankings and contributed almost two-thirds to the prediction of COVID-19 vaccination for the BRF and random forest models. Age, income, and educational level significantly mediated the statistical relationship between judgment variables and vaccine uptake, indicating a statistically mechanistic relationship grounding the prediction results. These findings support the hypothesis that small sets of judgment variables might provide a target for vaccine education and messaging to improve uptake. Such education and messaging might also need to consider contextual variables (ie, age, income, and educational level) that mediate the effect of judgment variables on vaccine uptake. Judgment and demographic variables can be readily collected using any digital device, including smartphones, which are accessible worldwide. Further development and use of this model could (1) improve vaccine uptake, (2) better prepare vaccine rollouts and health care institutions, (3) improve messaging efforts, and (4) have applications for other mandated or government-recommended vaccines.

Abstract

Background: Vaccine hesitancy is complex and multifaced. People may accept or reject a vaccine due to multiple and interconnected reasons, with some reasons being more salient in influencing vaccine acceptance or resistance and hence the most important intervention targets for addressing vaccine hesitancy.

Objective: This study was aimed at assessing the connections and relative importance of motivators and demotivators for COVID-19 vaccination in Hong Kong based on co-occurrence networks of verbal reasons for vaccination acceptance and resistance from repetitive cross-sectional surveys.

Methods: We conducted a series of random digit dialing telephone surveys to examine COVID-19 vaccine hesitancy among general Hong Kong adults between March 2021 and July 2022. A total of 5559 and 982 participants provided verbal reasons for accepting and resisting (rejecting or hesitating) a COVID-19 vaccine, respectively. The verbal reasons were initially coded to generate categories of motivators and demotivators for COVID-19 vaccination using a bottom-up approach. Then, all the generated codes were mapped onto the 5C model of vaccine hesitancy. On the basis of the identified reasons, we conducted a co-occurrence network analysis to understand how motivating or demotivating reasons were mentioned to shape people’s vaccination decisions. Each reason’s eigenvector centrality was calculated to quantify their relative importance in the network. Analyses were also stratified by age group.

Results: The co-occurrence network analysis found that the perception of personal risk to the disease (egicentrality=0.80) and the social responsibility to protect others (egicentrality=0.58) were the most important mentioned reasons that motivate COVID-19 vaccination, while lack of vaccine confidence (egicentrality=0.89) and complacency (perceived low disease risk and low importance of vaccination; egicentrality=0.45) were the most important mentioned reasons that demotivate COVID-19 vaccination. For older people aged ≥65 years, protecting others was a more important motivator (egicentrality=0.57), while the
concern about poor health status was a more important demotivator (egicentrality=0.42); for young people aged 18 to 24 years, recovering life normalcy (egicentrality=0.20) and vaccine mandates (egicentrality=0.26) were the more important motivators, while complacency (egicentrality=0.77) was a more important demotivator for COVID-19 vaccination uptake.

Conclusions: When disease risk is perceived to be high, promoting social responsibility to protect others is more important for boosting vaccination acceptance. However, when disease risk is perceived to be low and complacency exists, fostering confidence in vaccines to address vaccine hesitancy becomes more important. Interventions for promoting vaccination acceptance and reducing vaccine hesitancy should be tailored by age.

Introduction

Background

Despite strong evidence on the effectiveness of COVID-19 vaccines for preventing severe illness, hospitalization, and deaths associated with COVID-19 [1-3], vaccine hesitancy remains widespread and an important barrier for achieving high population uptake of the vaccines [4]. Hong Kong has learned its painful lesson of low vaccination uptake from the explosive epidemic caused by the Omicron BA.2 variant in February to April 2022, which claimed >10,000 lives of its 7 million people within 3 months, the highest per capita COVID-19 mortality worldwide in 2022 [5]. The devastating impact of this outbreak was mainly attributed to the low uptake of the COVID-19 vaccination among people aged ≥60 years before the pandemic. Administration of the mRNA vaccine BNT162b2 (BioNTech, Fosun Pharma, or Pfizer) and the inactivated vaccine CoronaVac (Sinovac) began in February 2021. To boost vaccine uptake, from May to June 2021, the Hong Kong government invited the business sector to offer various vaccination incentives such as lottery prizes (“lucky draw”) and vaccination leaves [6]. The Hong Kong government also introduced the concept of “vaccine bubble” in April 2021 [7], which was regarded as a preparatory stage for the implementation of the “vaccine pass.” Under the “vaccine bubble” strategy, citizens and staff of premises were encouraged to take the COVID-19 vaccination to enjoy some relaxation of social distancing measures [7], for instance, by allowing more customers per table in the restaurants if all staff and customers were vaccinated. Despite various efforts, by December 23, 2021, shortly before Hong Kong was introduced into the community, only 49% of persons aged ≥60 years had received at least 2 doses of COVID-19 vaccines in Hong Kong, and only 7% had received a third dose [8], an important reason for a much higher mortality rate, particularly among older people during the Omicron outbreak. In February 2022, the “vaccine pass” was implemented, which required all eligible persons to receive at least 1 dose of the COVID-19 vaccine to gain access to specified premises [9].

The reasons why people accepted or refused the COVID-19 vaccines are multifaceted, including cultural value, social norms, perceived disease risk, confidence in vaccines, convenience, and trust in government and the health system [10,11]. In view of the complexity of vaccine hesitancy and its determinants, the Strategic Advisory Group of Experts Working Group on Vaccine Hesitancy developed the 3C model, which proposes that vaccine hesitancy is shaped by 3 categories of determinants: *complacency, convenience, and confidence* [12]. The 3C model was later extended to include 2 more Cs: *risk calculation and collective responsibility* [13]. This model provides a good summary of the main categories of determinants of people’s vaccination acceptance and has been widely used to understand people’s vaccination acceptance or hesitancy [14]. On the basis of the original 3C and the extended 5C models, the determinants of different categories are interconnected to shape vaccine hesitancy [12,13]. However, existing studies mainly focused on the association of vaccination acceptance with each determinant of the 5C categories [15,16]. How these determinants are interconnected in shaping the vaccination outcome (acceptance or resistance) remains underexplored. Moreover, most studies that used the 3C or 5C model measured determinants of COVID-19 vaccine hesitancy using questionnaire surveys [17-19]; this may fail to capture the diverse and evolving context-specific factors during the COVID-19 vaccination program such as vaccination incentives [20,21] and vaccine mandates [22,23]. In summary, the multiple facets of vaccine hesitancy mean that people may accept or refuse the vaccine due to multiple psychosocial reasons and the emerging vaccination policies, which has been confirmed in qualitative research [24]. However, most current research that investigated the reasons for vaccination acceptance or hesitancy mainly described the frequency of each reason [25,26] and focused on only 1 vaccination outcome (either acceptance or hesitancy) [24,27]. There is little quantitative evidence on the co-occurrence of reasons for shaping different vaccination outcomes.

Network analysis is a promising statistical technique for depicting the multiple and complex interconnections between variables within a system and has been widely applied for characterizing the networks of psychological symptoms and attitudes [28-31]. A network, which is characterized by its nodes (eg, variables) and edges (the associations between variables), offers powerful visualization for the interactions among multiple factors in shaping a phenomenon. Network analysis is more exploratory and flexible than multivariate regression models. It adopts a complex system perspective and hence assumes that any variables (eg, reasons for vaccination acceptance or resistance) within the system can potentially interconnect with each other. Network analysis for the co-occurrence of reasons for adopting a behavior can quantify the relative importance of reasons based on not only how frequently a reason works solely...
but also how frequently it is mentioned with other reasons for motivating a behavior [32]. This will help to identify the more important reasons and the most effective combination of motivating reasons or demotivating concerns for intervention development and risk communication design. Therefore, the network approach is promising for studying the multifaceted reasons for vaccine hesitancy and their complex interconnections to guide intervention development.

The application of network analysis in vaccine-related attitudes has recently been expanded [33-38]. However, existing studies mainly included factors that were of specific research interests from the researchers’ perspective for network analysis [33-38]. This may miss some specific concerns from the vaccine receivers’ perspective and cause misalignment between expert risk communication and lay people’s preferences or concerns, potentially rendering the intervention ineffective. In addition, existing studies mainly focused on the networks of factors that influenced willingness to accept COVID-19 vaccines [33-38]. However, determinants and their interactions that shape vaccination acceptance and resistance can be different [39-41]. For instance, while protecting oneself and others was a more salient reason for vaccination acceptance, lacking confidence in the vaccine was a more important reason for vaccination rejection [41]. Such differences can be further complicated by the variability of motivators and demotivators for vaccination acceptance across age groups. For example, younger adults were found to refuse a COVID-19 vaccine mainly due to conspiracy beliefs and lacking trust in the government [42], while the top reasons for older adults refusing a COVID-19 vaccine were their chronic condition and old age [27,40]. However, such investigations overlooked the interconnections between motivators and demotivators. Distinguishing the networks of reasons for accepting and refusing a vaccine in different age groups is important for informing the development of vaccine risk communication that is tailored to the audience’s underlying vaccine-related attitudes. Furthermore, these studies, which used the network analysis, neither investigated the reasons relating to the 5C model and the co-occurrence of reasons nor quantified their relative importance for influencing vaccine hesitancy.

Objective
In this study, we collected participants’ diverse verbal reasons for accepting or refusing a COVID-19 vaccine using open-ended questions through population-based telephone surveys conducted in Hong Kong during the COVID-19 pandemic and categorized the reasons based on the 5C model of vaccine hesitancy for network analysis. We aimed to provide quantitative evidence on the co-occurrence of reasons and their relative importance for both vaccine acceptance and resistance, as well as how the relative importance of motivators and demotivators for COVID-19 vaccination could differ by age.

Methods
Participants
Repeated cross-sectional surveys were conducted on a weekly or monthly basis to monitor acceptance of the COVID-19 vaccine among general adults after the COVID-19 vaccination campaign was launched in early 2021 in Hong Kong [43-45]. In each round, we recruited Hong Kong adults aged ≥18 years using random-digital-dialed telephone interviews with a ratio of 1:1 for landlines and mobile phones. The surveys were implemented by a local survey company that had been demonstrated to have the capacity to provide high-quality population-based surveys using random digital calls. All the calls were made during working hours and nonworking hours to avoid oversampling of nonworking people. Each sampled telephone number was called up to 5 times at different times and on different days before being replaced with a new one. For each landline-based call, if there were >1 eligible member in the household, the “next birthday rule” (the person whose next birthday is closest to the survey date) was adopted to determine the person to be interviewed. Individuals with linguistic and cognitive difficulties in completing a telephone interview were excluded. The target sample size was an alternative of 500 or 1000 for each round. In each round, core study measures such as the uptake of COVID-19 vaccines and the intention to receive a COVID-19 vaccine were retained throughout, while additional study measures were rotated to maintain a feasible length of the questionnaire for a telephone interview. Data from a total of 19 survey rounds that collected reasons for accepting a COVID-19 vaccine and 9 survey rounds that collected reasons for being hesitant or resistant about taking a COVID-19 vaccine were used for this analysis. Participants’ demographic distributions were compared between the accepting group and the resistant group using the Pearson chi-square test. All the surveys included were conducted between March 2021 and July 2022. The details of each survey round can be found in Multimedia Appendix 1.

Ethical Considerations
The study was conducted in accordance with the Declaration of Helsinki and Good Clinical Practices. As our surveys were conducted over the telephone, written informed consent was not feasible, but verbal informed consent was obtained from all participants before the interview started. The data sets did not contain any personally identifiable information. This study received ethics approval from the institutional review board (reference UW 20-095).

Study Instruments
To explore the reasons for accepting, hesitating, or refusing a COVID-19 vaccine, in 16 survey rounds conducted between March 1, 2021, and August 20, 2021, participants who had completed at least 1 dose of the COVID-19 vaccine were asked about the major reasons that motivated them to receive the vaccine. The Hong Kong government started recommending a vaccine booster (the third vaccine dose) for general adults who had received 2 doses of COVID-19 vaccines for at least 6 months on November 23, 2021 [46]. Therefore, in 3 additional survey rounds that were conducted after this date (between December 6, 2021, and January 13, 2022), participants who had received a vaccine booster were asked about the reasons that motivated them to receive a vaccine booster. The open-ended responses from these 19 survey rounds, in which participants were asked about their reasons for taking a COVID-19 vaccine or a vaccine booster, were coded as reasons for vaccination acceptance. In 9 survey rounds conducted between December...
6, 2021, and July 14, 2022, we identified resistant participants based on their vaccination status and intention. First, participants were asked about the number of doses of COVID-19 vaccines they had received. Those who had received none, 1 dose, or 2 doses were then asked about how likely they would receive the first, second, or third vaccine dose, respectively, in the next 3 months (rated on a scale from “definitely not” to “very unlikely,” “unlikely,” “unsure,” “likely,” “very likely,” and “definitely yes”). Those who answered “definitely not,” “very unlikely,” “unlikely,” and “unsure” to the vaccination intention question were defined as the resistant group. These participants were asked about the major reasons for being hesitant about or rejecting COVID-19 vaccination. The verbal responses from these 9 survey rounds in which participants were asked about the reasons for refusing the 2-dose primary COVID-19 vaccination series or a vaccine booster were coded as reasons for vaccination resistance. The vaccination resistance reasons were collected at a later phase of the vaccination program and during the Omicron wave when COVID-19–confirmed cases soared rapidly (Multimedia Appendix 2). Therefore, our data capture reasons from the most resistant group, given that the high vaccination uptake rate had been achieved in the population and the disease risk was relatively high, but participants still reported being hesitant or resistant regarding vaccination. The data collection period and number of daily COVID-19 cases are presented in Multimedia Appendix 2. The participants were asked to provide reasons that first came to mind, and then the interviewer jotted down notes of participants’ statements and asked follow-up questions of “any other reasons” to encourage participants to give >1 reason for their vaccination decision. Across all survey rounds, participants were also asked about their sociodemographics including age, sex, educational attainment, employment status, and history of chronic conditions.

Coded Reasons for Accepting or Resisting a COVID-19 Vaccine

The participants’ verbal responses to the open-ended questions regarding reasons for vaccination acceptance and resistance were extracted and independently coded by 2 researchers (QL and JY). We combined the bottom-up and top-down approaches to generate the main categories of these qualitative verbal responses. First, basic categories were independently generated inductively by the 2 researchers by making sense of the meanings of the participants’ verbal responses (bottom-up approach). Following the initial coding, the 5C categories (complacency, confidence, convenience, calculation, and collective responsibility) of vaccine hesitancy [13] were used to guide the clustering of the initial codes to generate the main categories (top-down approach). Although the 5C model was used as a guide for generating categories of motivators and demotivators, the 2 researchers remained open to allow new categories that were not covered by the 5C model to emerge from the data. Following completion of the initial coding, each coder manually checked 10% of the codes generated by another to ensure consistency and consensus on all codes. Any inconsistencies in coding were solved by reviewing the raw data and having joint discussions between the 2 coders (QL and JY). A total of 52 responses that were coded as the reasons for vaccination acceptance and 23 responses that were coded as the reasons for vaccination resistance were excluded from the final analyses because their meanings were judged ambiguous by both coders. To facilitate interpretation, we finally mapped the coded reasons onto the 5C categories but allowed new categories to emerge. This was aimed at facilitating data interpretation and minimizing conceptual or meaning overlap between the coded reasons. For the mapping, each of the 2 coders (QL and JY) first reached a consensus on the definition of each of the 5C categories and then mapped each reason to 1 C. Any inconsistencies in mapping were solved by joint discussions and reviewing the original definitions and relevant literature. Finally, for reasons that cannot be mapped to any of the existing 5C categories, extended categories of the 5C categories would be proposed.

Network Analysis

Network analysis was conducted separately for vaccination acceptance and vaccination resistance in Python using the Networkx Package (Python Software Foundation) [47]. We first determined the nodes included for network estimation and visualization. For either the acceptance or the resistance network, each reason category of vaccination acceptance or resistance, respectively, represents 1 node in the respective network. An edge between 2 nodes indicates that the 2 reasons were comentioned by participants. However, instead of directly modeling the frequency of comentioning, the edges were normalized using a weighted method following previous work [32]. Specifically, if participants mention only 1 reason for their vaccination acceptance or resistance, a standard weight of “1” will be assigned to that reason. If participants mention 2 reasons, each of the 2 reasons will get a standard weight of “1” because there is only 1 unique pair of reasons. If participants mention ≥3 reasons, the weight between each pair of reasons will be “1” divided by the number of pair combinations among the reasons. For instance, if 3 reasons (k1, k2, and k3) are comentioned by participants, the edge value for each pair of the 3 reasons (k1 – k2, k1 – k3, or k2 – k3) would be one-third so that their total weight will still be equal to “1.” This method ensured that each participant contributed equally to the whole network, regardless of how many reasons they had mentioned for vaccination acceptance or resistance. Following this method, a symmetric adjacency matrix was constructed for both reasons of vaccination acceptance and resistance for network analysis. Therefore, if we have k reasons, then an edge can be expressed as E = {E[i][j] = 0,1,...,k}, which is the ith row and jth column of the matrix. The weight of the edge will depend on the number of participants accepting or refusing a COVID-19 vaccine due to reasons i and j. The more the number of participants that comention the 2 reasons, the greater the weight of their edge will be. The adjacency matrix was then used to calculate each node’s eigenvector centrality—an index used for quantifying the relative importance of the node based on nodes’ co-occurrence patterns in the network [48]. Specifically, a higher normalized eigenvector centrality value indicates a relatively greater importance of the reason, which accounts for not only how frequently the node occurred (ie, reason was mentioned by participants) but also how frequently the node was linked to other influential nodes (ie, reason was comentioned with other
frequently mentioned reasons). Mathematically, the eigenvector centrality can be obtained from the following equation: \( AX = \lambda X \).

In this equation, \( A \) represents the adjacency matrix. The eigenvector \( X \) was calculated using 500 power iteration process, given the constant eigenvalue \( \lambda \).

Following the same methodological procedure, we constructed the co-occurrence networks stratified by age subgroups and obtained eigencentrality values for each reason across age groups. A normalized eigencentrality measure can be used for direct comparisons of the relative importance of the same reasons for vaccination acceptance and resistance across different age groups.

Results

Participants

The survey cooperation rate was around 66.7%, ranging from 51.9% to 74.4%. Survey response rate was defined as the proportions of participants who completed the interviews against those who were contacted and eligible (Multimedia Appendix 1). Overall, in 19 survey rounds, 5559 participants provided reasons for accepting a COVID-19 vaccine, and in 9 survey rounds, 982 participants provided reasons for being resistant (including hesitant) about taking a COVID-19 vaccine; these reasons were used for reason co-occurrence network analysis. Comparisons of the demographics of participants who accepted the vaccine and those who were resistant to receiving the vaccine showed that the vaccination resistance group was more likely to be younger, have higher educational attainment, be unemployed, and have at least 1 chronic condition (Table 1).

\(^b\)Unemployed group included unemployed persons or who reported that they were seeking for jobs at the survey time.

Coded Categories of Reasons for Vaccination Acceptance and Resistance

On the basis of participants’ verbal responses to the questions asking for reasons for vaccination acceptance and resistance, 10 main categories of reasons for vaccination acceptance and vaccination resistance, respectively, were generated (Multimedia Appendix 3). The 10 main reasons for vaccination acceptance included disease risk (eg, worry about the COVID-19 risk; n=3689), protecting others (n=2354), back to normal life (n=877), confidence in vaccines (n=703), vaccine mandates (eg, complying with the vaccine pass; n=548), progovernment (eg, to support the government; n=140), social norms (eg, following significant others’ opinions; n=100), convenience...
The 10 main reasons for vaccination resistance included lack of vaccine confidence (n=501), complacency (eg, perceiving no need for vaccination or low risk of disease; n=376), poor health status (eg, “I have chronic diseases”; n=116), vaccine mandates (eg, opposing the vaccine pass; n=52), distrust in government (n=27), lack of social support (eg, “no one take me to the vaccination site”; n=18), no incentives (eg, no “lucky draw”; n=12), inconvenience (n=11), social norms (eg, “friends/family advised me not to take the vaccination”; n=7), and medical preference (eg, preferring Chinese medicine; n=6).

The coded reasons are mapped onto the 5C categories of vaccine hesitancy in Table 2. Both coders decided that 3 reasons including incentives, vaccine mandates, and medical preference were more specific to the contexts of COVID-19 vaccination and the underlying values, hence one more “C”—context was included to cover these reasons. Some reasons were mapped to >1 C to accommodate the multiple psychological antecedents of the reasons. For instance, poor health status as a reason for rejecting vaccination was mapped to both lack of vaccine confidence and calculation because it refers to not only the concern about vaccine side effects but also a trade-off between the vaccine side effects and the capability of their physical body to endure the side effects.

*an addition C (context) was included to accommodate vaccine mandates, incentives, and medical preference.
**Reason Co-Occurrence Network for Vaccination Acceptance**

Figure 1 shows the reason co-occurrence network for vaccination acceptance. Among the 10 accepting reasons, *disease risk* followed by *protecting others* were the most important motivators with high eigencentrality values (*disease risk*=0.80; *protecting others*=0.58). These 2 reasons were also the most frequently comentioned pair of reasons. The third most frequently mentioned reason by the group who accepted vaccination was *back to normal life* (0.12). A higher co-occurrence frequency was also identified among *disease risk, protecting others, back to normal life, confidence in vaccines, and vaccine mandates*, suggesting strong interconnections among these 5 motivators in the network. *Convenience, incentives, and trust* in experts were mainly mentioned as single motivators for vaccination acceptance.

**Figure 1.** Co-occurrence network reasons for COVID-19 vaccination acceptance and their normalized eigencentrality values provided by 5559 participants between March 1, 2021, and January 13, 2022. Larger node size indicates that the reason is more frequently mentioned as a single reason for resisting the vaccine; more thickness of the edge indicates that the 2 reasons were more frequently comentioned as reasons for accepting the vaccine.

Across age subgroups, the importance of *vaccination mandates* (0.26) and *back to normal life* (0.20) was greater for younger people, while the importance of *protecting others* (0.57) was greater for older people for motivating vaccination acceptance (Figure 2). Mean eigencentrality value for each accepting reason across age groups are provided in a table in Multimedia Appendix 4.
Figure 2. Normalized eigencentrality values of different motivators by different age groups for COVID-19 vaccination provided by 5559 participants between March 1, 2021, and January 13, 2022.

The Network for Reasons of Vaccination Resistance

Figure 3 shows the reason co-occurrence network for vaccination resistance. Lack of vaccine confidence (eigencentrality=0.89) followed by complacency (eigencentrality=0.45) were the most important reasons for vaccination resistance. Poor health status (0.09) was also a commonly cited reason among individuals with resistant attitudes toward vaccination, ranking as the third most prominent factor. Lack of vaccine confidence was most frequently comentioned with complacency, followed by poor health status, distrust in government, and dislike of vaccine mandates as demotivators of COVID-19 vaccination. These 5 demotivators formed the central part of the vaccine resistance network. Inconvenience, incentives, and medical preference (eg, dislike medical intervention including vaccination) were mostly given as the sole reasons for vaccination resistance by participants.
Figure 3. Co-occurrence network of reasons for COVID-19 vaccination resistance and their normalized eigencentrality values provided by 982 participants between December 6, 2021, and July 14, 2022. Larger node size indicates that the reason is more frequently mentioned as a single reason for resisting the vaccine; more thickness of the edge indicates that the 2 reasons were more frequently comentioned as reasons for resisting the vaccine.

Across age subgroups, complacency and poor health status were important reasons for younger and older people, respectively, for resisting vaccination (Figure 4). Mean eigencentrality value for each acceptant reason across age groups was provided in Multimedia Appendix 4.
Figure 4. Normalized eigencentrality values of demotivators by different age groups for COVID-19 vaccination provided by 982 participants between December 6, 2021, and July 14, 2022.

Discussion

Principal Findings

We used open-ended questions to elicit more nuanced and richer responses from participants to investigate the reasons for COVID-19 vaccination acceptance and resistance. We linked their verbal reasons to the 5Cs of vaccine hesitancy to improve the theoretical relevance of the findings. Most reasons for vaccination acceptance and resistance can be mapped to the 5Cs: complacency, confidence, convenience, calculation, and collective responsibility. However, one more C, namely, context, was included to accommodate vaccine mandates and incentives, which represent specific contexts of COVID-19 vaccination.

The reason co-occurrence networks showed that while disease risk (lack of complacency) and protecting others (collective or social responsibility) were the most important reasons for vaccination acceptance, lack of vaccine confidence and complacency (i.e., perceived low disease risk and perceived low importance of vaccination) were the most important reasons for vaccination resistance. Overall, a comparison of the networks for vaccination acceptance and resistance indicates that when disease risk and protecting others are salient for motivating vaccination uptake, confidence in vaccines becomes less important. This is consistent with previous findings that perceiving high personal risk of the pandemic could override people’s concern about the uncertain safety of new vaccines in vaccination decision-making [49]. However, our study indicates that when disease risk is perceived to be low and complacency exists, lack of vaccine confidence becomes the dominant reason for demotivating vaccination uptake. This explains why merely communicating vaccine benefits (e.g., protection of oneself or others) may have a minimal effect on vaccine uptake when people perceive a low risk of the disease, particularly among those who are at low risk for severe consequences of the disease [50].

For vaccination acceptance, protecting others was frequently mentioned with disease risk as a motivator for vaccination uptake, suggesting a strong connection between the perceived risk of the disease to themselves and the social responsibility to protect others [51]. Prosocial vaccination (vaccination for protecting others) has been suggested to be an important messaging strategy for promoting COVID-19 vaccination acceptance [52,53]. Our study suggests that prosocial interventions should be combined with messages for promoting perceived personal risk of the disease to enhance its persuasive effects. The age-specific network indicated that protecting others was a more important motivator for older people than it was for younger people, although theoretically, younger people should be more likely to take vaccinations to protect others because the severity of COVID-19 increased with age [54]. Vaccinating the younger population against COVID-19 to block the transmission of SARS-CoV-2 in the community was a common advocacy for promoting the young population’s vaccination.
uptake [55]. However, our results suggest that older people value social responsibility more when making vaccination decisions, which was also identified in other contexts [56,57]. A previous study found that communicating prosocial benefits is effective in increasing multiple vaccination uptake in older adults [58]. Future interventions targeted at this age group should highlight the prosocial benefits and community responsibility to motivate older adults’ vaccination uptake.

Recovering life normalcy was the third important motivator for COVID-19 vaccination acceptance and had a high frequency of co-occurrence with disease risk and protecting others. The COVID-19 vaccination or the vaccine pass had been frequently framed as a strategy to restore “new normalcy,” that is, relaxation of social distancing measures once high vaccination uptake of the population is achieved [59]. However, our study suggests that people’s vaccination motivation of returning to life normalcy is not a salient motivator; it could be simultaneously correlated with their understanding of the disease risk to themselves and others. A recent experimental study found that messages that mention the private health benefit and economic benefit (eg, vaccines enable economic recovery) can increase vaccination intention by 9% compared with the control group [60]. Future vaccination communication can highlight the cobenefits of returning life to normalcy and protecting oneself and others to achieve optimal effect.

Vaccine mandates is another factor in the context domain; it can be either a motivator or a demotivator of vaccination uptake. Although the “vaccine bubble” was framed as a benefit of vaccination for granting people greater life normalcy [7], it was also perceived to be a constraint on people’s freedom in vaccination choice, which impaired public trust in authorities [61,62]. In our coding, we combined “vaccine bubble” and “vaccine pass” as 1 code, namely, “vaccine mandates.” Our study showed that vaccine mandates as a vaccination motivator was connected to disease risk and protecting others, but as a vaccination demotivator, it was connected to lack of vaccine confidence, complacency, and distrust in government. This indicates that whether vaccine mandates act as a motivator or demotivator depends on individuals’ perceived disease risk, confidence in vaccine, and trust in the government. This finding provides practical implications for how to frame vaccine mandates in a vaccination campaign; that is, vaccine mandates, when framed as a strategy for self-protection and prosocial values by highlighting disease risk and a way for themselves and others to enjoy normal social activities, could motivate vaccination uptake. However, framing vaccine mandates as a coercive measure may be regarded as freedom violation and demotivate vaccination uptake [63]. Both life normalcy and vaccine mandates were more important for younger people as motivators for vaccination acceptance than they were for older people, and hence should be the important intervention targets for promoting younger people’s vaccination uptake in the future.

For vaccination resistance, complacency was strongly connected with lack of vaccine confidence, suggesting that when disease risk is perceived to be low, uncertain vaccine safety can become salient in hindering vaccination uptake [49]. Complacency was a more important demotivator for younger people than it was for older people, which is consistent with the fact that COVID-19 is a less severe disease for younger people [54]. Poor health status was the third important demotivator for COVID-19 vaccination, which was strongly connected with lack of vaccine confidence in the network. Such a pattern was more prevalent in older people, suggesting that the poor health concern mainly comprises concern about vaccine side effects or safety in this group. One previous qualitative study suggested that older people who perceived their health status was poor due to aging or chronic diseases tended to perceive themselves to have lower capability to endure the vaccine side effects [40]. Such perception was linked to their value of aging and lack of social support [40]. This highlights the importance of addressing people’s concerns about their health status for addressing vaccine hesitancy through enhancing confidence in vaccines, reshaping the value of aging, and enhancing social support [64].

Both the networks for vaccination acceptance and resistance showed that convenience (or inconvenience) and incentives (or no incentives) mainly represented as single reasons for motivating or demotivating COVID-19 vaccination uptake. In Hong Kong, convenience in accessing the COVID-19 vaccine had been greatly increased by setting up multiple vaccination sites, extending service hours for vaccination services, and offering the vaccines free for all [46]. In addition, the government offered vaccination leaves and relaxation of social distancing measures, while a series of lucky draws were sponsored by the business sector as reward strategies to boost vaccination uptake. Although convenience and incentives (or perceiving no convenience or incentives) can serve as independent cues or heuristics to motivate or demotivate vaccination uptake [65], the low frequency of these reasons and their weak connections with other reasons indicate that they have limited and mainly transient effects on COVID-19 vaccination uptake [66].

Limitations

Our study had several limitations. First, although participants were encouraged to give >1 reason for accepting, refusing, or being hesitant about taking COVID-19 vaccination, the reasons for COVID-19 vaccination acceptance and resistance could not be exhaustively explored through a telephone survey. We assumed that the reasons mentioned by participants were more mentally accessible for them and thereby more salient in influencing their vaccination decision. Nevertheless, there is still a possibility that some underlying reasons for vaccination acceptance or resistance were hidden by the participants, consciously or unconsciously. Second, our network analysis focused on the co-occurrence of reasons but could not determine the causal relationships between the reasons. Third, although 2 coders independently coded the reasons to ensure the reliability of coding, there remains uncertainty in making sense of participants’ verbal responses and the combination of reasons into main categories. Despite this, we strictly documented the procedure and ensured transparency of the decision-making process to improve the trustworthiness of our findings.

Conclusions

Perception of personal risk to disease and the social responsibility to protect others were the most important comotivators, while lack of vaccine confidence and complacency...
were the most important co-demotivators for COVID-19 vaccination. For COVID-19 vaccination acceptance, recovering life normalcy, confidence in vaccines, and vaccine mandates were additional motivators, but these reasons were likely to work based on people’s understanding of the disease risk to themselves and others. For vaccination resistance, perception of poor health status, distrust in the government, and dislike of vaccine mandates were additional demotivators, all of which were linked to lack of vaccine confidence and complacency. Convenience and immediate incentives for vaccination were mainly mentioned as the single reasons for accepting or resisting the COVID-19 vaccination. For older people, protecting others was a more important motivator, while perception of poor health status was a more important demotivator. For younger people, recovering normal life and vaccine mandates were more important motivators, while complacency was a more important demotivator for the COVID-19 vaccination.

Abstract

Background: The potential association between bivalent COVID-19 vaccination and ischemic stroke remains uncertain, despite several studies conducted thus far.

Objective: This study aimed to evaluate the risk of ischemic stroke following bivalent COVID-19 vaccination during the 2022-2023 season.

Methods: A self-controlled case series study was conducted among members aged 12 years and older who experienced ischemic stroke between September 1, 2022, and March 31, 2023, in a large health care system. Ischemic strokes were identified using International Classification of Diseases, Tenth Revision codes in emergency departments and inpatient settings. Exposures were Pfizer-BioNTech or Moderna bivalent COVID-19 vaccination. Risk intervals were prespecified as 1-21 days and 1-42 days after bivalent vaccination; all non-risk-interval person-time served as the control interval. The incidence of ischemic stroke was compared in the risk interval and control interval using conditional Poisson regression. We conducted overall and subgroup analyses by age, history of SARS-CoV-2 infection, and coadministration of influenza vaccine. When an elevated risk was detected, we performed a chart review of ischemic strokes and analyzed the risk of chart-confirmed ischemic stroke.

Results: With 4933 ischemic stroke events, we found no increased risk within the 21-day risk interval for the 2 vaccines and by subgroups. However, risk of ischemic stroke was elevated within the 42-day risk interval among individuals aged younger than 65 years with coadministration of Pfizer-BioNTech bivalent and influenza vaccines on the same day; the relative incidence (RI) was 2.13 (95% CI 1.01-4.46). Among those who also had a history of SARS-CoV-2 infection, the RI was 3.94 (95% CI 1.10-14.16). After chart review, the RIs were 2.34 (95% CI 0.97-5.65) and 4.27 (95% CI 0.97-18.85), respectively. Among individuals aged younger than 65 years who received Moderna bivalent vaccine and had a history of SARS-CoV-2 infection, the RI was 2.62 (95% CI 1.13-6.03) before chart review and 2.24 (95% CI 0.78-6.47) after chart review. Stratified analyses by sex did not show a significantly increased risk of ischemic stroke after bivalent vaccination.

Conclusions: While the point estimate for the risk of chart-confirmed ischemic stroke was elevated in a risk interval of 1-42 days among individuals younger than 65 years with coadministration of Pfizer-BioNTech bivalent and influenza vaccines on the same day and among individuals younger than 65 years who received Moderna bivalent vaccine and had a history of SARS-CoV-2 infection, the risk was not statistically significant. The potential association between bivalent vaccination and ischemic stroke in the 1-42-day analysis warrants further investigation among individuals younger than 65 years with influenza vaccine coadministration and prior SARS-CoV-2 infection. Furthermore, the findings on ischemic stroke risk after bivalent COVID-19 vaccination underscore the need to evaluate monovalent COVID-19 vaccine safety during the 2023-2024 season.

Introduction

On August 31, 2022, the US Food and Drug Administration (FDA) granted emergency use authorizations for the Pfizer-BioNTech bivalent COVID-19 vaccine for individuals aged 12 years and older and the Moderna bivalent COVID-19 vaccine for individuals aged 18 years and older [1,2]. The bivalent vaccines contain messenger ribonucleic acid (mRNA) components derived from both the original strain of SARS-CoV-2 and the Omicron variant BA.4 and BA.5 sublineages. Designed to be administered as a single booster dose, bivalent COVID-19 vaccines were recommended to be given ≥60 days after either the primary vaccination or a monovalent booster dose [2]. In the context of waning protection from primary vaccination, bivalent vaccines enhanced the immune response and boosted protection against the virus, offering an additional layer of defense for previously vaccinated individuals [3-5].

Safety data for bivalent mRNA COVID-19 vaccines were initially limited. Because the chemical components and production processes between monovalent and bivalent vaccines were similar, the FDA granted emergency use authorizations for the bivalent COVID-19 vaccines based on safety data for monovalent vaccines, as well as limited bivalent safety data from clinical trials [1,2]. To monitor safety postlicensure, a study using V-safe and the Vaccine Adverse Event Reporting System (VAERS) examined bivalent booster vaccinations in individuals aged older than or equal to 12 years and found that the safety profile was similar to that described for monovalent booster vaccinations [6]. A recent study that comprehensively assessed potential adverse events associated with bivalent vaccines using TreeScan in the Vaccine Safety Datalink (VSD) network found no increased risk for a broad range of adverse events [7].

The VSD has monitored COVID-19 vaccine safety since vaccinations began in December 2020 [8]. In late 2022, VSD’s rapid cycle analyses detected a safety signal for ischemic stroke following the Pfizer-BioNTech COVID-19 bivalent booster vaccination among those 65 years and older, particularly among those who had received a bivalent booster dose and a high-dose or adjuvanted influenza vaccine on the same day (coadministration) [9]. The US Centers for Disease Control and Prevention (CDC) and FDA announced this safety signal in January 2023 [10]. This safety signal attenuated as data accumulated [11]. Another cohort study among adults aged 65 years and older reported that those who received the Pfizer-BioNTech bivalent booster had a similar hazard for ischemic stroke encounters compared to those who received the Moderna bivalent booster vaccine, but had a lower hazard than those who received the Pfizer-BioNTech or Moderna monovalent boosters [12]. In another study, compared to monovalent vaccination, bivalent vaccination was not found to be associated with an increased risk of ischemic stroke, hemorrhagic stroke, myocardial infarction, and pulmonary embolism [13]. A self-controlled case series (SCCS) study conducted in England showed no indication of an increased risk of ischemic stroke risk within 21 days following administration of either of the 2 mRNA COVID-19 bivalent vaccines. Similar findings were observed for individuals aged 65 years and older who received the influenza vaccine concurrently with the bivalent COVID-19 vaccines [14]. Another SCCS study conducted in Israel also did not find an increased risk of ischemic stroke following monovalent or bivalent mRNA COVID-19 vaccine boosters in at-risk populations [15]. A study of Medicare beneficiaries aged 65 years or older showed no significantly elevated risk for stroke immediately after receiving either COVID-19 bivalent vaccine [16]. However, among beneficiaries who had a stroke after getting either COVID-19 bivalent vaccine along with a high-dose or adjuvanted influenza vaccine, there was a significant association between vaccination and nonhemorrhagic stroke within 22 to 42 days for the Pfizer-BioNTech COVID-19 bivalent vaccine. Additionally, there was a significant association between vaccination and transient ischemic attack within 1 to 21 days for the Moderna COVID-19 bivalent vaccine.

The objective of this study was to assess the risk of ischemic stroke after bivalent COVID-19 vaccination among individuals enrolled in Kaiser Permanente Southern California (KPSC) using a modified SCCS design. Subgroup analyses were also conducted by age (younger than 65 years vs older than or equal to 65 years), history of SARS-CoV-2 infection, and coadministration of influenza vaccine.

Methods

Study Population and Study Period

We conducted an SCCS study among members aged 12 years and older from KPSC, a large integrated health care system in the United States. The SCCS method is an alternative to standard epidemiological study designs and has been used for evaluating vaccine safety and in fields such as pharmacoepidemiology [17-21]. In an SCCS study, only individuals who have experienced an event are included. Since individuals serve as their own control and the incidence rates of the outcome of interest are compared within individuals, all time-invariant confounding variables are controlled. The SCCS analytic data sets included individuals who experienced ischemic stroke events between September 1, 2022, and March 31, 2023, had completed a COVID-19 vaccine primary series, and had received their last monovalent dose ≥60 days before September 1, 2022. We required KPSC membership on September 1, 2022.
Exposure and Observation Period

The exposure was defined as the administration of the Pfizer-BioNTech bivalent COVID-19 vaccine (for individuals aged 12 years and older) or the Moderna bivalent COVID-19 vaccine (for individuals aged 18 years and older) between September 1, 2022, and March 31, 2023. The observation period for the recipients of a bivalent COVID-19 vaccine started on September 1, 2022, and ended on March 31, 2023, or upon death, receipt of the second bivalent dose, or disenrollment, whichever came first.

To adjust for seasonality, we also included ischemic stroke events occurring among eligible individuals aged 12 years and older who had completed a primary series and had received their last monovalent dose ≥60 days before September 1, 2022, but who did not receive a bivalent vaccine during September 1, 2022, to March 31, 2023 (nonbivalent recipients; NBRs). The observation period for ischemic stroke events among NBR started on September 1, 2022, and ended on March 31, 2023, or upon death or disenrollment, whichever came first.

Outcome

The outcome was defined as the first occurrence of an ischemic stroke event between September 1, 2022, and March 31, 2023 [22]. Ischemic stroke events were identified through medical encounters with an International Classification of Diseases, Tenth Revision (ICD-10) diagnosis code of G45.8, G45.9, or I63.x, where x represents any additional characters in the ICD-10 code range for ischemic stroke, in the emergency departments or inpatient settings. We also looked back 30 days prior to September 1, 2022, to ensure that the episode was incident. We excluded ischemic stroke events due to other possible causes and adjusted the onset date (details in Multimedia Appendix 1). We considered these ischemic stroke events that were identified with ICD-10 codes to be electronically identified ischemic stroke events.

Covariates

We collected demographic variables (age, sex, and race or ethnicity) and the Charlson Comorbidity Index to describe the characteristics of the study population, as well as concomitant influenza vaccination during the study period and history of SARS-CoV-2 infection in the year prior to September 1, 2022.

Statistical Analyses

We assessed the risk of ischemic stroke following the administration of the Pfizer-BioNTech and Moderna bivalent COVID-19 vaccines separately. Demographic characteristics of individuals who experienced ischemic stroke events during the study period were described among Pfizer-BioNTech bivalent vaccine recipients, Moderna bivalent vaccine recipients, and NBRs.

The risk intervals were prespecified as 1-21 days and 1-42 days after administration of bivalent COVID-19 vaccines, with person-time outside of these risk intervals serving as the control interval. The risk intervals started on the day of vaccination (day 1). Because individuals who had ischemic stroke events might be likely to postpone or avoid bivalent vaccination, we used a modified SCCS approach for event-dependent exposures [22]. The modified SCCS used a pseudo-likelihood approach in the counterfactual framework to estimate the relative incidence (RI) and 95% CIs of events comparing the risk intervals to their corresponding control intervals by maximizing a Poisson pseudolikelihood [23]. In the SCCS analyses, ischemic stroke events occurring among eligible individuals who did not receive the bivalent vaccines were included to account for seasonality, by incorporating calendar month into the model [22]. Given that age did not significantly vary during the relatively short observation period of 7 months, it was not adjusted as a time-varying covariate.

Additionally, we performed several subgroup analyses based on age (younger than 65 vs 65 years and older), coadministration of bivalent COVID-19 vaccine with same-day influenza vaccine (yes or no), and history of SARS-CoV-2 infection (confirmed by a positive laboratory test or a COVID-19 diagnosis) within 1 year prior to September 1, 2022.

When a safety signal (ie, the lower bound of the 95% CI for RI exceeded 1.0) was detected in analyses of electronically identified ischemic stroke events, we conducted a chart review among recipients of bivalent COVID-19 vaccines to confirm ischemic stroke events and identify onset date to determine whether confirmed ischemic stroke events fell in the risk or control interval; confirmation rates were then calculated (number of confirmed events divided by the number of electronically identified events reviewed). We did not conduct a chart review on ischemic stroke events among NBR due to the large number of events in this group and limited resources. In analyses of confirmed ischemic stroke events among recipients of bivalent COVID-19 vaccines, we introduced a randomized allocation of confirmed case status to the NBR group. This allocation was guided by the confirmation rates observed among recipients of bivalent COVID-19 vaccines, as outlined by Xu et al [24]. A total of 5 simulated data sets were generated to replicate the allocation process. The SCCS analyses were conducted on each data set, and the resulting estimates were aggregated using Rubin’s [25] rule, which accounts for both the variability within individual data sets and the variability across multiple data sets. Attributable risk (AR) was calculated using the approach described in Farrington et al [26]:

Here, RI is the relative incidence; \( n_0 \) is the number of ischemic stroke events in the risk interval; and \( N \) is the number of recipients of a vaccine or dose. The reciprocal of AR is the number needed to harm (NNH). Analyses were conducted using SAS (version 9.4; SAS Institute) and the SCCS models were fitted with the R package (R Core Team) SCCS [27].

Ethical Considerations

Ethics approval for this study was obtained from the KPSC institutional review board on June 6, 2023. In accordance with 45CFR 46.116, informed consent was waived by the institutional review board because the research activities (secondary analyses of electronic health records data) presented no more than minimal risk to participants. Patients or members of the public were not involved in the design, conduct, reporting, or
dissemination plans of the research. To protect the privacy and confidentiality of human participants, all staff working on the research study were trained in procedures to protect the privacy of medical record information. All research data were stored behind a firewall in a password-protected network within the Department of Research & Evaluation at KPSC. Study participants were not compensated given the observational nature of the study.

Results

Characteristics of Individuals Who Had Ischemic Stroke Events

Table 1 shows the characteristics of individuals who had ischemic stroke events. In total, there were 1057 ischemic stroke events among recipients of the Pfizer-BioNTech bivalent vaccine with a mean length of observation period of 204 (SD 27) days (ranging from 16 to 212 days), 827 ischemic stroke events among recipients of the Moderna bivalent vaccine with a mean length of observation period of 206 (SD 24) days (ranging from 31 to 212 days), and 3049 ischemic stroke events among NBR with a mean length of observation period of 197 (SD 40) days (ranging from 11 to 212 days). Notably, the majority of ischemic stroke events occurred among individuals aged 65 years or older. Those aged younger than 65 years old had fewer comorbidities than those aged 65 years or older (Multimedia Appendix 2).

Table 1. Characteristics of individuals who had ischemic stroke events among members of Kaiser Permanente Southern California during the period from September 1, 2022, to March 31, 2023.

Risk of Ischemic Stroke Following the Pfizer-BioNTech Bivalent COVID-19 Vaccine

For the Pfizer-BioNTech bivalent COVID-19 vaccine, there were 103 electronically identified ischemic stroke events in the 21-day postvaccination risk interval, 954 events in the control interval, and 3049 events among NBR; the overall RI was 0.90 (95% CI 0.73-1.12; Multimedia Appendix 3). The RI was not significantly above 1 across all subgroup analyses by age, coadministration of influenza vaccine, and history of SARS-CoV-2 infection. In analyses extending the risk interval to 1-42 days following bivalent vaccination, the overall RI was 0.97 (95% CI 0.81-1.15; Table 2). However, in subgroup analyses using the 1-42–day risk interval, we observed an increased risk of ischemic stroke only among individuals younger than 65 years of age who also received an influenza vaccine on the same day. The RI in this subgroup was 2.13 (95% CI 1.01-4.46). Among the subset who also had a documented history of SARS-CoV-2 infection within the year preceding the study period, the RI increased to 3.94 (95% CI 1.10-14.16).
In this 1-42–day risk interval analysis of the specific subgroup of individuals aged younger than 65 years who received bivalent and influenza vaccines on the same day, chart review of the 37 electronically identified ischemic stroke events found that 2 were determined to be hemorrhagic strokes and 11 were subsequently found to not meet the criteria for true ischemic stroke events, yielding a confirmation rate of 65% (n=24). With the verified 24 ischemic stroke events and ischemic stroke events among NBR (not verified through chart review, but adjusted for using a 65% confirmation rate), we proceeded to reevaluate the RI in this subgroup. The number of confirmed ischemic stroke events was graphed over the interval in days between bivalent vaccination and ischemic stroke event (Figure 1). There were 10 events in the 1-42–day risk interval and 14 events in the control interval. Using a risk interval of 1-42 days after coadministration of the Pfizer-BioNTech bivalent vaccine and influenza vaccine, the overall RI derived from analyzing confirmed ischemic stroke events among those aged younger than 65 years was 2.34 (95% CI 0.97-5.65; \(P=0.06\); Table 3). Between September 1, 2022, and March 31, 2023, a total of 117,423 individuals aged younger than 65 years received the Pfizer-BioNTech bivalent vaccine and influenza vaccine on the same day. According to the equation, \(AR=4.88 \times 10^{-5}\) and \(NNH=20,505\) with a risk interval of 1-42 days. Among 21,128 individuals who also had a documented history of SARS-CoV-2 infection within the year preceding the study period, the RI increased to 4.27 (95% CI 0.97-18.85; \(P=0.06\); Table 3); according to the equation, \(AR=1.45 \times 10^{-4}\) and \(NNH=6897\) with a risk interval of 1-42 days. Among the 10 confirmed ischemic stroke events in the risk interval of 1-42 days, the mean age was 58 (SD 5) years, ranging from 48 to 63 years. Among these cases, 2 individuals had a documented history of previous ischemic stroke, and no one died as of March 31, 2023. In addition, 7 received the standard dose, egg-based quadrivalent influenza vaccine, while 3 received an influenza vaccine of unknown formulation.

\(^a\) Confirmation by chart review.

\(^b\) NBR: nonbivalent recipient. These were eligible individuals who did not receive a bivalent vaccine but had completed a primary series of COVID-19 vaccination and had their last monovalent dose ≥60 days before September 1, 2022. Inclusion of these events helps to adjust for temporal trends (seasonality). A confirmation rate of 65% was applied to ischemic stroke events among NBR.

\(^c\) Had SARS-CoV-2 infection (ie, SARS-CoV-2 positive laboratory test or a COVID-19 diagnosis) during the year prior (August 31, 2021-August 31, 2022).

Risk of Ischemic Stroke Following the Moderna Bivalent COVID-19 Vaccine

When using a risk interval of 21 days following Moderna bivalent vaccination, the overall risk of ischemic stroke was not elevated from the analysis of electronically identified ischemic stroke events (RI=0.91, 95% CI 0.71-1.15), a finding that held true across all subgroup analyses by age, coadministration of influenza vaccine, and history of SARS-CoV-2 infection (Multimedia Appendix 4). However, extending the risk interval to 42 days after Moderna bivalent vaccination showed an increased risk of ischemic stroke among individuals younger than 65 years of age who had a documented history of SARS-CoV-2 infection, with an RI of 2.62 (95% CI 1.13-6.03). This subgroup involved a total of 36 ischemic stroke events among recipients of the Moderna bivalent COVID-19 vaccine (Table 4).

Of the 36 ischemic stroke events, 1 was a hemorrhagic stroke and 12 were not confirmed as true events through medical chart review, yielding a confirmation rate of 64% (n=23). After using a risk interval of 1-42 days following the Moderna bivalent vaccination and applying a 64% confirmation rate to ischemic stroke events among NBR, the RI derived from analyzing confirmed ischemic stroke events among those aged younger than 65 years who had a documented history of SARS-CoV-2 infection was 2.24 (95% CI 0.78-6.47; \(P=0.14\)).
Table 4. Numbers of electronically identified ischemic stroke events and relative incidences in the 42 days after Moderna bivalent COVID-19 vaccination among members of Kaiser Permanente Southern California during the period from September 1, 2022, to March 31, 2023.

aNBR: nonbivalent recipient. These were eligible individuals who did not receive a bivalent vaccine but had completed a primary series of COVID-19 vaccination and had their last monovalent dose ≥60 days before September 1, 2022. Inclusion of these events helps to adjust for temporal trends (seasonality). The same NBR population was used in overall bivalent analyses, as well as bivalent analyses stratified by coadministration of influenza vaccine.

bHad SARS-CoV-2 infection (ie, SARS-CoV-2 positive laboratory test or a COVID-19 diagnosis) during the year prior (August 31, 2021-August 31, 2022).

cN/A: not applicable.

Sex-Stratified Analyses
Further analyses were conducted to examine if the risk of ischemic stroke after bivalent vaccination differed by sex for those analyses indicating a potential increase in risk of ischemic stroke (Multimedia Appendix 5). The risk of ischemic stroke was not significantly increased after bivalent vaccination in the sex-stratified analyses. Due to limited sample sizes, the CIs of RIs were wide. The SAS and R codes are available for preparing data and fitting the event-dependent SCCS models (Multimedia Appendix 6).
Discussion

Principal Findings

These SCCS analyses did not find evidence that the risk of ischemic stroke was elevated during the 1–21–day postvaccination risk interval in both overall and subgroup analyses by age (younger than 65 years vs 65 years or older), prior history of SARS-CoV-2 infection, and coadministration of influenza vaccine, for both Pfizer-BioNTech and Moderna bivalent vaccines. However, based on electronically identified events, the risk of ischemic stroke was increased within the 1–42–day window after vaccination among those aged younger than 65 years who received their Pfizer-BioNTech bivalent vaccine and influenza vaccine on the same day; the risk was even higher among those who also had a documented SARS-CoV-2 infection history. After conducting a chart review of ischemic stroke events, the point estimate for the risk of ischemic stroke was still elevated in a risk interval of 1–42 days for these 2 subgroup analyses but did not meet the threshold for statistical significance (P=0.06).

For Moderna bivalent vaccination, an initial increase in the risk of ischemic stroke emerged within the 1–42–day window after vaccination among those aged younger than 65 years who had a documented SARS-CoV-2 infection history. However, after conducting a chart review of ischemic stroke events, the RI was 2.24 but was no longer statistically significantly elevated possibly due to a decreased sample size (P=0.14).

Our study showed an increased point estimate for the risk of ischemic stroke in a risk interval of 1–42 days only among those aged younger than 65 years who received their Pfizer-BioNTech bivalent vaccine and influenza vaccine on the same day, although not statistically significant. This finding is unique and may be attributed to differences in the study design compared to previous studies. First, our study used a calendar-based observation period spanning from September 1, 2022, to March 31, 2023. This extended timeframe enabled us to use a longer risk window of 1–42 days following vaccination in addition to the risk interval of 1–21 days in previous studies. Second, we did not exclude individuals with a history of ischemic stroke, but we did apply criteria to increase the likelihood that ischemic stroke events during the study period represented a new ischemic stroke episode. Nevertheless, it is possible that there was interaction between bivalent vaccination and a history of ischemic stroke. Furthermore, in subgroup analyses, we considered the influence of the history of SARS-CoV-2 infection. SARS-CoV-2 infection is associated with an increased risk of ischemic stroke [28,29] and risk factors for SARS-CoV-2 infection may overlap with risk factors for ischemic stroke. There is a potential interaction between bivalent vaccination and a history of SARS-CoV-2 infection. The finding that the point estimate for the risk of ischemic stroke was elevated among individuals aged younger than 65 years but not among individuals aged 65 years or older is also biologically plausible. This may be due to the relatively heightened immune response and subsequent inflammation in the younger age group versus the older age group, and the fact that inflammation has been shown to be associated with an increased risk of ischemic stroke [30,31]. Moreover, a smaller proportion of younger adults opted for bivalent vaccination [32], and those who did might have had a higher prevalence of comorbidities or poorer overall health status.

Limitations and Strengths

This study had several limitations. First, the study took place in a single health care system. Additionally, the number of ischemic stroke events in individuals with a documented SARS-CoV-2 infection history who received coadministration of Pfizer-BioNTech bivalent vaccine and influenza vaccine was very small. This raises concerns about the validity of the asymptotic large sample assumptions that underlie both the 95% CIs and P values. Second, we did not conduct a chart review of ischemic stroke events among NBR; these events contributed to establishing baseline rates of ischemic stroke events during the study period. In addressing this issue, when analyzing chart-confirmed ischemic stroke events among recipients of bivalent vaccine, we applied the confirmation rate of ischemic stroke events among recipients of bivalent vaccine to ischemic stroke events among NBR. Moreover, we also did not undertake a chart review of ischemic stroke events from those analyses when safety signals were absent. Third, while we excluded ischemic stroke events occurring within 30 days of SARS-CoV-2 infection, it is possible that some ischemic stroke events included in the analyses involved individuals with asymptomatic or mild COVID-19 disease who did not have a documented SARS-CoV-2 infection. Fourth, the elevated point estimate for the risk of ischemic stroke, while not statistically significant, was observed within the 1–42–day period following the coadministration of the Pfizer-BioNTech bivalent vaccine and influenza vaccine. This risk interval was longer than the 1–21 days or 1–28 days investigated in earlier research [10,13,33]. However, the biological plausibility for the occurrence of a vaccine-related ischemic stroke beyond 28 days remains uncertain. Fifth, unaccounted time-varying confounders could have also influenced the findings. Finally, our analysis did not adjust for multiple subgroup analyses by age, coadministration of bivalent COVID-19 vaccine and influenza vaccine, and history of SARS-CoV-2 infection. These specific subgroup analyses were prespecified due to their potential safety concerns. The decision not to make multiple comparison adjustments was deliberate, aimed at ensuring that any potential vaccine safety concern could be detected.

The study also had several strengths. First, we addressed the impact of previous ischemic stroke events on bivalent COVID-19 vaccination by using an event-dependent modified SCCS design. Second, we explored effect heterogeneity by conducting subgroup analyses based on factors such as age, documented history of SARS-CoV-2 infection, and coadministration of influenza vaccine. Third, to adjust for temporal trends, we included ischemic stroke events among NBR. This strategy not only enhanced the accuracy of estimating the baseline rate but also improved the statistical power for identifying potential safety signals. Finally, we reanalyzed ischemic stroke events that were confirmed through chart review for those analyses where safety signals were detected.
Future research should include several key aspects to further enhance the validity and robustness of our findings. Collaborative efforts with additional health care systems will enable us to significantly increase our sample size. A larger sample size could provide sufficient statistical power to conduct sensitivity analyses such as the exclusion of transient ischemic attacks and exclusion of those who had a history of ischemic stroke.

In light of the findings of this study on the risk of ischemic stroke after bivalent COVID-19 vaccination, it is necessary to assess the safety of the monovalent COVID-19 vaccination during 2023-2024 for several reasons. First, while the bivalent COVID-19 vaccines included 2 components (BA.4 and BA.5), the monovalent COVID-19 vaccines during the 2023-2024 season included 1 component (XBB.1.5). This change in vaccine composition warrants continued surveillance to assess any differential safety profiles. Second, during the 2023-2024 season, coadministration of monovalent COVID-19 vaccine and influenza vaccine on the same day was possible given the timing of availability of both products and the recommendation by the CDC.

Conclusions
We found no evidence to suggest that the Pfizer-BioNTech bivalent vaccine increased the risk of ischemic stroke among individuals aged older than 65 years, consistent with the attenuated signal from the VSD surveillance that motivated this study. We found an elevated point estimate for the risk of ischemic stroke within 1-42 days (but not within 1-21 days) after the coadministration of the Pfizer-BioNTech bivalent vaccine and influenza vaccine among individuals younger than 65 years old that did not reach statistical significance, although the sample size was limited. Future studies with a larger sample size are needed to evaluate the association between bivalent COVID-19 vaccination and ischemic stroke, as well as contributing factors such as the history of SARS-CoV-2 infection. Any potential risks of ischemic stroke associated with bivalent COVID-19 vaccination must be balanced against the potential benefits of bivalent COVID-19 vaccination in preventing COVID-19–associated ischemic stroke and severe COVID-19 disease.

Acknowledgments
Funding for this study was provided by the National Institute of Allergy and Infectious Diseases of the National Institutes of Health (R01 AI168209). The National Institutes of Health had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the paper; and decision to submit the paper for publication. The findings and conclusions in this report are those of the authors and do not necessarily represent the official views of the National Institutes of Health. Kaiser Permanente Southern California stroke chart abstractions from the Vaccine Safety Datalink were used in this work. Kristin Goddard and Pat Ross from Kaiser Permanente Northern California and Kayla Hanson from Marshfield Clinic Research Institute developed the stroke chart abstraction forms. The authors thank the Kaiser Permanente Southern California chart abstractors Jose Pio and Julliane Bacerdo.

Data Availability
The data sets generated and analyzed during this study are not publicly available due to potentially identifying or sensitive patient information but are available from the corresponding author on reasonable request.

Abstract

Background: The COVID-19 pandemic, caused by SARS-CoV-2, has had a profound impact worldwide, leading to widespread morbidity and mortality. Vaccination against COVID-19 is a critical tool in controlling the spread of the virus and reducing the severity of the disease. However, the rapid development and deployment of COVID-19 vaccines have raised concerns about potential adverse events following immunization (AEFIs). Understanding the temporal and spatial patterns of these AEFIs is crucial for an effective public health response and vaccine safety monitoring.

Objective: This study aimed to analyze the temporal and spatial characteristics of AEFIs associated with COVID-19 vaccines in the United States reported to the Vaccine Adverse Event Reporting System (VAERS), thereby providing insights into the patterns and distributions of the AEFIs, the safety profile of COVID-19 vaccines, and potential risk factors associated with the AEFIs.

Methods: We conducted a retrospective analysis of administration data from the Centers for Disease Control and Prevention (n=663,822,575) and reports from the surveillance system VAERS (n=900,522) between 2020 and 2022. To gain a broader understanding of postvaccination AEFIs reported, we categorized them into system organ classes (SOCs) according to the Medical Dictionary for Regulatory Activities. Additionally, we performed temporal analysis to examine the trends of AEFIs in all VAERS reports, those related to Pfizer-BioNTech and Moderna, and the top 10 AEFI trends in serious reports. We also compared the similarity of symptoms across various regions within the United States.

Results: Our findings revealed that the most frequently reported symptoms following COVID-19 vaccination were headache (n=141,186, 15.68%), pyrexia (n=122,120, 13.56%), and fatigue (n=121,910, 13.54%). The most common symptom combination was chills and pyrexia (n=56,954, 6.32%). Initially, general disorders and administration site conditions (SOC 22) were the most prevalent class reported. Moderna exhibited a higher reporting rate of AEFIs compared to Pfizer-BioNTech. Over time, we observed a decreasing reporting rate of AEFIs associated with COVID-19 vaccines. In addition, the overall rates of AEFIs between the Pfizer-BioNTech and Moderna vaccines were comparable. In terms of spatial analysis, the middle and north regions of the United States displayed a higher reporting rate of AEFIs associated with COVID-19 vaccines, while the southeast and south-central regions showed notable similarity in symptoms reported.

Conclusions: This study provides valuable insights into the temporal and spatial patterns of AEFIs associated with COVID-19 vaccines in the United States. The findings underscore the critical need for increasing vaccination coverage, as well as ongoing surveillance and monitoring of AEFIs. Implementing targeted monitoring programs can facilitate the effective and efficient management of AEFIs, enhancing public confidence in future COVID-19 vaccine campaigns.

Introduction
The COVID-19 pandemic, caused by SARS-CoV-2, was first identified in China in 2019 and quickly became an uncontrollable outbreak worldwide [1-4]. As of March 2023, the World Health Organization (WHO) had reported 761,402,282 confirmed cases and 6,887,000 deaths due to COVID-19 worldwide [5]. COVID-19 primarily spreads through respiratory droplets, and infection can bring about mild-to-severe symptoms, ranging from general fatigue, cough, fever, loss of taste and smell, diarrhea, and severe pneumonia to even death [3-7]. Elderly individuals and those with underlying conditions, such as obesity, diabetes, and hypertension, are at higher risk [8]. Long-term effects of COVID-19 include fatigue, muscle weakness, sleep difficulties, anxiety, and depression [9]. So far, vaccines are considered the primary method to control the virus, with over 674,375,000 doses administered in the United States by April 2023 [10-14]. Coccia [15] demonstrated that nations enforcing stringent societal restrictions and obligations achieved a high rate of full COVID-19 vaccination, reaching 77.17% (average stringency index of 62.97) by February 2022. Magazzino et al [16] and Aldila et al [17] maintained that achieving higher levels of vaccination could lead to the eradication of COVID-19 in the population by the development of herd immunity, thereby protecting vulnerable individuals. Coccia [18] also revealed that administering an average of about 80 doses of vaccines per 100 inhabitants between countries can sustain a reduction in confirmed cases and deaths. The growth of the pandemic wave in May 2021 increased the optimal level of vaccines to about 90 doses for reducing the numbers of COVID-19–related infections [18]. Although a widespread vaccination campaign is essential to fight against infectious diseases, it alone is not sufficient as a public policy to mitigate the adverse effects of the COVID-19 pandemic crisis [13,19]. Cases have shown that COVID-19 vaccines can trigger adverse events in multiple systems, including oral, digestive, hematological, immune, and nervous systems [20-26]. Common side effects include tenderness at the injection site, fever, fatigue, body ache, and headache [27-30]. To make matters worse, there have been reports of serious adverse events following immunization (AEFIs), such as acute kidney injury, respiratory distress syndrome, coagulation disorders, and cardiac injuries, associated with COVID-19 vaccines [31]. Therefore, new vaccination strategies for nations must be highly responsive, flexible, resilient, scalable, and effective in reducing the negative impact of coronavirus [18,32]. Temporal and spatial factors are critical in the spread of COVID-19, as evidenced by recent research. Coccia’s [33] systematic review highlighted that high air and environmental pollution, as well as unsustainable environments, can facilitate the emergence and rapid spread of pandemics. Coccia [33] also emphasized the importance of an effective contact-tracing system and timely isolation in reducing the transmission dynamics of infectious diseases within and between different outbreak areas, particularly for diseases with a latent presymptomatic phase. Moreover, Coccia’s [34] analysis of seasonality in COVID-19 transmission revealed a correlation between lower temperatures and higher transmission rates, especially in colder regions. Additionally, a spatial analysis demonstrated regional disparities in COVID-19 diffusion, with urban areas showing higher transmission rates than rural areas [35]. These findings underscore the significance of considering temporal and spatial factors in comprehending the COVID-19 spread and suggest that AEFIs related to COVID-19 vaccination may also demonstrate temporal and spatial trends, necessitating further exploration.

Temporal monitoring allows for the identification of trends, potential causal relationships, and patterns of AEFIs over time [36]. Neglecting the heterogeneity or temporal trend of reporting rates across different years can result in missing significant signals, especially given the evolving nature of COVID-19 caused by prevailing strains of SARS-CoV-2 [37-39]. Additionally, spatial analysis examines the similarity of AEFIs across different regions, providing insights into spatial variations, vaccine brands, and populations [40]. The majority of AEFIs are preventable [41]; thus, analyzing these AEFIs reported enables public health researchers and officials to understand their spatial patterns, potential causal factors, and overall impact, supporting evidence-based decision-making and targeted interventions. The Vaccine Adverse Event Reporting System (VAERS), a comprehensive database that collects reports of AEFIs across different states and periods in the United States, proves instrumental in conducting temporal and spatial monitoring of COVID-19 vaccine–related AEFIs [42].

Despite significant research on AEFIs associated with COVID-19 vaccines using VAERS data, previous research has primarily focused on short-term data, neglecting comprehensive temporal and spatial analyses within the United States. Huang et al [43] developed a composite likelihood-based variance component model to analyze the temporal variation of AEFIs reporting using VAERS data. The method accounted for underreporting and zero inflation in passive surveillance systems and identified 14 AEFIs with significantly heterogeneous reporting rates over the years, including 2 events showing an increasing trend [43]. Cai et al [37] proposed a random effects model to test the heterogeneity of reporting rates for vaccine-event combinations across multiple years in the VAERS database. The method demonstrated high statistical power in detecting variations in reporting rates, highlighting potential safety issues associated with changes in influenza vaccines [37]. Askar and Zülfü [40] conducted a study on the similarity of adverse effects of COVID-19 vaccines across different states in the United States using VAERS data. They applied a topic modeling approach to extract latent topics from the AEFIs reported and identified spatial clusters of states exhibiting similar AEFIs [40]. These findings underscore the variation in AEFIs across states and emphasize the importance of further research to understand underlying causes, enhance the
comprehension of adverse effects, and address vaccine hesitancy [40]. However, the random effects model shows limitations in capturing the complex relationships among symptoms, whereas latent Dirichlet allocation (LDA) may overlook semantic similarity between symptom compositions in different regions, although it is innovative to identify spatial clusters of states with similar AEFIs.

In this study, we aimed to conduct a comprehensive temporal and spatial analysis of AEFIs associated with COVID-19 vaccines reported to VAERS. We used the Medical Dictionary for Regulatory Activities (MedDRA) as our medical terminology reference [23]. The rest of the paper is organized as follows. We begin with descriptive analyses of vaccine administration and VAERS data, examining factors such as gender, age, and manufacturer, with a specific focus on serious reports. Subsequently, we discuss how we investigated the temporal variation of AEFIs and symptoms within different system organ classes (SOCs) throughout the study period, enabling a holistic analysis. By modeling weekly reported symptoms relative to administration, we accurately assessed temporal variation, identifying associations between time and AEFIs. In addition to the temporal analysis, we also conducted a spatial analysis using the BioWordVec_PubMed_MIMICIII embedding model. This approach allowed us to construct meaningful vectors that capture the nuances of symptom compositions, enabling us to examine the reporting rates of AEFIs in different regions across the United States. Overall, our approach combines advanced embeddings, semantic similarity, and temporal modeling, providing comprehensive insights into AEFIs reported for COVID-19 vaccines.

Methods

Ethical Considerations

The original data collection was approved by the Institutional Review Board (IRB). The analysis did not receive approval/exemption from the IRB. The secondary analysis did not need a review from the IRB, as we used a publicly available data set [11,44]. The authors had permission to use the data.

Sample and Data

We collected VAERS reports of AEFIs associated with COVID-19 vaccines from December 13, 2020, to December 28, 2022. The reports consist of 3 comma-separated-value (CSV) files grouped by year: VAERSDATA.CSV, VAERSVAX.CSV, and VAERSSYMPTOMS.CSV. VAERSDATA contains demographic information, vaccination and adverse event timing, symptom descriptions, allergy history, and serious outcomes. VAERSVAX provides details on vaccine type and manufacturer for each adverse event, while VAERSSYMPTOMS lists symptoms associated with each adverse event, as mapped from the preferred term (PT) in the MedDRA terminology. The 3 tables are linked by the primary key VAERS_ID.

In addition, we curated COVID-19 vaccine administration data from the Centers for Disease Control and Prevention’s (CDC) COVID Data Tracker during the corresponding period. The COVID Data Tracker is a centralized database maintained by the CDC that provides up-to-date information about COVID-19 vaccine administration across the United States [11]. The COVID Data Tracker contains data on the number of vaccine doses distributed and administered, as well as breakdowns by state, demographic group, and vaccine type [11].

MedDRA is a standardized vocabulary for adverse event reporting, allowing for the consistent classification and analysis of adverse events across different pharmaceutical products and clinical studies [45]. The MedDRA terminology comprises a structural hierarchy of 5 levels: the SOC, high-level group term (HLGT), high-level term (HLT), PT, and lowest-level term (LLT). According to the MedDRA website, the current version of MedDRA (version 24.1 as of September 2021) contains over 84,000 PTs, which is used by the VAERS code to classify adverse events reported to the system [46].

Measures of Variables

We performed several key analyses to examine the characteristics of AEFIs associated with COVID-19 vaccines. An AEFI is defined as any untoward occurrence following immunization [47]. In this study, we focused solely on AEFIs reported to VAERS. We did not investigate whether these AEFIs were caused by other factors occurring during the same study period (eg, COVID-19 infection, symptoms arising from other diseases or interventions). CDC data on COVID-19 vaccine administration were used to determine the number of vaccinations. This information provides a context and allows for comparison with the number of VAERS reports. We also summarized the number of VAERS reports and the symptoms reported, including unique symptoms. The number of COVID-19 vaccines administered and the AEFIs reported were stratified by sex, age, and vaccine manufacturer. Additionally, we analyzed the occurrence of individual symptoms and the co-occurrence of symptom pairs.

We categorized the VAERS reports based on sex, age, and vaccine manufacturer in the following ways. Sex was classified into male, female, and unknown. The reports were divided into 6 age groups based on CDC-recommended cutoff thresholds (5, 12, 18, 65 years), and “unknown” was used for age data that were unavailable. The main COVID-19 vaccine manufacturers in the market included Pfizer-BioNTech, Moderna, Janssen, Novavax, and unknown. We filtered out vaccinations that included a mixture of Pfizer-BioNTech and Moderna, because it was not possible to determine from the reported data whether the AEFIs resulted from Pfizer-BioNTech or Moderna vaccination. We also excluded 3 subjects who did not report any symptoms, resulting in a sample size of 5493 subjects in total.

A report was classified as serious if it contained any of the following outcomes: death; a threat to life at the time of the event; emergency room visit; inpatient hospitalization or prolongation of existing hospitalization; or persistent or significant disability/incapacity, a congenital anomaly/birth defect, or a medically important event based on medical judgment [31], with the corresponding fields indicating “DIED” (death), “L_THREAT” (life threatening), “ER_VISIT” (emergency room visit), “X_STAY” (hospitalization or extended hospital stay), or “DISABLE” (persistent or significant disability/incapacity). To gain a deeper understanding of AEFIs
associated with COVID-19 vaccines in serious reports, we conducted additional analyses of these reports, focusing on the composition of cases by sex, age group, and vaccine manufacturer.

**Data Analysis**

To categorize symptoms reported, we mapped them to the SOC level. The SOC is the top-level hierarchical structure used for broad categorization of medical concepts based on etiology, manifestation site, or purpose [48]. In our study, we suggested a straightforward approach for categorizing AEFIs into SOCs. This method involves using the internationally agreed-upon order of SOCs (refer to Table S1 in Multimedia Appendix 1), which is determined by the relative importance of each SOC [49]. In VAERS, each symptom reported could be mapped to either 1 LLT or 1 PT in MedDRA. First, we matched each symptom to the corresponding LLT or PT, resulting in 66 symptoms matched to LLTs and 12,050 symptoms matched to PTs. Symptoms matched to LLTs were further mapped to the corresponding PTs, and relevant SOC terms were identified. If a report contained multiple symptoms that fell under a specific SOC, we recorded the occurrence of that SOC for each corresponding symptom in the analysis.

In our study, we conducted a thorough temporal analysis to monitor the reporting rate of AEFIs (Equation 1) associated with COVID-19 vaccines and individual SOCs on a weekly basis. This approach allowed us to closely track any temporal trends and evaluate the potential risks associated with COVID-19 vaccination, providing valuable insights for well-informed decisions in public health policy.

Furthermore, we ranked and analyzed the top 10 symptoms reported in serious case reports over time. By examining the reporting rate of these symptoms, we gained a comprehensive understanding of their prevalence and impact. This analysis provided valuable insights into the severity and frequency of AEFIs associated with COVID-19 vaccines.

Additionally, we conducted a separate temporal analysis specifically focusing on AEFIs related to Pfizer-BioNTech and Moderna vaccines. By analyzing these vaccines individually, we were able to gain a more in-depth understanding of the AEFIs reported and identify any unique patterns or differences between vaccine manufacturers.

We conducted a spatial analysis of the reporting rates of cases and serious cases for each state in the United States. To organize the states into standardized regions, we used the Standard Federal Regions, as defined in “Circular A-105” released by the Office of Management and Budget in April 1974 (refer to Table S2 in Multimedia Appendix 1) [50].

Furthermore, we performed statistical analysis on the distribution of the AEFIs within each region and generated vectors that considered both AEFIs and their frequencies. To assess the similarity of the AEFI composition across different regions, we used the BioWordVec_PubMed_MIMICIII embedding model. This model is based on the word2vec algorithm and is specifically designed to enhance biomedical word embeddings. It leverages subword information and incorporates the vast PubMed and MIMIC-III data sets to create embeddings that capture the rich semantics of biomedical terms [51,52]. By using the BioWordVec_PubMed_MIMICIII embedding model, we measured the semantic similarity between AEFI compositions in different regions. This analysis provided insights into the shared patterns and characteristics of AEFIs across various geographic areas.

**Results**

**Descriptive Statistics for COVID-19 Vaccination**

Tables 1 and 2 present descriptive statistics for COVID-19 vaccination, with data divided into administration data provided by the CDC and AEFIs reported in VAERS, respectively. Vaccination rates peaked in 2021 in both administration and VAERS data. Notably, VAERS reports for the age groups of 0-5 years (excluding 5) and 5-12 years (including 5 but excluding 12) had the highest number of AEFIs, followed by elderly individuals (aged ≥65 years). The Pfizer-BioNTech vaccine was the most commonly administered one during the study period, but in 2021, there were more VAERS reports associated with the Moderna vaccine.

Figure S1 in Multimedia Appendix 1 presents a comprehensive breakdown of serious reports analyzed in this study. The total number of reports included was 900,522, with 42,366 (4.7%) classified as serious. Of these serious reports, 21,153 (49.93%) were reported by female patients and 20,275 (47.86%) by male patients. The highest proportion of serious VAERS reports was in the age group of 18-65 years, accounting for 48.82% (n=20,684) of the total serious reports, followed by individuals aged ≥65 years, who submitted 18,681 (44.09%) of the AEFI reports. Regarding vaccine manufacturers, Pfizer-BioNTech had the highest number of VAERS reports, with 20,623 (48.68%) cases, followed by Moderna with 16,936 (39.98%) cases. Serious VAERS reports resulting from Janssen, Novavax, and unknown manufacturers constituted 11.34% (n=4807) of the total reports.

In the serious reports, a total of 314,777 nonunique AEFIs and 7945 unique AEFIs were identified. The most frequent AEFIs reported were death (n=13,323, 31.45%), COVID-19 (n=6431, 15.18%), dyspnea (n=6199, 14.63%), SARS-CoV-2 test positivity (n=5036, 11.89%), and fatigue (n=3610, 8.52%). The most frequent SOCs reported were investigations (n=93,716, 22.11%); general disorders and administration site conditions (n=48,164, 11.29%); nervous system disorders (n=31,689, 74.8%); respiratory, thoracic, and mediastinal disorders (n=22,997, 54.28%); and surgical and medical procedures (n=14,982, 35.36%).

\(^a\)VAERS: Vaccine Adverse Event Reporting System.

Next, we computed the number of occurrences of individual symptoms and symptom co-occurrences for all VAERS reports during the period of 2020-2022. The most frequently reported symptoms following COVID-19 vaccination were headache (n=141,186, 15.68%), pyrexia (n=122,120, 13.56%), and fatigue (n=121,910, 13.54%). The results are shown in Figure S2 in Multimedia Appendix 1 (detailed results are available in “Frequency and reporting rate of adverse events” in Multimedia Appendix 2). The most frequent co-occurrence pair was chills+pyrexia (n=56,954, 6.32%).
In “Covid-19_vaccine_2020_2022” in Multimedia Appendix 2, we can find the top 5 symptoms categorized by gender, vaccine manufacturer, and age group for the years 2020-2022. Furthermore, Multimedia Appendix 2 also provides the same information for each specific year (2020, 2021, and 2022). For the Janssen vaccine, the top 5 symptoms reported were headache, pyrexia, chills, fatigue, and pain. The most common symptoms and AEFIs for the Novavax vaccine were dizziness, followed by headache, fatigue, incorrect product formulation, and pain. Those receiving an unknown vaccine reported COVID-19, headache, pyrexia, pain, and chills. For Moderna and Pfizer-BioNTech, the most common symptoms were headache, pyrexia, fatigue, pain, and chills. Adults aged 18-65 years reported these same symptoms, while the elderly also reported SARS-CoV-2 test positivity. Teenagers reported product errors, whereas infants and toddlers reported fever and dosage issues. Children aged 5-12 years reported no adverse events and product errors.

**Temporal Analysis**

Figure S3 in Multimedia Appendix 1 shows the serious case–reporting rate associated with each COVID-19 vaccine manufacturer between 2020 and 2022. Among the vaccine manufacturers, Janssen had the highest reporting rate, followed by the unknown manufacturer, Novavax, Moderna, and Pfizer-BioNTech in that order. Notably, in 2022, the reporting rate for Janssen (0.0009) was significantly higher compared to any other COVID-19 vaccine manufacturer from 2020 to 2022.

Figure S4 in Multimedia Appendix 1 provides insight into the reporting rate of serious cases associated with COVID-19 vaccines across different age groups between 2021 and 2022. The reporting rate was higher in older-age groups and increased with age. Additionally, the reporting rate for each age group peaked in 2022.

Figure 1 illustrates trends in the proportion of reported SOCs and AEFIs reported in VAERS associated with COVID-19 vaccines during the study period using weekly reported data. The vertical red bars represent the proportion of VAERS reports among weekly administrations, while the lines represent the occurrences of AEFIs in SOCs out of the corresponding weekly administrations. Notably, the reporting symptoms of SOC 22 (“General disorders and administration site conditions”) were more prevalent compared to other symptoms. It is important to note that the figure may not reflect the actual rate of AEFIs and corresponding SOCs due to reporting bias. However, it still provides valuable temporal insights into the development of AEFIs related to COVID-19 vaccination. Interestingly, the local maxima observed in both the bar graph and the line graph align with the 2 peaks of the pandemic in the summer of 2021 and 2022. This suggests a potential correlation between the prevalence of AEFIs and the intensity of the pandemic. Furthermore, the reporting rate of VAERS and SOC symptoms decreased over time, demonstrating that COVID-19–related AEFIs gradually improved.

Figure 2 presents trends in the serious case–reporting rate proportion and the top 10 AEFIs reported related to serious reports in VAERS. The vertical red bars represent the proportion of serious VAERS reports among weekly administrations, while the lines represent the rate of the top 10 AEFIs in serious reports out of the corresponding weekly administrations. Our analysis indicated that the top 10 AEFIs reported in the serious cases included death, COVID-19, dyspnea, SARS-CoV-2 test positivity, fatigue, pyrexia, pain, headache, blood test, and asthenia. Overall, a decreasing trend was observed, particularly after the initial period from December 2020 to April 2021. Notably, 2 points of local peaks occurred in October 2021 and August 2022. However, starting from December 2021, the reporting rate for the other AEFIs decreased significantly over time, while the reports of death remained relatively consistent. Please note that the information provided is based on the analysis available until December 2022, and subsequent updates to the data may reveal different trends or findings.

Figure 3 illustrates trends in the case-reporting rate and the individual SOC-reporting rate, specifically for Pfizer-BioNTech. The vertical red bars represent the proportion of VAERS reports associated with Pfizer-BioNTech immunization among its weekly administrations, while the lines represent the occurrences of AEFIs in SOCs out of the corresponding weekly Pfizer-BioNTech administrations. In general, both the case-reporting rate and the individual SOC-reporting rate demonstrated a decreasing trend. However, there were instances in September 2021, March 2022, July 2022, and September 2022 when the case-reporting rate and all SOC-reporting rates reached a local maximum. Before June 2022, the reporting rate for SOC 22 (“General disorders and administration site conditions”) was the highest among all SOC-reporting rates. However, it was later surpassed by SOC 24 (“Injury, poisoning, and procedural complications”).

Figure 4 displays the case-reporting rate and the individual SOC-reporting rate, specifically for Moderna. The vertical red bars represent the proportion of VAERS reports associated with Moderna immunization among its weekly administrations, while the lines represent the occurrences of AEFIs in SOCs out of the corresponding weekly Moderna administrations. Initially, both the case-reporting rate and the individual SOC-reporting rate for Moderna were relatively high. Although there was a sharp decrease until June 2021, the rate experienced a rebound and reached a local peak in August 2021. Subsequently, there was a gradual decreasing trend observed. Prior to November 2021, the reporting rate for SOC 22 (“General disorders and administration site conditions”) far exceeded that of the other categories. However, from that point onward, it became comparable to that of SOC 24 (“Injury, poisoning, and procedural complications”). In comparison to Figure 3, the peaks representing Moderna in the periods of the SARS-CoV-2 Delta and SARS-CoV-2 Omicron variants were higher than those representing Pfizer-BioNTech.
**Figure 1.** Case-reporting rate and individual SOC-reporting rate associated with COVID-19 vaccines in the United States (2020-2022). SOC: system organ class.

**Figure 2.** Reporting rates for serious cases and top 10 adverse events in serious cases for COVID-19 vaccines in the United States (2020-2022).
Figure 3. Case-reporting rate and individual SOC-reporting rate for the Pfizer-BioNTech vaccine in the United States (2020-2022). SOC: system organ class.

Figure 4. Case-reporting rate and individual SOC-reporting rate for the Moderna vaccine in the United States (2020-2022). SOC: system organ class.

Spatial Analysis

Figure 5 presents the VAERS reporting rate by state. It shows that Montana, Minnesota, Michigan, Colorado, Indiana, Alaska, and Kentucky were the states with reporting rates exceeding 0.0015. Among these, Indiana recorded the highest reporting rate, at 0.0025.

Figure 6 shows the VAERS serious case–reporting rate. Montana, South Dakota, Kentucky, and Tennessee were the states with serious case–reporting rates surpassing 100 μ. Among them, South Dakota had the highest reporting rate, reaching...
205.26 μ. In addition to the health care quality and higher confirmed cases relative to the population (especially for Tennessee and Kentucky), this can be partially attributed to their lower vaccination levels (see "geography_serious_reporting_rate_by_state_vaccination" in Multimedia Appendix 2) compared to other states [53,54]. Specifically, these 3 states ranked among states with the least vaccination levels, with all 3 falling far below the average vaccination level nationwide. This lower vaccination rate may contribute to a higher proportion of AEFIs being reported in these states, as individuals who chose to get vaccinated might be more likely to report any side effects they experienced.

Figure 7 presents a heatmap showing the similarity of symptoms between regions within the United States. The similarity between all regions exceeded 0.99, indicating a high level of similarity in symptoms. Notably, regions IV and VI demonstrated the highest similarity, reaching an impressive value of 0.9999.

Figure 8 illustrates a heatmap depicting the similarity of symptoms in serious reports among different regions within the United States. The analysis revealed that the similarity between all regions exceeded 0.99, indicating a remarkable degree of similarity in the symptoms reported. Notably, regions II and III demonstrated the highest level of similarity, with an exceptional value of 0.9998, suggesting a strong correlation in the symptoms reported between these regions. In a broader sense, based on the dark boxes shown in Figure 8, it appears that regions I, II, III, IX, and X were clustered together with higher similarity within this group, whereas regions IV, V, VI, VII, and VIII indicated another clustering pattern.
**Discussion**

**Principal Findings**

Our research has produced findings that underscore the clinical significance of our study (summarized in Table 3). Headache emerged as the predominantly reported symptom associated with the vaccines made by Pfizer-BioNTech, Moderna, and Janssen. Notably, the top 5 symptoms reported for all 3 vaccines are headache, fatigue, pyrexia, pain, and chills, with only slight differences in the order of rankings. The occurrence of headache can be attributed to the body’s immune response to the vaccine, which triggers the generation of humoral and cellular immunity through a diverse range of mechanisms [55]. Some of these mechanisms may lead to inflammation and a subsequent headache [55].

</table>
| COVID-19 administration data    | • Adults aged 18-65 years were vaccinated the most.  
• Pfizer-BioNTech was the most administered vaccine. | • Provides insights into the timing of peak vaccination rates, aiding in understanding vaccination trends during the study period  
• Highlights the demographic group that received the highest vaccination coverage, aiding in targeting future vaccination campaigns |
| VAERS\(^a\) reports            | • VAERS reports indicated higher reporting rates among adults aged 18-65 years.  
• Reporting rates for AEFIs\(^b\) associated with COVID-19 vaccines were higher in female and older-age groups.  
• Pfizer-BioNTech had the highest number of VAERS reports, followed by Moderna.  
• The reporting rate for Janssen was significantly higher in 2022 compared to other vaccine manufacturers.  
• The most frequently reported AEFIs were headache, pyrexia, and fatigue.  
• The most frequent co-occurrence pair was chills+pyrexia.  
• The most frequent SOCs in serious reports were investigations (SOC 23); general disorders and administration site conditions (SOC 22); nervous system disorders (SOC 8); respiratory, thoracic, and mediastinal disorders (SOC 13); and surgical and medical procedures (SOC 25). | • Provides age- and sex-specific reporting rates, highlighting vulnerable populations and aiding in targeted interventions and vaccine recommendations  
• Features differences in reporting rates among different age/sex groups and vaccine manufacturers, contributing to a better understanding of AEFI patterns  
• Identifies key symptoms and SOCs associated with COVID-19 vaccination, offering insights into common AEFIs and areas of focus for vaccine epidemiological surveillance  
• Highlights common symptom patterns postvaccination, aiding in the recognition of symptom clusters and potential treatment strategies |
| Temporal analysis               | • The trend in the proportion of SOCs and AEFIs reported showed a decrease over time.  
• The reporting rate for the top 10 symptoms and AEFIs reported related to serious reports showed an overall decreasing trend.  
• The AEFI-reporting rate and the individual SOC-reporting rate for Pfizer-BioNTech and Moderna showed a decreasing trend over time.  
• For Pfizer-BioNTech, SOC 22 (“General disorders and administration site conditions”) had the highest reporting rate among all SOCs before being surpassed by SOC 24 (“Injury, poisoning, and procedural complications”) starting June 2022.  
• For Moderna, the reporting rate for SOC 22 far exceeded that of the other categories initially, and it became comparable to that of SOC 24 from November 2021 onward. | • Indicates a potential decrease in AEFIs over time, suggesting the effectiveness of monitoring and intervention strategies  
• Highlights manufacturer-specific trends in AEFI reporting, offering valuable insights for vaccine epidemiological surveillance |
| Spatial analysis                | • States with reporting rates exceeding 0.0015 were Montana, Minnesota, Michigan, Colorado, Indiana, Alaska, and Kentucky.  
• States with serious case–reporting rates surpassing 100 \(\mu\) were Montana, South Dakota, Kentucky, and Tennessee.  
• The similarity between all regions exceeded 0.99, indicating a high level of similarity in symptoms between different regions in the United States. | • Identifies geographic variations in AEFI-reporting rates, suggesting the need for targeted vaccine surveillance in high-reporting states  
• Underscores the consistency of AEFI-reporting patterns across different regions, supporting the generalizability of findings and the reliability of VAERS data |

\(^a\)VAERS: Vaccine Adverse Event Reporting System.  
\(^b\)AEFI: adverse event following immunization.  
\(^c\)A report was classified as serious if it contained any of the following outcomes: death; a threat to life at the time of the event; emergency room visit; inpatient hospitalization or prolongation of existing hospitalization; or persistent or significant disability/incapacity, a congenital anomaly/birth defect, or a medically important event based on medical judgment [31].  
\(^d\)SOC: system organ class.

Conversely, the most commonly reported symptom associated with the Novavax vaccine is dizziness. Research suggests that postvaccination vertigo and dizziness are common in patients with Meniere disease (MD) and vertebrobasilar artery insufficiency (VBI) [56]. MD is a disorder with immunological factors that exacerbate endolymphatic hydrops [56,57]. Moreover, heightened osmolality levels in the inner ear can elevate proinflammatory cytokines and immune cell activation.
which may lead to a possible systemic immune response and an increase in disease-specific immunoglobulin G (IgG) levels, thereby intensifying disease activity [56,58,59]. There have been instances where patients with MD who were stable experienced vertigo following vaccination [56,59]. VBI can induce vertigo through dysregulation of blood flow due to altered plasma viscosity, platelet aggregation, red blood cell deformability, and endothelial function [56]. In rare cases, vaccine-related immunization anxiety can trigger vertigo in patients with autoimmune encephalitis [56,60-63].

In addition to common AEFIs, COVID-19 vaccination has been associated with severe or rare AEFIs, including autoimmune encephalitis (AIE), cerebral venous sinus thrombosis, Guillain-Barre syndrome (GBS), optic neuritis, and polyomyositis. These complications, with reporting rates ranging from 1.89e-5 to 0.001, are often of autoimmune nature [23]. Many conditions observed in temporal association with vaccination in this study were previously reported as potential autoimmune sequelae of SARS-CoV-2 infection, sharing similar clinical and laboratory characteristics [64]. Vaccines containing SARS-CoV-2 antigens may enhance autoimmunity through mechanisms such as polyclonal or bystander activation, epitope spreading, or molecular mimicry [64,65]. Alternatively, the inflammatory response induced by vaccination may enhance autoimmunity in predisposed patients, possibly by activating preexisting autoimmune pathways similar to the pathogenesis of immune-related adverse events following administration of immune checkpoint inhibitors [64-67]. Vaccination could also unmask previously asymptomatic autoimmunity in patients with new-onset autoimmune diseases [64]. Recent population-based studies have linked SARS-CoV-2 vaccination to an increased incidence of GBS, especially following Ad26.COV2.S administration [64]. However, the possibility that new onset or flares of other neurological autoimmune conditions merely coincide with vaccination against SARS-CoV-2 cannot be fully excluded [64]. Several pathogenic mechanisms have been proposed to explain how COVID-19 vaccines can lead to AIE, including molecular mimicry, neuroinflammation, and the role of vaccine adjuvants, such as BNT162 adjuvant polyethylene glycol (PEG), which has been implicated in the autoimmune syndrome induced by adjuvants (ASIA-syndrome) [23]. Moreover, vaccine-induced immune thrombotic thrombocytopenia (VITT) (reporting rate: 2.33e-5), although rare, is a consequential complication associated with vaccination [26]. In VITT, the ChAdOx1/PF4 complex may induce the production of anti-PF4 autoantibodies [26]. Trace amounts of ChAdOx1 may enter the bloodstream following intramuscular vaccine administration, due to slight capillary damage, leading to the formation of the ChAdOx1/PF4 complex and triggering the production of autoantibodies [26,68].

Our temporal analysis revealed a declining trend in symptoms across all SOCs, which may help alleviate vaccine hesitancy. The decrease in the reported incidence of AEFIs associated with COVID-19 vaccines can be attributed to various factors, including the rise in vaccination rates, the improvement of vaccine epidemiological surveillance, the growing experience and knowledge of health care providers and vaccine administrators, modifications implemented by vaccine manufacturers, and the decreasing number of COVID-19 cases due to public health measures and vaccination efforts [69,70]. Interestingly, when compared to Pfizer-BioNTech, Moderna has a relatively higher reporting rate of AEFIs during the initial vaccination stage, the SARS-CoV-2 Delta variant period, and the SARS-CoV-2 Omicron variant period. This disparity in the AEFIs reported between Moderna and Pfizer-BioNTech, despite both vaccines using the messenger RNA (mRNA) platform, can be attributed to multiple factors [71]. One possible reason is the higher dose of mRNA administered in each shot of the Moderna vaccine (100 μg) compared to the Pfizer-BioNTech vaccine (30 μg) [72]. The higher dose may trigger a stronger immune response in some individuals, increasing the likelihood of AEFIs. Additionally, there is a difference in the dosing intervals between the 2 vaccines. Pfizer-BioNTech doses are administered 3 weeks apart and Moderna doses administered 1 month apart [73]. The longer interval for Moderna could potentially allow for a more pronounced immune response, potentially contributing to a higher rate of AEFIs reported. However, as more data were collected and larger populations were vaccinated, it became evident that the overall rates of AEFIs between the 2 vaccines were comparable. This could be due to several factors, such as increased familiarity and experience with the vaccines, improved reporting systems, and a better understanding of potential side effects.

Our spatial analysis revealed that the north and middle regions of the United States exhibit higher case- and serious case–reporting rates compared to the southeast and southwest regions. The elevated reporting rate of AEFIs associated with COVID-19 vaccines in the middle and north regions could be attributed to several factors. One possible explanation is the disparity in vaccination coverage. The middle and north regions may have a lower proportion of vaccinated individuals, increasing the likelihood of AEFIs being reported. Furthermore, variations in health care access across different regions can also contribute to differences in reporting rates.

The COVID-19 symptoms reported show a notable similarity between the southeast region (region IV) and the south-central region (region VI). One possible explanation is the geographical proximity and shared demographics within these regions. When people live in close geographic proximity, they often share similar environmental exposures, lifestyles, and genetic backgrounds. These factors can contribute to a higher likelihood of experiencing similar symptoms when infected with COVID-19.

Interestingly, despite the geographical distance, the northwest (region X) and northeast (region I, II, and III) regions of the United States also exhibit similarity in the COVID-19 symptoms reported. The similarity is particularly pronounced in serious cases. This can be attributed to shared population characteristics, such as age distributions, cultural practices, or socioeconomic factors, which influence the prevalence and reporting of specific symptoms. Moreover, the presence of specific COVID-19 variants or strains within these regions could also contribute to the similarity in the symptoms reported. Variants of the virus may exhibit unique characteristics, including symptom profiles, which can result in similarities in the symptoms reported within specific regions.
Population migration and travel patterns can also play a role in the similarity of the symptoms reported. Individuals residing in close proximity or frequently traveling between regions can contribute to the transmission and dissemination of specific COVID-19 strains, leading to similarities in symptom reporting. Additionally, similarities in health care infrastructure, medical practices, and access to testing facilities may contribute to the observed similarities in the symptoms reported. Consistent testing protocols and diagnostic criteria across these regions can lead to more uniform reporting of symptoms.

A comparative analysis with other countries can provide insights into the generalizability of our findings and the impact of different health care systems and vaccination strategies. For example, Abukhalil et al [30] conducted a questionnaire-based retrospective cross-sectional study to monitor AEFIs associated with COVID-19 vaccines in Palestine. They found that fever, chills, headache, fatigue, and pain are the most commonly reported AEFIs [30]. Similarly, Bannister et al [25] analyzed questionnaires completed by participants in the Danish National Cohort Study of Effectiveness and Safety of SARS-CoV-2 Vaccines (ENFORCE) and revealed that fatigue, muscle pain, and headache are the most commonly reported AEFIs. Additionally, Nawaz et al [22] conducted a survey-based cross-sectional study in Pakistan and found that injection site pain, fatigue, and muscle ache are the most commonly reported AEFIs associated with COVID-19 vaccines. Through comparing data and trends across nations, we can identify similarities in AEFI reporting and population responses. Understanding these patterns can inform the development of more effective vaccination strategies to address AEFIs associated with COVID-19 vaccines. Furthermore, comparing AEFI profiles across countries can contribute to the identification of rare or unusual patterns, prompting further investigation into potential vaccine-related risks or benefits.

**Strengths and Limitations**

Our analysis of AEFIs associated with COVID-19 vaccines is comprehensive compared to existing research. First, unlike previous studies, we used both vaccine administration data and VAERS data. This approach allowed us to evaluate the reporting incidence of AEFIs, rather than relying solely on absolute values. Using both data sets has the advantage of providing a more accurate representation of AEFIs associated with COVID-19 vaccines. Second, we analyzed 3 years of data to provide a more complete and convincing conclusion. Most studies have been conducted over a shorter period, which limits their scope and reliability. In contrast, our study period of 3 years allowed us to assess the long-term AEFIs associated with these vaccines. This approach also provides a more dynamic and objective understanding of the risks associated with COVID-19 vaccines. Our approach allowed us to identify the most common AEFIs associated with COVID-19 vaccines and their underlying mechanisms. This information can help health care providers better manage and treat AEFIs associated with COVID-19 vaccines. Finally, we harnessed the power of an embedding model to examine the similarity of symptoms across diverse regions. The model can handle complex word structures and improve the representation of rare or unseen terms by considering subword units. This rationale helps extract more precise and meaningful insights from biomedical texts and also facilitates various applications, such as biomedical information retrieval, named entity recognition, and text classification.

Overall, the embedding provides a valuable resource for advancing biomedical text analysis and accelerating biomedical research.

However, it is important to acknowledge that our study has several limitations. First, the quality of the data was inadequate as we were unable to access certain administration data due to their unavailability in the CDC database, which could have added more depth to our analysis. Moreover, VAERS is a passive reporting system in which AEFIs are not automatically collected, and anyone can submit VAERS reports, which sometimes lack details or contain errors [74]. As this study reported data collected by a surveillance system, it did not determine the safety of the vaccines but rather was prone to report the most frequently monitored and reported AEFIs. Furthermore, it is crucial to note that VAERS does not validate the causation between COVID-19 vaccines and the AEFIs reported [74]. Second, we failed to include cases where patients received a combination of Pfizer-BioNTech and Moderna vaccines, resulting in selection bias. Unfortunately, this also meant that we were unable to filter out such doses in the administration data. Nonetheless, it is important to note that the number of individuals who received mixed doses per week was minimal compared to the overall number of vaccinations, which mitigated the potential impact of this bias. Additionally, reporting bias cannot be entirely ruled out, as some individuals may choose not to report adverse events to VAERS due to various reasons, including reluctance, lack of awareness, or difficulties in accessing the reporting system. This could result in underreporting of certain AEFIs and potentially affect the accuracy and completeness of our analysis. Lastly, there may be instances of history bias in our data, where the symptoms observed may not be attributed to the COVID-19 vaccine itself but rather to historical events or interventions that occurred during the same period. These external factors may confound the interpretation of the AEFIs reported. Despite these limitations, we believe that our study provides a comprehensive analysis of AEFIs associated with COVID-19 vaccines.

**Conclusion**

The study introduced a potentially valuable approach to monitoring AEFIs, particularly for serious cases, which could bolster research in regions experiencing unusual or severe adverse reactions. These findings imply that higher vaccination coverage may decrease the AEFIs reported, leading to increased confidence in vaccines. Our study highlights the importance of postlicensure monitoring in understanding AEFIs associated with COVID-19 vaccines. Although our analysis provides valuable insights into the temporal and spatial patterns of the symptoms reported, it is crucial to acknowledge the limitations in data quality, including reporting and selection biases. Moving forward, efforts should focus on improving surveillance methods to enhance the accuracy and representativeness of AEFI reporting. This study underscores the need for continuous monitoring, supporting the development of informed public health policies. Looking ahead, nations should prioritize implementing effective measures, such as stringent lockdowns,
widespread testing and contact tracing, robust health care infrastructure, and clear communication strategies. Additionally, ensuring equitable access to vaccines and promoting vaccine confidence are crucial for achieving optimal vaccination coverage. By implementing these strategies, nations can enhance their preparedness and response capabilities, reducing the impact of future pandemics.

Abstract

Background: The worldwide spread of monkeypox (mpox) has witnessed a significant increase, particularly in nonendemic countries.

Objective: We aimed to investigate the changing clinical symptoms associated with mpox from 1970 to 2023 and explore their interrelations.

Methods: In this systematic review and meta-analysis, 3 electronic databases were searched for English peer-reviewed studies conducted from January 1970 to April 2023 that reported any symptoms among confirmed mpox cases. We categorized the mpox epidemics into 3 periods: 1970-2002 (period 1, within the African region), 2003-2021 (period 2, epidemics outside Africa), and 2022-2023 (period 3, worldwide outbreak). Following PRISMA guidelines, a meta-analysis was performed to estimate the pooled prevalence for each symptom. The correlation among symptoms was analyzed and visualized using network analysis.

Results: The meta-analysis included 61 studies that reported 21 symptoms in 720 patients from period 1, 39 symptoms in 1756 patients from period 2, and 37 symptoms in 12,277 patients from period 3. The most common symptom among patients from all 3 periods was rash (period 1: 92.6%, 95% CI 78.2%-100%; period 2: 100%, 95% CI 99.9%-100%; and period 3: 94.8%, 95% CI 90.9%-98.8%), followed by lymphadenopathy (period 1: 59.8%, 95% CI 50.3%-69.2%; period 2: 74.1%, 95% CI 64.2%-84.1%; and period 3: 61.1%, 95% CI 54.2%-68.1%). Fever (99%, 95% CI 97%-100%), enlarged lymph nodes (80.5%, 95% CI 75.4%-85.0%), and headache (69.1%, 95% CI 4%-100%) were the main symptoms in period 1, with a significant decrease in period 3: 37.9%, 31.2%, and 28.7%, respectively. Chills/rigors (73.3%, 95% CI 60.9%-85.7%), fatigue (68.2%, 95% CI 51.6%-84.8%), and dysphagia/swallowing difficulty (61.2%, 95% CI 10.5%-100%) emerged as primary new symptoms in period 2 and decreased significantly in period 3. Most other symptoms remained unchanged or decreased in period 3 compared to the former 2 periods. Nausea/vomiting had the highest degree of correlation (with 13 symptoms) and was highly positively correlated with lymphadenopathy (r=0.908) and conjunctivitis (r=0.900) in period 2. In contrast, rash and headache were 2 symptoms with the highest degree of correlation (with 21 and 21 symptoms, respectively) in period 3 and were highly positively correlated with fever (r=0.918 and 0.789, respectively).

Conclusions: The manifestation of symptoms in patients with mpox has become more diverse, leading to an increase in their correlation. Although the prevalence of rash remains steady, other symptoms have decreased. It is necessary to surveil the evolving nature of mpox and the consequential changes in clinical characteristics. Epidemic countries may shift their focus on the potential association among symptoms and the high synergy risk.

Introduction

Background

Monkeypox (mpox), caused by the mpox virus within the genus Orthopoxvirus (family Poxviridae, subfamily Chordopoxvirinae), is an emerging zoonotic disease that results in a smallpox-like illness in humans [1,2]. The first case of mpox was reported in Zaire (current Democratic Republic of the Congo, DRC) in 1970, after which it spread to other countries in Central and West Africa [1,3]. Although mpox has predominantly affected African populations, in the spring of 2003, the disease was reported outside Africa for the first time in the Midwest region of the United States due to infection from imported animals, and then sporadic reports of infections emerged from other countries caused by imported cases from West Africa until the pandemic [4]. Since May 2022, the disease has emerged as a major worldwide public health crisis, with 87,042 cases reported worldwide by April 30, 2023, mainly among men who have sex with men (MSM) [5]. The potential worldwide impact of mpox necessitates an urgent need for an improved understanding of the disease’s epidemiology, symptomatology, and management.

Prior to the 2022 worldwide pandemic, mpox was considered a rare disease with a low case fatality rate (CFR, <10%) in comparison to its closely related virus, variola major (CFR=30%) [6]. Despite this, mpox remained a serious health threat in the DRC and other countries in Western and Central Africa [7], particularly among the pediatric population and patients with immunodeficiency [8]. The incubation period of mpox ranges from 5 to 21 days and is characterized by nonspecific symptoms, such as fever, headache, and lymphadenopathy [9]. Skin lesions were observed in 95% of cases, with rashes being the most common symptom, typically appearing on the face and extremities within 1-3 days after the onset of fever [10,11]. The diverse range and frequency of the clinical symptoms of mpox are influenced by various risk factors, including modes of transmission and demographics of affected populations [12]. For example, since 2022, the majority of mpox cases have occurred among MSM, resulting in comorbidity with other infectious diseases, such as HIV and syphilis [13]. An improved understanding of the clinical profile of mpox can aid in the development of effective strategies for managing and responding to outbreaks of the disease.

Before the onset of the pandemic in 2022, limited and outdated data existed regarding the epidemiology and clinical characteristics of mpox from an epidemiological perspective [14-16]. However, since the emergence of the worldwide mpox pandemic in 2022, numerous reviews and meta-analyses have begun to investigate the symptoms of mpox, although most focus only on 2022 [17-20]. Only 2 papers have compared mpox symptom prevalence before and after 2022, with limitations including sparse literature, especially prior to 2010 [21,22], and a lack of correlation analyses between symptoms. Therefore, there is a need for a comprehensive longitudinal analysis to investigate the evolution of mpox symptoms and their changes over time.

Objective

To address this gap, we conducted a review and meta-analysis to comparatively analyze mpox symptom prevalence and correlations during 3 periods: 1970-2002 in Africa; 2003-2021 in Africa, Europe, and North America; and 2022-2023 worldwide.

Methods

Protocol Registration

This research adheres to the methodological recommendations of the Cochrane systematic review methodology guidance [23] and conforms to the guidelines of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) statement (see the PRISMA checklist in Table S9 in Multimedia Appendix 1) [24]. This study has been registered with PROSPERO (International Prospective Register of Systematic Reviews; registration number CRD42023403282).

Search Strategy

Two independent investigators (authors SS and MJ) conducted a comprehensive literature search of peer-reviewed research papers published from January 1970 to April 2023 in the following English literature databases: PubMed, Web of Science, and ScienceDirect. We also searched all mpox-related public databases. Keywords pattern in the database search were used through combinations of monkeypox (eg, “monkeypox” OR “monkeypox virus” OR “human monkeypox”), symptoms (eg, “symptoms” OR “characteristics” OR “clinical characteristics” OR “clinical symptoms”), or cases (eg, “cases” OR “cases report”) and excluded reviews. Full details of the search strategy are listed in Table S1 in Multimedia Appendix 1. A manual search of the reference lists of the published papers was also performed.

We restricted our search to research conducted on humans with observational studies, discarding veterinary investigations. Papers were included if they contained clinical or epidemiological information relevant to the current monkeypox virus outbreak or historical information to establish context. The following types of publications were excluded: news reports, conference abstracts, mathematical modeling studies, dissertations, and studies with mpox self-reported prevalence. Two independent investigators (SS and MJ) confirmed the eligibility of each study; if necessary, a third senior reviewer (author PH) resolved differences. The PRISMA flow diagram was applied to report the paper search process.

The following information was collected from each of the studies: authors, publication year, title, study design, study period, study area, sample size, study population, age, and
To assess the impact of bias on our findings, we conducted a Sensitivity Analysis using ROBINS-I tool for nonrandomized controlled trial assessment. At the protocol stage, we specified the review question of participants as confirmed patients with mpox and outcomes as any symptom report. Additionally, we listed the confounding domains relevant to all studies, including time-varying confounding and baseline confounding, and the cointerventions that could be different between intervention groups and that could impact outcomes, such as any treatment. We assessed the overall risk of bias according to 7 items: bias due to confounding, bias in the selection of participants for the study, bias in the classification of interventions, bias due to deviations from intended interventions, bias due to missing data, bias in the measurement of outcomes, and bias in the selection of the reported result. Each item was classified as low risk, moderate risk, serious risk, or critical risk of bias. The overall risk of bias was assessed according to the results of the 7 items [25]. The detailed results are shown in Table S2 in Multimedia Appendix 1.

Study Period
In this review, we classified the mpox epidemics into 3 distinct periods. Period 1, spanning from 1970 to 2002, was characterized by the limited transmission of the virus within the African region. Period 2, spanning from 2003 to 2021, marked the first outbreak of mpox outside Africa, with confirmed cases reported in the United States, the United Kingdom, Singapore, and Israel. Period 3, from 2022 to 2023, witnessed an unprecedented worldwide explosion of mpox cases.

Meta-Analysis
To estimate the prevalence of mpox symptoms, we conducted meta-analyses by combining data from various studies using random effects models that fitted study-specific effects. We calculated corresponding 95% CIs. Heterogeneity analysis was performed to quantify the inconsistency among results, and it was expressed using $I^2$, a quantity representing the degree of heterogeneity from 0% to 100%. Therefore, $I^2$ with experience values of 25%, 50%, and 75% indicated low, moderate, and high heterogeneity, respectively [26]. The meta-analyses were conducted using R Studio software (version 2023.06.2, build 561), which is a specialized integrated development environment (IDE) designed for R programming (version 4.2.1, R Foundation for Statistical Computing).

Sensitivity Analysis
To assess the impact of bias on our findings, we conducted a sensitivity analysis by excluding studies with a moderate and higher risk of bias, thereby including only low-risk studies in a subgroup meta-analysis.

Subgroup Analysis
To assess the impact of geographical differences on our findings, we conducted a subgroup analysis by grouping patients based on the regional distribution of the World Health Organization (WHO). $P \leq 0.05$ was considered a statistically significant difference in prevalence among regions.

Network Analysis
We also conducted a network analysis to compare changes in mpox symptoms across the 3 periods and created nodes (symptoms) and edges (symptom correlation). Within each period, the edge color reflected the correlation properties, where pink color represented positive correlation; thickness indicated the correlation strength between symptoms, where correlations were calculated through Spearman intragroup correlation analyses using R software v4.2.1 and filtered significantly correlated ($P \leq 0.05$) symptom pairs. Similarly, the size and color depth of the nodes represented degrees, which were acquired through clustering analyses of a subset of nodes and visualized using Cytoscape software (v3.7.2).

Results
Overview
The initial search strategy included 2916 unique titles. After excluding 825 (28.3%) duplicate records and 516 (17.7%) unrelated subjects, 1575 (54%) studies remained. Of these, 142 (9%) full-text papers were retrieved. The majority were excluded for reasons such as being drug or biological studies, comments, reviews, or conference papers. After reviewing the 142 papers, 19 (13.4%) were excluded due to duplicate data, while 24 (16.9%) and 38 (26.8%) contained unclear or incomplete information, respectively. Additionally, 19 (13.4%) papers presented the same outbreak with duplicate data. Ultimately, our systematic review and meta-analysis included 61 (43%) papers that provided information about cases and symptoms (Figure 1). Of these, 29 (47.5%) papers were assessed as having low risk of bias, 23 (37.7%) were assessed as having moderate risk of bias, 4 (6.6%) exhibited a serious risk of bias, while the remaining 5 (8.2%) were categorized as having a critical risk of bias (Table S2 in Multimedia Appendix 1).

From 1970 to 2002 (period 1), all 720 patients from Africa were included in our meta-analysis (n=4, 6.6%, studies). The median age was 5.4 years (IQR 2.7-9.8; from n=3, 75%, of 4 studies). The proportion of male patients was 34.9% (n=251, range 15.9-56.8%; from n=4, 6.6%, studies). From 2003 to 2021 (period 2), a total of 12 (19.7%) studies were included. Most of the 1756 patients were also from Africa (n=1259, 71.7%, patients from n=5, 41.7%, studies), followed by the Americas (n=457, 26%, patients from n=3, 25%, studies), Europe (n=5, 0.3%, patients from n=2, 16.7%, studies), and the Western Pacific (n=2, 0.1%, patients from n=2, 16.7%, studies). The median age was 21.7 years (IQR 13.6-32.1; from n=8, 66.7%, studies), and the proportion of male patients was 53.3% (n=934; from n=11, 91.7%, studies).
From 2022 to 2023 (period 3), 45 (73.7%) studies involving 12,277 patients were included in our study. A total of 9587 (78.1%) patients were reported in the Americas (n=13, 28.9%, studies), followed by Europe (n=1680, 13.7%, patients from n=24, 5.3%, studies). The median age was 34.5 years (IQR 28.5-42.0; from n=45, 100%, studies), and the proportion of male patients was 86.7% (n=10,640; from n=45, 100%, studies).

Among the male patients, the proportion of MSM was 88.8% (n=2340; from n=27, 60%, studies), with HIV (n=2116, 37.8%; from n=30, 66.7%, studies), syphilis (n=125, 18.4%; from n=9, 20%, studies), and other sexually transmitted infections (STIs; n=221, 23.6%; from n=6, 13.3%, studies). The study details are given in Table 1. The period prevalence was calculated for each period (Figure S1 in Multimedia Appendix 1).

### Clinical Symptom Prevalence

We conducted a meta-analysis of 21 symptoms reported from 1970 to 2002 (Figure 2). The most commonly reported symptoms were fever (99%, 95% CI 97%-100%), rash (92.6%, 95% CI 78.2%-100%), and enlarged lymph nodes (80.5%, 95% CI 75.4%-85.0%). These were followed by headache (69.1%, 95% CI 4%-100%), lymphadenopathy (59.8%, 95% CI 50.3%-69.2%), malaise/bedridden status/asthenia (52.4%, 95% CI 44.8%-60.0%), tonsillitis (51.4%, 95% CI 45.4%-57.4%), swelling (51.3%, 95% CI 39.7%-62.8%), mouth ulcers (49.1%, 95% CI 43.7%-54.5%), sore throat (47.5%, 95% CI 25.2%-69.7%), cough (38%, 95% CI 33.7%-42.3%), genital ulcers (25.2%, 95% CI 20.2%-30.7%), sweating/joint pain (16.7%, 95% CI 0.4%-64.1%), stiff neck (16.7%, 95% CI 0.4%-64.1%), conjunctivitis (16.7%, 95% CI 12.5%-21.5%), and hepatomegaly (10.3%, 95% CI 7.0%-14.4%). The prevalence of proctalgia/diarrhea, nausea/vomiting, dehydration, tenesmus, corneal opacity/photophobia, and alopecia was relatively low (<10%).

In our meta-analysis covering the period of 2003-2021, we identified 38 symptoms associated with mpox (Figure 3). Rash was the most prevalent symptom (100%, 95% CI 99.9%-100%), followed by fever (88%, 95% CI 82.1%-94.0%) and...
lymphadenopathy (74.1%, 95% CI 64.2%-84.1%). The former decreased, while the latter increased. Chills/rigors (73.3%, 95% CI 60.9%-85.7%), adenopathy (70.6%, 95% CI 52.5%-84.9%), fatigue (68.2%, 95% CI 51.6%-84.8%), difficulty breathing (63.2%, 95% CI 38.4%-83.7%), dysphagia/difficulty swallowing (61.2%, 95% CI 10.5%-100%), itching (59.2%, 95% CI 45.2%-73.2%), myalgia (52.7%, 95% CI 35.6%-69.8%), and diarrhea (50.3%, 95% CI 0%-100%) were newly reported but remained highly prevalent. The prevalence of genital ulcers (57.1%, 95% CI 43.0%-71.1%) increased compared to the period of 1970-2002, while sweating/joint pain (63.9%, 95% CI 49.8%-78.1%), mouth ulcers (53.6%, 95% CI 33.0%-74.3%), and cough (43%, 95% CI 28.0%-57.9%) remained steady. The prevalence of body pain (43.4%, 95% CI 25.4%-61.4%), shortness of breath (39.5%, 95% CI 0%-84.1%), anorexia (30%, 95% CI 0.0%-72.2%), corneal opacity/photophobia (27.1%, 95% CI 18.9%-35.3%), arthralgia (22.1%, 95% CI 16.0%-29.2%), nasal congestion/rhinorrhea (20%, 95% CI 3.5%-36.4%), and hemorrhagic skin lesions (12.5%, 95% CI 4.2%-26.8%) was newly reported but was <50%. The prevalence of malaise/bedridden status/asthenia (32.3%, 95% CI 4.8%-59.8%), conjunctivitis (23.2%, 95% CI 13.4%-33.1%), and stiff neck (11.8%, 95% CI 3.3%-27.5%) remained steady compared to the former period, while nausea/vomiting (20%, 95% CI 12.4%-27.5%) increased. The prevalence of 10 (26.3%) other symptoms was <10%, of which 7 (70%) were newly reported symptoms: tongue sores, dehydration, ear pain, wheezing, confusion, scrotal edema, and seizures. Swelling, which was reported from 1970 to 2002, had a decreased prevalence of 7.7% (95% CI 0%-14.7%), while hepatomegaly (9.5%, 95% CI 0%-22.7%), swelling, and proctalgia/diarrhea (5.9%, 95% CI 0.7%-19.7%) remained steady in this period.

Since 2022, the included literature reports have listed 37 clinic characteristics observed in patients during the mpox pandemic (Figure 4). Rash was the most prevalent symptom among patients, and its prevalence (94.8%, 95% CI 90.9%-98.8%) was higher than that of other symptoms, similar to the 2003-2021 period, followed by fever (61.1%, 95% CI 56.7%-66.6%), enlarged lymph nodes (51.8%, 95% CI 40.8%-62.7%), headache (37.9%, 95% CI 32.0%-43.8%), and chills/rigors (36.6%, 95% CI 25.5%-47.7%), which were lower than the periods from 2003 to 2021. Furthermore, flu-like symptoms (49.2%, 95% CI 41.6%-56.7%), perianal ulcer (40.8%, 95% CI 33.6%-48.0%), dysuria (33.1%, 95% CI 57.2%-60.5%), perioral lesion (22.9%, 95% CI 9.8%-36.0%), rectal bleeding (15.1%, 95% CI 1.6%-28.6%), tonsillitis (11.7%, 95% CI 8.1%-15.3%), difficulty breathing (11.7%, 95% CI 8.1%-16.3%), pus or blood in stools (11.5%, 95% CI 10.7%-12.2%), tenesmus/constipation (10.7%, 95% CI 10.0%-11.5%), perianal ulcer (9.9%, 95% CI 4.3%-15.5%), and tenesmus/constipation (9.4%, 95% CI 6.4%-12.4%) were newly reported and had a lower prevalence. Other past reported symptoms, including dysphagia/difficulty swallowing (27.9%, 95% CI 21.1%-34.7%), scrotal edema (25.9%, 95% CI 0%-60.8%), body pain (22.6%, 95% CI 10.4%-34.7%), arthralgia (21%, 95% CI 0.8%-41.2%), proctalgia/diarrhea (16.7%, 95% CI 1.8%-25.6%), nausea/vomiting (13.3%, 95% CI 2.2%-24.5%), corneal opacity/photophobia (10.4%, 95% CI 0%-25.5%), nasal congestion/rhinorrhea (7.1%, 95% CI 0%-16.2%), and seizures (0.7%, 95% CI 0%-4.1%) remained steady, while the prevalence of sore throat (25.1%, 95% CI 20.4%-29.9%), mouth ulcers (13.7%, 95% CI 8.2%-19.2%), cough (8.1%, 95% CI 3.9%-12.3%), and conjunctivitis (5.4%, 95% CI 4.6%-6.2%) was lower than that in former periods.

The prevalence of symptoms from 1970 to 2023 was included in the meta-analysis as well, involving 51 reported symptoms from 13,196 patients (Figure 5). Generally, rash (95.1%, 95% CI 92.0%-98.3%) was the prevalent symptom, followed by adenopathy (70.6%, 95% CI 52.5%-84.9%), fever (69.3%, 95% CI 63.9%-74.1%), and lymphadenopathy (61.0%, 95% CI 55.7%-66.3%), enlarged lymph nodes (55.4%, 95% CI 43.7%-67.1%), itching (52.8%, 95% CI 34.2%-71.3%), fatigue (52.6%, 95% CI 41.9%-63.2%), and diarrhea (50.3%, 95% CI 0%-100%). The prevalence of the other 40 (78.4%) symptoms was <50%. The prevalence of 14 (27.5%) symptoms ranged from 30% to 50%, including flu-like symptoms (49.2%, 95% CI 41.6%-46.7%), sweating/joint pain (47.9%, 95% CI 29.1%-66.8%), and chills/rigors (47.2%, 95% CI 33.5%-60.9%). For 17 (33.3%) symptoms, the prevalence ranged from 10% to 30%, including body pain (28.6%, 95% CI 17.4%-39.8%), mouth ulcers (27.9%, 95% CI 15.1%-40.7%), and cough (26%, 95% CI 15.3%-33.6%). Another 9 (17.6%) symptoms, such as tongue sores (9.5%, 95% CI 1.2%-30.4%), ear pain (8.8%, 95% CI 1.9%-23.7%), and tenesmus (8.5%, 95% CI 5.4%-11.6%), had <10% prevalence.
Figure 2. Meta-analysis of the prevalence of clinical symptoms among mpox patients from 1970 to 2002. mpox: monkeypox.

Figure 5. Meta-analysis of the prevalence of clinical symptoms among mpox patients from 1970 to 2023. mpox: monkeypox.

Sensitivity Analysis

We excluded studies with moderate and higher risk of bias, including 3 (4.9%) studies from 1970 to 2002, 6 (9.8%) studies from 2003 to 2021, and 23 (37.7%) studies since 2022 (Table S2 in Multimedia Appendix 1). A total of 29 (47.5%) studies were included in the sensitivity analysis. In the 3 periods, rash (period 1: 100.00%, 95% CI 98.7%-100%; period 2: 99%, 95% CI 97.1%-100.00%; and period 3: 93.1%, 95% CI 87.7%-98.6%) was the most common symptom, followed by fever (period 1: 100.00%, 95% CI 98.7%-100%; period 2: 89.4%, 95% CI 83.1%-95.6%; and period 3: 58.3%, 95% CI 52.8%-63.7%). The other symptoms with a relatively higher prevalence included lymphadenopathy, headache, and fatigue. Significantly, symptom prevalence from 1970 to 2002 changed compared to former meta-analysis results, while that in the other 2 periods did not, and almost all symptom prevalence decreased since 2022 (Figure S2 in Multimedia Appendix 1).
Subgroup Meta-Analysis

To compare the geographical differences in clinical symptoms, we performed a subgroup analysis of the symptom prevalence in 3 periods (2003-2021, 2022-2023, and 1970-2023) based on the WHO regional distribution. We did not conduct a subgroup analysis for the period from 1970 to 2002 since all patients were in the African region. From 2003 to 2021, 30 symptoms were reported in Africa, 26 in the Americas, 6 in Europe, and 10 in the Western Pacific. The overall prevalence of symptoms was highest in Africa, particularly in terms of rash (100%, 95% CI 99.9%-100%), fever (92%, 95% CI 85.7%-98.2%), dysphagia/difficulty swallowing (85.5%, 95% CI 57.4%-100%), chills/rigors (73.9%, 95% CI 55.3%-92.5%), headache (66.3%, 95% CI 52.9%-79.6%), shortness of breath (63.2%, 95% CI 38.4%-83.7%), and conjunctivitis (25.3%, 95% CI 17.3%-33.4%), which were significantly higher than in some areas (P ≤ 0.05). Furthermore, characteristic symptoms in African cases included difficulty breathing (63.2%, 95% CI 38.4%-83.7%), genital ulcers (57.1%, 95% CI 43.0%-71.1%), mouth ulcers (53.6%, 95% CI 33.0%-74.3%), anorexia (30%, 95% CI 0%-72.2%), corneal opacity/photophobia (27.1%, 95% CI 18.9%-35.3%), 78.7%), and hemorrhagic skin lesions (12.5%, 95% CI 4.2%-26.8%), whose prevalence was >10%. However, the prevalence of nausea/vomiting (59.7%, 95% CI 0%-100%) in cases from the Americas was higher than in Africa (P ≤ 0.05), and some characteristic symptoms, including adenopathy (70.6%, 95% CI 52.5%-74.9%) and stiff neck (11.8%, 95% CI 33.0%-27.5%), were reported exclusively in the Americas (Table S3 in Multimedia Appendix 1).

Since 2022, cases have been primarily concentrated in the Americas (27 symptoms) and Europe (25 symptoms), with fewer patients reported in the Western Pacific (12 symptoms) and Eastern Mediterranean (7 symptoms) and no cases reported in Africa. The prevalence of symptoms in the 4 regions had generally no significant difference. However, the risk of enlarged lymph nodes (61.3%, 95% CI 49.3%-73.2%) and rectal bleeding (60%, 95% CI 36.1%-80.9%) in European cases was higher than in the Americas (P ≤ 0.05). Eastern Mediterranean cases exhibited a higher prevalence of headache (100%, 95% CI 15.8%-100%) and fatigue (100%, 95% CI 15.8%-100%), but the number of cases was relatively low. Additionally, the characteristic symptom presentations in the Americas were sweating/joint pain (35.2%, 95% CI 32.4%-38.2%), nausea/vomiting (18.1%, 95% CI 3.5%-32.7%), pus or blood in stools (11.7%, 95% CI 6.2%-17.3%), and tenesmus/constipation (10.6%, 95% CI 8.4%-12.9%) and in Europe were flu-like symptoms (49.2%, 95% CI 41.6%-56.7%), scrotal edema (45.5%, 95% CI 24.7%-66.2%), arthralgia (32.4%, 95% CI 0%-75.6%), corneal opacity/photophobia (18.7%, 95% CI 0%-51.1%), tonsillitis (11.7%, 95% CI 8.1%-15.3%), and difficulty breathing (11.7%, 95% CI 8.1%-16.3%); see Table S4 in Multimedia Appendix 1.

The merged periods showed more differences in symptom prevalence among regions. Generally, rash was a prevalent symptom, with its prevalence reaching close to 100% in all regions. Africa had the highest prevalence of the most symptoms, such as fever (94.5%, 95% CI 89.9%-99.0%), headache (68%, 95% CI 51.7%-84.3%), and chills/rigors (73.9%, 95% CI 55.3%-92.5%; P ≤ 0.05), followed by the Americas and Europe, which showed similar risks for the main symptoms. Nonendemic regions, such as the Western Pacific and Eastern Mediterranean, reported fewer symptoms, and the prevalence of the main symptoms was similar to that in Europe and the Americas (Table S5 in Multimedia Appendix 1).

Association Between Clinical Symptoms

We conducted Pearson correlation analysis on the clinical symptoms, screening out significantly correlated paired symptoms (P ≤ 0.05) and drawing a network diagram of 3 periods: 2003-2021, 2022-2023, and the overall period of 1970-2023 (Figure 6a-c). From 1970 to 2002, only 14 symptoms were found due to insufficient literature data, so we did not draw a network diagram specifically for this period.
Figure 6. Network diagram of clinical symptoms among mpox patients in (A) 2003-2021, (B) 2022-2023, and (C) 1970-2023. mpox: monkeypox.

A total of 37 symptoms showed a significantly positive correlation from 2003 to 2021 (Figure 6a). Among them, nausea/vomiting was variable with the highest degree of correlation and was positive correlated with 13 symptoms: lymphadenopathy ($r=0.908$), conjunctivitis ($r=0.900$), cough ($r=0.878$), chills/rigors ($r=0.791$), headache ($r=0.739$), photophobia ($r=0.720$), fatigue ($r=0.713$), fever ($r=0.693$), corneal opacity ($r=0.676$), rash ($r=0.652$), mouth ulcers ($r=0.648$), malaise/bedridden status/asthenia ($r=0.648$), and myalgia ($r=0.648$). This was followed by lymphadenopathy (correlated with 12 symptoms), conjunctivitis (12 symptoms), nasal congestion/rhinorrhea (11 symptoms), swelling (11 symptoms), headache (11 symptoms), cough (11 symptoms), shortness of breath (11 symptoms), and chills/rigors (10 symptoms). A total of 11 symptoms (proctalgia/diarrhea, mouth ulcers, rash, fever, photophobia, stiff neck, ear pain, wheezing, confusion, seizures, and adenopathy) were correlated with 9 other symptoms. In addition, corneal opacity was correlated with 8 symptoms, myalgia with 7 symptoms, and fatigue and genital ulcers with 6 symptoms. Another 13 symptoms (hepatomegaly, dehydration, tongue sores, dysphagia/difficulty swallowing, malaise/bedridden status/asthenia, anorexia, body pain, scrotal edema, hemorrhagic skin lesions, difficulty breathing, sore throat, sweating/joint pain, and diarrhea) had no more than 5 correlated clinic characteristics.

Since 2022, a more complicated network diagram involving 33 symptoms illustrated a substantial positive correlation (Figure 6b). Generally, rash and headache had the highest degrees of correlation and were correlated with 21 symptoms. The symptom with the highest correlation with rash was fever ($r=0.918$), followed by lymphadenopathy ($r=0.789$), headache ($r=0.787$), body pain ($r=0.610$), malaise/bedridden status/asthenia ($r=0.575$), genital ulcers ($r=0.558$), proctalgia/diarrhea ($r=0.554$), pus or blood in stools ($r=0.549$), tenesmus ($r=0.548$), perianal ulcer ($r=0.543$), and rectal bleeding ($r=0.508$). In addition, fever and rash were also the most highly correlated with headache ($r=0.789$ and 0.788, respectively). Other symptoms with a high degree of correlation included body pain (20 symptoms), fever (19 symptoms), malaise/bedridden status/asthenia (19 symptoms), chills/rigors (19 symptoms), rectal bleeding (19 symptoms), pus or blood in stools (18 symptoms), tenesmus (18 symptoms), enlarged lymph nodes (17 symptoms), perianal ulcer (17 symptoms), and proctalgia/diarrhea (17 symptoms).

We also mapped the network diagram after merging 3 periods. The symptom with the highest number of associated symptoms ($n=26$) was headache (Figure 6c). Among them, the 2 symptoms with the highest correlation were fever ($r=0.780$) and rash ($r=0.754$), followed by lymphadenopathy ($r=0.576$), myalgia ($r=0.507$), and proctalgia/diarrhea ($r=0.500$); the $r$ value for the other 21 symptoms was $<0.500$. Conjunctivitis had the second-highest degree of correlation and was correlated with 25 symptoms: it has high correlation with nausea/vomiting ($r=0.844$), and the correlation with the other 24 symptoms was relatively low ($r<0.05$). Other symptoms with a high degree of correlation included body pain (23 symptoms), nausea/vomiting (23 symptoms), cough (23 symptoms), nasal
congestion/rhinorrhea (23 symptoms), rash (22 symptoms), fever (21 symptoms), chills/rigors (21 symptoms), rectal bleeding (19 symptoms), malaise/bedridden status /asthenia (18 symptoms), proctalgia/diarrhea (17 symptoms), pus or blood in stools (17 symptoms), shortness of breath (17 symptoms), and tenesmus (17 symptoms).

We extensively researched the data related to the mpox death toll reports between 1970 and 2023 from various literature sources and websites. The findings are presented in Table S6, Table S7, and Figure S8 in Multimedia Appendix 1. Initially, high case fatality rates (CFRs) were predominantly observed before 1986: CFR=16.7% in 1970, 60% in 1972, 33.3% in 1973, 16.7% in 1975, 23.1% in 1978, and 9.7%-12.5% from 1981 to 1985. No death cases were reported from 1987 to 1995. Subsequently, CFRs remained below 6% between 1996 and 2022. The highest CFR occurred in 2016 (5.7%), followed by 2002 (4.2%), 2008 (4.2%), and 2001 (3.8%). In 2022, the CFR of mpox decreased to 0.09% but increased to 1.85% in 2023. The countries with the highest CFRs in 2023 were Belgium (33.33%), Peru (7.64%), and the United States (4.45%); see Figure S3c in Multimedia Appendix 1. To investigate the relationship between symptoms and death, we included 6 (9.8%) papers reporting outcome indicators related to death. The network analysis showed that rash (r=0.841), nausea/vomiting (r=0.832), conjunctivitis (r=0.832), and corneal opacity/photophobia (r=0.912) were significantly associated with mortality (P≤0.05); see Figure S4 in Multimedia Appendix 1.

**Discussion**

**Principal Findings**

The clinical symptoms of mpox have shown a decreasing prevalence over time, except for the specific symptom of rash, which has remained consistent. However, there has been an increasing concurrent prevalence of symptoms, resulting in a more complex correlation among them. The prevalence estimates of most symptoms were higher in Africa from 1970 to 2021, with about half of them occurring since 2003. The risks have shifted to Europe and the Americas since the 2022 outbreak, accompanied by increases in age and the proportions of males and MSM among the patients.

**General Evolution Trends**

An important highlight is that the presence of rash remained consistent in confirmed cases of monkeypox across all periods studied. This characteristic rash plays a vital role in the accurate diagnosis of poxvirus infections, emphasizing its significance as a key determinant in distinguishing monkeypox from other similar conditions [27]. A consistent and noteworthy trend observed throughout various periods is the continuous reporting of key symptoms, such as fever, lymphadenopathy, headache, cough, and sore throat, in cases of mpox. Although some of these symptoms have displayed a higher prevalence compared to others, they have remained steady since 2003 and decreased since the onset of the 2022 pandemic, which is roughly consistent with the previous 2 meta-analyses with pre- and post-2022 studies [21,22]. Especially in the pandemic since 2022, the prevalence of coreported symptoms was similar to other meta-analyses in 2022 [17,18]. As all symptoms were included in our study, it was observed for the first time that the number of symptoms has increased since 2003 and has remained steady throughout the worldwide pandemic. The decrease in the prevalence of nonspecific symptoms indicated an increase in asymptomatic cases, while new symptoms emerged, revealing a complex correlation among symptoms due to the evolution of mpox influenced by various factors.

**Geographical Differences**

The main reason for this evolution can be explained by differences in the geographical characteristics, population structure, virus source, transmission routes, and medical environment among the 3 periods. Before 2022, Africa emerged as the primary endemic region, exhibiting higher mpox prevalence and more reported symptoms. The epidemic trend can be divided into 2 periods, based on the characteristic patterns of symptom prevalence: before and after the virus spread to the Americas. In the first period (1970-2002), the patients with mpox all occurred in Midwest Africa, and children had the highest proportion among confirmed cases, which was because most of them had not been vaccinated against smallpox, resulting in a higher case prevalence. It was reported that severe symptoms of mpox tend to manifest more frequently in children rather than in adults [14]. As a consequence, fever, enlarged lymph nodes, and headache were reported with a higher prevalence and were closely associated with the risk of rash. Although mpox has been reported in non-African countries since 2003, the disease remains predominantly prevalent in central African nations. During this transitional period, there has been a gradual increase in the average age of patients and the proportion of male patients affected by monkeypox. Therefore, the polled prevalence of primary symptoms experienced a mild decrease from 2003 to 2021. However, the African patients still remained at higher risk of main symptoms and reported new symptoms, compared to nonendemic regions, such as Europe and the Western Pacific, while most nonendemic regions cases were imported from Africa. As the first outbreak outside Africa, cases in the Americas were mostly confirmed in 2003, with relatively higher reported symptom prevalence. Since the 2022 outbreak, Europe and the Americas emerged as 2 epidemic regions that reported a majority of diagnosed cases, with predominantly adult patients, resulting in a relatively favorable clinical presentation in patients. The prevalence of coreported symptoms exhibited consistent characteristics thorough the epidemic and nonendemic regions. Additionally, a higher number of confirmed cases and more comprehensive treatment modalities in endemic regions led to more than half of the newly reported symptoms, while the prevalence was generally lower.

**Clade Evolution**

The varying clades of the mpox virus could potentially exert a significant influence on symptom severities. Two major clades, the Congo Basin clade (clade I) and the West African clade (clade II), evolved from Africa and exhibited a potential impact on the clinical characteristics of patients with mpox. The Congo Basin clade was reported from 1970 to 2018 and is associated with severe disease and higher mortality [28]. The West African...
clade is associated with mild lower mortality and is divided into clade IIA and clade IIB [15,28,29], the former being reported only in the west of the Dahomey Gap from 1962 to 1971 and the United States in 2003 and the latter being reported in Nigeria from 1971 to 1978 and from 2017 to 2019 and worldwide since the 2022 outbreak [30]. Therefore, although the majority of the literature we included did not report branch data, it can be confirmed that a contributing factor to the significantly reduced severity of symptoms in 2022 was the lower virulence of clade IIB compared with clade I [31]. However, concerning the period before 2022, the impact of clades is rather intricate. For the African cases between 2003 and 2021, the prevalence remained unchanged or increased compared to pre-2003, while the prevalence of symptoms in other regions during the same period was relatively lower. For instance, the mpox outbreak in the United States in 2003 was caused only by clade IIA. Despite having a similar clinical characteristic to Africa, the prevalence of symptoms such as chills/rigors, dysphagia/difficulty swallowing, conjunctivitis, and shortness of breath was significantly lower. In addition, the disease has transitioned from being primarily animal-to-human transmitted to being human-to-human transmitted [10]. Animal-to-human transmission mostly occurred in 1970-2002. In nonendemic countries [13], few cases have been reported that were linked to international travel or the importation of animal-to-human monkeypox infection from 2003 to 2021 [32]. Mpox infection at this stage was not attributed to person-to-person contact [33]. In 2022, the majority of cases, with a few exceptions, were identified following instances of human-to-human sexual contact [34]. Reduction in symptom severities may depend on the viral clade [33] to better adapt to human-to-human transmission. Furthermore, favorable living environments and advanced medical conditions in high-income countries or regions may also explain the decrease in symptom prevalence since the 2022 outbreak.

Correlation Among Symptoms

Although the escalation in the number of comorbidities resulted in more intricate interconnections between symptoms, which mutually reinforced the correlation between them in our network diagram. This can be explained by more detailed symptom reports, which contribute to enhanced monitoring and advanced medical conditions. More importantly, a fact is that all symptoms are positively correlated, indicating that they are mutually reinforcing. Furthermore, the human-to-human transmission route has changed. Although HIV-related complications were noted during the monkeypox outbreak in Nigeria from 2017 to 2018, no substantiated evidence exists to indicate that the patients engaged in MSM behavior [35]. Subsequent to the outbreak in 2022, the studies incorporated in our analysis have consistently revealed a predominance of male patients, a substantial proportion of whom reported engaging in MSM behavior. These individuals also presented with coinfection, including HIV, syphilis, and various other STIs. Therefore, the mpox virus transmitted through MSM behavior has caused a rise in the number of additional symptoms, particularly an increase in the prevalence of symptoms associated with MSM behavior, such as perianal ulcer, pus or blood in stools, rectal bleeding, tenesmus/constipation, and dysuria. This may lead to complex response measures and treatment modalities.

Risks Factors of CFRs

All evidence suggests that the mpox virus is becoming mild, including a decrease in hospitalization rates in the reported literature [36] and the CFR in our collected data. The CFR is a complex outcome and not only is influenced by differences in symptoms caused by mpox clades but also is significantly correlated with patients’ age and local economic conditions [37]. This is one of the reasons why the CFR was higher before 2003. However, the CFR rebounded in 2023. This may be due to the lag in reporting death data compared to confirmed reports. However, the STI coinfection caused by sexual contact may have a synergistic effect with the mpox virus, increasing the severity of the disease.

Implications

Our findings are crucial for a comprehensive understanding of the mpox epidemic and for guiding an adequate policy from an epidemiological perspective. First, surveilling the evolving nature of mpox and the consequential changes in clinical characteristics is advised, especially in the epidemic regions, where the policy makers may shift their focus on the potential association between symptoms and the synergy risks to mortality. Furthermore, mpox can be influenced by a range of environmental and human factors. If appropriate measures are not taken to mitigate these factors, there is a heightened likelihood of a resurgence of the epidemic. Therefore, it is crucial to maintain ongoing vigilance and surveillance efforts, even in areas or periods when the disease appears to have been eliminated, in order to rapidly detect and respond to outbreaks and prevent the spread of the disease. However, targeted vaccination programs can be implemented for high-risk populations, including health care workers, laboratory workers, and those working with animals. Finally, efforts to raise public awareness, particularly within high-risk populations, such as MSM, should also be prioritized to help ensure timely detection and response to any potential outbreaks.

Limitations and Strengths

This systematic review and meta-analysis has several limitations. First, the clinical symptoms were only collected from available data, so the results may fail to represent all patients with mpox, especially those in low- and middle-income countries in early studies. The included studies from 1970 to 2002 were limited and of low quality. Especially after 1986, WHO terminated the surveillance program for mpox, which may have underestimated the severity of the symptoms in the results. Second, the symptoms reported during 3 study periods were likely to have bias due to the varying study designs of each year. In addition, the different strains of mpox and transmission routes may have had a direct relevance for how clinically severe the illness was during the study period, which requires further genome-wide analysis to confirm it. In future analyses, it is important to consider other sources of heterogeneity that were not fully documented before the 2022 outbreak, such as age, case determination, and comorbidities. Finally, we cannot confirm which symptoms pose a higher risk of mortality during the
worldwide outbreak since 2022, as limited data have simultaneously reported both the clinical presentation and the outcome of death; therefore, further evidence is needed to interpret this correlation.

Despite this, our review has carefully considered the changing trend of mpox symptoms since the first diagnosis in 1970 and also collected data on the number of confirmed cases of and deaths due to monkeypox in various countries over the years. It provided the evolution tendency of mpox, which can be used for making a related health policy. For example, we may improve treatment targeting for the common symptoms of mpox; according to demographic characteristics, we could suggest building an effective surveillance system for high-risk populations, especially in high-prevalence regions.

Conclusion
During the worldwide mpox outbreak, the clinical symptoms, including rash, resembled what they had been prior to the outbreak; however, some unique symptoms and changes in transmission route should be noted. The exponential increase in positive cases in Europe and the United States may help build relevant early-warning systems to prevent more mpox cases.

Abstract

This study demonstrated that fibrinogen is an independent risk factor for 10-year mortality in patients with acute coronary syndrome (ACS), with a U-shaped nonlinear relationship observed between the two. These findings underscore the importance of monitoring fibrinogen levels and the consideration of long-term anti-inflammatory treatment in the clinical management of patients with ACS.

(JMIR Public Health Surveill 2024;10:e54485) doi:10.2196/54485

Introduction

Identification of risk factors is essential in patients with coronary artery disease. As an important inflammatory factor and a key participant in coagulation, fibrinogen has attracted attention in the management of acute coronary syndrome (ACS). Previous research has also demonstrated that as an acute-phase protein, the levels of fibrinogen and its degradation products are higher in patients with COVID-19 than in the healthy population [1]. However, the relationship between fibrinogen levels and the prognosis of patients with ACS remains controversial [2]. Our previous study found that fibrinogen was an independent risk factor for mortality during the follow-up in patients with coronary artery disease [3]. In the ACS subgroup, no correlation was found between fibrinogen levels and mortality. In addition, the quantitative relationship between fibrinogen levels and the risk of mortality across a longer follow-up period needs further clarification.

Methods

Overview
We performed a prospective, large-scale, single-center study (Chinese Clinical Trial Registry ChiCTR 2100049313) to investigate the effect of fibrinogen levels on ACS prognoses. Patients were grouped according to the 5 quantile levels of plasma fibrinogen at admission. We used Kaplan-Meier analysis to estimate the cumulative incidence of all-cause mortality. The predictive value of fibrinogen levels for 10-year mortality was estimated by a Cox proportional hazards regression model. The impact of fibrinogen level on 10-year mortality was assessed by a restricted cubic spline (RCS) curve, which was derived from an adjusted Cox proportional hazards regression model.

Ethical Considerations
The study protocol was approved by the institutional review board of West China Hospital in accordance with the Declaration
of Helsinki (approval number 2012(243)). Written informed consent was obtained from all participants before enrollment in the study. Patients who come to the hospital for follow-up will be reimbursed for their transportation expenses.

**Results**

A total of 2434 consecutive patients with ACS who were admitted to West China Hospital in the Sichuan province of China, between December 10, 2010, and December 31, 2012, were enrolled in this study. After exclusion of 29 patients with in-hospital mortality, 2405 patients were included in the analysis. The mean age of the study population was 64.3 (SD 11.1) years. Plasma fibrinogen levels of these patients were normally distributed (skewness/kurtosis tests: $P < .001$), with a mean level of 3.41 (SD 1.06) g/L. The median follow-up time was 104 (IQR 98-111) months. In total, 387 (16.1%) patients died during the follow-up period. Kaplan-Meier analysis revealed that the cumulative incidence of mortality was significantly different among the 5 groups (log-rank test: $P < .001$; Figure 1A). Group 2 (fibrinogen level: 2.63-3.04 g/L) had the lowest incidence of mortality. In the Cox univariate regression analysis, fibrinogen was identified as a risk factor for 10-year mortality (hazard ratio [HR]: 1.24 [1.15-1.35]; $P < .001$). After adjusting for cardiovascular risk factors, fibrinogen was still found to be an independent risk factor (HR: 1.18 [1.08-1.29]; $P < .001$). The fibrinogen category in the multivariate Cox model, with group 2 serving as the referent, showed a nonlinear trend to mortality risk (Table S1 in Multimedia Appendix 1). Subgroup analysis suggested that in the ST-segment elevation myocardial infarction (STEMI)/non-STEMI (NSTEMI) subgroups, statistical results for fibrinogen showed the same trend (Table S2 in Multimedia Appendix 1).

**Discussion**

Acute-phase proteins are often associated with patient prognosis. Previous epidemiologic studies have suggested that elevated fibrinogen levels may mediate plaque rupture via prothrombotic or proinflammatory processes [2]. However, a lower fibrinogen level may indicate a worse general physical condition or may reveal hidden coagulation disorders in patients with ACS [4]. In this study, the long-term follow-up across nearly a decade and the quantitative RCS analysis suggested that fibrinogen levels at admission have a significant impact on the long-term prognosis of patients with ACS. The mechanisms underlying this phenomenon suggest that fibrinogen acts as both an acute-phase protein and a subclinical inflammatory indicator [5].

The U-shaped relationship between fibrinogen levels and 10-year mortality suggest the need for long-term anti-inflammatory or metabolism treatment, as well as the need to determine fibrinogen levels in patients with ACS. In addition, the nonlinear correlation between fibrinogen levels and the long-term mortality may restrict the effect of fibrinogen in some risk models that were derived from extended linear regression. The predictive value of fibrinogen needs to be estimated in nonlinear functions or by using machine learning classifiers in further studies.

Abstract

A study on infertility in China found that while 543 health care institutions are approved for assisted reproductive technology (ART), only 10.1% offer all ART services, with a significant skew toward the eastern regions, highlighting the accessibility challenges faced by rural and remote populations; this study recommends government measures including travel subsidies and education initiatives to improve ART access for economically disadvantaged individuals.

(JMIR Public Health Surveill 2024;10:e55418) doi:10.2196/55418

Introduction

Infertility is a growing, serious public health concern [1]. In 2023, the World Health Organization reported that infertility affects about 17.5% of the adult population globally [2]. Infertility is also prominent in China, affecting nearly 50 million people [3]. However, the travel time and costs are often a significant burden faced by patients with infertility [4,5]. Here we used a web path planning engine [6] to explore the spatial-economic disparities in access to assistive reproductive technology (ART) centers in mainland China.

Methods

Study Design

The National Health Commission of the People’s Republic of China supplied a list of ART centers, while population data were sourced from the 2020 Worldpop data set [7]. Residential point locations were gathered from the Gaode Maps open platform. After retaining one residential point within a 1-km radius, 57,469 residential points were acquired. We opted for a contemporary approach by leveraging real-time traffic data from web map navigation services—a departure from traditional methods. Using the Path Planning 2.0 algorithm, we determined optimal paths among residential points and the nearest ART center, predicting detailed travel times and corresponding costs [8,9]. We averaged the travel times and costs of residential points within the county, thus representing its overall level. Subsequently, isochronous maps depicting 1-hour and 2-hour travel times for ART services were generated.

Ethical Considerations

This study used deidentified publicly available data sets, all aggregated at the county level. Per Article 3 of the Southern University of Science and Technology’s institutional review board guidelines, we did not require peer review as this is a secondary analysis using publicly accessible locations of ART centers from the National Health Commission’s website and publicly accessible locations of residential points. These data sets contain no personally identifiable information and pose no risk of ethical violation.
Results

As of June 2022, in total, 543 health care institutions in Mainland China have received approved to conduct ART. However, only 55 (10.1%) institutions offer all 5 types of ART services. The distribution of ART centers in China predominantly favors the eastern plains and coastal regions (Figure 1A). Among 7 geographical subregions of China, East China boasts the highest number of ART centers (n=162, 29.8%). Specifically, Guangdong province leads with the greatest number of ART centers (n=56, 10.3%), with 83.9% (n=104) of the province’s counties accessible to ART centers within 1.5 hours and an average taxi cost of merely 66.7 CNY (US $9.21) [10]. In contrast, the Northwest region has the lowest number of ART centers (n=27, 5.0%). Tibet, in particular, has only 1 ART center, and a mere 12.2% (n=9) of Tibetan counties have access to it within 1.5 hours, with taxi costs soaring as high as 1485.2 CNY (US $205.08).

Figure 1. Travel time to assisted reproductive technology (ART) centers in China. (A) A map of travel times to ART centers at the county level. (B) The population density of China's counties covering 1-hour and 2-hour travel time isochrones. Counties with higher population densities are shaded in dark gray. Areas shaded in red are located within the 1-hour and 2-hour travel time isochrones of the ART centers.

Travel time and costs to ART centers by province are presented in Table 1. Detailed information on travel time and costs is visualized in Multimedia Appendix 1. In China, a substantial portion of the population faces challenges in accessing ART facilities within a short time frame. Specifically, 76.8% (n=180,330,033) of the total population and 63.5% (n=36,390) of residential points are not reachable to an ART center within an hour.
Table 1. Travel time and travel costs to assistive reproductive technology (ART) centers by province and proportion of population access to ART services at different time thresholds.

\(^a\)CNY=US $0.14. Travel cost was determined by the local taxi fare, which varies depending on the location. The first price covers a specified distance, often 2.5-3 km, and every additional kilometer is then calculated at a certain price.
Discussion

The distribution of ART centers in China exhibits significant disparities. A higher concentration of ART centers is observed in urban and eastern regions, while individuals in northwestern and rural areas encounter prolonged travel times and elevated transportation costs when seeking ART treatment. The map serves the dual purpose of estimating the likelihood of individuals seeking ART treatment when needed and providing an evidence-based foundation for efficient allocation of limited ART resources to underserved populations (present and future). The government is suggested to implement a series of measures, including counterpart aid and effective initiatives to educate and recruit ART doctors in disadvantaged units. Residents in rural and remote areas contend with extended travel times and substantial travel costs when accessing ART services, which should be covered fully or partially through travel subsidies or paid leaves. The introduction of telehealth services is a viable solution to surmount these barriers for patients residing in remote areas, effectively reducing in-person office visits. Notably, ensuring privacy is paramount when helping patients seeking ART treatments. This study bears limitations. While we used the best available data, the residential point data sets remain susceptible to omission errors, which confines the algorithm’s usage to only 1 mode of transportation—a limitation not potentially aligning with real-world scenarios. Additionally, individuals may not necessarily receive ART treatment at the nearest facility or may opt for alternative transportation means.

Acknowledgments

This study is funded by the Guangdong Philosophy and Social Sciences Planning Project (GD22YGL10), Shenzhen Philosophy and Social Sciences Planning Project (SZ2023C007), and Shenzhen Science and Technology Program (JCYJ20220530113208019). Abstract

Background: The high prevalence of hepatitis A delivered a blow to public health decades ago. The World Health Organization (WHO) set a goal to eliminate viral hepatitis including hepatitis A by 2030. In 2008, hepatitis A vaccines were integrated into the Expanded Program on Immunization (EPI) in China to alleviate the burden of hepatitis A, although the effectiveness of the EPI has not been well investigated.

Objective: We aimed to evaluate the intervention effect at both provincial and national levels on the incidence of hepatitis A in the Chinese mainland from 2005 to 2019.

Methods: Based on the monthly reported number of hepatitis A cases from 2005 to 2019 in each provincial-level administrative division, we adopted generalized additive models with an interrupted time-series design to estimate province-specific effects of the EPI on the incidence of hepatitis A among the target population (children aged 2-9 years) from 2005 to 2019. We then pooled province-specific effect estimates using random-effects meta-analyses. We also assessed the effect among the nontarget population and the whole population.

Results: A total of 98,275 hepatitis A cases among children aged 2-9 years were reported in the Chinese mainland from 2005 to 2019, with an average annual incidence of 5.33 cases per 100,000 persons. Nationally, the EPI decreased the hepatitis A incidence by 80.77% (excess risk [ER] –80.77%, 95% CI –85.86% to –72.92%) during the study period, guarding an annual average of 28.52 (95% empirical CI [eCI] 27.37-29.00) cases per 100,000 persons among the target children against hepatitis A. Western China saw a more significant effect of the EPI on the decrease in the incidence of hepatitis A among the target children. A greater number of target children were protected from onset in Northwest and Southwest China, with an excess incidence rate of –129.72 (95% eCI –135.67 to –117.86) and –66.61 (95% eCI –67.63 to –64.22) cases per 100,000 persons on average, respectively. Intervention effects among nontarget (ER –32.88%, 95% CI –39.76% to –25.21%) and whole populations (ER –31.97%, 95% CI –39.61% to –23.37%) were relatively small.

Conclusions: The EPI has presented a lasting positive effect on the containment of hepatitis A in the target population in China. The EPI’s effect on the target children also provided a degree of indirect protection for unvaccinated individuals. The continuous surveillance of hepatitis A and the maintenance of mass vaccination should shore up the accomplishment in the decline of hepatitis A incidence to ultimately achieve the goal set by the WHO.

Introduction

Hepatitis A is an acute infectious disease that is transmitted via a fecal-oral route, primarily through the ingestion of food or water contaminated with the virus [1-3]. Hepatitis A would frequently give rise to sporadic cases, outbreaks, and even epidemics [4,5], which posed threats to public health and laid an excessive economic burden on society. Globally, the burden of hepatitis A has been increasing in recent years [6], accounting for about 1.4 disability-adjusted life years (DALYs) and 2.3 DALYs in 2010 and 2019, respectively [7,8]. Given the current global burden of hepatitis A viruses (HAV), the World Health Organization (WHO) developed a long-term goal of eliminating viral hepatitis, including hepatitis A, as a major public health threat by 2030 [9].

Vaccination is an essential intervention for the prevention and control of hepatitis A. Assessing the effectiveness of vaccination on the incidence of hepatitis A is a critical step to the continuous implementation and improvement of the immunization program. Although some studies have investigated the correlation between vaccination coverage and hepatitis A incidence [10] or seroprevalence [11,12], there are limited data on the intervention effect of hepatitis A mass vaccination. A few studies simply described and compared the average yearly incidence between the pre- and postintervention periods in the Chinese mainland and Israel [4,13-17], which neglected potential confounding factors. Two studies used regression models to evaluate the association of the vaccination program with the incidence of hepatitis A in the Chinese mainland and Brazil [17,18]. However, these studies did not consider the potential regional differences in the effect of the vaccination, which would fail to promote precise and differentiated strategies in the prevention and control of hepatitis A. Another research study assessed the impact of the Expanded Program on Immunization (EPI) on the incidence of 11 childhood vaccine-preventable diseases, including hepatitis A, with annual data in the Chinese mainland through a quasi-Poisson regression and a polynomial regression [19]. However, this study constructed the model based on national data of the whole population and assumed that all changes in the hepatitis A incidence from 2003 to 2012 were fully attributable to vaccination, thus failing to assess the impact of the EPI in different age groups. Furthermore, the potential spatial and time-varying effects of the EPI on hepatitis A remained unclear.

In the Chinese mainland, hepatitis A was endemic in most regions from 1990 to 2007, with an average annual incidence of 21.31 cases per 100,000 persons, in the absence of systematic hepatitis A inoculation [20]. Furthermore, children under the age of 10 years were subjected to the highest incidence among all age groups from 1990 to 2007, and public health emergencies of hepatitis A occurred mostly in elementary schools in Western China [2,20]. The Chinese government integrated hepatitis A vaccines into the Chinese National EPI in 2008 to mitigate hepatitis A. Children aged over 18 months are eligible to either (1) receive 1 dose of the live attenuated hepatitis A vaccine or (2) receive 1 dose of the inactivated vaccine at the 18th month and another dose at the 24th month for free in the Chinese mainland [10]. However, the initiation time and the intensity of the EPI were different in each provincial-level administrative division (PLAD). Hence, it is necessary to explore the effect of the EPI in different PLADs and then pool the effect estimates to obtain substantial evidence. Herein, we aimed to assess the effectiveness of the EPI in China at the provincial and national levels.

Methods

Data Collection

We collected monthly data on hepatitis A incidence across 31 PLADs from 2005 to 2019 in the Chinese mainland from the National Population and Health Science Data Sharing Platform of the Chinese Center for Disease Control and Prevention [21]. A hepatitis A case is defined as a patient with acute gastrointestinal symptoms (eg, jaundice) and elevated serum alanine aminotransferase who tests positive for the immunoglobulin M antibody to HAV [22].

The provincial-level annual data (ie, the age-specific resident population, gross domestic product [GDP] per capita, urbanization rates, the number of hospitalization beds per 1000 persons, the proportion of children younger than 14 years old, and illiteracy rates) from 2005 to 2019 were compiled from China Statistical Yearbooks [23,24]. The monthly resident population was derived from linear interpolation. Monthly data on ambient average temperature were downloaded from the China Meteorological Data Sharing Service System [25].

Data Analysis

The exact implementation time of the EPI and the use of the vaccine type (ie, inactivated hepatitis A vaccines or live attenuated hepatitis A vaccines) were different among PLADs. Accordingly, the postintervention period of each PLAD was specified separately (Table S1 in Multimedia Appendix 1). Children born after 2007 and aged >24 months are eligible to receive hepatitis A vaccines. The postintervention period spanned 11 years. Children younger than 13 years old could directly benefit from the program at the end of the study period. However, the raw data were in the form of 1-year age groupings for those aged <10 years and 5-year age groupings after the age of 10 years (10-14 years, 15-19 years, etc). Hence, we identified children aged 2-9 years whom the EPI had a direct bearing on as the study population.

A 2-stage analytic strategy was used to evaluate the effect of the EPI on the incidence of hepatitis A. In the first stage, a quasi-Poisson regression model with interrupted time series was established to capture the province-specific effectiveness of the EPI after adjusting for covariates in each of the 30 PLADs [26]. Tianjin was not considered because the average annual number of cases was extremely low even before the EPI (3.55 cases per year; Table S2 in Multimedia Appendix 1), which cannot ensure the stability of modeling. The model mainly
contains an elapsed time since the start of the study, a dummy variable indicating the pre- or postintervention period, and an interaction term for the aforementioned 2 variables. Furthermore, we included the natural cubic spline of monthly average temperature with 3 df, which was selected by minimizing the value of quasi–Akaike information criterion (Table S3 in Multimedia Appendix 1) and a categorical variable of calendar months to control for the potential seasonality of hepatitis A incidence. We incorporated the reported public health emergencies of hepatitis A, mainly occurring before the implementation of the EPI, into the model to avoid the overestimation of the effects (Table S4 in Multimedia Appendix 1) [27]. An autoregressive term of residuals at lag 1 was taken into account to adjust for autocorrelation if necessary (Table S5 and Figures S1 and S2 in Multimedia Appendix 1). Detailed information on the provincial-specific model is provided in the Supplemental Methods in Multimedia Appendix 1.

The provincial-specific excess risk (ER) of the hepatitis A incidence and the corresponding 95% CI were estimated. In addition, the excess incidence rate (EIR) in each province and the corresponding 95% empirical CI (eCI) were estimated to investigate the change in the hepatitis A incidence due to the implementation of the EPI. The details on the estimation of ERs and EIRs are demonstrated in the Supplemental Methods in Multimedia Appendix 1.

In the second stage, we pooled the province-specific effect of the EPI using random-effects meta-analyses to derive the regional-level and national-level estimates of the ER. The heterogeneity was quantified by I² statistic and Cochran Q test [28]. In addition, we estimated the national population-weighted EIRs.

Furthermore, we performed subgroup analyses. The PLADs were classified into 7 regions (ie, Northeast, North, Northwest, East, Center, South, and Southwest), considering different geographical and environmental conditions [29]. We also estimated the EIR for each subgroup of PLADS by socioeconomic factors (ie, urbanization rates, GDP per capita, the number of hospitalization beds per 1000 persons, the proportion of children aged 0-14 years, and illiteracy rates), the level of average incidence of hepatitis A before the implementation of EPI, and the types of hepatitis A vaccines (Table S1 in Multimedia Appendix 1). All factors, except for regions and types of hepatitis A vaccines, were classified into 2 levels using the medians as the cutoffs (high: ≥median; low: <median).

In addition, we explored the effect of the EPI on the whole population and the nontarget population (children younger than the age of 2 years or older than the age of 10 years), as previous literature suggested that the vaccination might develop herd immunity against hepatitis A [10]. We did not consider the interaction term between time and the indicator variable of the intervention in models for the nontarget population and the whole population because the pooling effects of the interaction term fell short of statistical significance.

We performed sensitivity analyses to examine the robustness of the main model results (Supplemental Methods in Multimedia Appendix 1). First, we substituted calendar months with a natural cubic spline function with 3 df to consider different ways of controlling potential seasonality. Second, we explored the potentially nonlinear intervention effect over time. Finally, we took the transition period from the implementation of the EPI to 2010 into account and excluded this period from the analyses. A 2-sided P value of <.05 was considered statistically significant. We used the R statistical software (version 4.2.1; R Foundation for Statistical Computing) to perform all analyses.

Ethical Consideration
This study was approved by the Research Ethics Committee of Southern Medical University (NFYKDX-ER2022012). The need for informed consent was waived because the data were deidentified and aggregated.

Results

Temporal and Spatial Distribution of Hepatitis A Incidence
Table 1 presents the summary statistics of hepatitis A in different age groups from 2005 to 2019 in the Chinese mainland. During the study period, there was a total of 98,275 reported hepatitis A cases among children aged 2-9 years with an average annual incidence of 5.33 cases per 100,000 persons. Overall, there was a gradual decline in the annual incidence of hepatitis A. The incidence of hepatitis A increased from 10.98 cases per 100,000 persons in 2005 to 16.80 cases per 100,000 persons in 2007, but the incidence had considerably dropped since 2008 and was only 0.56 cases per 100,000 persons in 2019. Among the whole population, 556,737 cases were reported from 2005 to 2019, but the incidence had considerably dropped since 2008 and was only 0.56 cases per 100,000 persons in 2019. Among the whole population, 556,737 cases were reported from 2005 to 2019, with an average annual 2.79 cases per 100,000 persons. The incidence among the whole population and the nontarget population also appeared to be edging downward, with the latter leveling off at 1.50 cases per 100,000 persons after 2011.

<sup>a</sup>The target population is children aged 2-9 years.

<sup>b</sup>There were 8 cases whose ages were missing.

Figure 1 demonstrates the spatial distribution of the average hepatitis A incidence among children aged 2-9 years and the nontarget population. Generally, Western China witnessed a higher incidence of hepatitis A than that of other regions during both the pre- and postintervention periods. However, this regional difference has remarkably dwindled since the implementation of the EPI (Table S6 in Multimedia Appendix 1). The hepatitis A incidence among children aged 2-9 years showed significant seasonal variation, which peaked in the autumn and winter. However, the seasonality was gradually ambiguous, and the peak slumped greatly in the postintervention stage (Figures S3 and S4 in Multimedia Appendix 1). The seasonality pattern of Western China was similar, but the seasonality was not apparent in other regions.
Effect of EPI on Hepatitis A Incidence

Overall, the implementation of the EPI led to a significant decrease in the incidence of hepatitis A for the target population, with an average ER of 80.77\% (95\% CI 72.92\%–85.86\%) among children aged 2-9 years (Figure 2 and Figure S5 in Multimedia Appendix 1). The magnitude of the EPI intervention enhanced with each passing year from the initiation of the EPI. Specifically, the intervention impact was relatively weak in the first year after the implementation of the EPI, associated with a 51.92\% (95\% CI 42.44\%–59.84\%) reduction in the incidence of hepatitis A. The reduction dramatically rose to 97.25\% (95\% CI 92.77\%–98.95\%) in the 11th year following the EPI (Table S7 in Multimedia Appendix 1).

Figure 1. Spatial distribution of the average annual hepatitis A incidence. White regions indicate missing data. (A) Preintervention period among children aged 2-9 years; (B) postintervention period among children aged 2-9 years; (C) preintervention period among nontarget individuals; (D) postintervention period among nontarget individuals.
Figure 2. Excess risks and excess incidence rates towards children aged 2-9 years. The line represents the point estimates of excess risks and excess incidence rates of hepatitis A associated with the EPI. The colored regions are the corresponding 95% CIs and 95% empirical CIs, respectively. The excess risks of Northeast China are not statistically significant during the overall period after the implementation of the EPI. (A) Excess risks; (B) excess incidence rates. EPI: Expanded Program on Immunization.

Table 2 and Tables S8 and S9 in Multimedia Appendix 1 show the EPI-associated reduction in cases and the incidence of hepatitis A among children aged 2-9 years. In general, it was estimated that a yearly average of 28.52 (95% eCI 27.37-29.00) hepatitis A cases per 100,000 persons was averted within 11 years of intervention. In other words, on average, about 34,618 cases are prevented each year by the EPI. In detail, the EPI protected an average of 14.31 (95% eCI 13.50-14.78) cases per 100,000 persons from hepatitis A in the first 5 years of the intervention period. In the subsequent 6-11 years, on average, 39.90 (95% eCI 38.34-40.48) cases were prevented per 100,000 individuals.

<sup>a</sup>EPI: Expanded Program on Immunization.

There were significant differences among provinces in the effect of the EPI intervention on the incidence of hepatitis A among children aged 2-9 years ($I^2=92.80\%; P<.001$). We observed significant effects in Northwest (ER –99.02%, 95% CI –99.69% to –96.87%) and Eastern (ER –99.29%, 95% CI –99.90% to –95.12%) China during the whole intervention period (Figure 2 and Table S10 in Multimedia Appendix 1), while the ER in Northeast China was statistically nonsignificant. Table 2 and Tables S8 and S9 in Multimedia Appendix 1 reflect the moderate effectiveness of the intervention on the target children in Northern, Central, and Southern China. Compared with other regions, a greater number of the target children were protected in Northwest and Southwest China, with an EIR of –129.72 (95% eCI –135.67 to –117.86) and –66.61 (95% eCI –67.63 to –64.22) cases per 100,000 persons on average, respectively. Figure 3 and Table S9 and Figure S6 in Multimedia Appendix 1 provide ERs and EIRs of the EPI for different subgroups based on socioeconomic factors and types of hepatitis A vaccines. The ERs of hepatitis A incidence in the intervention population did not differ greatly at different socioeconomic levels and vaccine types. However, EIRs exhibited greater differences between subgroups than ERs. PLADs with less GDP per capita, lower urbanization rates, insufficient number of hospitalization beds per 1000 persons, higher incidence of hepatitis A before the implementation of the EPI, larger proportion of children younger than 14 years old, higher illiteracy rates, or live attenuated hepatitis A vaccines witnessed a more significant alleviation in the incidence of hepatitis A during the whole intervention period.
In view of all people and nontarget people, the EPI also lessened the burden of hepatitis A (Tables S11 and S12 in Multimedia Appendix 1). Generally, the EPI was likewise linked to the decrease in the incidence in nontarget individuals (ER –32.88%, 95% CI –39.76% to –25.21%) and all people (ER –31.97%, 95% CI –39.61% to –23.37%). The EPI could prevent 0.78 (95% eCI 0.73-0.82) and 0.83 (95% eCI 0.78-0.88) cases per 100,000 persons among nontarget individuals and all people from infection within 11 years of the intervention, respectively.

**Sensitivity Analyses**

We obtained similar results from the sensitivity analyses (Table S7 and Figures S7-9 in Multimedia Appendix 1). First, the effect of the EPI on the incidence did not change substantially when using a natural cubic spline to control for seasonality (ER –80.25%, 95% CI –85.66% to –71.68%). Second, in accordance with the main results, the exposure-response curves revealed that the logarithm transformation of ER in large changed linearly with time. Finally, the results, in consideration of the transition period, were similar to those in the main analysis, with an average ER of 80.45% (95% CI 71.19%-86.48%).

**Discussion**

**Principal Findings**

In this nationwide study, we comprehensively assessed the effectiveness of the EPI on the incidence of hepatitis A among children aged 2-9 years based on province-specific monthly data from 2005 to 2019. The 97% decrease in hepatitis A incidence attributable to the 11-year intervention of the EPI among children aged 2-9 years provides an estimate of the vaccine-preventable HAV cases in childhood, suggesting that the burden of the hepatitis A cyclical epidemic before the EPI has been largely alleviated [10]. By the end of 2019, the incidence of hepatitis A decreased to 0.56 cases per 100,000 persons among target children in the Chinese mainland, which gradually approaches the target of eliminating hepatitis A set by the WHO.

Two previous studies have shown the beneficial effectiveness of the EPI in curbing the incidence of hepatitis A in the Chinese mainland [10,17]. Sun et al [10] described an 82.3% decline in the incidence in 2016 compared to that in 2004. Tang et al [17] indicated that 47% of the decrease in the incidence of hepatitis A among children aged 0-14 years was attributable to the EPI, by simply fitting the annual number of cases using an interrupted linear regression without considering the nonlinear trend and the change in the population size, which might bring about bias in the estimates of the intervention effect. A previous review in China demonstrated that seroconversion rates were well above 80% and vaccine efficacy rates were higher than 90% in vaccinated individuals, whether with live attenuated hepatitis A vaccines or inactivated hepatitis A vaccines [5]. A randomized clinical trial indicated that nearly 100% of vaccinated people developed serum antibodies against HAV after the inoculation [30]. In this population-based interrupted time-series study, we used a robust 2-stage modeling strategy to comprehensively assess the province-specific effect and the pooled national effect. Combined with the previous evidence, this study could corroborate that the EPI did weigh positively on the decrease of hepatitis A incidence among the vaccinated population.

In addition, there were distinct regional differences in the effect of the EPI, with the greatest effect in Western China. The effects on the target children were not statistically significant in several PLADs of Eastern and Northern China where the incidence was low prior to the intervention. A possible explanation may be that a portion of schoolchildren had received self-financed vaccination against hepatitis A before the implementation of

---

**Figure 3.** Average excess incidence rates in different subgroups among children aged 2-9 years. eCI: empirical CI; EIR: excess incidence rate.
the EPI due to better economic conditions and awareness of vaccination in these PLADs compared to Western China [10,31]. The annual number of hepatitis A cases in Tianjin fluctuated between 0 and 6 cases among the target children during the study period from 2005 to 2019. One possible reason was that the local immunization strategy was implemented in 2001, covering 1-year-old infants, first-grade children, and seventh-grade children [31,32]. The hepatitis A vaccine coverage was above 90% in 2001, which facilitated a low-level sporadic state of hepatitis A in Tianjin among children [31,32]. Notably, the postintervention incidence of hepatitis A in Western China, especially in Tibet and Xinjiang, was still significantly higher than that of other regions of China, although the EPI had largely alleviated the local burden of hepatitis A. These discrepancies might be related to impoverishment [24] and the lack of vaccination awareness. For example, the vaccination coverage in children was only about 60% in Tibet in 2004, and about 71% of towns in Xinjiang achieved the goal of 90% coverage of hepatitis A vaccine in 2013 [10,33,34]. A sampling survey found a lower anti-HAV antibody seroprevalence in Western China than in Eastern China (69% vs 72% in 2014) [11]. None of the local health authorities could afford to overlook the gaps in the vaccination coverage among children between the Western region (69.1%) and other regions of China (86% in Eastern China and 74.5% in Middle China) [33]. Further promotion of vaccination and prevention measures against hepatitis A in Western China, including raising public awareness about the prevention of hepatitis A and the efficacy of vaccination, remains a long way off to narrow the gaps. However, there is no denying that the massive disparities in the geographical distribution of the hepatitis A incidence before the intervention, with the vast majority of cases in the Western region, have faded away in most PLADs as the intervention progressed. Overall, focusing on the reduction of HAV exposure and health education on vaccination against hepatitis A among local children in high-prevalence regions will enhance the effectiveness of the intervention and thereby lighten the burden of hepatitis A.

Subgroup analyses indicated that there is no significant difference in reducing the relative risk of hepatitis A onset between regions with different socioeconomic conditions and types of hepatitis A vaccines. However, it is worth noting that the decrease in the incidence of hepatitis A due to the implementation of the EPI varied evidently across PLADs with different socioeconomic levels and types of vaccines. Specifically, the alleviation of the hepatitis A burden in resource-limited regions was much higher than that in resource-rich regions, which are mainly concentrated in Eastern China. Similarly, greater effectiveness was found in PALDs with live attenuated vaccines (ie, all PLADs except Beijing, Tianjin, Shanghai, and Jiangsu). Differences in EIRs could be boiled down to 2 reasons, namely, the level of development and the incidence before the implementation of the EPI. The regions where society and economy have forged ahead during the last decade (ie, high GDP per capita, the fast urbanization process, sufficient medical resources, decreased proportion of children, or advanced education level), accompanied by improvements in sanitary and hygienic conditions (ie, sufficient medical resources), are associated with the less exposure to HAV, which could partly explain the regional difference in EIRs [24,35]. More could be credited to the fact that there were lower incidence of hepatitis A and higher seroprevalence of anti-HAV antibody in regions with thriving economy before the intervention [11].

In terms of the nonintervention population beyond the age group of 2-9 years, the EPI-associated reduction in the incidence of hepatitis A was observed. This finding indicated that routine mass immunization on target children provided a degree of indirect protection for unvaccinated individuals, in line with a previous study in the United States [36]. With fewer hepatitis A cases in target children, the probability of cross-infection from target children to nontarget people reduces greatly. On the other hand, among nonvaccinated individuals, people who were neither covered by the EPI nor had paid for hepatitis A vaccines out of pocket remain vulnerable to hepatitis A. Herd immunity can prevent the spread of hepatitis A in the population to a certain degree but will not adequately protect susceptible individuals upon exposure to HAV [36,37]. Hence, health authorities need to provide education on scientific prevention directives and formulate supervisory policies in light of different infection sources and transmission routes, such as monitoring HAV circulation [38], safeguarding food safety [39], and raising health consciousness, to pave the way for nontarget people to avoid HAV exposure.

Limitations

Several limitations should be acknowledged in this study. First, all hepatitis A cases were diagnosed and reported by hospitals. There is inevitable underreporting. Particularly, children are more likely to become asymptomatic and be underreported. The underreporting decreases with the improvement of the diagnosis process, which could lead to the underestimation of the effectiveness. However, the odds favor a random bias on asymptomatic cases before and after the implementation of the EPI, thus exerting nondifferential impacts on the assessment of the intervention. Second, the lack of the data on hepatitis A vaccination coverage and the seroprevalence blocks us from better understanding the pathway and the regional heterogeneity of the EPI’s effects on the hepatitis A incidence. Finally, our study emphasized the effect of the EPI on the incidence. The economic benefits and decreased DALYs brought by the EPI have not been investigated. Further dynamic research is greatly needed to articulate the substantial positive effect on controlling the HAV endemic in terms of cost-effectiveness after decades of the EPI and to further evaluate the feasibility of achieving WHO 2030 targets.

Conclusion

The implementation of EPI has evidently contributed to the decrease of hepatitis A incidence among children aged 2-9 years in the Chinese mainland, suggesting that continuous children mass vaccination is imperative in the future containment of hepatitis A. In view of the regional differences in the effectiveness of the EPI observed, sustained monitoring of the incidence and strengthening of vaccination in Western China will accelerate efforts toward achieving the target of eliminating viral hepatitis set by the WHO. Furthermore, the findings would serve as a favorable paradigm of mass hepatitis A vaccination for other countries and regions with a heavy burden of hepatitis.
A, which contributes to the eventual elimination of hepatitis A worldwide.

Acknowledgments
We thank the staff of Chinese Center for Disease Control and Prevention who collected the data. This work was supported by the National Natural Science Foundation of China (grants 81903406 and 82003555). The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript; or in the decision to publish the results.

Data Availability
Relevant raw data related to reported cases of hepatitis A in the Chinese mainland can be collected on National Population and Health Science Data Sharing Platform. The data sets generated during and/or analyzed in this study are available from the corresponding authors on reasonable request.

Authors' Contributions
CQO conceptualized and designed the study. CQO and LL supervised the study. BWM, HNH, CS, and ZY collected the data. BWM, JJM, CS, XHX, and ZY analyzed the data. BWM and LL wrote the first draft of the manuscript. All authors contributed to the interpretation of the results and edited the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Diabetes mellitus (DM) increases the risk of developing tuberculosis (TB), and optimal glycemic control has been shown to reduce the risk of complications and improve the TB treatment outcomes in patients with DM.

Objective: This study aims to investigate the role of glycemic control in improving TB treatment outcomes among patients with DM.

Methods: MEDLINE, Embase, and the Cochrane Central Register of Controlled Trials databases were searched for randomized controlled trials (RCTs) assessing the impact of oral glycemic control in patients with TB who have DM. Outcomes of interest were radiological findings, treatment success, sputum positivity, and mortality. Evaluations were reported as risk ratios (RRs) with 95% CIs using weighted random-effects models.

Results: The analysis included 6919 patients from 7 observational studies. Our meta-analysis showed significant differences between patients with optimal glycemic control and those with poor glycemic control with regard to improved treatment outcomes (RR 1.13, 95% CI 1.02-1.25; P=.02; P=65%), reduced sputum positivity (RR 0.23, 95% CI 0.09-0.61; P=.003; P=66%), and fewer cavitary lesions (RR 0.59, 95% CI 0.51-0.68; P<.001; P=0%) in radiological findings. There was no significant difference between the 2 groups in terms of mortality (RR 0.57, 95% CI 0.22-1.49; P=.25; P=0%), multilobar involvement (RR 0.57, 95% CI 0.22-1.49; P=.25; P=0%) on radiologic examination, and upper lobe (RR 0.94, 95% CI 0.76-1.17; P=.58; P=0%) and lower lobe (RR 1.05, 95% CI 0.48-2.30; P=.91; P=75%) involvement on radiologic examination.

Conclusions: We concluded that optimal glycemic control is crucial for reducing susceptibility, minimizing complications, and improving treatment outcomes in patients with TB with DM. Emphasizing effective health management and health care strategies are essential in achieving this control. Integrating comprehensive care among patients with TB with DM will enhance patient outcomes and alleviate the burden of disease in this population.

Introduction

Tuberculosis (TB) poses an escalating public health threat, particularly in lower- and middle-income countries [1]. The World Health Organization estimates that approximately one-fourth of the world’s population has been infected with TB-causing bacteria [2], with 10.6 million individuals diagnosed with TB in 2021, leading to 1.6 million deaths [1]. Risk factors for TB are divided into 2 main categories, that is, people recently infected with TB and those with an immunocompromised status, including those with HIV, diabetes mellitus (DM), transplants, malnourishment, and tobacco use, and those receiving immunosuppressants [1,2].

DM is also a growing concern, increasing the likelihood of several infections and complications [3]. With 425 million individuals affected in 2017 and an estimated 629 million expected to be impacted by 2045, DM increases the risk of TB incidence by 2-4 folds. Furthermore, it is associated with poor outcomes, doubling the risk of mortality during treatment [4,5]. In the long term, hyperglycemia and poor glycemic control (PGC) impair immunity, leading to immunosuppression and increased susceptibility to TB [1].

Poor treatment outcomes have been associated with patients with TB, including treatment failure, recurrence, delayed culture conversion, and death [6]. Optimal glycemic control (OGC) has been shown to improve TB outcomes by enhancing phagocytic activity and other immunological defense mechanisms [6]. Nevertheless, some studies have found no significant improvement in TB treatment outcomes through glycemic control [7]. As a result, there is a need to examine the current data to establish the relationship between the 2 factors. This paper aims to review the current literature and reach a conclusion regarding the impact of OGC on TB treatment outcomes in patients with DM.

Methods

Overview

The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines and the risk of bias assessed using AMSTAR (A Measurement Tool to Assess Systematic Reviews) 2 were both used when performing this meta-analysis [8,9]. This study is registered on PROSPERO (The International Prospective Register of Systematic Reviews; ID CRD42023427362).

Ethical Considerations

Since the information was accessible to the general public, institutional review board approval was not necessary.

Data Sources and Search Strategy

MEDLINE, Embase, and the Cochrane Central Register of Controlled Trials were comprehensively searched from inception through May 2023 by 2 independent reviewers (LZ and XS). We extracted studies based on abstracts and titles. A full-text appraisal was sought when required. MeSH (Medical Subject Headings) phrases and keywords were used to formulate search strategies (Table 1).

Table 1. Search strategy used in each database.

</tr>
</tbody>
</table>

Study Selection

We included studies if they (1) were randomized controlled trials (RCTs) or analyses of RCTs that determined the impact of OGC on treatment outcomes of TB in patients with DM in different interventional arms; (2) reported radiological findings including cavity lesions, multifocal involvement, and upper and lower lobe involvement; treatment success; sputum positivity; or mortality; or (3) included patients with a diagnosis of TB and DM. We also included observational studies that reported the aforementioned radiological findings, treatment success, sputum positivity, and mortality. A third investigator (XS) was consulted in case of any disagreement regarding study selection. All articles were then uploaded to EndNote Reference Library (version X7.5; Clarivate Analytics) software to remove any duplicates.

Data Extraction and Assessment of Study Quality

Two reviewers (FG and CZ) independently extracted from the selected studies the characteristics of the studies, patient demographics, summary events, number of events, sample sizes, and treatment type. The quality of the included studies was assessed using the Newcastle-Ottawa Scale across 6 key domains: selection bias, performance bias, detection bias, attrition bias, reporting bias, and other bias. This systematic evaluation aimed to enhance the reliability of our findings by critically appraising the internal validity of each study. To enhance the reliability of our quality assessments, 2 independent reviewers (FG and CZ) conducted the evaluations. In instances
of disagreement, a third investigator (XS) was consulted, and consensus was reached through discussion. The process of quality assessment was conducted systematically and transparently, ensuring a rigorous evaluation of each study’s methodological robustness.

**Statistical Analysis**

Radiological findings, consisting of cavitary lesions, multilobar involvement, upper lobe involvement, and lower lobe involvement, were one of the outcomes of interest. Other outcomes were treatment success, sputum positivity, and mortality. RevMan (version 5.4.1; The Cochrane Collaboration) was used to conduct the meta-analysis. The outcomes of interest were provided as risk ratios (RRs), assessing the association between exposure and disease, indicating the risk of developing the disease in the exposed group versus the nonexposed group with 95% CIs and aggregated using an inverse variance–weighted random effects model. Forest plots were used to graphically display the pooled analyses. The Higgins $I^2$ was used to assess heterogeneity between trials; a value of 25%-50% was regarded as low, 50%-75% as moderate, and >75% as serious. In all cases, a $P$ value less than .05 was considered significant.

**Results**

**Search Results**

Our initial search yielded 2760 potentially relevant articles, of which 21 were selected for full-text review. Upon further exclusions, 7 observational studies, with a total of 6919 patients, were shortlisted for data extraction [10-16]. The PRISMA flowchart in Figure 1 shows the literature search in detail.

**Study Characteristics and Quality Assessment**

Study characteristics and baseline demographics are summarized in Table 2. Observational studies were assessed to be of moderate to high quality, achieving scores from 4 to 6 out of a maximum of 9 on the Newcastle-Ottawa scale (Table 3).
Table 2. Baseline characteristics of the included studies.

Outcomes

**Treatment Outcome**

Five studies reported treatment outcomes among patients with TB, which included patients who completed the treatment and were completely cured. Our meta-analysis revealed a significant difference in treatment outcomes between patients with OGC and those with PGC (RR 0.86, 95% CI 0.74-1.00; P=0.05; I²=51%; Figure 2).

**Sputum Positivity Following Treatment**

Three studies reported sputum positivity as an outcome among patients with TB. Sputum positivity was more likely among patients with PGC than among those with OGC (RR 0.23, 95% CI 0.09-0.61; P=0.003; I²=66%; Figure 3).

**Mortality**

Two studies reported mortality as an outcome among patients with TB. Mortality was not significantly different between patients with OGC and those with PGC (RR 0.57, 95% CI 0.22-1.49; P=0.25; I²=0%; Figure 4).
Radiological Outcomes

A total of 3 studies reported radiological findings among patients with TB. These findings were further divided into cavitary lesions, multilobar involvement, isolated upper lobe involvement, and lower lobe involvement.

Cavitary Lesions

Three studies reported cavitary lesions as one of their radiological findings. Patients with OGC had a lower risk of cavitary lesions than those with PGC (RR 0.59, 95% CI 0.51-0.68; \( P < .001; \ I^2 = 0\% \); Figure 5).

Multilobar Involvement

Among the 3 studies reporting radiological findings, 2 reported multilobar involvement. There was no significant difference between patients with OGC and those with PGC (RR 0.82, 95% CI 0.58-1.17; \( P = .27; \ I^2 = 0\% \); Figure 6).

Isolated Upper or Lower Lobe Involvement

Two studies reported isolated lower lobe involvement, while 1 study reported isolated upper lobe involvement as their radiological outcomes. There was no significant difference between patients with OGC and those with PGC for both upper (RR 0.94, 95% CI 0.76-1.17; \( P = .58; \ I^2 = 0\% \)) and lower lobe involvement (RR 1.05, 95% CI 0.48-2.30; \( P = .91; \ I^2 = 75\% \); Figures 7 and 8).

Discussion

Principal Findings

This meta-analysis evaluating the impact of OGC among patients with TB reports several key findings. First, patients with OGC demonstrated a decreased risk of the aforementioned treatment outcomes. Second, we observed decreased sputum positivity in patients with OGC compared to that in patients with suboptimal glycemic control. Third, there was a decreased risk of cavitary lesions on radiologic examination among patients with OGC.
The analysis revealed a significant improvement in treatment outcomes among patients with OGC compared to those with PGC. This finding is consistent with those of previous studies highlighting the importance of glycemic control in reducing the risk of complications and improving treatment responses in individuals with DM [17,18]. The ability to achieve OGC may enhance the body's immune response, leading to better control of the TB infection and a more favorable treatment outcome [19]. Moreover, our analysis showed that patients with OGC had decreased sputum positivity. This may be attributable to the quicker clearance of bacteria from the airways, resulting in earlier detection. The decreased sputum positivity following OGC points toward the clinical benefits and importance of achieving OGC among patients with TB.

There was no significant difference in mortality between patients with OGC and those with PGC. This result contradicts the findings of previous studies that have linked DM to an increased risk of mortality among patients with TB [20]. It is important to note that the studies included in the meta-analysis might have varied in terms of follow-up duration and other factors that could influence mortality outcomes. Further research is needed to better understand the relationship among glycemic control, TB treatment outcomes, and mortality.

Patients with OGC had a lower risk of cavitary lesions than those with PGC, according to our analysis. Cavitary lesions are indicative of advanced disease and are associated with an increased risk of TB transmission [21]. This finding suggests that OGC may aid in preventing the progression of disease and decreasing the risk of transmission. However, multilobar involvement, isolated upper lobe involvement, and isolated lower lobe involvement did not differ significantly between patients with OGC and those with PGC. This indicates that OGC may have a limited effect on the distribution of TB lesions in the lungs [22].

Publication bias—the tendency of studies with positive or statistically significant results to be published more readily than those with null or negative results—is a concern in meta-analyses. However, due to the limited number of studies available for each outcome, the statistical power of Egger and Begg tests may have been compromised. As such, the ability to draw definitive conclusions regarding publication bias is constrained. To mitigate this limitation, we attempted to include a broad range of studies by searching multiple databases and imposing minimal restrictions on study design. Additionally, we actively sought unpublished studies, conference abstracts, and gray literature to reduce the impact of publication bias. However, despite these efforts, it is essential to interpret our findings with caution, considering the potential influence of publication bias on the reported results.

Overall, our findings indicate that OGC is essential for enhancing TB treatment outcomes and lowering the risk of advanced disease. In patients with TB, health care providers should consider screening for DM and managing glycemic control [23]. To thoroughly comprehend the relationship among DM, glycemic control, and TB outcomes, additional research is required.

In evaluating the robustness of our findings, we conducted a thorough quality assessment using the Cochrane Risk of Bias Tool, systematically appraising studies across key domains. While our inclusive approach aimed to minimize publication bias by considering a broad range of studies and actively seeking unpublished data, the limitations in conclusively identifying and mitigating publication bias should be acknowledged. Regarding heterogeneity, variations in study design, patient populations, glycemic control thresholds, and outcome measurements were identified as potential sources. These factors introduce complexity and may limit the generalizability of our results. Clinicians should interpret our findings with caution, considering the diverse contexts and populations represented in the included studies. Future research addressing standardized definitions of glycemic control and consistent outcome measures will contribute to a more nuanced understanding of the relationship between glycemic control and TB treatment outcomes.

Our comprehensive findings have clinical implications for both individual patient care and public health strategies in the context of TB management. Notably, OGC not only improves overall TB treatment outcomes but also has emerged as a critical factor in reducing its infectiousness, as evidenced by the observed decreases in sputum positivity and the lower risk of cavitary lesions. The reduction in sputum positivity implies a potential limitation on TB transmission, presenting a dual benefit for both individual patients’ well-being and broader public health goals. Additionally, the lower risk of cavitary lesions, indicative of advanced TB disease, signifies a potential avenue for mitigating the contagiousness of patients with TB. Clinicians should emphasize the importance of achieving and sustaining OGC, recognizing its dual impact on individual health and community-level TB transmission. Integrated health care strategies focusing on glycemic control in patients with TB are vital, providing actionable insights for clinicians and public health practitioners alike and contributing to the overarching goal of TB control and prevention. While our findings provide valuable insights into the association between glycemic control and TB outcomes in patients with DM, generalizing these results to a wider population requires caution. The unique characteristics of patients with TB with DM, the potential variations in glycemic control thresholds, and the diverse health care settings may limit the direct applicability of our findings to those without DM or with different comorbidities. Furthermore, the prevalence of observational studies in our analysis introduces biases that may affect the external validity of our results. Caution is advised in extending these findings to diverse patient populations, and future research should explore the relationship between glycemic control and TB outcomes in broader contexts, considering various comorbidities and health care settings.

However, there are some limitations to consider in interpreting the results. First, the included studies were observational in nature, which may introduce biases, such as selection bias and confounding factors that could influence the results. Moreover, an observational study design has variability in its population, selective and incomplete reporting, and improper randomization, which may contribute to the heterogeneity observed in this
study. Second, heterogeneity was observed in some of the studies, which may be attributed to differences in study design, patient populations, and glycemic control thresholds across the included studies. The limited research carried out on this topic shows that OGC is an important predictor of outcomes in patients with TB; however, there are some discrepancies, which may raise doubt among clinicians. Thus, future investigation on this topic is warranted in order to derive a robust conclusion.

Conclusions
In conclusion, our meta-analysis compiled data from observational studies assessing glycemic control in patients with TB, and our results suggest that OGC may have a significant impact on improving treatment outcomes and reducing sputum positivity in patients with TB. However, no significant difference was found in mortality between patients with OGC and those with PGC. OGC was also associated with a lower risk of cavitary lesions but had no significant effect on multilobar or isolated upper or lower lobe involvement. These findings highlight the importance of early detection of TB in patients with DM so that OGC can be provided promptly to those patients, thus improving their outcomes. This topic warrants further research, especially RCTs focusing on mortality and other outcomes in different severities of TB among patients with DM.

Abstract

Background: The unprecedented emergence of the COVID-19 pandemic necessitated the development and global distribution of vaccines, making the understanding of global vaccine acceptance and hesitancy crucial to overcoming barriers to vaccination and achieving widespread immunization.

Objective: This umbrella review synthesizes findings from systematic reviews and meta-analyses to provide insights into global perceptions on COVID-19 vaccine acceptance and hesitancy across diverse populations and regions.

Methods: We conducted a literature search across major databases to identify systematic reviews and meta-analysis that reported COVID-19 vaccine acceptance and hesitancy. The AMSTAR-2 (A Measurement Tool to Assess Systematic Reviews) criteria were used to assess the methodological quality of included systematic reviews. Meta-analysis was performed using STATA 17 with a random effect model. The data synthesis is presented in a table format and via a narrative.

Results: Our inclusion criteria were met by 78 meta-analyses published between 2021 and 2023. Our analysis revealed a moderate vaccine acceptance rate of 63% (95% CI 0.60%-0.67%) in the general population, with significant heterogeneity ($I^2 = 97.59$%). Higher acceptance rates were observed among health care workers and individuals with chronic diseases, at 64% (95% CI 0.57%-0.71%) and 69% (95% CI 0.61%-0.76%), respectively. However, lower acceptance was noted among pregnant women, at 48% (95% CI 0.42%-0.53%), and parents consenting for their children, at 61.29% (95% CI 0.56%-0.67%). The pooled vaccine hesitancy rate was 32% (95% CI 0.25%-0.39%) in the general population. The quality assessment revealed 19 high-quality, 38 moderate-quality, 15 low-quality, and 6 critically low-quality meta-analyses.

Conclusions: This review revealed the presence of vaccine hesitancy globally, emphasizing the necessity for population-specific, culturally sensitive interventions and clear, credible information dissemination to foster vaccine acceptance. The observed disparities accentuate the need for continuous research to understand evolving vaccine perceptions and to address the unique concerns and needs of diverse populations, thereby aiding in the formulation of effective and inclusive vaccination strategies.

Introduction

The global health landscape has been profoundly altered by the emergence of COVID-19, triggered by SARS-CoV-2. First identified in Wuhan, China, in December 2019, this virulent pathogen swiftly traversed continents, leading the World Health Organization (WHO) to categorize the situation as both a pandemic and public health emergency of international concern. The repercussions of this pandemic have been multifaceted, with a staggering death toll and profound impact on socioeconomic structures worldwide [1]. In the face of this unprecedented challenge, the global community recognized the pressing need for effective countermeasures. Although therapeutic interventions were explored, the primary focus shifted to preventive strategies, with vaccines against COVID-19 emerging as the most promising solution [2]. The efficacy of this approach, however, is contingent not just on the scientific success of vaccine development but equally on the global populace’s acceptance of these vaccines [3].

By the midpoint of 2022, the scientific community had successfully developed, trialed, and secured emergency use authorization for several vaccines [4]. However, the distribution of these vaccines unveiled pronounced disparities [5]. Higher-income nations, with their robust health care infrastructures and financial resources, rapidly initiated vaccination drives. In stark contrast, many resource-limited countries faced challenges ranging from limited vaccine access to infrastructural constraints [6]. A more insidious challenge that emerged globally, irrespective of a country’s economic status, was vaccine hesitancy. Rooted in a complex interplay of factors, including safety apprehensions, distrust toward health advisories, cultural nuances, and the deluge of misinformation, vaccine hesitancy has been observed across diverse geographies, from Africa and Europe to North America [3].

Empirical studies conducted across various regions have painted a mixed picture of vaccine acceptance [3,7]. Although certain demographics exhibited a commendable eagerness to embrace vaccination, others displayed pronounced skepticism [3,8]. These disparities in vaccine acceptance, if unchecked, have the potential to impede global strides toward achieving herd immunity, a critical milestone in the fight against the pandemic. Recognizing the pivotal role of vaccine acceptance in the trajectory of the pandemic, it becomes imperative to understand the nuances of global vaccine perceptions. Numerous systematic reviews and meta-analyses have been published, shedding light on factors that are driving vaccine hesitancy and acceptance [8-17].

In this context, our umbrella review sought to collate and synthesize findings from these diverse studies, aiming to present a holistic understanding of global COVID-19 vaccine acceptance rates and hesitancy rates. This approach offers a comprehensive
overview of existing evidence, highlighting consistencies and discrepancies across studies. By assessing the quality and breadth of current research, umbrella reviews identify knowledge gaps and inform evidence-based decision-making. They serve as a valuable tool for policymakers, clinicians, and researchers, providing a holistic understanding of a topic without the need for sifting through numerous individual studies. Through this study, we aspired to provide valuable insights that can steer future vaccination strategies, ensuring they are both effective and inclusive. Our umbrella review aimed to collate and synthesize findings from these diverse studies to present a comprehensive understanding of global COVID-19 vaccine acceptance and hesitancy rates.

**Methods**

The method for conducting this umbrella review was based on the framework set forth by the Joanna Briggs Institute [18]. This study adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guideline [19] (Multimedia Appendix 1). This study was registered in PROSPERO.

**Inclusion Criteria**

We specifically targeted meta-analyses of epidemiological studies that investigated either the acceptance/willingness or hesitancy toward the COVID-19 vaccine. Our scope was global, encompassing studies from all geographical locations without any specific focus on a particular population. This inclusivity ensured that our review captured a diverse range of perspectives and settings. However, to maintain the rigor and specificity of our review, we excluded certain types of publications. Specifically, narrative or systematic reviews that did not include a meta-analysis, conference abstracts, and letters to the editors were not considered. In essence, our inclusion criteria were centered on meta-analyses of prospective, retrospective, or cross-sectional studies that evaluated rates of vaccine acceptance or hesitancy (Table S1 in Multimedia Appendix 2).

**Literature Search**

We conducted a comprehensive literature search across 4 major databases: PubMed, Scopus, Embase, and the Cochrane Database of Systematic Reviews. The search spanned from the inception of each database until August 20, 2023. To ensure a thorough retrieval of relevant articles, “keyword search” and “textword search” were used, and different search phrases were combined using Boolean and proximity operators. Specifically, we used the terms (“meta-analysis” OR “systematic review”) AND (Acceptance OR willingness OR hesitancy OR intention OR unwillingness) AND (“COVID-19” OR “Sars-cov-2” OR “corona“”). To further enhance the robustness of our search, we also manually screened the reference lists of the identified articles. This step ensured that we did not overlook any pertinent studies that might not have been captured through the database search. For transparency and replicability, the complete search strategy, including all terms and combinations used, is documented in Table S2 in Multimedia Appendix 2. Importantly, we did not impose any filters or restrictions during our search. This means that articles of any type, published in any year, and in any language were considered, ensuring a broad and inclusive search scope.

**Screening**

The screening process for this systematic review was conducted by 2 independent authors, structured into 2 sequential steps to ensure unbiased selection and comprehensive coverage of relevant studies. The first step, primary screening, involved scrutinizing the titles and abstracts of identified articles to shortlist those potentially relevant to topic. Subsequently, in the second step, articles that passed the primary screening were subjected to a thorough full-text review. During this stage, the authors carefully evaluated the complete content of each article, focusing on the removal of duplicates and a more detailed assessment of each study’s relevance and alignment with the review’s scope and objectives. To enhance the precision and efficiency of our screening process, we used the specialized software Nested Knowledge with its AutoLit function, instrumental in streamlining our workflow and improving the accuracy of article selection. In cases of disagreement or uncertainty between the 2 reviewers, a third reviewer with senior expertise was engaged to mediate and provide decisive judgment, ensuring a consensus-based approach to the final selection of studies.

**Data Extraction**

During the data extraction process, 2 independent authors systematically reviewed each study that met our inclusion criteria. From each eligible meta-analysis, they gathered a comprehensive set of details. This included the first author's name, year of publication, type of study design, total number of participants, type of population, and the date when the database search was conducted. Additionally, they extracted the pooled acceptance rate for each subgroup and specific number of participants within these subgroups, accompanied by their 95% CIs. Furthermore, they documented the P values for pooled effects, the results from the Egger or Beggs test (which measures publication bias), and the I² statistics, which offer insights into the heterogeneity of the studies. Any associated P value for significance was also recorded. Given the complexity of the data and the importance of accuracy, any discrepancies or disagreements that arose between the 2 primary authors were diligently addressed. They consulted a third, senior reviewer to ensure consistency and precision in the data extraction process.

**Assessment of Methodological Quality**

To ensure the rigor and reliability of our review, the methodological quality of each included meta-analysis was meticulously evaluated. This assessment was jointly undertaken by 2 authors using the well-established AMSTAR-2 (A Measurement Tool to Assess Systematic Reviews) tool [20], which is recognized for its robustness in appraising systematic reviews. Based on the criteria set by AMSTAR-2, studies were categorized into 1 of 4 methodological quality grades: high, moderate, low, or critically low. A study was deemed to be of high quality if it exhibited no flaws or only a single minor defect. In contrast, a moderate quality designation was given to studies that presented multiple minor defects. The distinction between...
minor and major defects was made based on the guidelines provided by the AMSTAR-2 tool. Any disagreements or uncertainties regarding the quality grading were discussed and resolved collaboratively between the 2 authors to ensure a consistent and objective assessment.

Data Analysis

Data analysis was conducted using STATA version 17. Proportions, along with their 95% CIs, were pooled from all included eligible meta-analyses for each outcome and based on the population [21]. We used a random effects model to compute the combined effect sizes, recognizing the inherent variability among the studies and providing a more conservative estimate of the overall effect. The degree of variability or heterogeneity in outcomes across studies was quantified using the $I^2$ metric. Values for $I^2$ can range from 0% to 100%, with higher values indicating greater heterogeneity. We predetermined specific thresholds to assess the statistical significance of the observed heterogeneity. The 95% prediction interval provides a more comprehensive understanding of the range in which the true effect size lies, considering the observed heterogeneity. A $P$ value <0.05 was considered statistically significant.

Results

Search Results

We identified a total of 662 articles through the primary search, of which 263 duplicates were eliminated, leaving 399 for title and abstract screening. In the primary screening (title and abstract), 214 articles were excluded, leaving 185 articles for full-text screening (Figure 1). We excluded 108 articles for various reasons, including only systematic reviews without a meta-analysis and the incorrect population, outcomes, or study design. As a result, 77 articles fulfilled the eligibility criteria. Additionally, we conducted a citation search to maintain the rigor of the review and found 4 relevant articles, of which 1 was included. This umbrella review ultimately identified 78 meta-analyses that met the inclusion criteria.

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram illustrating the screening and selection process.

Characteristics of Meta-Analyses and Quality Assessment

Table S3 in Multimedia Appendix 2 [9-17,22-90] presents an overview of all included meta-analyses published between 2021 and 2023. These studies looked at different groups, such as the general population; health care workers; parents; pregnant women; migrant workers; Black or African communities; Chinese communities; and people with specific health conditions such as cancer, HIV, diabetes, inflammatory bowel disease, and epilepsy. The focus of these meta-analyses was on outcomes such as the rates of vaccine acceptance, hesitance, willingness, uncertainty, and unwillingness, as well as the intention to receive vaccines. Most of the meta-analyses included articles from around the world, while some concentrated on specific countries. The quality of these meta-analyses was evaluated using the AMSTAR-2 criteria. Among the meta-analyses examined, 19 meta-analyses were rated as being of high quality; 38 meta-analyses received a moderate quality rating; 15 meta-analyses received a low quality rating, which points to potential limitations in their methodology; and 6 meta-analyses were classified as having critically low quality, implying significant concerns about their methods and the reliability of their findings (Table S4 in Multimedia Appendix 2 [9-17,22-90]).
Vaccine Acceptance and Hesitancy Among Populations

Table 1 provides a summary of vaccine acceptance and hesitancy rates among different populations. Acceptance rates were studied in 58 systematic reviews and meta-analyses, and 12 distinct reviews reported on hesitancy rates (Table 2).

**Vaccine Acceptance**

We synthesized findings from 29 systematic reviews to assess the vaccine acceptance rate in the general population. The pooled acceptance rates ranged from 51% to 81%. Our meta-analysis revealed a consolidated vaccine acceptance rate of 63% (95% CI 0.60%-0.67%). Notably, a high level of heterogeneity was observed, with an $I^2$ of 97.59% (Figure 2). The 8 systematic reviews focused on individuals with chronic diseases reported a pooled acceptance rate of 69% (95% CI 0.61%-0.76%) and an $I^2$ of 87.5% (Multimedia Appendix 3). Health care workers were the focus of 10 systematic reviews and meta-analyses, indicating a 64% acceptance rate (95% CI 0.57%-0.71%) and a heterogeneity $I^2$ of 91.72% (Multimedia Appendix 4). Vaccine acceptance was comparatively lower among pregnant women, as depicted by 9 systematic reviews, showing a rate of 48% (95% CI 0.42%-0.53%) and an $I^2$ of 74.2% (Multimedia Appendix 5). Similarly, 5 systematic reviews presented a 61.29% acceptance rate (95% CI 0.56%-0.67%) with 50% heterogeneity for parents consenting for their children (Multimedia Appendix 6). Vaccine acceptance among migrants and refugees was investigated by 2 reviews, showing a prevalence of 69% (95% CI 0.56%-0.82%; Multimedia Appendix 7).
Vaccine Hesitancy

Figure 3 shows the forest plot of COVID-19 vaccine hesitancy for different populations. Vaccine hesitancy in the general population was reported by 5 systematic reviews, with the observed hesitancy varying between 25% and 42%. Our meta-analysis showed a pooled vaccine hesitancy rate of 32% (95% CI 0.25%-0.39%), with a high level of heterogeneity ($I^2=73.90\%$). In older adults, 1 review reported a hesitancy rate of 27% (95% CI 0.15%-0.38%). For Black people or African Americans, vaccine hesitancy was 35% (95% CI 0.26%-0.45%) in another review. Pregnant or breastfeeding women exhibited a higher hesitancy rate of 48.4% (95% CI 0.43%-0.53%), as reported by another systematic review. Results on the hesitancy rates among parents considering vaccinating their children were provided by 2 reviews, revealing a pooled hesitancy rate of 39% (95% CI 0.07%-0.70%), accompanied by a high level of heterogeneity ($I^2=95.7\%$). Migrant workers exhibited a hesitancy
rate of 31% (95% CI 0.21%-0.41%) according to 1 study. Last, health care workers showed a rate of 29% (95% CI 0.18%-0.33%), as concluded from 2 systematic reviews.

**Figure 3.** Forest plot showing COVID-19 vaccine hesitancy rates for different populations. REML: restricted maximum likelihood.

**Discussion**

Our umbrella review synthesized findings from numerous systematic reviews and meta-analyses, providing insights into global vaccine acceptance and hesitancy rates across diverse populations and geographies. The consolidated acceptance rate of 63% in the general population indicates a moderate level of willingness to receive the vaccine.

The emergence of the COVID-19 pandemic necessitated the prompt development and distribution of vaccines to curb the spread of the virus and mitigate its adverse impacts on global health, economies, and societies [91]. As of the midpoint of
2021, several vaccines had received emergency use authorization, signifying a milestone in the fight against the pandemic. However, the realization of the potential of these vaccines is significantly influenced by the global population's acceptance and willingness to get vaccinated [92,93]. However, the significant heterogeneity observed in this and other populations studied underscores the diverse and complex landscape of vaccine perceptions globally [53]. The vaccine acceptance rates among health care workers and individuals with chronic diseases were relatively higher, possibly reflecting a better understanding of the disease's risk and the vaccine's benefits by these populations [94,95]. However, the observed heterogeneity suggests diverse opinions and possibly varied information dissemination within these groups. The disparities in vaccine acceptance and hesitancy across populations are emblematic of the intricate tapestry of perceptions, beliefs, and information access that characterize the global populace. For instance, the lower acceptance rates observed among pregnant women and parents consenting for their children are likely influenced by concerns about vaccine safety in these vulnerable groups, emphasizing the need for targeted communication strategies addressing these concerns [96].

The pronounced disparities in vaccine acceptance across different populations highlight the urgent need for tailored, population-specific intervention strategies [97]. A one-size-fits-all approach may not address the unique concerns, misconceptions, and information needs of different demographic groups. For example, pregnant women exhibited lower acceptance and higher hesitancy rates, possibly due to concerns regarding the vaccine's impact on pregnancy and the fetus [98,99]. Addressing such specific concerns through targeted awareness campaigns and counseling can enhance vaccine acceptance in this group. Similarly, the lower acceptance rates in parents consenting for their children necessitate interventions addressing parental concerns about vaccine safety and efficacy in children [100]. Engaging pediatricians and child health care providers in vaccine advocacy can potentially alleviate parental apprehensions and foster trust. The high heterogeneity observed across studies denotes the existence of multiple influencing factors, including cultural, socioeconomic, educational, and individual beliefs, which vary extensively within and across populations [101,102]. The variations may also reflect the differences in study designs, populations, and time frames, emphasizing the need for standardization in future research to facilitate comparability and generalizability [103].

The emergence of vaccine hesitancy as a global phenomenon irrespective of a country's economic status underscores the influential role of information dissemination and public perception in shaping vaccine-related behaviors [104,105]. Misinformation and distrust in health advisories have been pivotal in fostering hesitancy, indicating the need for credible, clear, and consistent communication from health authorities and governments [106-110]. Addressing misinformation necessitates a multifaceted approach involving the collaboration of health care providers, public health officials, social media platforms, and community leaders. The propagation of accurate, comprehensible, and transparent information regarding vaccine development, efficacy, and safety can contribute to counteracting misinformation. Health care workers, with an acceptance rate of 64%, play a crucial role in shaping public perceptions and behaviors regarding vaccination [111]. As trusted sources of health information, health care providers can effectively address concerns, clarify misconceptions, and advocate for the benefits of vaccination [63,68]. Their interactions with patients and communities can significantly influence vaccine acceptance, especially in populations with high hesitancy levels, such as pregnant women and parents. However, the hesitancy rate of 29% among health care workers is concerning, as it can potentially impact their vaccine advocacy efforts. Addressing the concerns and information needs of health care workers is imperative to fostering confidence in vaccines and enhancing their role as vaccine advocates.

The acceptance and hesitancy rates in specific communities, such as Black or African American and Chinese communities, underscore the impact of cultural and community nuances on vaccine perceptions [112,113]. Culturally sensitive approaches, community engagement, and addressing systemic barriers are essential to enhancing vaccine acceptance in such communities [114,115]. The 80% acceptance rate in Chinese communities may be indicative of the influence of community norms, government policies, and public health campaigns in shaping vaccine perceptions. Understanding the sociocultural dynamics and leveraging community influences can be instrumental in developing effective strategies to enhance vaccine acceptance in different cultural contexts.

This umbrella review, although offering insights into global vaccine acceptance and hesitancy, does possess limitations inherent to the studies included. The substantial heterogeneity across these studies hinders the ability to draw definitive conclusions and underscores the necessity for a cautious interpretation of the findings. Variations in study designs, targeted populations, time frames, and geographic locations highlight the need for standardization in future research to improve comparability and generalizability. Our review only included articles published in English. The overlap of the same primary studies is inevitable; different systematic reviews might have included the same primary studies.

Future research should focus on exploring the underlying factors influencing vaccine acceptance and hesitancy in diverse populations and contexts. Qualitative studies can provide in-depth insights into individual beliefs, perceptions, and information needs, enabling the development of targeted interventions. Longitudinal studies can assess the temporal variations in vaccine perceptions and the impact of evolving information landscapes on vaccine-related behaviors.
Authors' Contributions
TAR, PS, RI, and AD conceived of or designed the study. AAR, HAA, MFAS, NAAK, MA, AAALI, HAA, IHN, SR, and NK collected the data. KALM, MNK, SG, and QSZ analyzed the data. PS, TAR, RI, and AD drafted the manuscript. KALM, MNK, SG, and QSZ critically revised the manuscript. All authors gave final approval for submission. All authors attest they meet the ICMJE criteria for authorship.

Conflicts of Interest
None declared.

Abstract

Background: The Ministry of Health in Côte d’Ivoire and the International Training and Education Center for Health at the University of Washington, funded by the United States President’s Emergency Plan for AIDS Relief, have been collaborating to develop and implement the Open-Source Enterprise-Level Laboratory Information System (OpenELIS). The system is designed to improve HIV-related laboratory data management and strengthen quality management and capacity at clinical laboratories across the nation.

Objective: This evaluation aimed to quantify the effects of implementing OpenELIS on data quality for laboratory tests related to HIV care and treatment.

Methods: This evaluation used a quasi-experimental design to perform an interrupted time-series analysis to estimate the changes in the level and slope of 3 data quality indicators (timeliness, completeness, and validity) after OpenELIS implementation. We collected paper and electronic records on clusters of differentiation 4 (CD4) testing for 48 weeks before OpenELIS adoption until 72 weeks after. Data collection took place at 21 laboratories in 13 health regions that started using OpenELIS between 2014 and 2020. We analyzed the data at the laboratory level. We estimated odds ratios (ORs) by comparing the observed outcomes with modeled counterfactual ones when the laboratories did not adopt OpenELIS.
**Results:** There was an immediate 5-fold increase in timeliness (OR 5.27, 95% CI 4.33-6.41; \( P < .001 \)) and an immediate 3.6-fold increase in completeness (OR 3.59, 95% CI 2.40-5.37; \( P < .001 \)). These immediate improvements were observed starting after OpenELIS installation and then maintained until 72 weeks after OpenELIS adoption. The weekly improvement in the postimplementation trend of completeness was significant (OR 1.03, 95% CI 1.02-1.05; \( P < .001 \)). The improvement in validity was not statistically significant (OR 1.34, 95% CI 0.69-2.60; \( P = .38 \)), but validity did not fall below pre-OpenELIS levels.

**Conclusions:** These results demonstrate the value of electronic laboratory information systems in improving laboratory data quality and supporting evidence-based decision-making in health care. These findings highlight the importance of OpenELIS in Côte d’Ivoire and the potential for adoption in other low- and middle-income countries with similar health systems.

**Introduction**
Clinical laboratories provide critically important data for disease investigations and supply timely information for public health. Laboratory results help identify and characterize pathogens, conduct routine surveillance, and respond to communicable and noncommunicable diseases. Effective and timely laboratory services help achieve national disease priorities and global targets including the Sustainable Development Goals and the 95-95-95 targets launched by the Joint United Nations Programme on HIV/AIDS [1-5].

Clusters of differentiation 4 (CD4) testing is critical for monitoring the immune status of people living with HIV and the risk of opportunistic infections. Health care providers depend on laboratory results to decide on differentiated care models and tuberculosis screening [6]. For a national HIV program to be highly successful and reduce HIV-related deaths, the health system must integrate data from an effective clinical laboratory system. Access to quality laboratory services remains a challenge in low- and middle-income countries (LMICs), and many still rely on paper-based records [7]. Throughout the cascade of care, paper documents and records require a careful chain of possession, tracking, and version control, and their use and sometimes loss can impede an already complex process of service delivery. Problems in data quality could occur at every step of this manual process, jeopardizing the quality of care.

Laboratory information systems (LISs) are an important part of the infrastructure for laboratory operation and information management. According to the requirements for quality and competence of medical laboratories issued by the International Organization for Standardization (ISO), most of the information management requirements are for electronic systems [8]. This signals that, to reach ISO standards, laboratories should use electronic rather than paper-based LISs. The World Health Organization established the Stepwise Laboratory Quality Improvement Process Toward Accreditation (SLIPTA) checklist to guide clinical laboratories in Africa through continuous quality improvement toward accreditation to international standards [9]. The SLIPTA checklist highlights computerized LISs as an integral step to ensuring laboratory operation and fulfilling the criteria of laboratory information management on ensuring data quality, data storage and backup, and patient confidentiality [9]. The lack of effective electronic LISs is one of the barriers to quality laboratory service delivery in LMICs [10].

LISs can improve the quality of care, patient safety, and disease surveillance [10-14]. Compared to paper-based information systems, electronic LISs provide more timely and more accurate monitoring and reporting of turnaround time, test failure rates, and other laboratory quality indicators essential to informing clinical care [10]. The features in the Open-Source Enterprise-Level Laboratory Information System (OpenELIS) are intended to ensure data timeliness, completeness, and validity. Control elements and graphical widgets such as drop-down menus and radio buttons make data entry easier and faster, supporting data timeliness and validity. Required data fields must be completed to generate the laboratory result for a patient, assuring data completeness. Valid ranges displayed alongside each test result, the flags for manual review of out-of-range results, and the mandatory validation step before generating results help ensure data validity.

The International Training and Education Center for Health (I-TECH) has been collaborating with the Ministry of Health, Public Hygiene, and Universal Health Coverage (MSHPCMU) in Côte d'Ivoire since 2009 with funding from the United States President’s Emergency Plan for AIDS Relief to build a functional, accredited diagnostic and laboratory network for effective HIV care and treatment. One of the key program interventions is establishing and supporting the use of OpenELIS interfacing with laboratory testing analyzers [15]. From 2009 to 2021, OpenELIS was installed at 108 laboratories in Côte d'Ivoire, including 68 sites that use it primarily for HIV data, 1 for food and drug safety data, 27 for tuberculosis data only, and 12 sites that use OpenELIS for routine laboratory testing data.

This study aims to estimate the effect of OpenELIS on data quality indicators including data completeness, timeliness, and validity, using CD4 testing data. Specifically, we aimed to answer the following questions: (1) Did the use of OpenELIS in Côte d'Ivoire’s clinical laboratories lead to statistically significant improvements in the data quality outcomes? (2) If so, what was the magnitude of the improvements compared to the counterfactual scenario in which the laboratories had not
adopted OpenELIS? and (3) Had the improvements persisted after the initial adoption of OpenELIS?

Beyond a single study of the effect of an LIS on laboratory turnaround time in Peru [16], there is limited evidence on how LIS interventions enhance data quality in LMICs. Findings from our study will provide evidence on the effectiveness of the OpenELIS intervention in improving data quality; inform policy recommendations and guidance for the Côte d'Ivoire MSHPCMU; and inform decision makers elsewhere to consider adopting OpenELIS in countries with a context similar to Côte d'Ivoire.

Methods

Study Design and Data Sources

We conducted an interrupted time-series analysis using weekly time-series data. The interrupted time-series analysis is a quasi-experimental design in the evaluation of health care interventions or policies that are introduced at a specific time [17,18]. We hypothesized that, compared to paper registries, OpenELIS would improve laboratory data quality measured by 3 primary outcomes, that is, timeliness, completeness, and validity (Figure 1). Timeliness was defined as the proportion of test results produced within 1 day upon receiving test samples. Completeness was defined as the proportion of test results having complete data on all 4 required data fields, namely patient identifier, age, sex, and result date. Validity was defined as the proportion of CD4 cell count test results that were within the valid range (0-2000 cells/mm³).

We collected time-series data in January 2021 from 21 clinical laboratories across 13 health regions in Côte d'Ivoire that started using OpenELIS between 2014 and 2020 (Figure 2). The time frame of the time-series data covered up to 48 weeks before a laboratory started using OpenELIS until up to 72 weeks after. This sampling considered adequate representation in terms of geography and service capacity, as well as the feasibility of data collection. A total of 5 sites were regional reference laboratories that provided HIV viral load testing services, 3 were regional laboratories that were not reference sites for HIV viral load testing, and 13 were part of either at general hospitals or urban hospitals that provided HIV-related laboratory services at the district level. We abstracted deidentified, individual-level patient data for all outcomes from laboratory paper registries for the preimplementation period and from local OpenELIS servers for the postimplementation period. Data were aggregated by laboratory and organized by week to model the outcomes. The number of laboratories whose data were incorporated in the analyses for timeliness, completeness, and validity was 8, 21, and 20, respectively. The reasons why the number of laboratories for each outcome was different are the following. To estimate the timeliness of the data in paper registries, we needed to link individual-level records from test sample reception registries with those from test result registries by unique medical record number. A total of 13 of the 21 sampled laboratories did not have any sample reception registries from before they started using OpenELIS, so we could only estimate changes in timeliness at 8 laboratories. Accidents such as fire and flood were the most common reasons why laboratories were missing paper records, and some laboratories destroyed paper records older than 5 years because the national policy only requires 5 years for archiving paper records. To estimate completeness, we had all necessary data from all 21 sampled sites. To estimate validity, we needed data on CD4 cell counts, but 1 laboratory did not record CD4 cell counts in OpenELIS. Therefore, we could only estimate changes in validity for 20 sites.
**Figure 1.** Data flow process for a typical clinical laboratory test in Côte d’Ivoire (A) before and (B) after adopting OpenELIS. * denotes the difference between OpenELIS and a paper-based laboratory information system. Figure 2. The 13 health regions in Côte d’Ivoire where data were collected from paper registries and OpenELIS for the evaluation of the effect of OpenELIS on data quality in Côte d’Ivoire from 2014-2020. OpenELIS: Open-Source Enterprise-Level Laboratory Information System. Adapted from Wikimedia [19], which is published under Creative Commons Attribution 4.0 International License [20].

Statistical Analysis

We used a mixed-effects, segmented logistic regression model to examine the trend of the primary outcomes and their changes associated with OpenELIS implementation. We estimated odds ratios (ORs) representing weekly outcomes compared with outcomes that would have occurred if the laboratories had not adopted OpenELIS. We reported both the level change and slope change, specifically investigating the abrupt changes in outcomes observed during the first week of OpenELIS implementation and the weekly changes in the trend starting from the second week of OpenELIS implementation.

We included fixed-effect monthly indicator variables in the models to account for seasonal effects, random intercepts to account for clustering at the laboratory level, and random slopes over time. We also accounted for the weekly number of HIV clients recorded at a given laboratory as weight. The logistic regression model equation we used was:

\[
y_{it} = \alpha_0 + \alpha_T \cdot \text{Time} + \alpha_OE \cdot OE_{i1} + \alpha_OE \cdot OE_{i2} + \alpha_P \cdot \text{Post time} + \alpha_M \cdot \text{Month} + \epsilon_{it}
\]

where \( i \) indicates laboratory and \( t \) indicates week as the time unit. \( y_{it} \) represents the proportion of laboratory records achieving each of the 3 primary outcomes comparing the factual to the counterfactual; \( \alpha_0 \) represents the model intercept with a fixed effect and a random effect at the laboratory level; \( \text{Time} \) counts the weeks from the earliest preimplementation time point until the latest postimplementation time point; \( \text{OE} \) is the dummy variable indicating the weeks when a laboratory \( i \) was using OpenELIS (1 for the first week when a laboratory started using and thereafter and 0 otherwise); \( \text{Post time} \) counts the weeks after the first week of implementation; and \( \text{Month} \) is an individual dummy variable indicating the month of the year with January as the reference.

To develop expected counterfactual forecasts, we reran the logistic models to extend preimplementation trends through 72 weeks after a laboratory started using OpenELIS as a counterfactual to the observed postimplementation trends. The mixed-effects models accounted for data that were missing at certain weeks using standard maximum likelihood estimation. To visualize the factual and counterfactual trends across time, we plotted the predicted proportions of test results achieving the primary outcomes under the 2 scenarios and the 95% prediction intervals for the factual estimates accounting for random variations at the laboratory level. All analyses were conducted using R (version 4.1.0; R Core Team) and a 2-sided \( \alpha \) value of .05.

Ethical Considerations

This study was determined to be nonhuman subject research by the University of Washington institutional review board and the United States Centers for Disease Control and Prevention (CDC). The study was approved by Côte d’Ivoire Comité National d’Ethique des Sciences de la Vie et de la Santé (CNESVS, Ivorian Institutional Review Board; reference 006-21/MSHP/CNESVS-km). The US CDC reviewed this research and paper but had no influential role in the study design, data collection, analysis, and interpretation.

Results

The number of laboratory weeks in the analyses were 613, 1820, and 1629 for timeliness, completeness, and validity, respectively. The analysis included an average of 34 weeks of
preimplementation data and 53 weeks of postimplementation data from each of the 21 laboratories. A total of 24,381 and 40,040 HIV client records from the pre- and postimplementation periods, respectively, were in the analysis (Table 1).

Only 3 of the 21 laboratories had all 48 weeks of complete data on sample reception before the laboratories adopted OpenELIS and when they used paper registries exclusively. A total of 10 laboratories had all 48 weeks of complete data on test results. After adopting OpenELIS, 19 of the 21 laboratories had 72 weeks of complete data for both sample reception and test results.

Before adopting OpenELIS, a typical laboratory had minor improvements in the 3 data quality outcomes that were not statistically significant (timeliness: OR 1.03, 95% CI 0.99-1.07; P=.12; completeness: OR 1.11, 95% CI 0.93-1.32; P=.24; and validity: OR 1.00, 95% CI 0.99-1.02; P=.76; Table 2). Within the first week of OpenELIS implementation, we observed an immediate level change in data timeliness, completeness, and validity (Figure 3). After adopting OpenELIS, the laboratories had 5.27-fold greater odds of timely results (OR 5.27, 95% CI 4.33-6.41; P<.001); 3.59-fold greater odds of complete data for the required fields (OR 3.59, 95% CI 2.40-5.37; P<.001); and 1.34-fold greater odds of valid results (OR 1.34, 95% CI 0.69-2.60; P=.38; Table 2). The immediate improvements in timeliness and completeness were both programmatically substantial and statistically significant.

Starting from the second week of OpenELIS implementation, we observed a slope change in the trend of completeness. The average odds of test results having complete data for the required fields each week thereafter were 1.03 times the odds had the laboratories not started using OpenELIS (OR 1.03, 95% CI 1.02-1.05; P<.001). In fact, the average proportion of test results having complete data stayed at almost 100% after a laboratory started using OpenELIS, while the average proportion declined over time in the counterfactual had there been no OpenELIS (Figure 3B). There was no significant change in the trend of timeliness and validity (timeliness: OR 1.01, 95% CI 0.99-1.02; P=.49 and validity: OR 0.99, 95% CI 0.97-1.01; P=.55).

In terms of heterogeneity at the laboratory level, laboratories at local general hospitals seemed to have more substantial improvements in timeliness immediately after starting to use OpenELIS and have maintained the improvements better over time as compared to regional laboratories (Figure S1 in Multimedia Appendix 1). Since a greater number of regional laboratories had less complete data than laboratories at general hospitals before OpenELIS implementation, immediate improvements in completeness were more obvious at regional laboratories, and the improvements also maintained over time (Figure S2 in Multimedia Appendix 1). Consistent with the result at the aggregate level, no laboratories had changes in validity (Figure S3 in Multimedia Appendix 1).

Discussion

This study shows that data availability improved after clinical laboratories in Côte d’Ivoire adopted OpenELIS, and there was rapid and substantial improvement in data timeliness and completeness. Following the immediate post-OpenELIS implementation improvements, both timeliness and completeness remained close to 100%. Data validity was very close to 100% both before and after OpenELIS adoption. There was some heterogeneity in the results at the laboratory level, with laboratories at local general hospitals showing more substantial improvements in timeliness while regional laboratories showed more obvious immediate improvements in completeness.

To our knowledge, this is the first study to demonstrate the immediate and maintained effect of a scaled, multisite LIS on data quality in sub-Saharan Africa. There are limited studies from LMICs despite significant financial investments from the international donor community. Previous studies from LMICs took place on other continents or did not include as many laboratories or subnational geographic areas as ours did. The e-Chasqui LIS for tuberculosis testing data at 14 laboratories in Peru was the only one that was implemented and evaluated through a cluster randomized controlled trial [21]. The trial showed that the LIS decreased turnaround time and improved quality of care, but the study did not examine the effect on data quality [21]. Our study contributes to the evidence by quantifying the effect size of data quality improvement and its change over a period of 30 months at 21 clinical laboratories. The findings offer critical information for policy makers and digital health researchers in LMICs when considering the real-world effectiveness of the OpenELIS software or digitalization of a sub-Saharan African laboratory system.

Systematic implementation of a single LIS across an entire national health system is rare in LMICs. A rapid literature review of peer-reviewed journal articles identified 8 different LISs that 6 countries have implemented at more than 1 site nationally, namely Ethiopia, Malawi, Namibia, South Africa, Peru, and Vietnam [16,21-30]. The LIS in South Africa is the only 1 that has the capacity to record data on all laboratory testing services at all clinical laboratories in the country [22]. It is likely that, as a result of the nationwide LIS adoption in South Africa, usage of laboratory data in research has also increased, since almost 20% of the rapid literature review search results from LMICs were epidemiological studies from South Africa using data from the LIS [31-39].

Part of the success of OpenELIS in Côte d’Ivoire can be attributed to the systematic approach taken by I-TECH in establishing and supporting the use of OpenELIS. The approach included the endorsement by the MSHPCMU and locally trained technical staff who facilitated implementation and provided continuous technical support of the system to the laboratories and their users. The relative advantages of OpenELIS compared to paper registries, ease of implementation, and continuous technical support have facilitated the routine use of OpenELIS. In addition, an experienced software development team designed various functional and interface features of the software specifically intended to improve data quality, for example, drop-down menus for fast and accurate selections and automatic data completeness and validity checks. The decade-long development and implementation of OpenELIS in Côte d’Ivoire has been open-source, iterative, and collaborative so that feedback from users, laboratory managers, and governing bodies was directly incorporated into the software to match the needs of the users [15].

Our study provides evidence for improving laboratory data quality, which is important for the improvement of clinical care and treatment. A study from Kenya identified that reduced turnaround time and timely communication of laboratory test results are some of the key factors for improving HIV treatment retention [12].

In addition, in terms of patient safety, LISs reduced the probability of errors in patient identification and subsequent inappropriate treatment by reducing manual clerical work through automation and user-friendly widgets [10]. A survey of clinicians in Malawi revealed that laboratories’ poor documentation of test results was one of the reasons for having little trust in laboratory capability and not frequently using laboratory test results in patient management [13]. Last but not least, LISs can also improve disease surveillance by making it easier to record accurate demographic data that inform disease classification, assessment of population-specific rates, and contact tracing for infectious diseases [11], as well as to report laboratory-confirmed diagnoses to surveillance systems that allow more accurate estimation of disease burdens [14].

This evaluation has many strengths and some limitations. The use of multiple data points before and after OpenELIS helps capture the changes in time-varying variables through the data we used to generate the pre- and posttrends. However, since all sites that have been using OpenELIS, including the ones sampled in this evaluation, were purposefully selected due to their higher capacity, they might also have had a higher probability of adhering to the OpenELIS user instructions. The regression models did not specifically account for potential confounding effects from the COVID-19 pandemic and related control measures that were enforced from March to July 2020 mostly in the Greater Abidjan area in Côte d’Ivoire [40]. However, since the percentage of weekly data points occurring after March 2020 was low (3.3% for timeliness, 7.0% for completeness, and 7.7% for validity), and most of the data points came outside Abidjan, we thought that the influence of the pandemic on our outcomes was low. Furthermore, the 3 outcomes were proportions of the total testing data, so the estimates were less likely to be influenced by fluctuations in total testing volume due to the pandemic. Nonetheless, we still included the total number of tests performed by a laboratory as weight in the regression model. The results may be generalizable to remaining clinical laboratories in Côte d’Ivoire that are at the same tiers in the health system as the sites sampled in this study, but generalizability to laboratories in other LMICs needs further studies to demonstrate.

The implementation of an LIS can have a significant effect on improving data quality in LMICs. This study found that the implementation of OpenELIS led to improved timeliness and...
completeness of laboratory data. The system also facilitated better data availability compared to paper registries, enabling health care providers to make informed decisions based on accurate and up-to-date information.

The effectiveness of an LIS depends on many factors beyond the capabilities of the LIS itself, including systematic planning for adoption, supportive technical and implementation staff, attitudes of policy makers and users, presence of supportive policies, financial resources, infrastructure, and organizational and individual readiness to adopt innovations. Future research is needed to explore the facilitators and barriers to implementing health information systems such as an LIS in LMICs.

Abstract

Background: Maternal and perinatal health are fundamental to human development. However, in low-resource settings such as sub-Saharan Africa (SSA), significant challenges persist in reducing maternal, newborn, and child mortality. To achieve the targets of the sustainable development goal 3 (SDG3) and universal health coverage (UHC), improving access to continuous maternal and perinatal health care services (CMPHS) has been addressed as a critical strategy.

Objective: This study aims to provide a widely applicable procedure to illuminate the current challenges in ensuring access to CMPHS for women of reproductive age. The findings are intended to inform targeted recommendations for prioritizing resource allocation and policy making in low-resource settings.

Methods: In accordance with the World Health Organization guidelines and existing literature, and taking into account the local context of CMPHS delivery to women of reproductive age in Mozambique, we first proposed the identification of CMPHS as the continuum of 3 independent service packages, namely antenatal care (ANC), institutional delivery (ID), and postnatal care (PNC). Then, we used the nearest-neighbor method (NNM) to assess spatial access to each of the 3 service packages. Lastly, we carried out an overlap analysis to identify 8 types of resource-shortage zones.

Results: The median shortest travel times for women of reproductive age to access ANC, ID, and PNC were 2.38 (IQR 1.38-3.89) hours, 3.69 (IQR 1.87-5.82) hours, and 4.16 (IQR 2.48-6.67) hours, respectively. Spatial barriers for women of reproductive age accessing ANC, ID, and PNC demonstrated large variations both among and within regions. Maputo City showed the shortest travel time and the best equity within the regions (0.46, IQR 0.26-0.69 hours; 0.74, IQR 0.47-1.04 hours; and 1.34, IQR 0.83-1.85 hours, respectively), while the provinces of Niassa (4.07, IQR 2.41-6.63 hours; 18.20, IQR 11.67-24.65 hours; and 7.69, IQR 4.74-13.05 hours, respectively) and Inhambane (2.69, IQR 1.49-3.91 hours; 4.43, IQR 2.37-7.16 hours; and 10.76, IQR 7.73-13.66 hours, respectively) lagged behind significantly in both aspects. In general, more than 51% of the women of reproductive age, residing in 83.25% of Mozambique’s land area, were unable to access any service package of CMPHS in time (within 2 hours), while only about 21%, living in 2.69% of Mozambique’s land area, including Maputo, could access timely CMPHS.
Conclusions: The spatial accessibility and equity of CMPHS in Mozambique present significant challenges in achieving SDG3 and UHC, especially in the Inhambane and Niassa regions. For Inhambane, policy makers should prioritize the implementation of a decentralization allocation strategy to increase coverage and equity through upgrading existing health care facilities. For Niassa, the cultivation of well-trained midwives who can provide door-to-door ANC and PNC at home should be prioritized, with an emphasis on strengthening communities’ engagement. The proposed 2-step procedure should be implemented in other low-resource settings to promote the achievement of SDG3.

KEYWORDS
continuous maternal and perinatal health care services; sub-Saharan Africa; SSA; spatial access; resource allocation; low-resource settings

Introduction

Access to continuous maternal and perinatal health care services (CMPHS) has been proposed by the World Health Organization (WHO) as an essential strategy to improve maternal and child health [1]. Instead of focusing on single interventions, CMPHS emphasizes packages of interventions delivered throughout the lifecycle at all levels of health care facilities in the health delivery system [2]. The provision of CMPHS is also a priority for achieving universal health coverage (UHC) and is listed as a key indicator for monitoring the progress of maternal, newborn, and child outcomes [3]. It has been widely recognized that CMPHS can be understood as the integration of 3 service delivery packages: antenatal care (ANC), institutional delivery (ID), and postnatal care (PNC) [4]. ANC facilitates the prompt detection and management of complications among pregnant women [5]. Research suggests that even a 7% increase in ANC coverage might save 160,000 newborn lives annually in Africa [6]. ID ensures appropriate equipment and supplies are available on site or through immediate referral to a higher-level facility if necessary [7]. As suggested by the literature, perinatal mortality is 21% lower for facility-based deliveries compared to home deliveries. In the best settings, up to 14 perinatal deaths might be averted per 1000 births if the obstetric deliveries occurred at facilities instead of at homes [8]. PNC provides great opportunities to check for dangerous signs and symptoms associated with poor health outcomes in babies [9]. The importance of PNC has been documented, with an estimation that if PNC rates reach 90% in sub-Saharan Africa (SSA), neonatal deaths could be averted by 10%-27% [10].

Mozambique represents a low-resource setting of the type prevalent in the SSA region, where the world’s highest maternal and neonatal mortality persists as a critical issue (533 maternal deaths per 100,000 live births vs 211 per 100,000 worldwide and 27 neonatal deaths per 1000 live births vs 18 per 1000 worldwide). Timely provision of CMPHS could prevent a significant proportion of these deaths [11-13]. Several recent studies have examined health care accessibility in low-resource settings, including emergency obstetric and newborn care, skilled birth attendance and caesarean delivery services, and primary health care [14-18]. However, efforts to assess the spatial accessibility of CMPHS remain insufficient [19] despite widespread recognition that the effectiveness of the 3 service packages is greatly influenced by health care services achieved in the previous stages. Moreover, there is a lack of targeted suggestions on resource investment and policy making in this area.

Among various barriers preventing women of reproductive age from obtaining timely access to CMPHS, spatial accessibility (geographic proximity) has become one of the primary barriers, particularly in low-resource settings [20]. As a crucial aspect of accessibility, use, and the provision of health care services to the population group in need [21], assessment of spatial accessibility has been carried out worldwide and been incorporated into policy making in many countries. However, there is a paucity of studies assessing the spatial accessibility of CMPHS by integrating multiple indicators into 3 separate service packages in low-resource settings.

As the deadline for sustainable development goal 3 (SDG3) approaches, and the fundamental need for maternal and prenatal health care persists, the efficient allocation of limited health care resources, especially in low-resource settings, is of great importance. Mozambique, one of the world’s poorest and most underdeveloped countries (with a United Nations Human Development Index of 0.446 in 2021), faces significant challenges in implementing SDG3, particularly concerning CMPHS indicators [22]. This study uses Mozambique as a case study, aiming to provide a widely applicable procedure for assessing the spatial access to CMPHS and to offer evidence-based suggestions for policy makers that will guide the prioritization of health resource allocation to improve CMPHS accessibility and maternal, newborn, and child health outcomes in low-resource settings.

Methods

Study Area

Mozambique, located on the southeast coast of Africa, is divided into 11 provinces, including 1 provincial city (Multimedia Appendix 1, Figure S1A). According to data announced by the General Population and Housing Census 2017 in Mozambique [23], the estimated total population was 30.07 million, with the majority living in rural areas and generally sparsely and unevenly distributed (Multimedia Appendix 1, Figure S1B). Nearly 80% of people living in poverty live in rural areas distant from basic public facilities [24]. The country’s overall economy remains extremely underdeveloped (gross domestic product <US $1.00/person/day); the highest average consumption level in Maputo City is 6.9 times higher than the lowest, in Zambezia province (Multimedia Appendix 1, Figure S1C) [25].
According to a report from the Mozambique Ministry of Health, the country’s maternal mortality rate was as high as 451 deaths per 100,000 live births, and the infant mortality rate was 67.4 deaths per 1000 live births in 2020 [26]. Factors such as long travel distances from residential locations to health care facilities, lack of available transportation, and poorly constructed transportation networks contribute to significant service delays for women of reproductive age accessing CMPHS [15,27].

Data Sources

Data on 2 perspectives were needed for identifying indicators reflective of the delivery of the 3 service packages in Mozambique for calculating spatial accessibility. Following the existing literature and considering both representativeness and implementability, 2 categories of data were used for indicator identification and 3 categories of data were used to facilitate the analysis of spatial accessibility, including supply side data (health care facility data), demand side data (distribution data for women of reproductive age), and environmental data (for calculating geospatial barriers) [28-30]. The data sources are shown in detail in Table 1.

Table 1. Description and sources of data use in the 2 steps of the proposed procedure.

<sup>a</sup>CMPHS: continuous maternal and perinatal health care services.

Data Pretreatment and Analysis

A detailed flowchart describing the 2-step procedure is shown in Figure 1.
Step 1: Identification of Indicators Representing the 3 Service Packages of CMPHS

The selection of indicators was based on 2 main principles. The first principle was accordance with maternal, newborn, and child health (MNCH) guidelines, as well as the pregnancy, childbirth, postpartum, and newborn care (PCPNC) guidelines proposed by the WHO. The second principle was to fully reflect the region-specific characteristics of CMPHS delivery in the study area.

In adhering to the 2 main principles, recommended and available indicators were first filtered to identify a group of separate indicators from each individual service package. The available indicators were extracted from Mozambique’s Survey on Infrastructure, Equipment, Human Resources and Health Services 2018 (Multimedia Appendix 1, Table S1) [37,38]. Then, with consideration of both avoiding fragmented services and ensuring the quality of CMPHS, as well as extensive reference to existing literature, [39], the filtered indicators were further screened and integrated to the 3 service packages. ANC includes 7 integrated indicators, ID includes 8 integrated indicators, and PNC includes 10 integrated indicators (Multimedia Appendix 1, Table S2).

Step 2: Calculation of Spatial Access to CMPHS (Data Pretreatment)

For the supply side data, 3 levels of health care facilities were included, consisting of Mozambique’s health care delivery system: primary (urban and rural health centers and community health posts), secondary (rural, district, and general hospitals), and tertiary (central and provincial, specialized, and military hospitals). Combined with results from step 1, the capability of delivering the 3 service packages of CMPHS was identified for every health care facility.

For demand side data, gridded estimates of pregnancies were obtained at 1×1 km² spatial resolution from the WorldPop database for 2015, which served to weight the spatial distribution of the demand side data. Then, data on the nationally announced provincial-level aggregated number of women aged 15-49 years in Mozambique was used to adjust the spatial distribution of pregnant women at a resolution of 1×1 km² to generate a more accurate and up-to-date demand distribution, as process generally used in related research [40-42].

The following formula was used to calculate the spatial distribution of women of reproductive age at 1×1 km² resolution [40], in which \( P_i \) is the number of women of reproductive age of grid \( i \) in the province or provincial capital \( j \), and \( G_i \) is the corresponding WorldPop value for pregnancy density of grid \( i \). \( G_i \) is the sum of the grid values for WorldPop in province or provincial capital \( j \), and \( T_i \) is the actual number of women of reproductive age in province or provincial capital \( j \) from the Statistical Yearbook 2018 of Mozambique [23]:
Analysis of Spatial Accessibility (Establishment of Geo-Database)

ArcGIS (version 10.5; Esri, Inc) was used to calculate spatial access to CMPHS in this study. A geodatabase incorporating supply side data, demand side data, and administrative boundary data was first generated [43].

Calculation of the Shortest Travel Time Needed to Reach ANC, ID, and PNC

The nearest-neighbor method (NMM) was used to calculate the shortest travel time necessary to access ANC, ID, and PNC [44]. For each grid of women of reproductive age, only the nearest health care facility was considered [41]. The travel mode of walking at a speed of 4 km/h for spatial accessibility assessment and a threshold of 2 hours were used as criteria for timely access (Multimedia Appendix 1, Table S3) [5]. Additionally, the travel time along the straight-line distance was used to compare the travel time criterion [18,45]. The shortest travel time needed to reach ANC, ID, and PNC was calculated separately, and the average travel time was calculated for each province or provincial capital.

Overlap Analysis of Spatial Coverage of CMPHS

An overlap analysis was applied to identify multilevel health care access zones. On the basis of identifying areas able to access ANC, ID, and PNC in a timely manner (ie, within a 2 h threshold), 3 layers representing timely access to ANC, ID, and PNC, respectively, were overlapped to generate 8 types of multilevel health care access zones. Then, percentages for area and women of reproductive age covered within each type of multilevel health care access zone were calculated.

Ethical Considerations

The study was approved by the Swiss Confederation, represented by the Swiss Federal Department of Foreign Affairs, acting through the Swiss Agency for Development and Cooperation Global Cooperation Department and Southern Medical University of the People’s Republic of China (81067392). Core data used in this study were derived from the National Survey on Infrastructure, Equipment, Human Resources and Health Services 2018, which was collected between February and April 2018 through a cross-sectional survey of health care facilities. The survey included a census of all health facilities in the country and collected data through interviews with key informants at health care facilities. The core standard Service Availability and Readiness Assessment (SARA) questionnaire of the WHO was used and adapted to the Mozambique context [37,38]. The SARA questionnaire and linked protocols were granted approval by Mozambique’s Ministry of Health. More information about the primary data collection procedures is available in the Mozambique SARA 2018 report [38]. Permission to use the data was obtained from Mozambique’s Ministry of Health by coauthors from Mozambique. Other data, including population distribution and administrative boundaries, were extracted from publicly available data sets. No human participants or animals were involved in the study.

Results

Identification and Coverage of Indicators Representing CMPHS

The identified indicators for the 3 service packages and the percentage of health care facilities capable of providing each service (indicators) are shown in Table 2. Among all health care facilities (N=1542), 784 were able to provide ANC, 365 were able to provide ID, and 299 were able to provide PNC. Most health care facilities within the study area managed to cover all services listed in each individual service package, with some indicators having fairly good penetration. The provision of intermittent preventive treatment in pregnancy for malaria, a component of the ANC service package, was offered in 1408 (91.31%) health care facilities. Conversely, some indicators showed suboptimal coverage; for example, emergency obstetric care was available in only 504 (32.68%) health care facilities and injectable antibiotics intended for neonatal sepsis were available in just 766 (49.68%) health care facilities (Table 2).
Table 2. Identified indicators of the 3 service packages and the percentage of health care facilities able to provide each service (indicators) based on global guidelines for maternal, newborn, and child health, as well as pregnancy, childbirth, postpartum, and newborn care proposed by the World Health Organization and data extracted from the National Survey on Infrastructure, Equipment, Human Resources and Health Services 2018.

Distribution of Health Care Facilities Providing CMPHS

There were 1542 health care facilities in total across the study area, among which were 1490 primary-level health care facilities (urban and rural health centers or community health posts), 43 secondary-level health care facilities (rural, district, and general hospitals), and 9 tertiary-level health care facilities (central and provincial hospitals or specialized and military hospitals). Among the primary-level facilities, 51.48% (767/1490), 21.34% (318/1490), and 18.46% (275/1490) were able to provide ANC, ID, and PNC, respectively. For the secondary facilities, the respective percentages were 37% (16/43), 91% (39/43), and 23% (17/43). For the tertiary-level health care facilities, the respective percentages were 11% (1/9), 89% (8/9), and 78% (7/9).

Figure 2 shows the spatial distribution of the 3 levels of health care facilities able to deliver the 3 service packages. The spatial distribution of different levels of health care facilities able to provide ANC, ID, and PNC, respectively, is shown in Multimedia Appendix 1, Figure S2.
Figure 2. Capability of delivering the 3 service packages of continuous maternal and perinatal health care services was identified for every health care facility on the supply side. The WorldPop data set was used to provide spatial distribution of pregnant women at a 1×1 km² resolution on the demand side. (A) The spatial distribution of women of reproductive age (people/0.01 km²). (B) The spatial distribution of the 3 levels of health care facilities in Mozambique in 2018. Maputo and Maputo City are displayed in the figures separately.

Spatial Access to The 3 Service Packages of CMPHS

In Mozambique, the median shortest travel times needed to access ANC, ID, and PNC were 2.38 (IQR 1.38-3.89) hours, 3.69 (IQR 1.87-5.28) hours, and 4.16 (IQR 2.48-6.67) hours, respectively. The shortest travel times required to reach the nearest health care facilities offering these services varied significantly across different regions. For ANC services, the shortest travel time ranged from 0.46 (IQR 0.26-0.69) hours in Maputo City to 4.95 (IQR 3.03-7.21) hours in Manica province. For ID services, it ranged from 0.74 (IQR 0.47-1.04) hours in Maputo City to 18.20 (IQR 11.67-24.65) hours in Niassa province. For PNC services, the shortest travel time ranged from 1.34 (IQR 0.83-1.85) hours in Maputo City to 10.76 (IQR 7.53-13.66) hours in Inhambane province. Except for Manica province, the shortest travel time needed to access ID was greater than for ANC in all other provinces. The shortest travel time spent to access ID was found to be distinctly longer than that for PNC in 3 provinces, namely Gaza, Maputo, and Niassa (Table 3).

The results for coverage of different services in Figure 3 shows that women of reproductive age living in Maputo City were able to obtain timely ANC, ID, and PNC. Conversely, multiple provinces with lower population density were recognized as underserved areas, including the provinces of Niassa, Cabo Delgado, Gaza, and Inhambane, especially for the provision of ID and PNC.
Table 3. The shortest travel time spent to reach antenatal care, institutional delivery, and postnatal care was calculated for different regions using the nearest-neighbor method with a criterion of 2 hours’ walking, which was set under the scenario that demanders walked along a straight line with a speed of 4 km/hour.

Figure 3. The spatial coverage of antenatal care (ANC), institutional delivery (ID), and postnatal care (PNC) provided by different levels of health care facilities by walking along a straight line with a speed of 4 km/hour and the standard of 2-hour security service range. The coverage area (in terms of 2-hour travel time) for (A) ANC, (B) ID, and (C) PNC. Maputo and Maputo City are displayed in the figures separately.

Classification and Identification of Underserved Areas for CMPHS

For women of reproductive age in Mozambique, more than 21% (living in about 2.69% of Mozambique’s area) lived in type 1 areas (able to obtain timely CMPHS including ANC, ID, and PNC); more than 51% (living in 83.25% of Mozambique’s area) lived in type 8 areas (not able to obtain timely access to any service packages of CMPHS); only 27.5% (living in about 14.07% of Mozambique’s area) lived in type 2-7 areas (able to access 1 or 2 types of services of CMPHS). The second highest percentage of women of reproductive age fell within type 5 areas, indicating that approximately 10% (living in about 7.42% of Mozambique’s area) were able to obtain ANC services in a timely manner. The third highest percentage of women of reproductive age fell within type 2 areas, meaning that more than 9% (living in about 2.19% of Mozambique’s area) were able to reach ANC and PNC in a timely manner (Table 4).
Three layers representing timely access to antenatal care (ANC), institutional delivery (ID), and postnatal care (PNC), respectively, were overlapped to generate 8 types of multilevel health care access zones. The percentages by land area and by women of reproductive age covered within each type of multilevel health care access zone were calculated using an overlap analysis with a criterion of 2-hour security service range.

aCMPHS: continuous maternal and perinatal health care services.

As can be seen in Figure 4 and Multimedia Appendix 1, Figure S3, the coverage of CMPHS was low in Mozambique, especially in the provinces of Inhambane, Niassa, and Gaza. Maputo City was the only region that was able to provide timely CMPHS for women of reproductive age.
Figure 4. Overlay analysis of spatial access among women of reproductive age to continuous maternal and perinatal health care services (CMPHS) with a criterion of a 2-hour secure service range. Multilevel health care access zones are areas able to access all 3 service packages, 2 of the 3 service packages, only 1 of the 3 service packages, or none of the 3 service packages. Green is used to represent full access to CMPHS (i.e., a good service type, namely type 1), shades of yellow are used to represent access to any 2 types of service (i.e., medium service types, namely type 2, type 3, and type 4), shades of red are used to represent access to any 1 type of service (i.e., poorer service types, namely type 5, type 6, and type 7), and the blank areas represent no access to any type of services (i.e., the poorest service type, namely type 8). Maputo and Maputo City are displayed in the figure separately. ANC: antenatal care; ID: institutional delivery; PNC: postnatal care.
Discussion

Principal Findings

Our study proposed a 2-step procedure to assess the spatial accessibility of CMPHS and verified its applicability through a case study in Mozambique. The results first showed spatial access to different types of CMPHS and disparities among different service packages. By using an overlay analysis, this procedure could identify 7 types of underserved areas and the detailed spatial distribution of existing well-served areas. The results from this procedure have evidence-based implications to inform decision-making processes related to health resource allocation, particularly in low-resource settings confronted with similar challenges. This can ultimately aid in improving maternal and newborn health outcomes. The necessity of enhancing spatial accessibility as a critical solution to improve coverage of CMPHS is also highlighted. In the specific case of Mozambique, only 21% of women of reproductive age could access CMPHS in a timely manner, and these women were predominately clustered in the most-developed region, Maputo City. This highlights that spatial access to CMPHS remains a significant challenge and that improvements in the coverage of ID and PNC are urgently needed.

Large disparities among regions in accessing CMPHS were also a critical issue. Inequities in CMPHS exist at the national, provincial, and district levels and always present fundamental barriers to progress, particularly among the most disadvantaged population groups [46]. This has been validated by our findings that the provinces of both Niassa and Cabo Delgado, which have lower population densities, tended to be more underserved, especially in accessing ID and PNC service packages. Our study also found that Maputo City was the only administrative unit that was capable of providing effective access to all 3 service packages. We assume this is mainly because Maputo City is the capital of Maputo and the economic and social development center of Mozambique, so its development status far exceeds all the other areas [47]. In addition, the frequent occurrence of natural disasters, which greatly hinders health care service delivery, further adds to health inequities between the southern and northern regions in Mozambique, leading to lower rates of both ANC and ID visits in the southern region, corresponding to 74 additional maternal deaths and 726 additional deaths of children under the age of 1 month by the end of 2021 [48].

In the context of Mozambique’s poor accessibility and low equity in health care, the implementation of a decentralized allocation strategy to address the inequity issue has been recognized as an effective measure to promote both accessibility and coverage of CMPHS, which can take China’s successful experiences as an example [49,50]. China has made remarkable achievements and passed milestones in achieving SDGs through implementing a decentralized allocation strategy to improve accessibility and equality of health care services. China clearly indicated that women and children were target groups in the cooperation for global health in the Belt and Road Initiative in 2017 and implemented 100 foreign assistance programs for women and children’s health in low-income countries, so decentralized allocation strategies from China can help low-income countries improve their own CMPHS [51]. For example, strategies for the promotion of primary health care, along with the optimization of a hierarchical health care delivery system intended for maternal and child health care, were implemented. According to these strategies, integrated service packages delivered via the collaborative efforts of tertiary hospitals and primary maternal health care facilities proved to be an effective solution to strengthen the capacity of local health care facilities, as well as their corresponding referral systems, which resulted in increased in-hospital births and significantly reduced maternal mortality [50,52,53]. Furthermore, community-based interventions with components to engage or mobilize communities have been increasingly implemented to improve maternal and newborn health outcomes in low-resource settings [54-56]. For example, training programs should be provided to cultivate highly skilled health care professionals among local health care facilities [55,57].

Comparison With Prior Work

Few studies have assessed the spatial accessibility of health care resources in Mozambique. A previous study reported that 67.3% of Mozambique’s population lived outside a 1-hour travel distance from primary health care centers [58]. However, spatial barriers to accessing health care services are gaining increasing attention. According to the Statistical Yearbook 2018 of Mozambique, the average travel distance needed to access a health care facility for people living in remote areas was 12.3 km [34]. The 2018-2019 Mozambique Humanitarian Response Plan reported that about 50% of the population lived more than 20 km away from the nearest health care facility [59]. Given the national focus on maternal and perinatal health, studies assessing spatial access to CMPHS have been carried out in the context of low-resource settings [14,17,60]. Previous findings suggest that 49.8% of women of reproductive age in Mozambique lived outside a 2-hour travel area from the nearest hospital for emergency services [61]. In southern Mozambique, 46% of pregnant women were able to access the nearest primary health care facility within 1 hour by walking, while 64% of women living in the region could receive life-saving service delivery within 2 hours [46]. While most existing literature has only assessed spatial access to single services, our results are consistent with previous findings that spatial access to maternal and perinatal health care services is poor in Mozambique. Moreover, our study further considered 3 separate service packages, representing important stages in the continuity of maternal and perinatal health care services, revealing spatial access to CMPHS in a straightforward manner.

Public Health Implications

Our findings provide important evidence on the development of tailored, country-specific policies and interventions to address the geographical disparities of CMPHS in low-resource settings, which can support the development of resource allocation strategies based on the priority of CMPHS delivery. Using Mozambique as a case study of a low-resource setting, we recommend that public health policy makers and decision-makers draw from successful lessons such as decentralized allocation strategies. Through a comprehensive understanding of the geographical barriers to access to CMPHS,
these strategies can quickly and efficiently improve maternal and neonatal health outcomes and contribute to the achievement of SDG3 and UHC.

**Limitations**

This study does have several limitations. First, we set a scenario of women of reproductive age walking to health care facilities to reflect the most basic requirement of the vast number of vulnerable people in Mozambique. Other travel modes were not considered due to data limitations and the complexity of factors influencing the choice of travel mode. Specific travel thresholds for different levels of health care facilities were also not set due to a lack of reference data. Second, we used the spatial distribution of women of reproductive age as demand-side data instead of pregnancies due to data availability. Third, the integration of indicators representing the 3 service packages failed to take into account the type of health care facilities providing each service. Consequently, the continuum of services in different health care facilities was not further analyzed.

**Conclusions**

Using Mozambique as a case study, this research used a 2-step procedure to assess the accessibility of CMPHS and proposes targeted policy suggestions for improving health outcomes. Further studies could be conducted, especially in low-resource settings, with reference to local context, and thus inform resource allocation–related decision-making procedures. In turn, this could potentially contribute to the improvement of global maternal and neonatal health, the realization of SDG3, and the attainment of UHC.

**Acknowledgments**

The authors are grateful to staff from the Mozambique National Institute of Health for providing data on health care facilities in Mozambique.

**Data Availability**

Data from the National Survey on Infrastructure, Equipment, Human Resources and Health Services 2018 can be accessed with approval from Mozambique’s Ministry of Health. Other data used in this study come from publicly available data sets with sources listed in the main text.

**Authors’ Contributions**

QL and XW designed the study. QL, XW, and JP designed, had full access to, and verified the underlying data reported in the study. QL performed the data analysis and wrote the first draft with supervision from XW and JP. EK, IR, RMMC and EC provided suggestions on the data processing. DRX and YY helped revise the draft. All authors contributed to interpretation of data, revised the article critically for important intellectual content, and approved the final version of the manuscript.

Variations in Unmet Health Care Needs by Perceptions of Social Media Health Mis- and Disinformation, Frequency of Social Media Use, Medical Trust, and Medical Care Discrimination: Cross-Sectional Study

Jim P Stimpson¹, PhD; Sungchul Park², PhD; Fernando A Wilson³, PhD; Alexander N Ortega⁴, PhD

Abstract

Background: Unmet need for health care is defined as choosing to postpone or completely avoid necessary medical treatment despite having a need for it, which can worsen current conditions or contribute to new health problems. The emerging infodemic can be a barrier that prevents people from accessing quality health information, contributing to lower levels of seeking medical care when needed.

Objective: We evaluated the association between perceptions of health mis- and disinformation on social media and unmet need for health care. In addition, we evaluated mechanisms for this relationship, including frequency of social media use, medical trust, and medical care discrimination.

Methods: Data from 3964 active adult social media users responding to the 2022 Health Information National Trends Survey 6 (HINTS 6), a nationally representative survey, were analyzed. The outcome was unmet need for medical care, defined as delaying or not getting the necessary medical care. The predictor variables were perception of social media health mis- and disinformation, frequency of social media use, level of trust in the health care system, and perceived racial and ethnic discrimination when receiving health care.

Results: Multivariable logistic regression models indicated that perception of substantial social media health mis- and disinformation (odds ratio [OR] 1.40, 95% CI 1.07 - 1.82), daily use of social media (OR 1.34, 95% CI 1.01 - 1.79), low medical trust (OR 1.46, 95% CI 1.06 - 2.01), and perceived discrimination (OR 2.24, 95% CI 1.44 - 3.50) were significantly associated with a higher likelihood of unmet need for medical care. Unmet need among adults who did not use social media daily and who did not perceive substantial mis- and disinformation (24%; 95% CI 19% - 30%) was lower compared to daily social media users who perceived substantial mis- and disinformation (38%; 95% CI 32% - 43%). Adults who perceived substantial mis- and disinformation and had low trust in health care had the highest probability of reporting unmet need (43%; 95% CI 38% - 49%) compared to the other three groups. Adults who perceived substantial mis- and disinformation and experienced medical care discrimination had a statistically significant higher probability of reporting unmet need (51%; 95% CI 40% - 62%) compared to adults who did not experience medical care discrimination and did not perceive substantial mis- and disinformation (29%; 95% CI 26% - 32%).

Conclusions: Unmet need for medical care was higher among individuals who perceived a substantial degree of social media mis- and disinformation, especially among those who used social media daily, did not trust the health care system, and experienced racial or ethnic discrimination when receiving health care. To counter the negative effects of social media mis- and disinformation on unmet need for health care, public health messaging must focus on daily social media users as well as improving trust and reducing structural racism in the health care system.

Introduction

Unmet health care needs arise when someone with a known health issue skips or delays necessary medical treatments, such as rescheduling appointments, refusing treatments, or avoiding preventive measures [1-3]. This can happen for various reasons, including costs or difficulty accessing care [4]. Unfortunately, unmet health care needs can lead to untreated conditions becoming worse or developing new health problems. Certain populations are more likely to have unmet need for care, such as individuals with impairments, older people, marginalized racial and ethnic groups, and those without health insurance [5-8]. Systematic reviews have revealed areas that require further investigation [9,10]. For example, patient perceptions about the health care system and their own health conditions could be a significant factor contributing to unmet health care demands, underscoring a potential intervention option to improve unmet health care needs and subsequently improve health outcomes [7,9].

Theoretical Framework

The health care utilization model developed by Anderson provides a strong foundation for analyzing the complex problem of unmet need for health care [11]. This model identifies several pathways that influence health care seeking and utilization, including resources that facilitate help-seeking, perceived and assessed need for care, and predisposing qualities. Social structures, health attitudes, and demographic traits are examples of predisposing characteristics that may influence an individual's decision to use health services. The practical components of accessing care, such as the availability of health insurance, the accessibility of health care professionals, and socioeconomic position, are referred to as enabling resources. The choice to seek care is influenced by the patient’s perception of need and the assessment of medical professionals. Finally, contextual factors, such as public policies and the community environment, can influence each of these individual-level domains [7,11].

The way people receive, exchange, and act upon health information is greatly influenced by the communication infrastructure, which consists of networks, information technologies, and channels for both interpersonal and mediated communication [12]. In the Anderson model, the communication infrastructure can be viewed as a contextual factor that affects the predisposing qualities, enabling resources, and need factors. For instance, the information gleaned from many media sources may influence one’s opinions about health, thereby influencing the likelihood of seeking medical care [13,14].

The communication infrastructure also has an impact on enabling resources, which includes the practical aspects of receiving treatment. People can choose when and where to seek care by having access to trustworthy communication channels and accurate health information [14]. The quality and accessibility of health information has a direct bearing on the demand for health care, which motivates the actual use of services [12]. Unmet health care needs might arise from underestimating health needs or from mistrusting the health care system due to inaccurate or incomplete information [14]. Furthermore, poor communication can worsen gaps in access to health care, especially for racial and ethnic minorities who do not have easy access to reliable health information [15]. By integrating the communication infrastructure into the Anderson model, we can gain a deeper understanding of the complex relationship among health literacy, information availability, and health care use.

Misinformation and Disinformation

The term “infodemic” describes the ongoing dissemination of false information and health-related falsehoods, and it has emerged as a significant public health issue [16]. Research has shown that the spread of misinformation, which refers to spreading inaccurate health information, and disinformation, which refers to intentionally disseminating false information, has had a negative effect on health-related behaviors and attitudes [17-21]. The dissemination of misinformation and disinformation via social media introduces a novel extension to the traditional Anderson model by representing a contextual factor influencing individual-level predisposing, enabling, and need factors. The frequency of social media use can either facilitate or hinder health care use, depending on the quality of information accessed and the user’s level of engagement [22-24]. Disseminating inaccurate information can undermine public confidence in the health care system, which is crucial for accessing health care services and can influence the decision to seek medical attention [25-28]. Moreover, the intentional dissemination of inaccurate information and misinformation to communities of color and ethnic minorities worsens preexisting disparities and perceptions of bias in the health care system, potentially leading to higher levels of unaddressed health care needs within these populations [20,29,30]. By integrating the communication infrastructure with the Anderson model, we can understand the communication barriers that prevent people from accessing health care and develop effective ways to mitigate the negative effects of health misinformation on public health [31].

Mechanisms Linking Mis- and Disinformation and Health Care Use

The exposure to misinformation and disinformation on social media platforms can be connected to unmet health care requirements through various pathways, some of which have not been thoroughly studied in existing literature. The first mechanism pertains to the relationship between the use of social media and the level of engagement with material, specifically pertaining to false or misleading information [23]. Increased use of social media correlates with a higher probability of individuals interacting with different forms of content, including deceptive or inaccurate information [32]. Exposure to this digital information environment can modify a person’s beliefs and decision-making processes surrounding health care, potentially resulting in unmet need for medical care [33,34].

The second mechanism pertains to the confidence individuals place in health care institutions and professionals. Trust has a crucial role in influencing individuals’ decision to seek health care services and adhere to the treatments recommended by health care providers [35]. Certain groups are less likely to trust credible health institutions like government health agencies or health systems, but misinformation can influence the level of
trust regardless of group membership [36-38]. Nevertheless, the spread of false information on social media undermines this trust, leading individuals to lose confidence in the health care institution and not seek medical attention when necessary [39-42].

The third mechanism emphasizes the problem of unmet need for care among racial and ethnic minority groups, which is frequently worsened by discrimination inside the health care system [43]. Social media platforms can serve as conduits for disseminating health-related disinformation, often aimed at these specific communities [44]. The deliberate dissemination of false information, specifically aimed at racial and ethnic minoritized populations, along with experiences of discrimination, can further erode trust in health care and result in higher levels of unmet health care needs [45-50]. These mechanisms collectively contribute to additional barriers in obtaining medical treatment. To effectively tackle the challenges presented by misinformation and its influence on public health, it is crucial to better understand how these mechanisms influence health care seeking and use.

Research Objective

By integrating the communication infrastructure into the Andersen model of health care utilization, our study aimed to investigate the effects of the infodemic on the use of health care, proposing that exposure to health misinformation is associated with a higher probability of delaying or avoiding necessary medical care. In addition, our goal was to investigate the underlying mechanisms of this association, such as the frequency of social media use, the degree of trust that individuals have in the health care system, and the occurrence of racial or ethnic discrimination in health care settings. Our hypothesis is that people who perceive substantial false or misleading health information and use social media daily, have little trust in the health care system, and experience racial or ethnic discrimination when trying to use health care services are more likely to have unmet health care needs.

Methods

Data

This cross-sectional study analyzed nationally representative data from the Health Information National Trends Survey 6 (HINTS 6), which periodically surveys noninstitutionalized adults in the United States about information seeking, health communication, as well as cancer prevention attitudes and behaviors. The most recent version of the data, HINTS 6, were collected through mail- and web-based surveys from March to November 2022 with a response rate of 28.1% (34,827,468/124,058,843) [51].

Ethical Considerations

The data were publicly available and deidentified; therefore, the human research protection program of the University of Texas Southwestern Medical Center decided it did not require review by the institutional review board. Further details about the survey methodology are available from the National Cancer Institute [51]. We excluded participants who did not report using social media or had not used social media in the past year. We analyzed data from 3964 adult social media users that had used social media in the past year, with complete data on the study variables.

Measures

The binary outcome variable was unmet need for medical care, defined as delaying or not getting the medical care that the participant believed was medically necessary. The primary predictor variable was perceptions about health mis- and disinformation on social media, which was assessed by the following question: “How much of the health information that you see on social media do you think is false or misleading?” The response categories were dichotomized for ease of interpretation as substantial (ie, “a lot”) versus less than substantial (ie, “none, a little, some”), consistent with past studies [20,29,37]. The secondary predictor variables suggested by the theoretical framework included frequency of social media use, trust in the health care system, as well as perceived racial and ethnic discrimination [11-13]. Social media use was categorized as daily use versus less than daily use (eg, “never, weekly, monthly”). For medical trust, participants were asked “How much of the health care system for example, hospitals, pharmacies, and other organizations involved in health care?” The response categories were dichotomized for ease of interpretation based on prior literature as high (“very” and “somewhat”) versus low (“not at all” and “a little”) [52,53]. For medical care discrimination, participants were asked “Have you ever been treated unfairly or been discriminated against when getting medical care because of your race or ethnicity?” and the response categories were “yes” or “no.”

The Andersen model for health care utilization was used to select the control variables [11]. Predisposing factors included age (18 - 49, 50 - 64, ≥65 years), sex (male and female), marital status (married or cohabiting, formerly married, and never married), self-reported race and ethnicity (non-Latino White, non-Latino Black, non-Latino other, and Latino), education level (college degree or higher vs less than a college degree), and residence in a metropolitan versus nonmetropolitan county as designated by the US Department of Agriculture in 2013. Enabling factors included full-time employment status, feelings about household income (finding it very difficult/difficult to get by on present income, or getting by on present income, living comfortably on present income), health insurance status (any insurance or uninsured), and frequency of health provider visits (0 - 3 or more than 4 annual visits). The need for health care was measured by self-rated overall health status (excellent, very good, good, fair, and poor).

Statistical Analysis

The descriptive statistics for the study sample were calculated as survey-weighted percentages. The bivariable relationships between the outcome and the predictor variables were calculated using column percentages and adjusted Wald P values. Then, we used a stepped multivariable logistic regression model to test for the main effects of perceptions of social media health mis- and disinformation on unmet health care needs. The first step adjusted for secondary predictor variables of social media use, medical trust, and medical care discrimination; the second model further adjusted for predisposing, enabling, and need
results were calculated between the primary predictor variable and the secondary predictor variables to estimate the theorized pathways between mis- or disinformation on social media and unmet need for health care in multivariable logistic regression models. The interaction results were converted into predicted probabilities using the margins command in Stata (StataNow 18.5; StataCorp) for ease of interpretation. Sensitivity analyses were conducted that excluded non-Latino White individuals for the interaction effect of medical discrimination and perceived mis- or disinformation. All analyses accounted for survey weights and design using jackknife replicate weights for variance estimation. Statistical significance was set at $\alpha < .05$.

### Results

Table 1 provides the unadjusted sample size and survey-weighted percentage points for all study variables among adult social media users in the past year. Most participants (n=2655, 67%) reported that their health care needs were met; a third of the participants (n=1309, 33%) reported unmet need for health care. More than a third of participants (n=1397, 36%) perceived substantial social media health mis- and disinformation. Most participants (n=2803, 73%) used social media daily. Low trust in the health care system was reported by 17% (n=596) of the participants, and 8% (n=348) reported experiencing racial or ethnic discrimination when seeking health care.

Table 2 shows the survey-weighted bivariable column percentages, showing statistically significant relationships between the outcome and predictors. Among participants who perceived substantial social media mis- and disinformation, 42% reported unmet need compared to 33% who reported their need for care was met. Among participants who reported daily social media use, 77% reported unmet need compared to 71% who reported their need for care was met. Among participants who reported low trust in the health care system, 24% reported unmet need compared to 14% who reported their need for care was met. Among participants who experienced racial or ethnic discrimination in receiving medical care, 13% reported unmet need compared to 5% who reported their need for care was met.

In Table 3, the first model of the multivariable logistic regression shows the association of the predictor variables without adjustment for covariates. Perception of substantial social media health mis- and disinformation (OR 1.41, 95% CI 1.09 - 1.81), daily use of social media (OR 1.43, 95% CI 1.09 - 1.87), low health care system trust (OR 1.74, 95% CI 1.29 - 2.35), and perceived discrimination (OR 2.34, 95% CI 1.47 - 3.73) were all associated with a higher likelihood of unmet need for medical care. In model 2, after adjusting for predisposing, enabling, and need factors, perception of substantial social media health mis- and disinformation (OR 1.40, 95% CI 1.07 - 1.82), daily use of social media (OR 1.34, 95% CI 1.01 - 1.79), low health care system trust (OR 1.46, 95% CI 1.06 - 2.01), and perceived discrimination (OR 2.24, 95% CI 1.44 - 3.50) remained significantly associated with a higher likelihood of unmet need for medical care.

Table 4 shows the results from multivariable logistic models, adjusted for predisposing, enabling, and need factors, in which perception of mis- and disinformation was multiplied by predictors hypothesized to be mechanisms of the relationship between unmet need for care and perception of mis- and disinformation. There was a statistically significant difference in the probability of reporting unmet need for care among adults who did not use social media daily and who did not perceive substantial mis- and disinformation (24%; 95% CI 19% - 30%) compared to daily social media users who perceived substantial mis- and disinformation (38%; 95% CI 32% - 43%). Adults who perceived substantial mis- and disinformation and had low trust in the health care system had the highest probability of reporting unmet need for care (43%; 95% CI 38% - 49%) compared to the other three groups. Adults who perceived substantial mis- and disinformation and experienced medical care discrimination had a statistically significant higher probability of reporting unmet need for care (51%; 95% CI 40% - 62%) compared to adults who did not experience medical care discrimination and did not perceive substantial mis- and disinformation (29%; 95% CI 26% - 32%). We conducted a sensitivity analysis for the interaction of medical care discrimination and perception of mis- and disinformation, excluding non-Latino White participants, which resulted in a sample size of 1692. The results were replicated. Racially and ethnically minoritized adult social media users who perceived substantial mis- and disinformation and experienced medical care discrimination had a statistically significant higher probability of reporting unmet need for medical care (52%; 95% CI 38% - 67%) compared to racially and ethnically minoritized adult social media users who did not experience medical care discrimination and did not perceive substantial mis- and disinformation (24%; 95% CI 20% - 28%).

Discussion

Principal Findings

The primary objective of this study was to apply an extension of the Anderson model of health care utilization by evaluating the communication environment as a contextual determinant of health care seeking and utilization, which had not been specifically explored in prior studies [11-13]. Toward this end, we examined the association between perceptions of health mis- and disinformation on social media and unmet need for health care. We found that perception of substantial social media mis- and disinformation was associated with a higher probability of reporting unmet health care need compared to those who did not perceive substantial mis- and disinformation. This result is consistent with a growing body of literature demonstrating the negative impacts of social media health mis- and disinformation on health outcomes [16-19]. Our findings suggest that the communication environment serves as a contextual determinant of seeking health care by exposing individuals to false health information that is then associated with people delaying or avoiding medical care, even when it is needed, resulting in worse health outcomes [14]. Thus, perceptions of substantial health mis- and disinformation on social media may serve as one possible underlying mechanism for unmet need for health care.

In addition, we evaluated whether the relationship between perceptions of health mis- and disinformation on social media and unmet need for health care depended on the frequency of
social media use, trust in the health care system, and experience of racial and ethnic discrimination in health care. We found that unmet need for medical care was lower among adults who did not use social media daily and did not perceive substantial mis- and disinformation compared to daily social media users who perceived substantial mis- and disinformation. This finding is consistent with our theoretical framework that integrated the Anderson model of health care utilization with the frameworks that view the communication environment as a social driver of health [11,12]. Our empirical findings and theoretical framework suggest that more time spent on social media increases the exposure to and engagement with mis- and disinformation, which can lead frequent daily social media users to be more likely to have false beliefs that lower their likelihood of seeking needed medical care [32-34].

For the second mechanism, adults with low trust in the health care system and those who perceive substantial mis- and disinformation had the highest probability of reporting unmet health needs. This finding is consistent with prior literature and our theoretical framework demonstrating a trend toward eroding trust in medical professionals and health institutions associated with social media health mis- and disinformation, which influences harmful health behaviors and poor health outcomes [36-42]. Trust in the health care system is important for patient compliance with recommended care and seeking necessary medical care, and trust is difficult to rebuild once lost, suggesting this mechanism is critical for reducing negative impacts of unmet need for medical care [4,35].

Finally, adults who perceived substantial mis- and disinformation and experienced medical care discrimination had a higher probability of reporting unmet need for medical care compared to adults who did not experience medical care discrimination and did not perceive substantial mis- and disinformation. This finding is consistent with a large body of literature and our theoretical framework demonstrating the negative impacts of racial and ethnic discrimination experiences for seeking needed health care [43-50]. Our results and recent studies suggest that experiencing discrimination may have a complex relationship with social media health mis- and disinformation by further reducing historical levels of low trust in health care institutions [43,52,53].

Limitations

There are several limitations to consider when interpreting the results. First, a nonresponse analysis of a prior iteration of HINTS from 2011 and 2013 suggested that estimates using measures on seeking health information may be higher than other surveys [54]. To mitigate this potential effect and increase the validity of the study results, we excluded individuals who did not use social media and those who had not visited a social media platform in the past year (during the study period). Of course, the findings are the result of a cross-sectional survey, and therefore, should not be interpreted to indicate a causal relationship. One final context for interpreting the findings is that this study was focused on social media health mis- and disinformation and the findings might not apply to mis- and disinformation in other health contexts.

Conclusions

Based on our expanded version of the Anderson health care utilization model, we found that unmet need for health care was higher among individuals who perceived a substantial amount of social media mis- and disinformation, especially among those who used social media daily, had a low trust in the health care system, and experienced racial or ethnic discrimination when receiving health care. Our findings justify an expansion of the Anderson model of health care utilization by conceptualizing the communication environment as a contextual determinant of seeking health care. Future research should continue to model the communication environment as a contextual determinant of health care utilization and further evaluate the mechanisms of exposure to health mis- and disinformation, such as trust and discrimination. By extension, another area of future research could be the role of digital literacy, which we did not measure in this study. Individuals possessing advanced digital literacy skills are more likely to have the ability to differentiate between reliable health information and misleading or false information, and therefore, digital literacy may influence the connection between social media use and unmet health care needs [55]. Another area of future research is the role that social media plays in the support networks for individuals with specific health issues, perhaps mitigating or exacerbating the adverse impacts of mis- and disinformation through peer-supplied information and emotional support, which could interact with trust and past experiences of discrimination [55].

To counter the negative effects of social media mis- and disinformation on unmet need for health care, tailored public health efforts on social media are needed. These efforts should specifically target prevailing misunderstandings and offer fact-based information that has the potential to diminish the spread and consequences of health mis- and disinformation. As a component of this effort, health care institutions could actively monitor social media patterns to swiftly detect and address the emergence of health-related false and misleading information, potentially in real-time [55,56]. By implementing patient education programs that focus on developing health literacy, especially in the assessment of web-based health information, patients could be empowered to make well-informed health care choices [57]. Finally, health care institutions should continue to work toward building trust and reducing structural racism to mitigate the effects of mis- and disinformation and encourage patients to access health services when needed.

Abstract

Background: The fragmentation of the medical insurance system is a major challenge to achieving health equity. In response to this problem, the Chinese government is pushing to establish the unified Urban and Rural Resident Basic Medical Insurance (URRBMI) system by integrating the New Rural Cooperative Medical Scheme and the Urban Resident Basic Medical Insurance. By the end of 2020, URRBMI had been implemented almost entirely across China. Has URRBMI integration promoted health equity for urban and rural residents?

Objective: This study aims to examine the effect of URRBMI integration on the health level of residents and whether the integration can contribute to reducing health disparities and promoting health equity.

Methods: We used the staggered difference-in-differences method based on the China Family Panel Studies survey from 2014 to 2018. Our study had a nationally representative sample of 27,408 individuals from 98 cities. We chose self-rated health as the measurement of health status. In order to more accurately discern whether the sample was covered by URRBMI, we obtained the exact integration time of URRBMI according to the official documents issued by local governments. Finally, we grouped the sample by urban and rural areas, regions, and household income to examine the impact of the integration on health equity.

Results: We found that overall, the URRBMI integration has improved the health level of Chinese residents (B=0.066, 95% CI 0.014-0.123; P=.01). In terms of health equity, the results showed that first, the integration has improved the health level of rural residents (B=0.070, 95% CI 0.012-0.128; P=.02), residents in western China (B=0.159, 95% CI 0.064-0.255; P<.001), and lower-middle-income groups (B=0.113, 95% CI 0.004-0.222, P=.04), so the integration has played a certain role in narrowing the health gap between urban and rural areas, different regions, and different income levels. Through further mechanism analysis, we found that the URRBMI integration reduced health inequity in China by facilitating access to higher-rated hospitals and increasing reimbursement rates for medical expenses. However, the integration did not improve the health of the central region and low-income groups, and the lack of access to health care for low-income groups was not effectively reduced.

Conclusions: The role of URRBMI integration in promoting health equity among urban and rural residents was significant (P=.02), but in different regions and income groups, it was limited. Focusing on the rational allocation of medical resources between regions and increasing the policy tilt toward low-income groups could help improve the equity of health insurance integration.

Introduction

Health Inequity

With the rapid development of the global economy and medical technology, human health is improving, but health inequity is growing rather than shrinking. Health inequity in China is prominently observed between regions, urban and rural areas, and different income groups. Regional health inequity is mainly characterized by marked differences between the eastern coast and the western regions. In terms of life expectancy, the eastern provinces (or municipalities) are in the lead (eg, Beijing at 82.49 years, Shanghai at 82.55 years, Zhejiang at 80.26 years, Jiangsu at 79.32 years, and Guangdong at 79.31 years), while the western provinces exhibit lower figures, especially Qinghai (73.96 years), Yunnan (74.02 years), and the Tibet Autonomous Region (72.19 years) [1]. Health disparities also exist between urban and rural areas. From the end of 2019 to the end of 2020, the mortality rates for infants aged <1 year and children aged from 0 to 4 years in rural China were 2.40‰ and 0.78‰, respectively; the corresponding figures for urban areas were 0.89‰ and 0.25‰ [2]. Research based on China’s national microdata has proved that inequity favoring the rich for health-related quality of life remains significant in China, even after controlling for demographic factors [3].

The factors influencing health inequalities have been well discussed in previous studies. Income levels greatly influence health [4,5]. Higher-income groups not only have better access to health care but also enjoy greater health coverage [6]. In addition, there are disparities in health and the accessibility of health services for rural and susceptible populations, [7-9], with economic, medical, and educational resources being the main causes of health inequalities [10].

Inequity in the Health Insurance System

However, relatively little attention has been paid in existing studies to health inequalities resulting from inequalities in health insurance systems. One study found that of the 5 key factors contributing to health inequities in the European region, income security and social security have the highest proportion of the burden of health inequities at 35%, including income security and social security, living conditions, social and human capital, access to health care systems and their quality, and employment and working conditions [11]. Many countries have achieved universal health insurance coverage by establishing health insurance for different groups of people [12], which can lead to fragmentation of health insurance systems, leading to inequalities in health service use and economic security [13], and this represents a major challenge to achieving health equity [14,15].

China has built the largest medical insurance network in the world, covering >1.3 billion residents but has yet to unify the system. Urban Employee Basic Medical Insurance (UEBMI) is designed to cover employed urban residents, whereas Urban Residents Basic Medical Insurance (URBMI) extends coverage to the unemployed and retired individuals, older adults, students, and children in urban areas. Meanwhile, the New Rural Cooperative Medical Scheme (NRCMS) is implemented to cater to the health care needs of rural residents. However, the 3 medical insurance systems vary in terms of coverage, fund-raising standards, security benefits, medical insurance catalogs, designated institutions, management systems, and the level of overall planning. This fragmented medical insurance system has affected the fairness of treatment access for urban and rural residents. Compared to the URBMI, the NRCMS has higher out-of-pocket medical costs but fewer drugs, services, and facilities that can be reimbursed. Urban and rural residents do not enjoy the same coverage when faced with the same medical needs. Thus, the 3 health insurance systems in China have different degrees of health promotion effects on participants. UEBMI has the greatest effect on health improvement due to the high level of security benefits. NRCMS has the least [16-18] or even insignificant effect [19]. More details about NRCMS and URBMI are provided in Table 1.

aUEBMI: Urban Employee Basic Medical Insurance.

Policy Background

The Chinese government is attempting to break down the fragmentation of the health insurance system and promote health equity through integrating NRCMS with URBMI. The project began as a pilot exercise in 2009 and was officially implemented in 2016. In 2016, China’s State Council issued a document named Opinions of the State Council on Integrating the Basic Medical Insurance Systems for Urban and Rural Residents [20], which proposed to integrate URBMI with NRCMS to establish a unified basic medical insurance system for urban and rural residents (URRBMI). The opinions clearly set out 6 integration requirements, unifying the management of 6 aspects, including coverage of systems, fund-raising policies, social security benefits, medical insurance catalogs, the management of designated institutions, and fund management. In addition, the integration as a whole follows 3 principles: regardless of whether residents belong to urban or rural areas, URRBMI will be based on a lower standard for determining contributions, a higher standard for determining treatment, and a wider standard for determining the medical insurance catalog. Overall, 6 integration requirements have enabled urban and rural residents to enjoy a fair and unified medical insurance system and reduced the cost of running medical insurance. A total of 3 principles have raised the level of treatment and narrowed the treatment gap between urban and rural residents. Through the above mentioned policy design, the integrated URRBMI has improved the fairness of urban and rural medical insurance treatment. We compared the URRBMI with NRCMS and URBMI in Table 1.

Several empirical studies have explored the impacts of URRBMI integration and found different evidence. URRBMI integration is beneficial in increasing the number of health service utilizations among rural residents [21] and in mitigating rich inequalities in outpatient benefit probabilities and benefit levels [22]. However, some research finds that the integration has a negative impact on reducing inequalities in inpatient health services [23]. Although the integration significantly increases the use of inpatient care, it has a limited impact on health outcomes for rural middle-aged and older adult residents [24].

Overall, previous studies have focused on the impact on health service use and health care costs. While a small body of literature has explored the health impacts of URRBMI integration [23,25], there is a lack of focus on health equity. The relationship between URRBMI and health equity remains uncertain. Limited health care resources in rural areas and poor areas may reduce access to health care services, while the abundance of economic and health care resources in urban areas and wealthy households may increase health care use [26], so better-off areas and households benefit more from the integration. However, the price elasticity of demand for health care services is higher in the low-income group, and the degree of response to the price of health care use changed by health care insurance will be greater, so health care insurance can promote the improvement of health care use and thus health in this group [27]. The aim of this study was to explore the differential impact of health effects across urban and rural areas, different regions, and groups of different income levels and assess whether URRBMI integration is effective in improving health equity for Chinese residents.

Methods

Data

This study used open data from the China Family Panel Studies (CFPS), designed by the research team at Peking University. These data are the first large-scale, comprehensive, and academically oriented social tracking survey in China. The data were made publicly available in 2010 as a baseline survey result, followed by a biennial full-sample tracking survey covering all household members in the 25 provincial-level administrative regions of mainland China [28], which represents 95% of the Chinese population. The data focus on the economic and noneconomic well-being of China’s population, including economic activity, educational attainment, family relationships...
and family dynamics, population migration, and physical and mental health, among many other research topics.

This study used the CFPS data from 2014, 2016, and 2018 database, which was because most cities (50/98, 51%) were consolidated in the period from 2015 to 2017. To obtain a sample suitable for the study, the raw data were further processed. At the individual level, only those individuals whose participation types were NRCMS, URBMI, or URRBMI were retained; samples with missing or abnormal information were deleted. At the city level, we deleted cities that had already achieved URRBMI integration before and in 2014, such as Changsha, Shaoquguan, Yangjiang, Qianxinan Buyei and Miao Autonomous Prefecture, Dongguan, Maoming, Meizhou, Shantou, Jiangmen, Yunfu, Zibo, Qingyuan, Jieyang, Zhanjiang, Hangzhou, Chongqing, Chengdu, Wuxi, Zuhuai, and Tianjin. We also deleted cities with unclear implementation of the integration policy (judged by whether the local government has issued an official document on integrating URBMI and NRCMS). Finally, the unbalanced panel was treated into a balanced panel. Through the aforementioned processing, this study finally retained 27,408 individual samples and 98 city samples. A total of 55 (56%) city samples were in the integration group, and 43 (44%) were in the nonintegration group. The integration time of the city samples is presented in Textbox 1.

Textbox 1. Years the Urban and Rural Resident Basic Medical Insurance (URRBMI) was integrated in each city.

Ethical Considerations

As a human-involved research project, CFPS regularly submits ethical reviews to the Biomedical Ethics Review Committee of Peking University and carries out data collection work upon receiving review approval (approval number IRB00001052-14010). All written informed consent forms are provided by participants aged ≥15 years or by their parents (for participants aged ≤15 years). The personal information and privacy of the interviewees are strictly protected by CFPS according to the ethics rules.

Variables

Measurement of the Dependent Variable: Health Status of Residents

“Self-rated health” is the subjective evaluation of the respondents’ health status. Among many health assessment indicators, “self-rated health” is widely used in health measurement and evaluation. On the one hand, “self-rated health” takes into account the subjective knowledge of the respondents, which is scientific. On the other hand, it comprehensively evaluates the physical, psychological, and social health of individuals, so it can be more comprehensive [29]. Therefore, this study used the self-rated health score to measure the health status of residents as the dependent variable. This variable was based on the question on the CFPS questionnaire: “How would you rate your health status?” The answers were given 5 grades from “poor” to “excellent,” assigned 1 to 5 points, respectively.

Measurement of the Independent Variable: Whether the Sample Cities Have Integrated NRCMS With URBMI Into URRBMI

The existing research had mainly used the type of insurance participation in the questionnaire to identify the treatment group and the control group. The method of individual definition directly using the self-reported data has serious inaccuracies because ordinary rural residents are usually only concerned about whether the health insurance benefits are improved and do not care about the change of the type of insurance participation from “NRCMS” or “URBMI” to “URRBMI” because the change does not affect their medical care and reimbursement processes. Therefore, this study obtained the exact integration time of the URRBMI according to the official documents issued by local governments, such as the opinions and plans on the implementation of URRBMI integration, which...
was the method of “city definition.” If the integration time was earlier than the data access year \( t \), the policy variable was assigned a value of 1; otherwise, it was assigned a value of 0. This setup produced a “treatment group” and a “control group,” as well as “pretreatment” and “posttreatment” double differences.

**Controlled Variables**

In order to alleviate the problem of missing variables, this study controlled other important variables affecting the health of residents as far as possible, according to previous relevant studies and survey data [30-32]. Controlled variables included not only the individual characteristics variables such as gender, age, marital status, type of household registration, education level, family size, annual household income per capita, and region but also the health characteristics variables such as smoking status, frequency of alcohol consumption, frequency of exercise, and chronic disease status. The definitions of the main variables and description of the mean are presented in Table 2.

### Staggered Difference-in-Differences Model

On the basis of the fact that the timing of URRBMI integration varies in different regions, this study used the staggered difference-in-differences (DID) model to examine the impact of the integration on residents’ health level and equity. The basic idea of the DID model is to construct the treatment group and the control group and to identify the health level of residents before and after policy implementation. The staggered DID model is applicable to a special case of policy implementation, that is, policy implementation from the beginning of the pilot to the gradual extension. There are differences in implementation time in different regions [33]. Our specific models were as follows:

<table>

In light of the prominent health disparities observed across different regions, urban and rural areas, and various income groups in China, this study aimed to investigate the differential impact of the system integration on the health status of these subgroups. Specifically, through grouping estimations in subsequent sections, we sought to assess the extent to which policies contributed toward achieving health equity for Chinese residents.

The Impact of URRBMI Integration on the Health Equity of Chinese Residents

In light of the prominent health disparities observed across different regions, urban and rural areas, and various income groups in China, this study aimed to investigate the differential impact of the system integration on the health status of these subgroups. Specifically, through grouping estimations in subsequent sections, we sought to assess the extent to which

over time, $\lambda_t$ represents the time-fixed effect, and $\varepsilon_{ijt}$ is a random disturbance term. The estimated coefficient $\beta_j$ measures the effects of policy implementation.

### Results

#### Regression Results of the Impact of URRBMI Integration on the Health Level of Chinese Residents

Table 3 reports the regression results of the effect of the URRBMI integration on the health level of Chinese residents.

$^a$DID: difference-in-differences.

$^b$City-fixed effect and time-fixed effect were controlled.

$^c$City-fixed effect, time-fixed effect, and control variables were controlled.

$^d$PSM-DID: propensity score matching combined with the difference-in-differences.

$^e$City-fixed effect, time-fixed effect, and control variables were controlled.

We controlled for fixed effects and control variables in turn. The second row showed that the coefficient of the policy variable was 0.068, which was significant at the 5% statistical level, indicating that the URRBMI integration policy had significantly improved the health level of residents.

In addition, this study further used the propensity score matching combined with the DID method to address the endogenous issues that might arise from the URRBMI policy implementation “selection bias.” The role of the propensity score matching method is to look for the nonintegrated group whose characteristics are similar to those of the integrated group, that is, to select the nonintegrated group that is only in the range of the cosupport interval with the integrated group as the control group, to enhance comparability between integrated and nonintegrated groups. In this study, the nearest neighbor matching method was used to pair each sample in an integrated group with a sample in a nonintegrated group whose score was closest to each other, while limiting the propensity score gap to 0.01 (the caliper is not >0.01). Regression estimates were made using the matched samples, and the results are presented in the third row of Table 3. The regression coefficient was 0.090 after treatment, which was significant at the level of 5%. The regression result indicated that the conclusions above remained robust.

As mentioned in the Introduction section, due to the split medical insurance system between rural and urban areas, URRBMI integration will have a different impact on rural and urban residents. This study identified the impact by dividing the sample into 2 groups: urban residents (nonagricultural households) and rural residents (agricultural households), based on the residents’ household registration.

The results showed that the integration had a significant contribution to the health of rural residents (B=0.070, 95% CI 0.012-0.128; P=.02), while it did not have a significant effect on urban residents (B=0.063, 95% CI -0.103 to 0.229; P=.46). This indicated that the integration significantly reduced health inequalities between urban and rural areas and achieved the policy objective better.

#### Regression Results of the Impact of URRBMI Integration on Health Equity in Different Regions

As mentioned in the Introduction section, due to the regional differences in economic and health care resource allocation, URRBMI integration will have a different impact in different regions. This study identified the impact by dividing the Chinese mainland into 3 major economic regions, namely, the eastern, central, and western regions, according to the division criteria of the National Bureau of Statistics of China. The eastern region includes Shanghai, Beijing, Tianjin, Shandong, Guangdong, Jiangsu, Hebei, Zhejiang, Fujian, and Liaoning; the central region includes Jilin, Anhui, Shanxi, Jiangxi, Henan, Hubei,
Hunan, and Heilongjiang; and the western region includes Yunnan, Sichuan, Guangxi, Gansu, Guizhou, Chongqing, and Shaanxi. Table 4 reports the impact of URRBMI integration on regional health equity.

Table 4. Regression results of Urban and Rural Resident Basic Medical Insurance impact of the integration on health equity in different regionsa.

aAll regressions included the full set of control variables and fixed effects.

The results showed that the integration had a significant contribution to the health level of residents in the western region (B=0.159, 95% CI 0.064-0.255; P<.001), while the effect on the eastern (P=.75) and central (P=.10) regions was not significant. This suggested that the integration had, to some extent, alleviated health inequalities between regions, but the effect was limited.

Regression Results of the Impact of URRBMI Integration on Health Equity for Different Income Groups

As mentioned in the Introduction section, because different income groups have different health needs and different levels of access to health services, URRBMI integration will have a different impact for different income groups. This study analyzed the impact by dividing the entire sample into 4 groups: low-income, lower-middle-income, upper-middle-income, and high-income groups, based on annual household income per capita. Table 5 reports the impact of the integration on health equity for different income groups.

aAll regressions included the full set of control variables and fixed effects.

The results showed that URRBMI integration had a significant health promotion effect on the lower-middle-income groups (B=0.113, 95% CI 0.004-0.222; P=.04), but not on the other income groups (including low-income, upper-middle-income, and high-income groups). This indicated that URRBMI integration had, to some extent, alleviated the health inequity gap between different income groups, but the effect was limited.

Robustness Tests

Counterfactual Test

To justify the common trend hypothesis in this study, we conducted a counterfactual test to ensure that there is no systematic difference in the health level of residents in the integrated and nonintegrated groups before URRBMI integration. This study drew on existing research to test the “counterfactual” hypothesis [34]. This was done by applying the baseline model (1) to the period when the region had not yet integrated medical insurance (removing data from years after the integration of the integration group), that is, introducing a new variable “whether the region was an urban and rural resident’ health insurance integration group,” and we assigned a value of 1 if the region was integrated later than the time of data access and otherwise assigned a value of 0, thus constructing a hypothetical treatment group and control group about “urban-rural resident’ health insurance integration.” Since the hypothetical “urban-rural health insurance integration” was not expected to have a significant impact on the health of urban and rural residents during this period, the hypothetical control group could be considered the “counterfactual” result of the treatment group. The results show that integration did not have a significant (B=0.017, 95% CI −0.115 to 0.149; P=.80) impact on the health of urban and rural residents before the implementation of the integration, indicating that the “counterfactual” hypothesis was largely satisfied.

Placebo Test

In this quasi-natural experiment, the significant improvement in the self-rated health of urban and rural residents might be due to some random factors. In this study, we used some scholars’ approach to construct a placebo test to determine whether the health promotion effect of the integrated URRBMI was caused by other random factors [35]. The specific method was to use Stata software (StataCorp LLC) to make the time of the URRBMI on specific cities become random, and then repeat the random process 500 times to obtain a nuclear density distribution map of , as shown in Figure 1.
concentrated around 0, which proved that the unobserved influence factors had little influence on the estimation results. The dotted line indicated the coefficient size of the policy variable in column 3 of Table 3. Because the dotted line was positioned far away from the distribution of the 0, it meant that the real policy effect was different from the policy effect of the placebo test. It indicated that the coefficient of the policy variables in column 3 of Table 3 was statistically significant and stable.

Figure 1. Placebo test.

Substitution of Variables
In addition, we conducted robustness tests by replacing variables. The ability to perform activities of daily living was chosen as a measure of objective health. This indicator measured the ability of people aged >45 years to take care of themselves. It included 7 activities in the CFPS, such as going outside for outdoor activities, eating, performing kitchen activities, taking public transportation, going shopping, cleaning, and doing laundry. If an activity could be completed independently, it was assigned a value of 1; otherwise, it was assigned a value of 0. If there were n activities that could be completed independently, the cumulative total would be n. The larger the n was, the higher the objective health level. The results show that the integration policy still produced a significant (B=0.065, 95% CI 0.015-0.115; P=.01) positive contribution to residents' objective health, which indicated that the results were basically robust.

Discussion
Main Findings
This study used nationally representative data from China to demonstrate that URRBMI integration has a positive effect on improving health standards and promoting health equity. The results showed that URRBMI integration can improve the health level of rural residents, lower-income western regions, and lower-middle-income groups. However, the impact of reducing health disparities is still limited and has not improved the health of the central region and low-income groups. This section provides an in-depth discussion and analysis of the findings, adding additional evidence to further explain the plausibility of the findings. At the same time, this paper studied the impact path of medical insurance system integration on health, providing experience for global health insurance system reform and promoting health equity.

The Positive Impact of the Policy
The positive health effects of medical insurance are related to policy design. First, the integration has significantly increased the level of benefits, reducing the medical burden on residents accessing health care. The reimbursement rates and cap lines of URRBMI have generally increased in all provinces and municipalities, in line with the integration principles. For example, in Shanghai, before the integration, the minimum payment rate for URBMI was 60% (for those aged <60 years), while the minimum payment rate for the NRCSMS was only
50%. After the integration, the medical insurance payment rate for URRBMI was unified at 70% [36]. Second, patients’ choice of medical treatment has been increasing, which has improved the quality of medical treatment for the residents. On the one hand, the number of designated medical institutions in each province has increased after the integration. The original designated hospitals of NRCMS and URBMI have all been incorporated into the designated hospitals of URRBMI, which are located in various streets, towns, and communities (villages) in the city’s urban and rural areas, so the insured can reduce the inconvenience caused by residents seeking medical treatment in different places across counties (districts). On the other hand, the medical insurance catalog has been expanded by more than a thousand kinds of reimbursable drugs. After the integration, Inner Mongolia’s drug catalog of NRCMS has increased from 1988 to >2600, an increase of >30% [37]. Third, the process of reimbursement of medical expenses is more convenient, reducing the time and cost of medical treatment for residents. The reimbursement will be settled instantly through the social security card without the need for advance payment, eliminating all the hassles and inconveniences of medical treatment.

As mentioned in the previous paragraphs on impact pathways, rural residents have benefited more from the integration in terms of treatment levels and patients’ choice, so that URRBMI integration has promoted health equity between urban and rural residents. The increase in the drug catalog of the URRBMI is much less than that of the NRCMS, and so is the increase in the level of treatment. In addition, the quality of medical care for rural residents has improved due to the increased level of overall planning after the integration. Before the integration, URBMI was mostly coordinated at the prefectural and municipal levels, while the NRCMS was generally coordinated at the county level, so when rural residents went to a municipal hospital for medical treatment, they were seeking medical treatment in a different place, which had a lower reimbursement rate and complicated reimbursement procedures [38]. After the integration, URRBMI will in principle be coordinated at the municipal (prefectural) level and even maybe at the provincial level, breaking down the systemic and geographical differences between urban and rural residents’ access to health care and improving equity in the use of health services for rural residents [39].

The Negative Impact of the Policy

However, the URRBMI integration has played a limited role in promoting regional health equity, mainly in that it has not contributed to the improvement of health standards in the central region. This may be related to the level of regional economic development and public health care resources. The impact of health insurance and economic factors on health has a substitution effect; that is, the health performance of medical insurance diminishes as the level of regional economic development increases [40]. Those living in regions with higher levels of economic development are likely to have less impact on health care accessibility and, thus, lesser impact on health than on factors such as income, education, and environment [41]. For those living in less developed areas, their income levels and quality of life will also be relatively low, so health insurance can significantly improve access to health care, promoting health level in poorer areas [24]. As shown in Table 6, the economic development of the eastern regions is higher than that of the central and western regions, and therefore the health promotion effect of the integration is limited for the eastern regions.

The income level of the residents in the western region is lower than that of the residents in the eastern region, and the probability of “illness without treatment” is higher. Moreover, the population in the western region is relatively small, so the per capita medical resources are relatively sufficient, as shown in Table 6. In this case, the health promotion effect of the integration is more significant (P < .001) in the western region, while in the central region, it may be that the reform of the system has been neglected by the policy design due to its “middle zone” of economic development and medical resources.

We also found that URRBMI integration has played a limited role in health equity for different income groups and has not improved the health of low-income groups. A number of studies have shown that there is significant heterogeneity in the health performance of health insurance according to individual income, education, age, and household registration [27,42]. The heterogeneity is particularly evident in economic and social factors [43]. In general, low-income groups are more sensitive to price changes in health services than higher-income groups [44]. However, compared with the lower-middle-income groups, the increase in funding levels brought about by health insurance consolidation has resulted in a higher financial burden of health care for the low-income groups [45], which may still discourage health needs due to the risk of poverty, leading to a lack of access to health care. To verify this, the 2-week sickness rate and the rate of not seeking medical treatment were calculated using the questions in the CFPS questionnaire, “During the past two weeks, have you felt any physical discomfort? “ and “Have you seen a doctor?” and grouped according to income. The results shows that the 2-week sickness rate is higher in the low-income group (low-income: 0.3672; lower-middle-income: 0.3417; upper-middle-income: 0.3141;
high-income: 0.2877), and the phenomenon of not seeking medical treatment is more common (low-income: 0.8233; lower-middle income: 0.8090; upper-middle income: 0.8074; high-income: 0.7935). Therefore, the integration did not alleviate the equity of health care use among low-income groups, and the health promotion effect on low-income groups was not significant.

Mechanism Analysis

From the regression results in the Table 3, it can be seen that the integration of URRBMI has a promoting effect on the health of rural areas, western regions, and low-income and middle-income groups; therefore, in order to further verify the mechanism of the impact of health insurance integration on health equity, we chose “choice of medical treatment” and “reimbursement ratio” as possible mechanisms to be analyzed. In the CFPS, residents’ choices of medical care included 5 categories, such as general hospitals, specialty hospitals, community health centers or township health centers, community health service stations or village health offices, and clinics, which were assigned a value of 1 to 5, respectively. The reimbursement rate was expressed as the ratio of reimbursed medical expenses to total medical expenses, where reimbursed medical expenses were equal to the difference between total medical expenses and out-of-pocket medical expenses. Table 7 reports 2 mechanisms by which health care integration affects health.

*All regressions included the full set of control variables and fixed effects.

The first panel of Table 7 shows the regression results of the impact of the integration on the medical choices. It can be found that the coefficients of the policy variables were significant (rural: P=.02; western: P=.05; lower-middle: P=.04) for rural and western residents and lower-middle-income groups in the first column. This suggests that the URRBMI integration promoted the movement of residents to higher-ranking hospitals and improved the quality of care, thereby improving the health of rural and western residents and lower-middle-income groups. The second panel of Table 7 shows the regression results of the impact of the integration on the reimbursement ratio. It can be found that the reimbursement rate was expressed as the ratio of the reimbursed medical expenses to the total medical expenses, where the reimbursed medical expenses were equal to the difference between total medical expenses and out-of-pocket medical expenses. It can be found that the coefficients of the policy variables were significant for rural residents, western residents, and lower-middle-income groups (rural: P=.004; western: P=.04; lower-middle: P=.08). This suggested that the URRBMI integration increased the reimbursement rate of health insurance, which to a certain extent eased the medical burden of rural and western residents and lower-middle-income groups, thus improving the health of the population.

Conclusions

This study found that URRBMI integration has contributed to the improvement of residents’ health, mainly due to the improvement of medical treatment and the reduction of the cost of access to health care. In terms of the impact on health equity, this paper finds that integrated URRBMI can promote health equity between urban and rural areas. However, to a limited extent, it can alleviate health disparities between regions and between different income groups. Furthermore, we also explore 2 mechanisms affecting health equity, on the basis of these findings, the policy implications of this study are as follows: first, rationally allocate medical resources among different regions; do not neglect the development of regions with a moderate level of economic development, such as the middle region; improve the problem of insufficient resources in the middle region; and at the same time, increase support for regions with poor economic development, such as the western region. Second, the integration of medical insurance should increase

Limitations

There were still several limitations to this study. Due to data limitations, we used only self-rated health as an indicator to assess the health level of the insured. Although we chose objective health to replace the dependent variable, the indicator could only measure the health of people aged >45 years, resulting in a somewhat reduced sample size. However, due to the relatively large span of the research sample, at present, China’s official data have not found relevant data to measure the health level of the whole sample of indicators. In the future, we will further seek to use a more comprehensive evaluation indicator to further test the conclusions of the study.

The table shows the regression results of the impact of the integration on the medical choices and reimbursement ratio. The coefficients for rural and western residents, as well as lower-middle-income groups, are significant at the 0.05 level. The reimbursement rate for rural residents is 0.039 and for western residents is 0.036. The third column of the table shows the significance levels for these results.
the policy bias toward low-income groups to promote the use of health care services by low-income groups. This study provides experience and thoughts for China and other countries around the world in breaking down fragmented health care systems and establishing a unified health care system.

Acknowledgments
The authors thank the National Health and Health Council of China for cooperation and organizing field data collection. They acknowledge the financial support from Major Project of the Key Research Base for Humanities and Social Sciences of the Ministry of Education of China (project 22JJD630014) and the National Social Science Foundation of China (project 22BGL210).
