Contents

Original Papers

Estimating the Epidemic Size of Superspreading Coronavirus Outbreaks in Real Time: Quantitative Study (e46687)
Kitty Lau, Jian Kang, Minah Park, Gabriel Leung, Joseph Wu, Kathy Leung ................................................................. 17

Association of Rest-Activity Rhythm and Risk of Developing Dementia or Mild Cognitive Impairment in the Middle-Aged and Older Population: Prospective Cohort Study (e55211)
Shahab Haghashegh, Chenlu Gao, Elizabeth Sugg, Xi Zheng, Hui-Wen Yang, Richa Saxena, Martin Rutter, Michael Weedon, Agustin Ibanez, David Bennett, Peng Li, Lei Gao, Kun Hu ................................................................. 32

Exploring Dynamic Changes in HIV-1 Molecular Transmission Networks and Key Influencing Factors: Cross-Sectional Study (e56593)
Yan He, Ying Tang, Qun Hua, Xin Li, You Ge, Yangyang Liu, Rong Tang, Ye Tian, Wei Li ................................................................. 46

A Metric of Societal Burden Based on Virus Succession to Determine Economic Losses and Health Benefits of China’s Lockdown Policies: Model Development and Validation (e48043)
Wenxiu Chen, Bin Zhang, Chen Wang, Wei An, Shashika Guruge, Ho-kwong Chui, Min Yang ................................................................. 60

Optimal Systolic Blood Pressure for the Prevention of All-Cause and Cardiovascular Disease Mortality in Older Adults With Hypertension: Nationwide Population-Based Cohort Study (e52182)
Jae Lee, Kyung Lee .................................................................................................................................................. 70

Sleep Health Analysis Through Sleep Symptoms in 35,808 Individuals Across Age and Sex Differences: Comparative Symptom Network Study (e51585)
Christophe Gauld, Sarah Hartley, Jean-Arthur Micoulaud-Franchi, Sylvie Royant-Parola ........................................................................ 80

Early Detection of 5 Neurodevelopmental Disorders of Children and Prevention of Postnatal Depression With a Mobile Health App: Observational Cross-Sectional Study (e58565)
Fabrice Denis, Florian Le Goff, Madhu Desbois, Agnes Gepner, Guillaume Feliciano, Denise Silber, Jean-David Zeitoun, Guedalia Assuied ................................................................. 9

Predicting the Population Risk of Suicide Using Routinely Collected Health Administrative Data in Quebec, Canada: Model-Based Synthetic Estimation Study (e52773)
JianLi Wang, Fatemeh Kharrat, Geneviève Gariépy, Christian Gagné, Jean-François Pelletier, Victoria Massamba, Pascale Lévesque, Mada Mohammed, Alain Lesage ........................................................................................................ 106

Factors Influencing Data Quality in Electronic Health Record Systems in 50 Health Facilities in Rwanda and the Role of Clinical Alerts: Cross-Sectional Observational Study (e49127)
Hamish Fraser, Michael Mugisha, Ian Bacher, Joseph Ngenzi, Christopher Seebregts, Aline Umuhire, Jeanine Condo ........................................................................................................ 118
Discovering Subgroups of Children With High Mortality in Urban Guinea-Bissau: Exploratory and Validation Cohort Study (e48060)
Andreas Rieckmann, Sebastian Nielsen, Piotr Dworzynski, Heresh Amini, Søren Mogensen, Isabel Silva, Angela Chang, Onyebuchi Aran, Wojciech Samek, Naja Rod, Claus Ekstrom, Christine Benn, Peter Aaby, Ane Fisker ................................................................. 602

Data-Driven Identification of Potentially Successful Intervention Implementations Using 5 Years of Opioid Prescribing Data: Retrospective Database Study (e51323)
Lisa Hopcroft, Helen Curtis, Richard Croker, Felix Pretis, Peter Inglesby, David Evans, Sebastian Bacon, Ben Goldacre, Alex Walker, Brian MacKenna ................................................................. 618

Development of Interoperable Computable Phenotype Algorithms for Adverse Events of Special Interest to Be Used for Biologies Safety Surveillance: Validation Study (e49811)
Ashley Holdefer, Jeno Pizarro, Patrick Saunders-Hastings, Jeffrey Beers, Arianna Sang, Aaron Hettinger, Joseph Blumenthal, Eírík Martínez, Lance Jones, Matthew Deady, Hussein Ezzeldin, Steven Anderson ................................................................. 628

Global, Regional, and National Burden of Myocarditis in 204 Countries and Territories From 1990 to 2019: Updated Systematic Analysis (e46635)
Qingyu Kong, Xue Xu, Meng Li, Xiao Meng, Cuifen Zhao, Xiaorong Yang ................................................................. 684

Challenges and Implications for Menopausal Health and Help-Seeking Behaviors in Midlife Women From the United States and China in Light of the COVID-19 Pandemic: Web-Based Panel Surveys (e46538)
Bobo Lau, Catherine Tang, Eleanor Holroyd, William Wong ................................................................. 704

The Framing Effect of Digital Textual Messages on Uptake Rates of Medical Checkups: Field Study (e45379)
Amnon Maltz, Stella Rashkovich, Adi Sarid, Yafit Cohen, Tamar Landau, Elina Saifer, Neta Amoral Belkin, Tamar Alcalay ................................................................. 718

Association Between Adherence to 24-Hour Movement Guidelines and Noncommunicable Disease Risk in Chinese Adults: Prospective Cohort Study (e47517)
Si Yi Huang, Yuxuan Gu, Shahmir Ali, Jingjing Xue, Ronghua Zhang, Xu Wen ................................................................. 758

Evaluating the Knowledge of and Behavior Toward COVID-19 and the Possibility of Isolating at a City Level: Survey Study (e47170)
Elise Verot, Robin Chaux, Julie Gagnaire, Paul Bonjean, Amandine Gagneux-Brunon, Philippe Berthelot, Carole Pelissier, Billal Boulama, Franck Chauvin, Bruno Pozzetto, Elisabeth Botelho-Nevers ................................................................. 771

Relationship Between Physical Exercise and Cognitive Function Among Older Adults in China: Cross-Sectional Population-Based Study (e49790)
Fubaihui Wang, Changqing Gao, Yantao Wang, Zhuo Li, Feiran Zheng, Yanan Luo ................................................................. 802

Impact of Healthy Lifestyle Factors on Life Expectancy and Lifetime Health Care Expenditure: Nationwide Cohort Study (e57045)
Wei-Cheng Lo, Tsuey-Hwa Hu, Cheng-Yu Shih, Hsien-Ho Lin, Jing-Shiang Hwang ................................................................. 836

Advancing Colorectal Cancer Detection With Blood-Based Tests: Qualitative Study and Discrete Choice Experiment to Elicit Population Preferences (e53200)
Clarence Ong, Alex Cook, Ker-Kan Tan, Yi Wang ................................................................. 854

Newspaper Coverage of Hospitals During a Prolonged Health Crisis: Longitudinal Mixed Methods Study (e48134)
Frank van de Baan, Rachel Gifford, Dirk Ruwaard, Bram Fleuren, Daan Westra ................................................................. 871

Web-Based Information on Spinal Cord Stimulation: Qualitative Assessment of Publicly Accessible Online Resources (e50031)
Tiev Miller, Ali Hossinzadeh, Thomas Thordarson, Tamila Kalimullina, Soshi Samejima, Claire Shackleton, Raza Malik, Martin Calderón-Juárez, Rahul Sachdeva, Andrei Krassioukov ................................................................. 884
Impacts of Smoking Ban Policies on Billiard Hall Sales in South Korea Using Objective Sales Information of a Credit Card Company: Quasi-Experimental Study (e50466)  
Jin-Won Noh, Jooyoung Cheon, Hohyun Seong, Young Kwon, Ki-Bong Yoo.  
895

CD4/CD8 Ratio Recovered as a Predictor of Decreased Liver Damage in Adults Infected With HIV: 16-Year Observational Cohort Study (e45818)  
Bingyu Liang, Rujing Sun, Yan Yan Liao, Aidan Nong, Jinfeng He, Mengqiu Zhu, Hui Hu, Li Ye, Hao Liang.  
917

AIDSVu Cities’ Progress Toward HIV Care Continuum Goals: Cross-Sectional Study (e49381)  
Nicole Hood, Nanette Benbow, Chandni Jaggi, Shamaya Whitby, Patrick Sullivan, AIDSVu Health Department Collaborators.  
929

Characteristics of Hepatitis B Virus, Hepatitis C Virus, and Syphilis Coinfection in People With HIV/AIDS Contracted Through Different Sources: Retrospective Study (e46750)  
Rongrong Yang, Rui Yuan, Xien Gui, Hengning Ke, Ke Zhuang, Hui Hu, Ling Li, Ling Feng, Xingxia Yu, Yajun Yan, Mingqi Luo.  
939

SARS-CoV-2 Infection, Hospitalization, and Associated Factors Among People Living With HIV in Southeastern China From December 2022 to February 2023: Cross-Sectional Survey (e51449)  
Wei Cheng, Yun Xu, Haibo Jiang, Jun Li, Zhigang Hou, Haibin Meng, Wei Wang, Chengliang Chai, Jianmin Jiang.  
951

A Machine Learning Model for Identifying Sexual Health Influencers to Promote the Secondary Distribution of HIV Self-Testing Among Gay, Bisexual, and Other Men Who Have Sex With Men in China: Quasi-Experimental Study (e50656)  
Yuxin Ni, Ying Lu, Fengshi Jing, Tianyuan Wang, Yewei Xie, Xi He, Dan Wu, Rayner Tan, Joseph Tucker, Xumeng Yan, Jason Ong, Qingpeng Zhang, Hongbo Jiang, Wencan Dai, Liqun Huang, Wenhua Mei, Yi Zhou, Weiming Tang.  
971

Attrition Rates in HIV Viral Load Monitoring and Factors Associated With Overdue Testing Among Children Within South Africa’s Antiretroviral Treatment Program: Retrospective Descriptive Analysis (e40796)  
Ahmad Haeri Mazanderani, Lebohang Radebe, Gayle Sherman.  
986

Examining HIV Testing Coverage and Factors Influencing First-Time Testing Among Men Who Have Sex With Men in Zhejiang Province, China: Cross-Sectional Study Based on a Large Internet Survey (e56906)  
Lin He, Tingting Jiang, Wanjun Chen, Shaoqiang Jiang, Jinlei Zheng, Weiyoug Chen, Hui Wang, Qiaoqin Ma, Chengliang Chai.  
999

Sex Differences in Clustering Unhealthy Lifestyles Among Survivors of COVID-19: Latent Class Analysis (e50189)  
Lan Le, Thi Hoang, Tan Nguyen, Tien Dao, Binh Do, Khue Pham, Vinh Vu, Linh Pham, Lien Nguyen, Hoang Nguyen, Tuan Tran, Trung Nguyen, Anh Nguyen, Hoan Nguyen, Phuc Nguyen, Hoai Nguyen, Thu Pham, Thuy Le, Thao Nguyen, Cuong Tran, Ha-Linh Quach, Kien Nguyen, Tuyen Duong.  
1022

Digital Dietary Behaviors in Individuals With Depression: Real-World Behavioral Observation (e47428)  
Yue Zhu, Ran Zhang, Shuluo Yin, Yihui Sun, Fay Women, Rongxun Liu, Sheng Zeng, Xizhe Zhang, Fei Wang.  
1039

Understanding Risk Factors for Oropharyngeal Gonorrhea Among Sex Workers Attending Sexual Health Clinics in 2 Australian Cities: Mixed Methods Study (e46845)  
Tiffany Phillips, Christopher Fairley, Kate Maddaford, Anna McNulty, Basil Donovan, Rebecca Gu, Ruth McIver, Rebecca Wigan, Rick Varma, Jason Ong, Denton Callander, Gabrielle Skelsey, My Myon Myong, Dylan O’Hara, Jade Bilardi, Eric Chow.  
1051

The Impact of Rapid Handpump Repairs on Diarrhea Morbidity in Children: Cross-Sectional Study in Kwale County, Kenya (e42462)  
Patrick Thomson, Justin Stoler, Michelle Byford, David Bradford.  
1117
Smoking Behavior Change and the Risk of Heart Failure in Patients With Type 2 Diabetes: Nationwide Retrospective Cohort Study (e46450)
Jung Yoo, Su-Min Jeong, Kyu Lee, Heesun Lee, Ji Yoon, Kyungdo Han, Dong Shin. 1307

The Impact of Prostate-Specific Antigen Screening on Prostate Cancer Incidence and Mortality in China: 13-Year Prospective Population-Based Cohort Study (e47161)
Xiaohao Ruan, Ning Zhang, Dawei Wang, Jingyi Huang, Jinlun Huang, Da Huang, Tsun Chun, Brian Ho, Ada Ng, James Tsu, Yongle Zhan, Rong Na. 1321

Assessing Global, Regional, and National Time Trends and Associated Risk Factors of the Mortality in Ischemic Heart Disease Through Global Burden of Disease 2019 Study: Population-Based Study (e46821)
Tingting Shu, Ming Tang, Bo He, Xiaozhu Liu, Yu Han, Chang Liu, Pedro Jose, Hongyong Wang, Qing-Wei Zhang, Chunyu Zeng. 1333

Depression and Anxiety Symptoms Among Cisgender Gay and Bisexual Men During the Onset of the COVID-19 Pandemic: Time Series Analysis of a US National Cohort Study (e47048)
Chloe Mirzayi, Drew Westmoreland, Matthew Stief, Christian Grov. 1353

Global Trends in the Incidence of Anxiety Disorders From 1990 to 2019: Joinpoint and Age-Period-Cohort Analysis Study (e49609)
Huiru Cao, Yang Wu, Hui Yin, Yanqi Sun, Hui Yuan, Mengjun Tao. 1361

Relationship Between Lipoprotein(a), Renal Function Indicators, and Chronic Kidney Disease: Evidence From a Large Prospective Cohort Study (e50415)
Yingxin Liu, Ruoting Wang, Shuai Li, Changfa Zhang, Gregory Lip, Lehana Thabane, Guowei Li. 1376

Impact of the COVID-19 Pandemic on the Personal Networks and Neurological Outcomes of People With Multiple Sclerosis: Cross-Sectional and Longitudinal Case-Control Study (e45429)
Clare Riley, Shruthi Venkatesh, Amar Dhand, Nandini Doshi, Katelyn Kavak, Elle Levit, Christopher Perrone, Bianca Weinstock-Guttman, Erin Longbrane, Philip De Jager, Zongqi Xia. 1391

Association of Visceral Obesity Indices With Incident Diabetic Retinopathy in Patients With Diabetes: Prospective Cohort Study (e48120)
Jiaheng Chen, Yu Li, Zimin Niu, Zhanpeng He, Yao Xie, Jose Hernandez, Wenyong Huang, Harry Wang, Guangzhou Diabetic Eye Study Group. 1410

Age Differences in the Association of Sleep Duration Trajectory With Cancer Risk and Cancer-Specific Mortality: Prospective Cohort Study (e50836)
Chenan Liu, Qingsong Zhang, Chenning Liu, Tong Liu, Mengmeng Song, Qi Zhang, Haijun Xie, Shiqi Lin, Jiangshan Ren, Yue Chen, Xin Zheng, Jinyu Shi, Li Deng, Hanping Shi, Shouling Wu. 1425

Arterial Stiffness and Obesity as Predictors of Diabetes: Longitudinal Cohort Study (e46088)
Canccan Cui, Zhiyuan Wu, Jia Zheng, Jiaqi Chu, Jiajia Xu, Yitian Qi, Zhenming Zhang, Zhihui Wang, Mengchao Zhang, Zhanhao Mo, Liangkai Cheng, Lei Ding, Xiaoping Kang, Lin Liu, Te Zhang. 1435

The Effect of the COVID-19 Pandemic on Non–COVID-19 Deaths: Population-Wide Retrospective Cohort Study (e41792)
Abraham Wai, Tsz Yip, Yui Wong, Chun Chu, Teddy Lee, Ken Yu, Wang So, Janet Wong, Carlos Wong, Joshua Ho, Timothy Rainer. 1448

Exploration of the Healthy Donor Effect Among 0.6 Million Blood Donors in China: Longitudinal Study (e48617)
Shu Su, Yang Sun, Xiaoyun Gu, Wenjie Wu, Xiaodong Su, Ting Ma, Aowei Song, Xinxin Xie, Liqin Wang, Qianke Cheng, Lingxia Guo, Lei Zhang, Jiangcun Yang. 1461
The Use of ICD-9-CM Coding to Identify COVID-19 Diagnoses and Determine Risk Factors for 30-Day Death Rate in Hospitalized Patients in Italy: Retrospective Study (e44062)
Barbara Giordani, Alessandra Burgio, Francesco Grippo, Alessandra Barone, Erica Eugeni, Giovanni Baglio. 1473

Effects of Face Mask Mandates on COVID-19 Transmission in 51 Countries: Retrospective Event Study (e49307)
Anatol-Fiete Näher, Matthias Schulte-Althoff, Marvin Kopka, Felix Balzer, Francisco Pozo-Martin. 1484

Temporal Trends of Asthma Among Children in the Western Pacific Region From 1990 to 2045: Longitudinal Observational Study (e55327)
Cheng-hao Yang, Xin-yu Li, Jia-jie Lv, Meng-jie Hou, Ru-hong Zhang, Hong Guo, Chu Peng. 1496

Investigating Nonspecific Effects of the Live-Attenuated Japanese Encephalitis Vaccine on Lower Respiratory Tract Infections in Children Aged 25-35 Months: Retrospective Cohort Study (e53040)
Siyi Zhan, Hongbo Lin, Yingying Yang, Tao Chen, Sheng Mao, Chuanxi Fu. 1513

Association Between Long-Term Exposure to Air Pollution and the Rate of Mortality After Hip Fracture Surgery in Patients Older Than 60 Years: Nationwide Cohort Study in Taiwan (e46591)
Shu-Han Chuang, Yi-Jie Kuo, Shu-Wei Huang, Han-Wei Zhang, Hsiao-Ching Peng, Yu-Pin Chen. 1526

Individual and Geospatial Determinants of Health Associated With School-Based Human Papillomavirus Immunization in Alberta: Population-Based Cohort Study (e45508)
Jennifer Malkin, Genevieve Jessiman-Perreault, Amanda Alberga Machado, Gary Teare, Joanne Snider, Syed Tirmizi, Erik Youngson, Ting Wang, Jessica Law, Thilina Bandara, Mika Rathwell, Cordell Neudorf, Lisa Allen Scott. 1549

Timely Pulmonary Tuberculosis Diagnosis Based on the Epidemiological Disease Spectrum: Population-Based Prospective Cohort Study in the Republic of Korea (e47422)
Yousang Ko, Jae Park, Jinsoo Min, Hyung Kim, Hyeon-Kyoung Koo, Jee Oh, Yun-Jeong Jeong, Eunhye Lee, Bumhee Yang, Ju Kim, Sung-Soon Lee, Yunhyung Kwon, Jiyeon Yang, Ji Han, You Jang, Jinsob Kim. 1565

Preeclampsia Onset, Days to Delivery, and Autism Spectrum Disorders in Offspring: Clinical Birth Cohort Study (e47396)
Sarah Carter, Jane Lin, Ting Chow, Mayra Martinez, Chunyuan Qiu, R Feldman, Rob McConnell, Anny Xiang. 1579

Mutual Associations of Exposure to Ambient Air Pollutants in the First 1000 Days of Life With Asthma/Wheezing in Children: Prospective Cohort Study in Guangzhou, China (e52456)
Fenglin Tian, Xingxi Zhong, Yufeng Ye, Xiaohan Liu, Guanhaoyi He, Culing Wu, Zhiqing Chen, Qijiong Zhu, Siwen Yu, Jingjie Fan, Huan Yao, Wenjun Ma, Xiaomei Dong, Tao Liu. 1589

Defining the Subtypes of Long COVID and Risk Factors for Prolonged Disease: Population-Based Case-Crossover Study (e49841)
Skyler Resendez, Steven Brown, Hugo Ruiz Ayala, Prahalad Rangan, Jonathan Nebecker, Diane Montella, Peter Elkin. 1604

Association of the Type of Public Pension With Mental Health Among South Korean Older Adults: Longitudinal Observational Study (e49129)
Seung Kim, Hyunkyu Kim, Sung Jeong, Eun-Cheol Park. 1617

Risk of Subsequent Primary Cancers Among Adult-Onset 5-Year Cancer Survivors in South Korea: Retrospective Cohort Study (e48380)
Yoon Choi, Myeonghee Lee, Eun Kim, Jae Lee, Inkyung Jung, Jae-Ho Cheong. 1631

Metabolic Score for Insulin Resistance and New-Onset Type 2 Diabetes in a Middle-Aged and Older Adult Population: Nationwide Prospective Cohort Study and Implications for Primary Care (e49617)
Hui Cheng, Zhishui Jia, Yu Li, Xiao Yu, Jia Wang, Yao Xie, Jose Hernandez, Harry Wang. 1644
The Incidence and Outcomes of Out-of-Hospital Cardiac Arrest During the COVID-19 Pandemic in South Korea: Multicenter Registry Study (e52402)
Heekyung Lee, Jae-hoon Oh, Hyuk Choi, Hyungoo Shin, Yongil Cho, Juncheol Lee. ................................................................. 1658

Association Between Socioeconomic Inequalities in Pain and All-Cause Mortality in the China Health and Retirement Longitudinal Study: Longitudinal Cohort Study (e54309)
Zhuo Zhang, Dongmei Xue, Ying Bian. ......................................................... 1669

A Multimorbidity Analysis of Hospitalized Patients With COVID-19 in Northwest Italy: Longitudinal Study Using Evolutionary Machine Learning and Health Administrative Data (e52353)
Dayana Benny, Mario Giacobini, Alberto Catalano, Giuseppe Costa, Roberto Gnavi, Fulvio Ricceri. .................................................. 1680

Spatiotemporal Pattern and Its Determinants for Newly Reported HIV/AIDS Among Older Adults in Eastern China From 2004 to 2021: Retrospective Analysis Study (e51172)
Gang Huang, Wei Cheng, Yun Xu, Jiezhe Yang, Jun Jiang, Xiaohong Pan, Xin Zhou, Jianmin Jiang, Chengliang Chai. ................................................. 1702

Association of Child Growth Failure Indicators With Household Sanitation Practices in India (1998-2021): Spatiotemporal Observational Study (e41567)
Lovely Jain, Sreya Pradhan, Arun Aggarwal, Bijaya Padhi, Ramaiah Itumalla, Mahalaqua Khatib, Shilpa Gadhane, Quazi Zahiruddin, Celso Santos, Khalid AL-Mugheed, Tahani Alrahbeni, Neelima Kukreti, Prakashini Satapathy, Sarvesh Rustagi, Petra Heidler, Roy Marzo. ........................................... 1716

Spatiotemporal Analysis of HIV/AIDS Incidence in China From 2009 to 2019 and Its Association With Socioeconomic Factors: Geospatial Study (e56229)
Ziyi Xie, Bowen Chen, Zhizhuang Duan. ..................................................... 1734

Pulmonary Tuberculosis Notification Rate Within Shenzhen, China, 2010-2019: Spatial-Temporal Analysis (e57209)
Peixuan Lai, Weicong Cai, Lin Qu, Chuangyue Hong, Kailin Lin, Weiguo Tan, Zhiguang Zhao. ......................................................... 1748

Spatiotemporal Epidemiological Trends of Mpox in Mainland China: Spatiotemporal Ecological Comparison Study (e57807)
Shuli Ma, Jie Ge, Lei Qin, Xiaoting Chen, Linlin Du, Yanbo Qi, Li Bai, Yunfeng Han, Zhiping Xie, Jiaxin Chen, Yuehui Jia. ........................................... 1762

Association Between Nitrogen Dioxide Pollution and Cause-Specific Mortality in China: Cross-Sectional Time Series Study (e44648)
Jie Zeng, Guozhen Lin, Hang Dong, Mengmeng Li, Honglian Ruan, Jun Yang. ................................................................. 1790

Eating Habits and Lifestyle Factors Related to Childhood Obesity Among Children Aged 5-6 Years: Cluster Analysis of Panel Survey Data in Korea (e51581)
Heemoon Lim, Hyejung Lee. ................................................................. 1804

Association Between Early-Life Exposure to Antibiotics and Development of Child Obesity: Population-Based Study in Italy (e51734)
Anna Cantarutti, Paola Rescigno, Claudia Da Borso, Joaquin Gutierrez de Rubalcava Doblas, Silvia Bressan, Elisa Barbieri, Carlo Giaquinto, Cristina Canova. ................................................................. 1816

Predicting the Transition to Metabolically Unhealthy Obesity Among Young Adults With Metabolically Healthy Obesity in South Korea: Nationwide Population-Based Study (e52103)
HyunHae Lee, Ji-Su Kim, HyeRin Shin. ................................................................. 1828

A Comprehensive Youth Diabetes Epidemiological Data Set and Web Portal: Resource Development and Case Studies (e53330)
Catherine McDonough, Yan Li, Nita Vangeepuram, Bian Liu, Gaurav Pandey. ................................................................. 1840
Effectiveness, Safety, and Acceptability of Primaquine Mass Drug Administration in Low-Endemicity Areas in Southern Thailand: Proof-of-Concept Study (e51993)  

Participatory Disease Surveillance for the Early Detection of Cholera-Like Diarrheal Disease Outbreaks in Rural Villages in Malawi: Prospective Cohort Study (e49539)  
Mariana Valerio, Beverly Laher, John Phuka, Guilherme Lichand, Daniela Paolotti, Onicio Neto. 1891

Estimation of the Population Size of Street- and Venue-Based Female Sex Workers and Sexually Exploited Minors in Rwanda in 2022: 3-Source Capture-Recapture (e50743)  
Elysee Tuyishime, Eric Remera, Catherine Kayitesi, Samuel Malamba, Beata Sangwayire, Ignace Habimana Kabano, Horacio Ruisenor-Escudero, Tom Olouch, Angela Umbo Chukwu. 1905

Triangulating Truth and Reaching Consensus on Population Size, Prevalence, and More: Modeling Study (e48738)  
Ian Fellows, Carl Corcoran, Anne McIntyre. 1917

Leveraging Routinely Collected Program Data to Inform Extrapolated Size Estimates for Key Populations in Namibia: Small Area Estimation Study (e48963)  
Talia Loeb, Kalai Willis, Frans Velishavo, Daniel Lee, Amrita Rao, Stefan Baral, Katherine Rucinski. 1930

Estimated Number of Injection-Involved Overdose Deaths in US States From 2000 to 2020: Secondary Analysis of Surveillance Data (e49527)  
Eric Hall, Patrick Sullivan, Heather Bradley. 1943

Out-of-Hospital Cardiac Arrest Before and During the COVID-19 Pandemic in Hong Kong: Registry-Based Study From 2017 to 2023 (e56054)  
Richard Xu, Ruiqi Sun, Siu-Ngor Fu. 1957

Brady Bennett, Stephanie DuBose, Ya-Lin Huang, Christopher Johnson, Karen Hoover, Jeffrey Wiener, David Purcell, Patrick Sullivan. 1972

Investigating the Interrelationships Among Mental Health, Substance Use Disorders, and Suicidal Ideation Among Lesbian, Gay, and Bisexual Adults in the United States: Population-Based Statewide Survey Study (e48776)  
Alex Chan, Hon Tam, Florence Wong, Gordon Wong, Lok Leung, Jacqueline Ho, Patrick Tang, Elsie Yan. 2028

Improving the Efficiency of Inferences From Hybrid Samples for Effective Health Surveillance Studies: Comprehensive Review of Quantitative Methods (e48186)  
Mansour Fahimi, Elizabeth Hair, Elizabeth Do, Jennifer Kreslake, Xiaolu Yan, Elisa Chan, Frances Barlas, Abigail Giles, Larry Osborn. 2039

Projected Time for the Elimination of Cervical Cancer Under Various Intervention Scenarios: Age-Period-Cohort Macrosimulation Study (e46360)  
Yi-Chu Chen, Yun-Yuan Chen, Shih-Yung Su, Jing-Rong Jhuang, Chun-Ju Chiang, Ya-Wen Yang, Li-Ju Lin, Chao-Chun Wu, Wen-Chung Lee. 2051

Predicting Lung Cancer Survival to the Future: Population-Based Cancer Survival Modeling Study (e46737)  
Fan-Tsui Meng, Jing-Rong Jhuang, Yan-Teng Peng, Chur-Ju Chiang, Ya-Wen Yang, Chi-Yen Huang, Kuo-Ping Huang, Wen-Chung Lee. 2072

Early Results of an Initiative to Assess Exposure to Firearm Violence in Ambulatory Care: Descriptive Analysis of Electronic Health Record Data (e47444)  
Nicole Cook, Megan Hoopes, Frances Biel, Natalie Cartwright, Michelle Gordon, Marion Sills. 2072
Revealing the Mysteries of Population Mobility Amid the COVID-19 Pandemic in Canada: Comparative Analysis With Internet of Things–Based Thermostat Data and Google Mobility Insights (e46903)
Kirti Sahu, Joel Dubin, Shannon Majowicz, Sam Liu, Plinio Morita. ................................................................. 2079

Search Engines and Generative Artificial Intelligence Integration: Public Health Risks and Recommendations to Safeguard Consumers Online (e53086)
Amir Ashraf, Tim Mackey, András Fittler. ................................................................. 2093

Ambulance Services Attendance for Mental Health and Overdose Before and During COVID-19 in Canada and the United Kingdom: Interrupted Time Series Study (e46029)
Graham Law, Rhiannon Cooper, Melissa Pirrie, Richard Ferron, Brent McLeod, Robert Spaight, A Siriwardena, Gina Agarwal, UK Canada Emergency Calls Data Analysis and GEospatial Mapping (EDGE) Consortium. ................................................................. 2104

Epidemiological Characteristics of Varicella in Anhui Province, China, 2012-2021: Surveillance Study (e50673)
Kun Xuan, Ning Zhang, Tao Li, Xingya Pang, Qingru Li, Tianming Zhao, Binbing Wang, Zhenqiu Zha, Jihai Tang. ................................................................. 2135

Epidemic Characteristics and Meteorological Risk Factors of Hemorrhagic Fever With Renal Syndrome in 151 Cities in China From 2015 to 2021: Retrospective Analysis (e52221)
Yizhe Luo, Longyao Zhang, Yameng Xu, Qiyuan Kuai, Wenhao Li, Yifan Wu, Licheng Liu, Jiaron Ren, Lingling Zhang, Qiufang Shi, Xiaobo Liu, Weilong Tan. ................................................................. 2149

Population Behavior Changes Underlying Phasic Shifts of SARS-CoV-2 Exposure Settings Across 3 Omicron Epidemic Waves in Hong Kong: Prospective Cohort Study (e51498)
Chin Chan, Shui Lee, Tsz Kwan, Samuel Wong, Eng-Kiong Yeoh, Ngai Wong. ................................................................. 2162

A Prediction Model for Identifying Seasonal Influenza Vaccination Uptake Among Children in Wuxi, China: Prospective Observational Study (e56064)
Qiang Wang, Liqiong Yang, Shixin Xu, Yuan Shen, Hui Jin, Leesa Lin. ................................................................. 2179

The Migrant-Local Difference in the Relationship Between Social Support, Sleep Disturbance, and Loneliness Among Older Adults in China: Cross-Sectional Study (e49253)
Mingli Pang, Jieru Wang, Mingyue Zhao, Rui Chen, Hui Liu, Xixing Xu, Shixue Li, Fanlei Kong. ................................................................. 2190

Impact of the Narcotics Information Management System on Opioid Use Among Outpatients With Musculoskeletal and Connective Tissue Disorders: Quasi-Experimental Study Using Interrupted Time Series (e47130)
Iyn-Hyang Lee, So Kim, Susin Park, Jae Ryu, Nam Je. ................................................................. 2204

Use of Sentinel Surveillance Platforms for Monitoring SARS-CoV-2 Activity: Evidence From Analysis of Kenya Influenza Sentinel Surveillance Data (e50799)
Daniel Owusu, Linus Ndegwa, Jorim Ayugi, Peter Kiruthia, Rosalia Kalani, Mary Okeyo, Nancy Otieno, Gilbert Kikwai, Bonventure Juma, Peninah Munyua, Francis Kuria, Emmanuel Okunga, Ann Moen, Gideon Emukule. ................................................................. 2216

Development of New Stringency Indices for Nonpharmacological Social Distancing Policies Implemented in Korea During the COVID-19 Pandemic: Random Forest Approach (e47099)
Catherine Apio, Kyulhee Han, Dooen Lee, Bogeom Lee, Taesung Park. ................................................................. 2229

Impact of the COVID-19 Pandemic on Health Care Utilization in the Vaccine Safety Datalink: Retrospective Cohort Study (e48159)
Lei Qian, Lina Sy, Vennis Hong, Sungching Glenn, Denison Ryan, Jennifer Nelson, Simon Hambidge, Bradley Crane, Ousseny Zerbo, Malini DeSilva, Jason Glanz, James Donahue, Elizabeth Liles, Jonathan Duffy, Stanley Xu. ................................................................. 2247
Impact of the COVID-19 Pandemic on People Living With Rare Diseases and Their Families: Results of a National Survey (e48430)
Maurizio Macaluso, Marc Rothenberg, Thomas Ferkol, Pierce Kuhnell, Henry Kaminski, David Kimberlin, Michael Benatar, Mirna Chehade, The Principal Investigators of the Rare Diseases Clinical Research Network – Cycle 4 .......................................................... 2257

Perspectives of European Patient Advocacy Groups on Volunteer Registries and Vaccine Trials: VACCELERATE Survey Study (e47241)

The Changing Landscape of Respiratory Viruses Contributing to Hospitalizations in Quebec, Canada: Results From an Active Hospital-Based Surveillance Study (e40792)
Rodica Gilca, Rachid Amini, Sara Carazo, Radhouene Doggui, Charles Frenette, Guy Boivin, Hugues Charest, Jeannot Dumaresq .......................................................... 2289

Updated Surveillance Metrics and History of the COVID-19 Pandemic (2020-2023) in Latin America and the Caribbean: Longitudinal Trend Analysis (e44398)
Lori Post, Scott Wu, Alan Soetikno, Egon Ozer, Yingxuan Liu, Sarah Welch, Claudia Hawkins, Charles Moss, Robert Murphy, Maryann Mason, Robert Havey, Alexander Lundberg .......................................................... 2306

The Impact of Wireless Emergency Alerts on a Floating Population in Seoul, South Korea: Panel Data Analysis (e43554)
Sungwook Yoon, Hyungsoo Lim, Sungho Park .......................................................... 2326

Assessing SARS-CoV-2 Testing Adherence in a University Town: Recurrent Event Modeling Analysis (e48784)
Yury García, Alec Schmidt, Leslie Solis, Maria Daza-Torres, J Montesinos-López, Brad Pollock, Miriam Nuño .......................................................... 2335

Persistence and Variation of the Indirect Effects of COVID-19 Restrictions on the Spectrum of Notifiable Infectious Diseases in China: Analysis of National Surveillance Among Children and Adolescents From 2018 to 2021 (e47626)

Abstract

Background: Novel coronaviruses have emerged and caused major epidemics and pandemics in the past 2 decades, including SARS-CoV-1, MERS-CoV, and SARS-CoV-2, which led to the current COVID-19 pandemic. These coronaviruses are marked by their potential to produce disproportionally large transmission clusters from superspreading events (SSEs). As prompt action is crucial to contain and mitigate SSEs, real-time epidemic size estimation could characterize the transmission heterogeneity and inform timely implementation of control measures.

Objective: This study aimed to estimate the epidemic size of SSEs to inform effective surveillance and rapid mitigation responses.

Methods: We developed a statistical framework based on back-calculation to estimate the epidemic size of ongoing coronavirus SSEs. We first validated the framework in simulated scenarios with the epidemiological characteristics of SARS, MERS, and COVID-19 SSEs. As case studies, we retrospectively applied the framework to the Amoy Gardens SARS outbreak in Hong Kong in 2003, a series of nosocomial MERS outbreaks in South Korea in 2015, and 2 COVID-19 outbreaks originating from restaurants in Hong Kong in 2020.

Results: The accuracy and precision of the estimation of epidemic size of SSEs improved with longer observation time; larger SSE size; and more accurate prior information about the epidemiological characteristics, such as the distribution of the incubation period and the distribution of the onset-to-confirmation delay. By retrospectively applying the framework, we found that the 95% credible interval of the estimates contained the true epidemic size after 37% of cases were reported in the Amoy Garden SARS SSE in Hong Kong, 41% to 62% of cases were observed in the 3 nosocomial MERS SSEs in South Korea, and 76% to 86% of cases were confirmed in the 2 COVID-19 SSEs in Hong Kong.

Conclusions: Our framework can be readily integrated into coronavirus surveillance systems to enhance situation awareness of ongoing SSEs.

KEYWORDS

coronavirus; superspreading event; SSE; epidemic size; severe acute respiratory syndrome; SARS; Middle East respiratory syndrome; MERS; coronavirus disease 2019; COVID-19
Introduction

In the past 2 decades, 3 coronaviruses have emerged and caused widespread public anxiety: SARS-CoV-1 in 2002; MERS-CoV in 2012; and most recently, SARS-CoV-2 in 2019. As of November 2023, the new COVID-19 caused by SARS-CoV-2 has led to more than 771 million confirmed cases and almost 7 million deaths [1]. Despite the differences in epidemiologic characteristics, all 3 coronaviruses are marked by transmission heterogeneity and the ability to produce disproportionally large clusters via superspreading events (SSEs) [2-10]. For instance, it is estimated that 19% of the cases caused 80% of the local transmission in the first wave of COVID-19 epidemic in Hong Kong by April 28, 2020 [11]. The overdispersed transmission pattern was also previously reported for both SARS and MERS [5,8,12].

SSEs are shaped by a combination of determinants originating from the virus, host, and environment [13]. The emergence of mutations and variants with increased transmissibility and greater immune escape mechanisms contribute substantially to the occurrence of SSEs [14]. Superspreaders, who are known to be unusually infectious, were reported to shed a higher viral load over an extended duration [15], which was exacerbated in the context of COVID-19 because significant proportion of these individuals who are infectious could transmit the virus before symptom onset (presymptomatic) or without showing any symptoms (asymptomatic) [16-20]. Certain environments facilitate the transmission, as evidenced by most SSEs of SARS and MERS being nosocomial outbreaks [2,21].

Although the exact mechanism of SSEs is not well established, monitoring SSEs in real time is critical to contain and mitigate epidemics of coronaviruses [22]. It is estimated that implementing control measures a week earlier would lead to a 2.6 times decrease in average epidemic size and a reduction of 4 weeks in average epidemic duration [21,23]. Real-time estimation of the epidemic size of SSEs allows us to proactively take timely measures, including resource planning and mobilization, testing, contact tracing, and implementing targeted interventions in high-risk settings. However, given the inherent heterogeneity of an epidemic, population-level measurements of the average transmissibility of a typical individual who is infectious, such as basic reproductive number ($R_0$) or effective reproductive number ($R_e$), are not appropriate for estimating the transmission potential of SSEs [5]. Here, we developed a framework based on back-calculation for SSE epidemic size estimation, allowing for a more comprehensive understanding of the transmission dynamics.

Methods

Ethical Considerations

This study involves secondary analysis of existing aggregate research data, including SARS-CoV-1 data from Leung et al [24], MERS data from Cowling et al [7], and COVID-19 data that are publicly available [25]. All data were deidentified and only aggregate data were used. The University of Hong Kong/Hospital Authority Hong Kong West Institutional Review Board approved the secondary analysis without requiring further consent. As participants were not directly involved in the current research activities, no compensation was provided to the individuals.

Model Assumptions

Back-calculation was first designed for short-term prediction of diseases with a long incubation period [26] and has also been applied to point-source outbreaks with limited onward transmission, such as Legionnaires disease [27]. We extended the method and focused on estimating the final size of symptomatic or laboratory-confirmed cases at the early stage of a coronavirus SSE, and asymptomatic cases were not considered in the estimation if they were not confirmed and reported.

We assumed that (1) all cases in a given SSE were infected at around the same time (eg, infected by the same superspreader or environmental exposure within a short period of time); (2) all cases followed the same probability distribution function (PDF) of the incubation period, the same PDF of the onset-to-confirmation delay, and the same PDF of the generation time; and (3) there was limited onward secondary transmission when the SSEs were controlled by sufficient contact tracing and timely responses. For SARS and MERS, we assumed that the $R_t$ of secondary transmission was 0, given their relatively lower potential of person-to-person transmission [2]. For COVID-19, which has much higher transmissibility and significant presymptomatic transmission, we assumed that the $R_t$ of secondary transmission could be greater than 1, but the transmission was restricted within 1 disease generation. We assumed that testing and contact tracing policies were the same within 14 days, given that the generation time for SARS-CoV-1, MERS, and ancestral SAR-CoV-2 are around 7 days (Table 1).

\(^a\)Secondary transmission can be measured by \(R_t\) within 1 disease generation. 

\(^b\)\(R_t\): effective reproductive number. 

\(^c\)Not applicable. 

\(^d\)The 60% presymptomatic transmission was included in the prior information.

Figure 1A-B summarizes the characteristics of coronavirus SSEs in disease surveillance. Here, the incubation period is the time interval between infection and symptom onset; in practice, there is a delay from symptom onset to case confirmation, and the time of symptom onset can be unavailable for asymptomatic infections or due to underreporting.
Figure 1. Characteristics of coronavirus SSEs. (A) Time of exposure, symptom onset, and case confirmation. The incubation period is the time interval between infection and symptom onset. The onset-to-confirmation delay is the time interval between symptom onset and confirmation. (B) Transmission between an infector-infectee pair: (a) transmission occurs after symptom onset of the infector (symptomatic transmission); (b) transmission occurs before symptom onset of the infector (presymptomatic transmission). The generation time is the interval between the exposure time of the infector and the infectee. (C) Approximate distribution of presymptomatic, asymptomatic, and symptomatic transmission for SARS, MERS, and COVID-19. (D) Simulated COVID-19 SSE. The undetected presymptomatic transmission pairs within 1 disease generation and R_t = 1.5 in a simulated COVID-19 SSE with 10 cases. R_t: effective reproductive number; SSE: superspreading event.

Estimating the Size of SSEs

We formulated the model to estimate the epidemic size of SSEs as follows. Let $X$ denote the incubation period with PDF $g(x)$ and $Y$ denote the onset-to-confirmation with PDF $h(y)$. For an SSE $j$, let $n_j$ be the total number of people infected at time 0 and $k_j$ be the number of symptomatic cases that have been confirmed up to (and including) time $t_j$ since the exposure time for this SSE.

Let $x_{ij}$ and $y_{ij}$ be the values of $X$ and $Y$ for the $i$th case in the $j$th SSE. Let $f(X,Y|\theta)$ be the joint probability distribution of $X$ and $Y$ with $\theta$ representing the parameters. We assume that $X$ and $Y$ are independent such that $f(X,Y|\theta) = g(x)h(y)$, and $F(X,Y|\theta)$ is the cumulative probability distribution of $f(X,Y|\theta)$. The number of symptomatic cases $k_j$ has a binomial distribution with SSE size $n_j$ and success probability $F(X+Y>r; \theta)$. Therefore, the likelihood function for $j$th SSE is:
If the time of symptom onset is known, let $M_{j,i}$ be the set of confirmed cases with known time from exposure to symptom onset and known time from symptom onset to confirmation with a size of $m_{j,i}$. If the time of symptom onset is unknown, let $M_{j,2}$ be the set of confirmed cases with unknown time from exposure to symptom onset but known time from exposure to confirmation with a size of $m_{j,2}$. Let $Z$ denote $X+Y$ with the probability distribution $q(z|\theta)$. The likelihood function for the $j$th SSE becomes:

The overall likelihood function for $w$ SSEs is:

We estimated the SSE size $n_j$ and other parameters $\theta$ using Markov chain Monte Carlo with Gibbs sampling and noninformative flat priors. We considered an estimate to be accurate if the 95% credible interval (CRI) covered the true value. An estimate was precise if the CRI had a relative error within 1.

### Model Validation

We simulated SSE scenarios based on the epidemiological characteristics of SARS, MERS, and COVID-19 (Figure 1C). For SARS and MERS to be considered under control, we assumed that there was a single exposure and no secondary transmission. For COVID-19, we assumed that 60% of the transmission occurred during the presymptomatic phase [19,20,35,39,40]. For example, if we simulated a single-exposure COVID-19 SSE with 10 cases, 6 (60%) second-generation cases were infected by the other 4 first-generation cases in the SSE during the presymptomatic phase. However, the 6 second-generation cases would be taken as first-generation infections directly linked to the primary exposure when the second-generation cases would be taken as first-generation during the presymptomatic phase. Thus, we assumed that all cases in the Amoy Gardens SSE were exposed to SARS-CoV-1 on March 15, and was discharged on March 19. He visited and stayed 1 night at the Amoy Gardens apartment complex, where he had diarrhea. Thus, we assumed that all cases in the Amoy Gardens SSE were exposed to SARS-CoV-1 on March 19. We used noninformative prior distribution for all parameters in the inference since no information about the incubation period and onset-to-confirmation delay could be estimated by bootstrapping from 50 or 100 cases before the occurrence of the simulated SSEs.

The SSE size estimation was performed starting from the time when 5% of all cases were observed until the time when 95% of all cases were observed. To compare scenarios with different epidemic sizes, we used relative size (ie, percentage of the cases observed in an SSE) and SSE duration (ie, percentage of the duration between the time of confirmation of the first and last case) in the assessment of the accuracy of the estimation.

### Case Studies

We applied our framework to the Amoy Gardens SSE for SARS in Hong Kong, nosocomial SSEs for MERS in South Korea, and 2 SSEs from the COVID-19 pandemic in Hong Kong. An alert would be issued when 10 or more cases were confirmed to link with the same index case, by which we assumed that we had minimal data to start the SSE size estimation.

#### Hong Kong Amoy Gardens SARS SSE

The Amoy Gardens SSE was the largest cluster in the 2003 Hong Kong SARS outbreak [4,24]. The index case developed symptoms on March 13-14, was admitted to the Prince Wales Hospital on March 15, and was discharged on March 19. He visited and stayed 1 night at the Amoy Gardens apartment complex, where he had diarrhea. Thus, we assumed that all cases in the Amoy Gardens SSE were exposed to SARS-CoV-1 on March 19. We used noninformative prior distribution for all parameters in the inference since no information about the incubation period and the onset-to-confirmation delay could be estimated before the Amoy Gardens SSE (Table 2). A total of 311 laboratory-confirmed cases were retrospectively confirmed and reported in the Amoy Gardens SSE.

\textsuperscript{a}SSE: superspreading event.
South Korea Nosocomial MERS SSEs

The MERS SSEs in South Korea in 2015 were the largest MERS outbreak outside of the Middle East, with 82.3% of all confirmed infections caused by only 5 (2.7%) cases [41,46]. The index case visited multiple clinics after traveling to the Middle East. He first developed fever and myalgia illness on May 11 and visited the same clinic on May 12, 14, and 15. The symptoms were not resolved and a cough developed on May 15. The index case was admitted to a secondary hospital (Cluster 1) on May 15 and transferred to a tertiary hospital in Seoul (Cluster 2) on May 17, where he was later diagnosed with MERS-CoV on May 20. Meanwhile, another large SSE took place in other hospitals and was traced back to this same index case (Cluster 3). We took May 15, the day that the index case visited Cluster 1, as the time of exposure of all cases in Cluster 1. In the series of nosocomial SSEs, the time of exposure would be different for each confirmed case depending on when they visited the contaminated hospitals. Therefore, 3 major nosocomial clusters (Cluster 1-3) with sizes of 29, 125, and 27 were studied retrospectively [7,41]. We used MERS data from the previous Middle East outbreaks as the prior information for parameter estimation (Table 2).

Hong Kong COVID-19 SSEs

For the COVID-19 case study, 2 linked Hong Kong restaurant SSEs in 2020 with relatively exclusive contact tracing were selected [25]. The first SSE took place at a restaurant of Tao Heung Holdings on July 9 where people gathered in a celebration event, resulting in an SSE of 42 cases. Soon, another SSE took place at another restaurant of Fulum Holdings on July 11, where hundreds of people attended a birthday party, resulting in an SSE of 44 cases. We assumed the time of exposure to be July 9 and July 11 for the 2 SSEs, respectively. Prior information on the incubation period and onset-to-confirmation delay from previous COVID-19 confirmed cases were used in the parameter estimation (Table 2).

Results

Model Validation

Inferred from the model simulation, we found that the accuracy and precision of our estimation increased with the size of the SSE (Figures 2 and 3). For SARS and MERS, with and without onset-to-confirmation delay, all Crls covered the true SSE size and the relative error was less than 1 for all simulated scenarios, when the estimation was performed at the time exceeding 50% of the duration of the SSE or when more than 60% of the cases were observed (Figure 2A-B). With the presence of onset-to-confirmation delay, the range of relative error doubled when the estimation was performed before 50% of the duration of the SSE or when less than 60% of the cases were observed (Figure 2C-D). Our method tended to overestimate the size in the early stage of an SSE when less than 20% of cases were reported, especially in the scenarios with onset-to-confirmation delay.
Figure 2. The accuracy and precision of SSE size estimation for simulated SARS and MERS scenarios. Scenario 1: (A) simulated SARS and MERS SSEs with no onset-to-confirmation delay, with size estimation performed at the time as the percentage of the duration of the SSE; and (B) simulated SARS and MERS SSEs with no onset-to-confirmation delay, with size estimation performed at the time by the percentage of cases observed and reported. Scenario 2: (C) simulated SARS and MERS SSEs with onset-to-confirmation delay, with size estimation performed at the time as the percentage of the duration of the SSE; and (D) simulated SARS and MERS SSEs with onset-to-confirmation delay, with size estimation performed at the time by the percentage of cases observed and reported. SSE: superspreading event.

If the presymptomatic transmission was not adjusted in the COVID-19 simulated SSEs, there would always be an underestimation even after 50% of the duration of the SSE or when more than 60% of the cases were observed (Figure 3A-D). For a typical COVID-19 SSE with 50 cases, the model would predict the final size to be around 30 when half of the cases were observed if second-generation infections cannot be distinguished from first-generation infections. If we could detect the transmission pattern of COVID-19 in time and adjust for presymptomatic transmission as per our prior information, the estimation would perform similarly well to the simulated scenarios of SARS and MERS when presymptomatic transmission was not included (Figure 3E-H).
Figure 3. The accuracy and precision of SSE size estimation for simulated COVID-19 scenarios. Scenario 3: (A) simulated COVID-19 SSEs with no onset-to-confirmation delay but 60% presymptomatic transmission, with size estimation performed at the time as the percentage of the duration of the SSE; and (B) simulated COVID-19 SSEs with no onset-to-confirmation delay but 60% presymptomatic transmission, with size estimation performed at the time by the percentage of cases observed and reported. Scenario 4: (C) simulated COVID-19 SSEs with both onset-to-confirmation delay and 60% presymptomatic transmission, with size estimation performed at the time as the percentage of the duration of the SSE; and (D) simulated COVID-19 SSEs with both onset-to-confirmation delay and 60% presymptomatic transmission, with size estimation performed at the time by the percentage of cases observed and reported. Scenario 5: (E) simulated COVID-19 SSEs with no onset-to-confirmation delay but 60% presymptomatic transmission adjusted in prior information, with size estimation performed at the time as the percentage of the duration of the SSE; and (F) simulated COVID-19 SSEs with no onset-to-confirmation delay but 60% presymptomatic transmission adjusted in prior information, with size estimation performed at the time by the percentage of cases observed and reported. Scenario 6: (G) simulated COVID-19 SSEs with onset-to-confirmation delay and 60% presymptomatic transmission adjusted in prior information, with size estimation performed at the time as the percentage of the duration of the SSE; and (H) simulated COVID-19 SSEs with onset-to-confirmation delay and 60% presymptomatic transmission adjusted in prior information, with size estimation performed at the time by the percentage of cases observed and reported. SSE: superspreading event.
Case Studies

In the case study of Amoy Gardens SARS SSE, the Crl covered the final SSE size and had a relative error within 1 in 4 days after the alert was issued, which was 25 days before the last case of the SSE was observed (Figure 4). At the time when the alert was issued, only 36.7% (114/311) of all cases were observed. The SSE size estimation became more accurate and precise thereafter.

Figure 4. Real-time size estimation of Amoy Gardens SARS SSE in Hong Kong in 2003. (A) Epidemic curve by time of symptom onset. (B) Epidemic curve by time of confirmation. (C) Real-time estimation of SSE size by the time since the exposure (May 19, 2003). The dash line indicates the actual epidemic size of the SSE. Crl: credible interval; SSE: superspreading event.

For the series of South Korea MERS SSEs, the Crls of Cluster 1, Cluster 2, and Cluster 3 covered the final SSE sizes with a relative error within 1 in 2 days, 3 days, and 0 days after the alert was issued, respectively, which were 4 days, 15 days, and 9 days before the last case of the respective SSE was observed (Figure 5). At the time when alerts were issued, 62% (18/29), 52% (65/125), and 41% (11/27) of all cases in the respective SSEs were observed, and the estimation converged sooner for later SSEs.
Figure 5. Real-time size estimation of nosocomial MERS SSEs in South Korea in 2015. (A) Epidemic curve by time of confirmation for Cluster 1, Cluster 2, and Cluster 3 denoted by blue, red, and yellow, respectively. (B) Real-time estimation of the SSE size of Cluster 1. (C) Real-time estimation of the SSE size of Cluster 2. (D) Real-time estimation of the SSE size of Cluster 3 by the time since the index case visited Cluster 1 (May 15, 2015). The dash line indicates the actual epidemic size of the SSEs. Crl: credible interval; SSE: superspreading event.

For the Tao Heung COVID-19 SSE in Hong Kong, the Crl covered the final SSE size and had a relative error within 1 in 5 days after the alert was issued, which was 20 days before the last case of the SSE was observed. At this time, 76% (32/42) of all cases were observed (Figure 6). Similarly, for the Fulum COVID-19 SSE, the Crl covered the final SSE size and had a relative error within 1 in 7 days after the alert was issued and 5 days before the last case was observed. At the time of issuing the alert, 86% (38/44) of all cases had been observed (Figure 6).

**Discussion**

In this study, we developed a framework based on back-calculation to estimate the epidemic size of coronavirus SSEs in real time. Our method bypassed the complexity of developing a transmission model and gave accurate estimates when there were limited secondary transmission within the SSEs. As expected, we found that the precision and accuracy of the size estimation increased with more observed cases, where large SSEs could be spotted earlier, such that immediate responses could be taken. The estimation performed better with the absence of onset-to-confirmation delay, and prior information on parameters improved the performance of the model. In the case study of MERS nosocomial SSEs, we used data from previous MERS cases from the Middle East to inform the estimation in South Korea. Accurate estimation was obtained sooner for Cluster 2 and Cluster 3 with more information about the distribution of the incubation period and the distribution of the onset-to-confirmation delay obtained after the occurrence of Cluster 1.

We showed that the epidemic size of coronavirus SSEs could be accurately estimated before 50% of the cases were reported when there was no undetected secondary transmission, such as in the SARS and MERS simulated scenarios, or when the secondary transmission was adjusted, such as in the COVID-19 simulated scenarios. In the retrospective study on the Amoy Gardens SARS SSE, we got a robust estimation as early as having only 37% of all the cases identified, and in practice, hospitals could prepare resources beforehand for such a large SSE. The estimation of SARS and MERS SSE sizes were more accurate compared with that of COVID-19 because most symptomatic infections would be confirmed and reported. For example, in the case study of Amoy Gardens, it was suspected that SAR-CoV-1 was excreted in the stool and transmitted through sewerage, and the SSE was identified early when many Amoy Gardens cases were traced back to the block where the index case had stayed [4,24].
However, our method tended to overestimate the size early in simulated SARS and MERS SSEs when the observed case number was low. For simulated COVID-19 SSEs, our method always underestimated the size when secondary transmission within the SSE was not detected or observed until later in the SSE. The real-time daily estimation could also be unstable, especially when little was known about the distribution of the incubation period and reporting delays. For example, in the Amoy Gardens SARS SSE, the time of exposure of some cases could be later than the common exposure time that we assumed (May 19, 2003), depending on the time they came into contact with the contaminated areas. The SARS-CoV-1 virus could also be transmitted via person-to-person contact or contamination of communal facilities such as elevators and doors other than sewage [47]. In the MERS case study, we bracketed the window of the exposure time and grouped the cases into 3 hospital SSEs based on the time of visiting specific hospitals.

The recall bias can be another source of errors, especially for COVID-19 infections where symptoms were relatively mild for many cases. Although we explored the source of uncertainty in our estimation, the required accuracy and precision depends on the potential impact of the SSEs, the available resources for control measures, and the requirement for decision-making. For example, to plan resource allocation and better prepare the health care system, the 95% upper bound of the size estimate should be used. For surveillance purposes, the 95% lower bound of the estimate can be used as a threshold to issue alerts and initiate actions. It could also be used as a conservative estimate of the minimal number of infections.

In summary, our framework can be applied to coronavirus SSEs when there is limited undetected secondary transmission or when secondary infection is accounted for. The emergence of more transmissible variants further complicates the situation [48], and intensive contact tracing and testing might be required to alert SSEs in time. Currently, with the COVID-19 pandemic transiting to the endemic phase and society returning to normalcy, our method can be integrated into coronavirus surveillance systems to monitor potential SSEs in large social gatherings.

Abstract

Background: The relationship between 24-hour rest-activity rhythms (RARs) and risk for dementia or mild cognitive impairment (MCI) remains an area of growing interest. Previous studies were often limited by small sample sizes, short follow-ups, and older participants. More studies are required to fully explore the link between disrupted RARs and dementia or MCI in middle-aged and older adults.

Objective: We leveraged the UK Biobank data to examine how RAR disturbances correlate with the risk of developing dementia and MCI in middle-aged and older adults.

Methods: We analyzed the data of 91,517 UK Biobank participants aged between 43 and 79 years. Wrist actigraphy recordings were used to derive nonparametric RAR metrics, including the activity level of the most active 10-hour period (M10) and its midpoint, the activity level of the least active 5-hour period (L5) and its midpoint, relative amplitude (RA) of the 24-hour cycle [RA=(M10-L5)/(M10+L5)], interdaily stability, and intradaily variability, as well as the amplitude and acrophase of 24-hour rhythms (cosinor analysis). We used Cox proportional hazards models to examine the associations between baseline RAR and subsequent incidence of dementia or MCI, adjusting for demographic characteristics, comorbidities, lifestyle factors, shiftwork status, and genetic risk for Alzheimer's disease.

Results: During the follow-up of up to 7.5 years, 555 participants developed MCI or dementia. The dementia or MCI risk increased for those with lower M10 activity (hazard ratio [HR] 1.28, 95\% CI 1.14-1.44, per 1-SD decrease), higher L5 activity (HR 1.15, 95\% CI 1.10-1.21, per 1-SD increase), lower RA (HR 1.23, 95\% CI 1.16-1.29, per 1-SD decrease), lower amplitude (HR 1.32, 95\% CI 1.17-1.49, per 1-SD decrease), and higher intradaily variability (HR 1.14, 95\% CI 1.05-1.24, per 1-SD increase) as well as advanced L5 midpoint (HR 0.92, 95\% CI 0.85-0.99, per 1-SD advance). These associations were similar in people
aged <70 and >70 years, and in non–shift workers, and they were independent of genetic and cardiovascular risk factors. No significant associations were observed for M10 midpoint, interdaily stability, or acrophase.

**Conclusions:** Based on findings from a large sample of middle-to-older adults with objective RAR assessment and almost 8-years of follow-up, we suggest that suppressed and fragmented daily activity rhythms precede the onset of dementia or MCI and may serve as risk biomarkers for preclinical dementia in middle-aged and older adults.

### Methods

**Study Population and Data Source**

We used longitudinal data on UKB participants (age range at baseline 43-79 years; 54% female) [28]. Upon enrollment, UKB participants completed a series of questionnaires that collected their demographic, lifestyle, and medical history information. Participants consented to releasing their electronic health records from the United Kingdom’s centralized National Health Service (NHS), which were then stored in the UKB’s Hospital Inpatient Data library [29]. In the UKB cohort, 103,711 participants completed actigraphy assessments between 2013 and 2015 (2.8 to 9.7 years after enrollment) [29]—the baseline of this study. We used follow-up data until September 2021 (maximum and median follow-up after actigraphy: 7.5 and 5 years, respectively). After excluding those participants with poor calibration of activity counts, significant gaps in data likely due to off-wrist periods, <6 days of collected data, dementia or MCI at baseline, or any missing covariate, 91,517 participants were included in this study.

**Ethical Considerations**

The UKB received approval from the North West Multi-centre Research Ethics Committee (11/NW/03820; 16/NW/0274; 21/NW/0157). This study was conducted under the terms of the UKB (33883) and Mass General Brigham Institutional Review Board (#2018P000356).

**Assessment of RARs**

Participants wore triaxial accelerometer devices (Axivity AX3; Axivity Ltd) for up to 7 days during the collection period. Prior actigraphy assessment of older adults [30,31] and existing criteria from the UKB [32] were used to perform quality checks. Activity counts in each 15-second epoch were derived from accelerometer data sampled at ~100 Hz (see Multimedia Appendix 1 [29,33]). The first 6 days of activity counts were used to obtain the following nonparametric RAR measures [34]: (1) activity counts during the most active 10-hour period of the 24-hour cycle (M10) and (2) the midpoint of the M10 period, (3) activity counts during the least active 5-hour period of the 24-hour cycle (L5)—likely representing hours during sleep, (4) the timing midpoint of the L5 period (L5 midpoint), (5) relative amplitude (RA) calculated as (M10-L5)/(M10+L5)—representing the robustness of a 24-hour rest-activity cycle; (6) interdaily stability (IS) that quantifies the stability of the 24-hour rhythm between different days (Multimedia Appendix 2); and (7) intradaily variability (IV) that describes the fragmentation of the rhythm (Multimedia Appendix 2; and (7) intradaily variability (IV) that describes the fragmentation of the rhythm (Multimedia Appendix 2).
Appendix 2). Cosinor analysis was also performed to derive 2 additional measures of 24-hour activity rhythms: the amplitude (midline to peak) and acrophase (time of the peak) of the 24-hour rhythm. All RAR data analyses were performed using the eZActi2 software [35,36].

Assessment of Dementia and MCI

Study participant hospitalization records were kept within the UK’s NHS during the follow-up period before being released by the UKB. The UKB provided algorithmically defined incidence of health matters from ICD-10 (International Classification of Disease, 10th Revision) codes. We obtained data from clinical coding of dementia (ICD-10 code: F05) and MCI (ICD-10 code: F0.67), and from the UKB algorithm “date of all-cause dementia” (field 42018). Age at death or the date of death was based on the death certificates in the NHS. The first occurrence of dementia or MCI (time-to-event) was the first date of diagnosis relative to the actigraphy assessment date.

Assessment of Covariates

The following covariates that may affect RARs were considered in this study: (1) demographics, including age at actigraphy, male or female designated sex of individuals, self-reported ethnicity as European or non-European, college-level education (reported as yes or no), and the Townsend deprivation index; (2) comorbidities, including sleep apnea (based on ICD-10 code G47.30), circulatory disease (based on reports of high cholesterol, diabetes, hypertension, ischemic heart disease, smoking, and peripheral vascular disease), BMI >30, and morbidity burden (classified at the time of actigraphy as none, moderate, or high based on previously used methods that summed the presence of diseases or disorders of the endocrine, connective tissue, gastrointestinal, hematological, musculoskeletal, immune, renal, and respiratory systems as well as any cancers) [37-40]; (3) lifestyle, including alcohol intake (categorized by daily use, 3-4 times per week, 1-2 times per week, a few times per month, and never), smoking status (categorized as current, previous, and never); (4) shiftwork (yes or no); and (5) genetics based on the polygenic risk score (PRS) for Alzheimer disease. We calculated the single PRS for Alzheimer disease using the PRS continuous shrinkage [41] method. This method calculates posterior effect size from genome-wide association study summary statistics with models comprising information of local linkage disequilibrium patterns, and thus reduces PRS error and improves performance. In this study we used genome-wide association study summary statistics from a recent study for Alzheimer disease [42], and the linkage disequilibrium reference panel matrices from the UKB. The PRS continuous shrinkage default settings were used, and after deriving the posterior summary statistics, we used PLINK2 [43,44].

Statistical Analysis

Cox proportional hazard models were used to assess the associations of RAR measures with the subsequent incidence of dementia or MCI. The results were reported as hazard ratios (HRs) with corresponding 95% CIs. For each RAR measure (except M10 midpoint, L5 midpoint, and phase), participants were divided into 4 quartiles (Q1-Q4). The highest quartile (Q4) was used as a reference for RA, M10, IS, and 24-hour amplitude; the lowest quartile (Q1) was used as a reference for L5 and IV. These reference levels were chosen based on prior findings and our hypothesis regarding the direction of the association of each RAR measure with the risk of dementia and MCI, that is, the level of the RAR measure that is hypothesized to be linked to the lowest risk of developing dementia was considered as the reference [37]. Acrophase, M10 midpoint, and L5 midpoint were categorized into 3 tertiles: earlier (6:00 AM-1:34 PM for acrophase, 6:00 AM-12:58 PM for M10 midpoint, and noon-2:47 AM for L5 midpoint), middle (1:34 PM-2:25 PM for acrophase, 12:58 PM-2:01 PM for M10 midpoint, and 2:47 AM-3:44 AM for L5 midpoint), and later (2:25 AM-6:00 AM for acrophase, 2:01 AM-6:00 AM for M10 midpoint, and 3:44 AM-noon for L5 midpoint) groups, and the middle groups were used as the reference [14,15,17]. Separate Cox models were also used to obtain HRs for 1 SD change in each RAR measure. Secondary analyses were performed to investigate (1) the associations between RAR measures and the risk of developing dementia (by excluding participants who only developed MCI); (2) the associations between RAR measures and risk of developing dementia or MCI after excluding those participants who were shift workers at baseline; (3) the interaction effects of Alzheimer disease PRS (<median PRS vs >median PRS) and RAR measures on the risk of developing dementia or MCI (by including interaction terms and also stratifying participants based on their PRS values); and (4) the interaction effects of age (<70 vs ≥70 years) and RAR measures on the risk of developing dementia or MCI (by including interaction terms and also stratifying participants based on their age). All statistical analyses were performed using JMP Pro (version 16, SAS Institute).

Results

Participant Characteristics

Table 1 describes the demographic, lifestyle, and clinical comorbidity data gathered from the 91,517 UKB participants who were included in this study. Most participants were of White European descent (>95%). In comparison to the 90,962 participants who did not develop dementia or MCI, those who did (n=555) were older (69.6 vs 62.4 years) and more likely to be male (n=308, 55.5% vs n=39,758, 43.7%), had lower levels of education (n=215, 38.7% vs n=39,372, 43.3% attended college), had a higher prevalence of sleep apnea (n=10, 1.8% vs n=771, 0.8%), and circulatory system disease (n=261, 47% vs n=22,273, 24.4%), had a higher morbidity burden (2.0, SD 1.8 vs 1.1, SD 1.3), and were more likely to be current or past smokers (n=40, 7.2% vs n=6271, 6.9% and n=342, 61.6% vs n=48,428, 53.2%).

Table 2 presents multivariable-adjusted HRs for dementia or MCI associated with RAR metrics when considered as quartiles of exposure or per SD difference. Figure 1 shows survival plots for incident dementia or MCI associated with RAR metrics. The risk of dementia or MCI was statistically higher in those with more suppressed and fragmented 24-hour activity rhythms as quantified by lower RA (multivariable-adjusted HR per 1-SD decrease=1.23, 95% CI 1.16-1.29; Q1 vs Q4, HR 1.88, 95% CI 1.46-2.41; Figure 1A), lower M10 (multivariable-adjusted HR per 1-SD decrease=1.28, 95% CI 1.14-1.44; Q1 vs Q4, HR 1.69, 95% CI 1.30-2.19; Figure 1B), higher L5 (multivariable-adjusted HR per 1-SD increase=1.15, 95% CI 1.10-1.21; Q4 vs Q1, HR 1.51, 95% CI 1.19-1.91; Figure 1C), and larger IV (multivariable-adjusted HR per 1-SD increase=1.14, 95% CI 1.05-1.24; Q4 vs Q1, HR 1.56, 95% CI 1.20-2.02; Figure 1D). Consistently, the risk of dementia or MCI was statistically higher in those with smaller 24-hour amplitude based on cosinor analysis (multivariable-adjusted HR per 1-SD decrease=1.32, 95% CI 1.17-1.49; Q1 vs Q4, HR 1.86, 95% CI 1.42-2.42; Figure 1E). In addition, participants with delayed L5 midpoint had a lower risk for dementia or MCI (multivariable-adjusted HR per 1-SD increase or ~75 min delay in L5 midpoint=0.92, 95% CI 0.85-0.99; Figure 1G). IS (Figure 1F), M10 midpoint (Figure 1H), and acrophase (Figure 1I) had no significant associations with the risk of dementia or MCI.

In addition, we found that the risk was higher for older participants (multivariable-adjusted HR for each year older at baseline=1.17, 95% CI 1.15-1.19) and male participants (multivariable-adjusted HR 1.33, 95% CI 1.11-1.58).

The associations between RAR measures and incident dementia or MCI remained similar when including only participants who developed dementia (Multimedia Appendix 3) or when excluding those shift workers (Multimedia Appendix 4). In addition, the associations between RAR metrics and risk of dementia or MCI were independent of PRS (P values >.10 for the interaction terms of PRS and all RAR measures; Multimedia Appendix 5) while higher PRS was associated with an increased risk of dementia or MCI (multivariable-adjusted HR per 1-SD increase=1.48, 95% CI 1.36-1.60). Moreover, the RAR-dementia or MCI associations appeared to be similar for the younger (<70 years old) and older (≥70 years old) participants (P values >.10 for the interaction terms of age group and all RAR measures, except M10; Multimedia Appendix 6).

Discussion

Principal Findings

In this large, prospective cohort study, we evaluated the association between RAR metrics, derived from wrist actigraphy, and incidence of dementia or MCI during a follow-up of up to 7.5 years. Our results underscore the significance of specific RAR metrics, notably RA, M10, amplitude, L5, L5 midpoint, and IV in delineating the dementia or MCI risk, independent of previously identified risk factors for dementia or cognitive decline.

Unlike previous studies, our analysis is based on a notably large sample size of >94,000 participants, using objective actigraphy assessments for RAR and spanning a broad age range of 43-79 years. This study adopted a longitudinal design with nearly 8 years of follow-up and comprehensively adjusted for known confounders, including demographic, shiftwork status, lifestyle, comorbidity, and genetics, to enhance the robustness of the results. Specifically, we showed that suppressed 24-hour rhythmicity (lower RA and 24-hour amplitude), accompanied by reduced activity levels (M10) during the active phase and increased activity levels during the resting phase (L5) as well as fragmented 24-hour rhythms (greater IV), were linked to the higher risk for dementia or MCI. These results are consistent with previous studies. For instance, using the Rush Memory and Aging Project data, the risk for Alzheimer dementia was higher in those with lower 24-hour amplitude and greater IV.
findings might be explained by unadjusted confounders that delay acrophase, M10, and L5 midpoints with a higher risk [14]. Xiao et al [17] reported a significant linear association of lower L5 midpoint (but not M10 midpoint) with higher risk for dementia (but not MCI) [14] observed an association between earlier L5 midpoint (but not M10 midpoint) and acrophase or M10 mid-time. L5 mid-time is usually related to the timing of sleep, whereas M10 mid-time and acrophase are related to the timing of peak activity. Previous research has similarly reported a lack of significant associations [13,14,17], our research contributes to more definitive insights into these complex associations with a substantially larger sample size. In a related study, Park et al [50] reported higher IS in older adults when compared to younger adults, and interpreted the results as the consequence of changes in daily schedules. This study raises a potential concern about the masking effect of daily schedules on RAR measures, especially IS [51]. An important follow-up question is how reliable IS can be in reflecting intrinsic changes in circadian regulation or predicting or capturing the long-term impacts of acute disturbed 24-hour behavioral cycles on circadian health and related cognitive changes. Future studies including circadian rhythms of other physiological variables or mathematical modeling for estimation of circadian rhythms [52-56] are needed to address the question.

The relationship between the RAR phase and dementia or MCI risk is still inconclusive. Our study identified earlier L5 mid-time as a risk factor for dementia or MCI, but not changes in acrophase or M10 mid-time. L5 mid-time is usually related to the timing of sleep, whereas M10 mid-time and acrophase are usually related to the timing of peak activity. Previous research has yielded varied results. For example, Lysen et al [13] did not observe any association between the circadian phase measured by L5 onset and risk of dementia or MCI, whereas Posner et al [14] observed an association between earlier L5 midpoint (but not M10 midpoint) with higher risk for dementia (but not MCI) [14]. Xiao et al [17] reported a significant linear association of delayed acrophase, M10, and L5 midpoints with a higher risk for dementia or MCI in older women. These inconsistent findings might be explained by unadjusted confounders that influence sleep timing, such as chronotype (ie, preferred sleep time), sleep disorders (eg, insomnia), use of sleep medication, and photoperiod. Future studies should consider controlling for such factors when clarifying relationships between the RAR phase and dementia or MCI.

Clinical Implications and Future Research

Our findings provide insights into the clinical practice and future research in dementia and MCI prevention, screening, and intervention. Specifically, incorporating assessments of sleep and rest-activity patterns into routine health evaluations might be beneficial for middle-aged and older adults. In geriatric care, routine monitoring and management of RAR may help evaluate the factors affecting cognitive health. Educating caregivers and family members about the importance of consistent rest-activity patterns could be incorporated into the home-based care for individuals at risk. Tailoring preventive and therapeutic strategies to individuals based on their RAR characteristics, especially in populations like shift workers, could also be effective. Future research should further clarify the causality of the associations between RAR and cognition, and test whether interventions that improve sleep hygiene, modify light exposure, or adjust physical activity levels can positively impact RAR and, consequently, help prevent or slow cognitive decline.

Strengths and Limitations

The strengths of this study include having a large sample size of more than 94,000 participants; using objective assessments of RAR using actigraphy; controlling for a large number of confounders, including demographic, lifestyle, comorbidity, genetics, and morbidity burden; large age range of participants (aged between 43 and 79 years); and the longitudinal study design with nearly 8 years of follow-up. Limitations of our study are as follows: (1) the majority of participants were of White European descent (>95%), limiting our ability to investigate racial or ethnic differences in the associations; (2) the rate of dementia or MCI events (~550 out of 94,000) appeared to be relatively low due to the overall young age of the participants (median age 63.5 years); (3) we were unable to differentiate between different types of dementia. However, this provides a great opportunity for future studies, when the participants became older, to investigate the long-term association of RAR and different types of dementia or MCI; (4) single-time assessment of actigraphy and covariates did not allow us to examine changes in RAR and dementia risk; (5) internal circadian clocks and environmental factors such as light exposure and social obligations were not assessed or controlled such that it is not possible to separate intrinsic and extrinsic influences on RAR.

Conclusions

We found that altered daily rest-activity patterns were linked to future risk of dementia or MCI, independent of other known risk factors. Monitoring of ambulatory daily motor activity or rest-activity patterns with wearable devices may provide a unique opportunity to identify people at higher risk of dementia or MCI.

Abstract

Background: The HIV-1 molecular network is an innovative tool, using gene sequences to understand transmission attributes and complementing social and sexual network studies. While previous research focused on static network characteristics, recent studies’ emphasis on dynamic features enhances our understanding of real-time changes, offering insights for targeted interventions and efficient allocation of public health resources.

Objective: This study aims to identify the dynamic changes occurring in HIV-1 molecular transmission networks and analyze the primary influencing factors driving the dynamics of HIV-1 molecular networks.

Methods: We analyzed and compared the dynamic changes in the molecular network over a specific time period between the baseline and observed end point. The primary factors influencing the dynamic changes in the HIV-1 molecular network were identified through univariate analysis and multivariate analysis.

Results: A total of 955 HIV-1 polymerase fragments were successfully amplified from 1013 specimens; CRF01_AE and CRF07_BC were the predominant subtypes, accounting for 40.8\% (n=390) and 33.6\% (n=321) of the specimens, respectively. Through the analysis and comparison of the basic and terminal molecular networks, it was discovered that 144 sequences constituted static molecular networks, and 487 sequences contributed to the formation of dynamic molecular networks. The findings of the multivariate analysis indicated that the factors occupation as a student, floating population, Han ethnicity, engagement in occasional or multiple sexual partnerships, participation in anal sex, and being single were independent risk factors for the dynamic changes observed in the HIV-1 molecular network, and the odds ratio (OR; 95\% CIs) values were 2.63 (1.54-4.47), 1.83 (1.17-2.84), 2.91 (1.09-7.79), 1.75 (1.06-2.90), 4.12 (2.48-6.87), 5.58 (2.43-12.80), and 2.10 (1.25-3.54), respectively. Heterosexuality and homosexuality seem to exhibit protective effects when compared to bisexuality, with OR values of 0.12 (95\% CI 0.05-0.32) and 0.26 (95\% CI 0.11-0.64), respectively. Additionally, the National Eight-Item score and sex education experience were also identified as protective factors against dynamic changes in the HIV-1 molecular network, with OR values of 0.12 (95\% CI 0.05-0.32) and 0.26 (95\% CI 0.11-0.64), respectively.

Conclusions: The HIV-1 molecular network analysis showed 144 sequences in static networks and 487 in dynamic networks. Multivariate analysis revealed that occupation as a student, floating population, Han ethnicity, and risky sexual behavior were independent risk factors for dynamic changes, while heterosexuality and homosexuality were protective compared to bisexuality. A higher National Eight-Item score and sex education experience were also protective factors. The identification of HIV dynamic
molecular networks has provided valuable insights into the characteristics of individuals undergoing dynamic alterations. These findings contribute to a better understanding of HIV-1 transmission dynamics and could inform targeted prevention strategies.

Introduction

AIDS, a sexually transmitted disease, is significantly influenced by the social and sexual network structure and characteristics of people living with HIV [1,2]. Understanding the social and sexual network structure of individuals infected with HIV is important for public health, as it facilitates comprehension of transmission dynamics within the population and informs targeted prevention and control measures [3-5]. Prior research examining the social and sexual network structure of people living with HIV has predominantly used field epidemiological techniques, including questionnaire surveys, peer tracing, and community follow-ups, to delineate the attributes of social and sexual transmission networks [6-9]. However, the extended latency period of HIV and the time gap between infection and diagnosis create a challenge for social communication networks that rely on self-reported data from individuals who are infected [10]. The quality of self-reported data provided by individuals who are infected may be influenced by various factors such as social discrimination, stigma, and privacy concerns. These factors can create barriers to accurate reporting and may result in underreporting or misrepresentation of information. Consequently, conventional epidemiological investigations, including behavioral surveys, exposure history assessments, and contact tracing, encounter difficulties in analyzing the structure and attributes of HIV transmission networks [11]. Alternative approaches and methodologies may need to be considered to overcome these difficulties and obtain a more comprehensive understanding of the HIV transmission network.

The HIV-1 molecular network has garnered extensive acknowledgment as an innovative technique that uses the gene sequences of individuals who are infected with HIV-1 to examine its transmission attributes [12]. It functions as a valuable supplement to the study of HIV-1 social and sexual networks [13-16]. The implementation and progression of the HIV-1 molecular network has introduced novel viewpoints for the prevention and control of HIV/AIDS [17-20]. The molecular network has been used to assess the efficacy of antiretroviral therapy in preventing secondary HIV transmission [21]. This approach is deemed a precise mechanism for HIV/AIDS prevention and control, enabling a more effective use of public health resources [22]. By identifying individuals or groups who are at a higher risk of transmitting HIV-1, targeted interventions can be implemented to prevent the spread of the virus and improve treatment outcomes. Furthermore, extensive investigations can promptly identify individuals with an undiagnosed infection within the transmission network. Moreover, the implementation of timely interventions among individuals who are uninfected in risk networks can effectively impede further dissemination and spread of HIV-1, thereby holding promising prospects for curtailing the spread of HIV and reducing the incidence of new infections. It becomes possible to optimize prevention efforts and achieve better outcomes in controlling the spread of HIV-1 [23].

Prior research on the impact of molecular networks on HIV risk has predominantly concentrated on static network characteristics, assessing the structural attributes of the network at a particular moment. Factors such as network size, density, and individual characteristics (eg, age, sex, occupation, risky sexual behavior, HIV-related knowledge, and attitudes) have been identified as important considerations in understanding HIV transmission patterns and implementing effective prevention and control measures [24,25].

Recent research has underscored the importance of dynamic features within the HIV molecular network [26,27]. Identified actively growing clusters, despite demographic and risk characteristics that may diverge from the overall population, warrant focused intervention prioritization. The dynamics of cluster growth offer valuable guidance for the allocation and prioritization of public health resources, thereby bolstering the utility of networks in assessing intervention efficacy. These dynamic changes intricately intertwine with the personal characteristics and behaviors of individuals who are infected. Real-time analysis of HIV-1 molecular network characteristics provides a framework for resource allocation toward swiftly evolving molecular clusters. This approach facilitates the identification and comprehension of ongoing transformations within molecular networks, thus enabling prompt interventions and response strategies [26,28]. However, prevailing research on molecular networks in China predominantly focuses on static networks at a single timepoint, with limited exploration of dynamic changes [29-32]. Our study specifically targets newly formed and dynamically growing molecular clusters to elucidate the dynamic changes within HIV-1 molecular transmission networks. By analyzing the primary influencing factors driving these dynamics, we aim to unravel the intricate nature of HIV molecular networks. Ultimately, this research endeavor seeks to empower public health initiatives with the capability to more effectively target HIV spread and implement tailored prevention measures through the active monitoring and analysis of molecular network dynamics.

Methods

Participants

From September 1, 2015, to June 30, 2019, this research was conducted in five districts of Nanjing: Qinhuai, Xuanwu, Qixia, Jiangning, and Gulou. The study focused on individuals who

https://publichealth.jmir.org/2024/1/e56593
were newly diagnosed with an HIV infection during this specific time frame. The Nanjing Center for Disease Control and Prevention was responsible for conducting confirmation testing on all individuals infected with HIV included in the study.

**Questionnaire Survey**

A structured questionnaire was used for the one-on-one survey, which took place in a separate room. The privacy of the participants was prioritized throughout the questionnaire survey procedure, and strict measures were implemented to uphold the confidentiality of participants’ personal data. The questionnaire covered various topics related to the participants. These included demographic information such as age, gender, occupation as a student or not, marital status, religion, ethnicity, transmission route, sexual orientation, geographical localities (floating population or not), and sex transmission disease history. Additionally, the questionnaire explored participants’ knowledge and behaviors related to HIV, including condom use, casual sexual partners, multiple sexual partners, anal sex, use of enhancers, experiences with sex education, and HIV/AIDS knowledge, using an 8-item questionnaire (National Eight-Item), which was designed by the Chinese Center for Disease Control and Prevention [33,34] (Multimedia Appendix 1).

**Specimen Collection and Storage**

Blood samples were collected from survey participants using EDTA anticoagulant tubes and transported to the Nanjing Center for Disease Control and Prevention, and the samples were processed within 12 hours. Plasma, lymphocyte enrichment solution, and red blood cells were separated and divided into separate tubes. The aliquoted cryopreservation tubes were labeled and stored at –80 °C.

**HIV-1 Polymerase Region Fragment Amplification**

The amplification of the HIV-1 virus was executed through the use of reverse transcription–polymerase chain reaction and nested polymerase chain reaction methodologies, in accordance with the protocols described earlier [35]. The amplification process was directed toward a segment of the polymerase (Pol) region of the specimen, with a specific focus on the 1-99 amino acids of the protease region and the 1-254 amino acids of the reverse transcriptase region (HXB2: 2253-3312). The length of the amplified sequence was 1060 base pairs. In cases where the amplified sequence was shorter than 1060 base pairs or samples failed to amplify, reamplification and sequencing were performed. HIV drug resistance was demonstrated as with our previous study [35].

**Identification of HIV-1 Subtypes in Nanjing**

The gene sequences that were sequenced with success underwent sorting and splicing procedures, while the possibility of contamination was addressed through the use of the web-based plagiarism detection tool, ElimDupes [36]. This study used the web-based HIV basic local alignment search tool (BLAST) for the identification and genotyping of HIV-1 in Nanjing. Furthermore, gene subtype reference sequences, such as CRF01_AE, CRF07_BC, CRF08_BC, CRF5501_B, B, CRF6701_B, and CRF6801_B, were procured from the HIV sequence database website, and a reference sequence data set was constructed in conjunction with the Nanjing HIV-1 gene sequence data. The gene evolution tree was constructed using an approximately maximum likelihood method in FastTree v2.1 (Morgan N Price) for comparative analysis, and the distribution of HIV-1 genotypes in Nanjing was determined based on the findings of the evolution tree.

**The HIV-1 Molecular Network in Nanjing**

An approximately maximum likelihood phylogenetic tree was constructed using FastTree v2.1. The tree was built under the general time reversible + gamma distribution + proportion of invariable sites nucleotide substitution model. The Shimodaira-Hasegawa test was performed to assess the support value for each node in the phylogenetic tree. A support value of 90% was used as the threshold for considering a node well supported. The genetic distance between pairs of sequences was calculated using the Tamura-Nei 93 (TN93) method; a genetic distance threshold ≤0.045 was used to identify potential transmission clusters [37,38]. The HIV-1 molecular network in Nanjing was constructed by using a combination of phylogenetic tree and gene distance (90% + 0.045) methods, which was demonstrated in our previous study [39]. The visual editing of HIV molecular transmission networks was accomplished using Cytoscape 3.10.1 (National Resource for Network Biology), a widely used platform for constructing molecular networks [40,41].

**Identification of Dynamic Changes in HIV-1 Molecular Networks**

The molecular network constructed from 2015 to 2017 served as the baseline molecular network (initial time point), while the molecular network observed from 2015 to 2019 represented the observed end point molecular network (final time point).

By comparing the baseline and observed end point molecular networks, the following definitions were derived. The static molecular network consists of unchanged molecular clusters and molecular clusters that do not appear in the observed end point molecular network. This means that the structure and members of these clusters remain constant during the observation period. The dynamic molecular network refers to the newly formed molecular clusters observed in the observed end point molecular network and the dynamically growing molecular clusters based on the baseline molecular network (Figure 1). This indicates that the clusters were formed within the observation period and may continue to grow or change over time.
Figure 1. The dynamic changes in molecular networks recognition. (A) shows the baseline molecular network, and (B) shows the observed end point molecular network. The molecular cluster composed of A, B, and C is the unchanged molecular cluster. The molecular cluster composed of H and I do not appear in the observed end point molecular network. The molecular cluster composed of D, E, F, J, and K is a dynamically growing molecular cluster. The molecular cluster composed of L, M, and N is the newly formed molecular cluster. The red spheres represent the dynamic molecular network, while the green spheres represent a statical molecular network.

Statistical Analysis

EpiData software (v3.1; Odense) was used to construct a database. Two individuals each input the questionnaire data into a computer, and the questionnaires’ completeness were verified using telephone follow-ups or secondary surveys to supplement any missing information. The classification data in this study were expressed as a percentage, and the chi-square test was used to compare various groups. Additionally, multivariate analysis was conducted using logistic regression analysis, with a test level of α=.05.

Ethics Approval

Written informed consent was obtained from all patients participating in the study, and the research protocol was approved by the Medical Ethics Committee of Zhongda Hospital of Southeast University (2017ZDKYSB045). Our survey is not anonymous; however, all investigators have signed confidentiality agreements to strictly protect the personal privacy information of the participants. The data used for statistical analysis has been deidentified, with the personal privacy information of the investigators removed. Additionally, each participant will receive a compensation of ¥100 (US $15).

Results

Subtypes of HIV-1 Pol Fragment Genome in Nanjing From 2015 to 2019

In this study, 955 HIV-1 Pol fragments were successfully amplified from 1013 specimens; the success rate of amplification was 94.27%. Subtype identification revealed that CRF01_AE and CRF07_BC were the predominant subtypes, accounting for 40.8% (n=390) and 33.6% (n=321), respectively. The remaining subtypes included URF, CRF67_01B, CRF68_01B, B, CRF55_01B, CRF08_BC, CRF58_01B, CRF59_01B, CRF87_cpx, and C, which accounted for 9% (n=86), 4.6% (n=44), 3.7% (n=35), 3.5% (n=33), 2.3% (n=22), 1.3% (n=12), 0.6% (n=6), 0.4% (n=4), 0.1% (n=1), and 0.1% (n=1), respectively.

Identification of HIV-1 Dynamic Molecular Network in Nanjing From 2015 to 2019

The baseline molecular network is the HIV-1 molecular network in Nanjing from 2015 to 2017 (Figure 2). A total of 295 HIV-1 sequences entered the network, with a clustering ratio of 56.8% (295/591), forming 75 molecular clusters. Among them, there were 38 CRF01_AE molecular clusters (122 sequences); 23 CRF07_BC molecular clusters (90 sequences); 2 CRF08_BC molecular clusters (5 sequences); 2 CRF6701_B molecular clusters (23 sequences); and 1 CRF6801_B molecular cluster (17 sequences), 1 CRF5501_B molecular cluster (8 sequences), 3 B subtype molecular clusters (8 sequences), 4 URF molecular clusters (19 sequences), and 1 CRF5901_B molecular cluster (3 sequences).

The observation end point molecular network is the HIV-1 molecular network in Nanjing from 2015 to 2019 (Figure 3). A total of 565 HIV-1 sequences were included in the network, with a clustering ratio of 59.2% (565/955), forming 124 molecular clusters. Among them, there were 57 CRF01_AE molecular clusters (233 sequences); 34 CRF07_BC molecular clusters (188 sequences); 2 CRF08_BC molecular clusters (6 sequences); 5 CRF6701_B molecular clusters (34 sequences); and 3 CRF6801_B molecular clusters (19 sequences), 3 CRF5501_B molecular clusters (14 sequences), 8 subtype B molecular clusters (20 sequences), 10 URF molecular clusters (46 sequences), and 2 other molecular clusters including 5 sequences (CRF5801_B 2 pieces, CRF5901_B 3 pieces).
By comparing the baseline and observed end point molecular networks, it was discovered that 144 sequences remained static or disappeared; these sequences formed molecular clusters that constituted a static molecular network. On the other hand, 487 sequences were found in newly formed or dynamically growing molecular clusters, contributing to the formation of dynamic molecular networks within the clusters where these sequences were located. In addition, the remaining 324 gene sequences were excluded from the analysis of the dynamic molecular network because they were absent from both the basic molecular network and the end point molecular network.

**Figure 2.** The baseline molecular network. The red spheres represent a dynamic molecular network, while the green spheres represent a statical molecular network. The number in the center of each sphere represents the degree of the molecular network.
The Impact of General Personal Characteristics on the Composition of Molecular Networks

The molecular network composition (dynamic and static) was taken as the dependent variable for univariate analysis. The findings indicated that the proportion of male individuals who were infected (460/596, 77.2%) entering the dynamic molecular network was marginally higher than that of female individuals (180/266, 69%), although no statistically significant difference was observed. Notably, a significantly higher proportion of infected individuals 20 years and younger entered the dynamic molecular network, with 89.2% (58/65) of such individuals being represented, compared to those older than 20 years (420/557, 75.4%); the difference was statistically significant ($P=0.02$). A significantly higher proportion of students who were infected (154/186, 82.8%) were found to have entered the dynamic molecular network compared to nonstudents who were infected (324/436, 74.3%; $P=0.02$). The study found significant variations in the proportion of infected individuals with different sexual orientations entering the dynamic molecular network. Specifically, the proportion of bisexual individuals who were infected entering the network was the highest (214/262, 81.7%). Additionally, the proportion of individuals who were infected from the floating population was significantly higher than that of the nonmigrant population (224/277, 80.9% vs 254/345, 73.6%), and the proportion of Han individuals who were infected entering the dynamic molecular network was higher than that of minority individuals who were infected. The study also observed a higher proportion of infection among single individuals, but there were no statistically significant differences in the proportion of people who were infected with different education levels, infection routes, religion, and history of sexuality (Table 1).

**The Impact of HIV-1–Related Knowledge and Risky Behaviors on the Molecular Network Composition of People Who Were Infected**

There was no significant difference in the proportion of people who were infected entering the dynamic molecular network with different condom use conditions ($P=.79$). However, the proportion of infected persons with casual sexual partners (381/479, 79.5%) was higher than that of patients without casual partners (97/143, 67.8%; $P=.004$). Moreover, the proportion of individuals who reported having multiple sexual partners and engaged in anal sex entering the dynamic molecular network was significantly higher compared to those who did not report such behaviors; these differences were statistically significant.
Additionally, the proportion of infected persons with qualified scores in the eight national items who had received sex education entering the dynamic molecular network was significantly lower than the proportion of infected persons with unqualified scores in the National Eight-Item and who had not received sex education. However, there was no statistical difference in the proportion of individuals who were infected who reported using enhancers compared to those who did not (P=.96; Table 2).

**Effect of Subtype, Drug Resistance, and Clusters of Differentiation 4 Value on Molecular Network Composition**

The statistical analysis revealed a significant difference in the proportion of infected individuals with a clusters of differentiation (CD4) value <500 cells/mm$^3$ entering the dynamic molecular network (363/459, 79.1%) compared to those with CD4 value ≥500 cells/mm$^3$ (115/163, 70.6%; P=.03). However, no statistically significant differences were observed in the proportion of infected individuals with different genotypes or drug resistance entering the dynamic molecular network. Further details can be found in Table 3.

Logistic Regression Multivariate Analysis

Taking the molecular network status of individuals infected with HIV-1 as the dependent variable (dynamic=1, static=0), the variables with statistical significance in univariate analysis (occupation, age, ethnicity, sexual orientation, floating population, casual sexual partner, multiple sexual partners, National Eight-Item scores, anal intercourse, singleness, sex education experience, and CD4) were included in the multivariate analysis. The assignments were as follows: occupation (student=1, nonstudent=0), age (<20 years=1, >20 years=0), ethnicity (Han=1, minority=0), sexual orientation (heterosexual=1, same sex=2, bisexual=3), floating population (yes=1, no=0), casual partner (yes=1, no=0), multiple sexual partners (yes=1, no=0), National Eight-Item score (qualified=1, unqualified=0), anal intercourse (yes=1, no=0), marital status (single=1, not single=0), sex education experience (yes=1, no=0), and CD4 (≥500 cells/mm³=1, <500 cells/mm³=0).

The findings of the multivariate analysis indicate that various factors, including occupation as a student, migrant status, Han ethnicity, engagement in occasional or multiple sexual partnerships, participation in anal sex, and being single, are independent risk factors for the dynamic changes observed in the HIV-1 molecular network, and the odds ratio (OR) values were 2.63 (95% CI 1.54-4.47), 1.83 (95% CI 1.17-2.84), 2.91 (95% CI 1.09-7.79), 1.75 (95% CI 1.06-2.90), 4.12 (95% CI 2.48-6.87), 5.58 (95% CI 2.43-12.80), and 2.10 (95% CI 1.25-3.54), respectively. Conversely, heterosexual and homosexuality appear to be protective factors against such changes when compared to bisexuality, with OR values of 0.12 (95% CI 0.05-0.32) and 0.26 (95% CI 0.11-0.64), respectively. Additionally, the National Eight-Item score and experience with sex education were also identified as protective factors against dynamic changes in the HIV-1 molecular network; the OR values were 0.12 (95% CI 0.05-0.32) and 0.26 (95% CI 0.11-0.64), respectively. Further details can be found in Table 4.

Discussion

Principal Findings

The study revealed a diverse distribution of HIV-1 subtypes in Nanjing, with CRF01_AE and CRF07_BC being the predominant subtypes. This observation aligns with the global trend of HIV-1 subtype distribution, with CRF01_AE and CRF07_BC commonly found in Asian regions [39,42]. The identification of various other subtypes, including URFs and less prevalent subtypes, emphasizes the genetic complexity of the HIV epidemic in the studied population.

The dynamic changes in the molecular networks were analyzed to understand the dynamics of HIV-1 transmission [43]. The network’s dynamic changes are indicative of potential transmission associations within it. The addition of new gene sequences can disrupt the existing network and give rise to novel networks, thereby revealing the evolving transmission patterns with greater precision. This approach facilitates the real-time monitoring of the molecular network’s dynamic changes, thereby enabling the prompt identification of rapidly expanding or emerging molecular clusters. Such information can inform targeted interventions and the evaluation of prior prevention and control measures [44].

By conducting a multifactor analysis of the HIV-1 molecular network’s dynamic changes, it was observed that individuals who were bisexual, had multiple sexual partners, had casual sexual partners, and engaged in anal sex were more likely to be present in the dynamic molecular network. Men who have sex with men (MSM) in China may face social and familial pressures that lead them to choose to marry women [45] but engage in extramarital same-sex relationships, thereby acting as a bridge for HIV transmission from high-risk groups to the general population [46]. Bisexual individuals have a higher incidence of unprotected sex, lower risk perception, and weaker awareness of self-protection, making them more susceptible to HIV transmission. Furthermore, individuals constrained by family and involved in fixed marital relationships have limited opportunities to engage with fixed same-sex partners, leading them to seek commercial same-sex services when they have sexual needs. Additionally, individuals who engage in sexual activity with multiple partners are prone to inconsistent condom use in contrast to those who engage in sexual activity with only one partner. The emergence of online social platforms has facilitated casual sexual encounters, resulting in a surge of inadvertent sexual behaviors. The failure to consistently use condoms during casual sexual activity significantly heightens the risk of HIV infection and transmission. The physiological vulnerability of the anus renders anal sex a higher-risk activity, and the lack of condom use during same-sex anal intercourse further exacerbates the risk of infection and transmission [47].

The findings of the analysis indicate that individuals with dynamic network connections are more likely to be affiliated with migrant, single, and student populations. The floating population serves as a significant conduit for HIV transmission across various regions. Furthermore, the population in question predominantly comprises sexually active young adults who spend prolonged periods away from their families, resulting in a dearth of both physical and emotional support. This lack of restraint renders them susceptible to engaging in high-risk behaviors related to HIV. The unattached demographic, unencumbered by familial obligations, exhibits a greater propensity for engaging in precarious conduct, such as engaging in casual sexual liaisons and maintaining multiple sexual partners, thereby heightening their susceptibility to contracting HIV and propagating the virus. In contemporary times, college students have emerged as a crucial cohort for HIV prevention and management. Despite possessing a higher level of education, this group manifests a significant disparity between their awareness and conduct. Their inclination toward seeking novelty coupled with the proliferation of diverse social media and mobile apps, which makes finding sexual partners online extremely convenient, further exacerbates this phenomenon. A study conducted by our research team revealed that a majority of university students infected with HIV contracted the virus through male-to-male sexual behaviors, with mobile apps serving as the primary platform for locating male sexual partners. The male-to-male sexual contacts exhibited a lack of awareness regarding the high prevalence of HIV/AIDS in their population, and they do not consistently use condoms during sexual encounters [48]. Higher National Eight-Item scores and sex education experience also emerged as protective factors, suggesting the potential role of knowledge and awareness in reducing transmission dynamics.

In response to these findings, Nanjing has implemented targeted measures to enhance the accessibility of HIV/AIDS pre-exposure prophylaxis (PrEP) and postexposure prophylaxis (PEP) services among MSM, especially the floating population of Nanjing [49,50]. These measures include improving the availability of PrEP and PEP medication and related health care services, developing educational programs to increase awareness and knowledge about PrEP and PEP, and engaging with MSM communities through community-based organizations and support groups.

Conclusion

We conducted HIV molecular network analysis in Nanjing from 2015 to 2019, and CRF01_AE and CRF07_BC were identified as the predominant subtypes. Molecular network analysis revealed dynamic changes in the HIV molecular network over time, with 487 sequences contributing to newly formed or dynamically growing molecular clusters. Multivariate analysis confirmed occupation as a student, a floating population, Han ethnicity, engaging in casual or multiple sexual partnerships, participation in anal sex, and being single as independent risk factors for dynamic network changes, while heterosexuality and homosexuality appeared to be protective factors when compared with bisexuality. Additionally, higher National Eight-Item scores and sex education experience were identified as protective factors against dynamic network changes. The findings emphasize the importance of targeted interventions addressing specific risk factors identified in the study. Strategies focused on education, awareness, and behavioral interventions may contribute to stabilizing or reducing the dynamic changes observed in the HIV-1 molecular network. Understanding the intricate dynamics of transmission networks is crucial for...
designing effective public health measures to control and prevent further spread of HIV.

**Limitations**

This study has the following limitations. First, the definition of dynamic network in this study is only based on the comparison of two time point networks, and multiple time point comparisons should be used to discover nascent networks and dynamic growth networks. Second, although we used the HIV Pol gene sequence from 2015 to 2019 to analyze the dynamic changes in the molecular network, the sample size was not large enough. Third, despite conducting the investigation in a one-on-one format, there remains a possibility of recall bias attributable to HIV-related stigma, compounded by the fact that the time of infection is unknown for many individuals.

Abstract

Background: The COVID-19 pandemic had a profound impact on the global health system and economic structure. Although the implementation of lockdown measures achieved notable success in curbing the spread of the pandemic, it concurrently incurred substantial socioeconomic costs.

Objective: The objective of this study was to delineate an equilibrium between the economic losses and health benefits of lockdown measures, with the aim of identifying the optimal boundary conditions for implementing these measures at various pandemic phases.

Methods: This study used a model to estimate the half-lives of the observed case fatality rates of different strains. It was based on global infection and death data collected by the World Health Organization and strain sequence time series data provided by Nextstrain. The connection between the health benefits and economic losses brought by lockdown measures was established through the calculation of disability-adjusted life years. Taking China’s city lockdowns as an example, this study determined the cost-benefit boundary of various lockdown measures during the evolution of COVID-19.

Results: The study reveals a direct proportionality between economic losses due to lockdowns and the observed case fatality rates of virus strains, a relationship that holds true irrespective of population size or per capita economic output. As SARS-CoV-2 strains evolve and population immunity shifts, there has been a notable decrease in the observed case fatality rate over time, exhibiting a half-life of roughly 8 months. This decline in fatality rates may offset the health benefits of maintaining unchanged lockdown measures, given that the resultant economic losses might exceed the health benefits.

Conclusions: The initial enforcement of lockdown in Wuhan led to significant health benefits. However, with the decline in the observed case fatality rate of the virus strains, the economic losses increasingly outweighed the health benefits. Consequently, it is essential to consistently refine and enhance lockdown strategies in accordance with the evolving fatality and infection rates of different virus strains, thereby optimizing outcomes in anticipation of future pandemics.

Introduction

Throughout history, there have been significant impacts on the global economy and public health from infectious diseases, such as the Spanish flu, Middle East respiratory syndrome (MERS), the bubonic plague, and the COVID-19 pandemic. Among measures to control the spread of diseases, lockdown is the most effective, as it can slow down the spread of a virus and potentially prevent a surge in cases and deaths in a short time. However, it can also result in significant economic costs, particularly in terms of lost jobs, reduced economic output, and increased government spending on relief measures [1-4]. Therefore, it is necessary to develop a quantitative method to assess the economic losses and health benefits of strict lockdown measures and their social costs in order to determine which levels of lockdown are sustainable. This will allow us to better prepare for future pandemics.

There has been previous international research on the balance between the health benefits and economic losses of pandemic lockdowns [5,6]. Some studies attempted to correlate the characteristic R0 value (effective transmission number) of virus transmission, as calculated using the SIR (susceptible-infected-recovered) model, with economic behavior [7-10]. Additionally, some studies have used discrete selection experiments to explore the lockdown boundary conditions [11-15]. However, while both methods offer insights into achieving balance, the former only considers the impact of a single parameter, the R0, while the latter is influenced by public fatigue with lockdown when determining the balance boundary. China’s prolonged 3-year lockdown measures during the COVID-19 pandemic resulted in noticeable lockdown fatigue, making it impractical to determine the lockdown boundary conditions through discrete selection experiments.

The World Health Organization (WHO) uses the concept of disability-adjusted life years (DALYs) to quantify the disease burden of various symptoms, whereas lockdown strategies lead to a reduction in individual social and work time, leading to significant productivity losses. Thus, time emerges as a crucial metric for quantifying the impact of lockdowns, with all associated factors being translatable into economic losses by time [16,17]. This allows for the comparison of health benefits and economic losses of various epidemic control policies using time-based or economic metrics. On the other hand, as the virus undergoes evolution and mutation, the comprehensive benefits of lockdown measures will change. Accompanying the reduced virulence of the virus and enhanced human immunity, numerous countries progressively eased their lockdown policies, notably Sweden, which was the first to revoke restrictions, in February 2022. China, the first country to face the COVID-19 epidemic, quickly implemented a city lockdown in Wuhan on January 23, 2020. As of December 7, 2022, China adjusted its dynamic “zero-COVID” policy and no longer implemented lockdowns.

Thus, it would be useful to find a quantitative method to determine when and how to implement epidemic control policies.

This study uses an optimization model to estimate the half-lives of the observed case fatality rates (OCFRs) of different strains based on global infection and death data collected by the WHO and strain-sequence time-series data provided by Nextstrain. We establish the connection between the health benefits and economic losses brought by lockdown measures through the calculation of DALYs. Taking China’s city lockdowns as an example, this study determines the cost-benefit boundary of various lockdown measures during the evolution of COVID-19. The main innovations of this research include (1) examining the half-lives of the OCFRs of different strains of the COVID-19 virus, (2) establishing a method for quantifying the economic losses and health benefits of lockdown based on comprehensive calculation of disease burden, and (3) identifying factors influencing the benefits of lockdown. This research will provide an effective tool for the management of COVID-19 and potential future infectious diseases, offering valuable references for government and business decision-making.

Methods

Ethical Considerations

The data used in this article were all obtained from a public website, and the study did not involve animal or human experiments, so an ethics committee review statement was not required.

Data Source

This study sourced the data on the number of SARS-CoV-2 deaths and infections from the WHO [18]. Additionally, temporal evolutionary data on various SARS-CoV-2 strains were acquired from Nextstrain [19].

Estimation Method for the OCFRs of SARS-CoV-2 Strains

The phenomenon of virus mutation succession is dynamic, evolving over time and potentially leading to the emergence of various mutant strains within a specific timeframe. Throughout this timeframe, the total fatality rate is influenced by the OCFRs of diverse strains, as depicted in equation 1:

\[ \text{OCFR} = \frac{\text{Total Deaths}}{\text{Total Infections}} \]

The equation used to calculate the half-life of the OCFR is given below:

\[ t_{1/2} = \frac{\ln(2)}{\lambda} \]

In the above equation, \( t \) refers to a specific time period, \( N_t \) refers to the total population at the time period \( t \), \( P_t \) refers to the overall population infection rate at time period \( t \), \( S_t \) refers to the total OCFR at time period \( t \), \( n \) refers to the number of different strains, \( x_{it} \) refers to the proportion of the \( i \)-th strain during time period \( t \), and \( s_{it} \) refers to the OCFR of the \( i \)-th strain during time period \( t \). This parameter can be obtained through multiple linear regression analysis of the OCFR over time, and the general solution to the equation is \( S_t = s_{it} \). As the proportion of different strains changed over time, this study selected the overall OCFR.
of the virus when the strain reached the maximum prevalence rate as the maximum possible observed fatality rate of the strain.

**Calculation of DALYs**

Using the classic 2-stage disease model recommended by the WHO, DALYs were used to quantify the disease burden of COVID-19:

\[
\text{DALYs} = \sum_{i} \left( \left( P_{i} \times N \right) \times \lambda ight)
\]

In the above equations, DALYs are per person-year (ppy), life-lost years (YLLs) refer to premature mortality ppy, years lived with disability (YLDs) are given ppy, \( i \) refers to different age groups (the whole population is divided into 8 age groups: 0-9 y, 10-19 y, 20-29 y, etc, until 70-80 y and >80 y), \( N \) refers to population number, \( P \) refers to population infection rate, \( S \) refers to OCFR, \( L \) refers to loss of life expectancy caused by death, \( DW \) refers to disease disability weight, \( LA \) refers to duration of the disease, \( P_{seq} \) refers to probability of sequelae, \( DW_{seq} \) refers to disability weight of sequelae, \( LB \) refers to duration of sequelae, and \( \lambda \) refers to the proportion of DALY loss caused by death. Table 1 lists the parameter values.

**Lockdown Economic Calculations**

There are 2 types of lockdown methods: blanket lockdown and local or partial lockdown. The former covers a region like an entire province, city, or district to stop many social activities as a whole; the latter covers small-scale entities such as buildings, corridors, and individual families. When an individual lived under lockdown, without mobility or direct contact with the outside world, contact with the virus was effectively avoided. Therefore, the benefit of implementing lockdown measures for a certain period of time was to reduce the population’s disease burden caused by virus infection. The disease burden and economic burden caused by large-scale infection with different strains of SARS-CoV-2 among the population during the epidemic can be calculated using equations 4 and 8. Typically, the disease burden under the condition of total infection or herd immunity can be considered as the possible benefit gained from implementing a lockdown. The difference between a blanket lockdown and local or partial lockdown lies in the scope. For a partial lockdown, the minimum benefit is to prevent the disease burden caused by local population infection from reaching the level of herd immunity, while the maximum possible benefit is to reduce the disease burden within the entire jurisdiction of the government or even globally, as the lockdown can prevent the virus from spreading worldwide. Particularly for highly contagious and fatal viruses such as Ebola and MERS, localized lockdowns can effectively prevent widespread transmission. For a blanket lockdown, the maximum benefit is to ensure that no one in a city becomes infected. Because local governments are responsible for their own economic gains, the product of the gross domestic product (GDP) output per person per year and the loss adjusted per year is used as a measure of the value of disease burden reduction [21,24]:

\[
\text{Economic Loss} = \text{GDP per person per year} \times \text{Loss adjusted per year}
\]

In the above formula, refers to the productivity weight. The values of \( \omega \) are shown in Table 1.

**Estimated Losses From Lockdown**

One of the major losses due to lockdown measures is the decline in GDP resulting from the reduction in social activities and mandatory remote work. According to calculations by the Chinese University of Hong Kong, a 2-week lockdown led to a 31% reduction in GDP for the corresponding month [20]; thus, a 1-month lockdown would be expected to reduce the GDP for that month by approximately 60%. Although lockdown measures have been associated with the exacerbation of chronic diseases.
and other side effects such as mental illness, this study does not address these aspects due to the lack of sufficient data. Therefore, the loss caused by lockdown can be calculated as follows:

\[ \text{Loss} = N \times T \]

In the above equation, \( N \) refers to the total population and \( T \) refers to the number of lockdown days. The values of \( N \) and \( T \) are shown in Table 1.

**Calculation of the Balance Between Economic Losses and Health Benefits of Blanket Lockdowns**

The health benefits of blanket lockdowns can be calculated by the maximum disease burden caused by overall infection or herd immunity (equation 10). The reduction in GDP resulting from the decrease in effective production time is commensurate in value.

\[ \text{GDP} = N \times P \]

In formulas 9, 10, and 11, \( T \) refers to the number of lockdown days, \( N \) refers to the total population under lockdown, GDP exists on both sides of the equation, and \( P \) refers to the infection rate based on the entire population. Table 1 lists the parameter values.

**Calculation of the Balance Between Economic Losses and Health Benefits of Partial Lockdowns**

Similarly, the balance between economic losses and health benefits of a partial lockdown refers to the equivalence between the health benefits resulting from the lockdown and the losses in GDP caused by the lockdown. The cost of the lockdown is primarily influenced by the size of the population affected; that is, there is a certain proportion of individuals in close contact with COVID-19 cases who cease their activities.

In equations 12 and 13, \( a \) refers to the number of people quarantined around an infected person. When \( a=1 \), only the infected person is quarantined. When \( a>1 \), people who have not been infected may also be restricted from activities. The number of close contacts, subclose contacts, and other companions (not necessarily infected) is determined when a positive infection is found, and there is a redundant cost. \( n \) refers to the number of people in a community, \( P \) refers to infection rate, and GDP per capita appears on both sides of the equation. Where life expectancy (\( L \)), \( \lambda \), and \( \omega \) are constants, the benefit and loss balance boundary is inversely proportional to the lockdown time (\( T \)) and lockdown population ratio (\( a \)) under the condition that the OCFR (\( S \)) is relatively stable. Table 1 lists the parameter values.

**Results**

**Time Series Trends in OCFRs of Different Strains**

Based on global mortality data from the WHO since December 2019 and lineage data provided by Nextstrain, Figure 1 illustrates an exponential decline over time in the OCFR of SARS-CoV-2, with a half-life of approximately 8 months. The OCFR for the original SARS-CoV-2 strain was between 3.8% and 8.4%, which then decreased to 2%-3% for the Beta, Gamma, and Lambda variants, and further dropped to 1%-2% for the Delta variant. During the Omicron phase, the OCFR significantly decreased, to about 0.5%. As of January 2023, the OCFR of SARS-CoV-2 in China has been reduced to below 0.1%. According to a report in *The Lancet*, the global OCFR for seasonal influenza from 1999 to 2015 ranged between 0.04% and 0.08%, nearing 0.1% for those older than 75 years [25]. These findings suggest that the OCFR of SARS-CoV-2 is now comparable to that of seasonal influenza. Strains with higher OCFR typically depend significantly on the host’s immune response, leading to reduced reproduction and survival rates, and thus become less competitive compared to less virulent but highly transmissible strains, eventually being replaced over time [26,27].
Balance Between Economic Losses and Health Benefits With Different Strains in a Blanket Lockdown

In the absence of prevention and control measures, SARS-CoV-2 will continue to infect individuals until herd immunity is achieved. For instance, on December 7, 2022, China adjusted its dynamic zero-COVID policy and no longer implemented lockdowns, leading to concentrated outbreaks of infections. In such a scenario, more than 70% of the population would form an immune barrier after being infected, preventing the virus from spreading continuously [28,29]. Therefore, the maximum loss resulting from complete liberalization is the infection of the entire population. Conversely, the greatest benefit lockdowns can offer to self-sustaining local governments is ensuring that no one within the jurisdiction becomes infected. Different strains have different disease burdens due to their different OCFRs. As the OCFRs of the strains decrease, the disease burden of the population also gradually decreases.

Based on the OCFR of each virus strain, the maximum disease loss can be estimated. In Figure 2, the left vertical axis represents the benefits brought by lockdown and the right vertical axis represents the time of the lockdown. Combined with Figure 1, it is clear that the quantitative value of disease losses (measured in DALYs) also declines as the OCFR declines. The maximum benefits from lockdown decrease as the virus strain’s OCFR decreases over time. Using equation 10, the net gain from lockdown can be calculated when health benefits exceed economic losses. For example, during the early lockdown period in Wuhan, involving strains 19A, 19B, and 20I, the health benefits of a 76-day lockdown surpassed the cost line.

Figure 1. Trends in the observed case fatality rate of SARS-CoV-2.

Figure 2. Relationship diagram of lockdown scale and lockdown duration during partial lockdown. DALY: disability-adjusted life year; ppy: per person-year; YLD: year lived with disability; YLL: life-lost year.
The results of the benefit and loss balance calculation indicate that the benefits yielded by the city lockdown strategy are correlated only with the OCFR and the lockdown duration, exhibiting a linear relationship between these 2 factors at the balance point of benefit and loss. As shown in Figure 2 (upper graph), there are 2 distinct zones on either side of the benefit and loss balance line: the benefit zone and the loss zone. When the OCFR is low, a shorter lockdown duration can produce health benefits. Conversely, with a higher OCFR, benefit is achievable even with an extended lockdown. For instance, when the OCFR in Wuhan reached 7% in January 2020, a lockdown period of up to 76 days could still have been beneficial. For the bubonic plague, which has an OCFR of up to 25% [30], a lockdown of more than a year could still produce a strong benefit. However, benefits tend to decline with succeeding virus strains. If the OCFR of a virus strain continues to decline, accompanied by higher false-negative nucleic acid tests, the duration of a lockdown will increase. When the OCFR drops to about 1%, a blanket lockdown is more likely to produce a loss.

Optimization of Local Lockdown Strategy

Partial lockdowns have lower cost than blanket lockdowns. According to equation 13, the balance between benefits and losses in a local lockdown is mainly determined by 3 factors: the duration of the lockdown, the size of the covered population, and the OCFR. The benefit from lockdowns primarily comes from reducing the disease losses caused by the epidemic, while losses are mainly due to the reduction in social per capita output, influenced by both the scale and duration of the lockdown. The ratios for different lockdown groups can vary, such as 1:3 (a family of three), 1:5 (5 mixed with 1), 1:10 (10 mixed with 1), 1:20 (20 mixed with 1), 1:40 (a unit), 1:200 (a building), and 1:2000 (a community) for closed management. If benefit calculations only consider the avoidance of infection among isolated individuals, redundant costs arise, as a certain proportion of uninfected individuals in the locked-down area will also waste socially effective labor time. The hyperbolic relationship between population ratio and duration is depicted in Figure 3, in which the upper part of the curve corresponds to losses and the lower left indicates benefits; the darker the color, the greater the likelihood of generating a benefit. When the OCFR is high, the area for benefits (the lower left of the balance line) becomes larger, indicating more flexibility in the scale and duration of the lockdown. When the OCFR is 10% and 1 person in a family of 4 is infected, the maximum lockdown time is 26 days. At this time, in order to reduce the lockdown rate and increase the lockdown benefit, the infected people can be centrally isolated, such as in a shelter. In January 2023, the OCFR for Omicron was less than 0.5% [18], which means that if more than 3 people in close contact were quarantined (with 3 nucleic acid tests mixed with 1), then a state of loss would begin after 2 days, and the quarantine and control measures would be unproductive.

Discussion

Principal Results

The management of COVID-19 health emergencies is a huge public challenge, and as of November 28, 2022, the global COVID-19 pandemic had affected a total of 640 million individuals and resulted in 6.63 million fatalities. In China, 9.63 million cases were recorded and 30,000 deaths reported. [20] Remarkably, the lockdown measures implemented in China demonstrated a significant impact, resulting in an estimated reduction of 100 million COVID-19 cases and 1.16 million deaths compared to the global average. China’s approach has thus proved highly effective in the battle against the pandemic.
and yielded substantial gains. Thus, this paper contributes to documenting and characterizing the history of the pandemic from an epidemiological perspective, refining knowledge about pandemics, enhancing the exploration of the effectiveness of pandemic response measures, establishing the boundary conditions for exiting a strong pandemic response, shortening the emergency transition time of the early response, and providing a knowledge base for designing and framing future pandemic scenarios.

This study discusses 2 types of lockdown strategies: blanket lockdowns and partial lockdowns. In the early stages of a pandemic, when detection levels are low, a blanket lockdown can delay the spread of the epidemic, thereby easing the burden on hospitals and allowing medical institutions time for emergency preparations. When the number of infected people is small and concentrated, improved detection capabilities, such as nucleic acid detection and other methods, can accurately locate and identify infected individuals. Then, a partial lockdown can gradually replace the blanket lockdown. When a person is confirmed to be infected, close contacts (e.g., direct contacts) or secondary contacts (e.g., indirect contacts) can be identified based on epidemiological findings. The isolation ratio boundary calculated in this study determines which type of contact should be isolated. However, lockdowns based solely on mass nucleic acid screening may not be suitable for all countries. From the perspective of survival and evolution, viruses tend to evolve toward decreased virulence and increased transmissibility. Therefore, with an increasing virus transmission rate and the presence of false negatives in nucleic acid testing, lockdown measures assisted by such screening become largely ineffective, and gatherings for mass nucleic acid testing increase the risk of infection. At this stage, zero transmission is basically impossible to achieve. When herd immunity has not been achieved, long-term, large-scale lockdowns and partial lockdowns are ineffective and only slow the spread of the epidemic, rather than stop it, while imposing a significant economic burden. In this context, sewage virus detection has emerged as a crucial complement. Experience gained from sewage virus monitoring in Hong Kong shows that this method has high sensitivity, reliably detecting 1 positive patient per 20,000 to 40,000 people at a 95% confidence level. Additionally, it can forecast the number of infected individuals 1 to 4 days in advance. Sewage virus detection not only reduces the cost of nucleic acid aggregation testing and the risk of infection but also minimizes the negative impact on productivity and daily life. Each sewage monitoring point can save the effective social time of around 30,000 people who would otherwise be waiting in queues for nucleic acid testing, thus promoting production and decreasing the spread of the epidemic. With many countries worldwide working toward establishing sewage virus monitoring systems, it is foreseeable that this approach will play a critical role in global epidemic prevention and control in the future.

Limitations
This study has certain limitations. First, lockdown strategies based on large-scale nucleic acid screening, as implemented in China, may be relatively uncommon in other countries due to factors such as strong government capacity for management and implementation, public cooperation, and the economic ability to bear the associated costs. Consequently, these strategies may not be feasible for all countries and regions. While large-scale nucleic acid screening can effect and accurately identify infected individuals, false-positive results from nucleic acid tests may undermine the effectiveness of lockdown measures. Furthermore, queues and gatherings of individuals awaiting nucleic acid testing could undermine social distancing efforts and increase the risk of infection.

Second, the calculation of the half-life of the OCFR in this study is based on values derived from GISAID (Global Initiative on Sharing All Influenza Data) statistics rather than the virus’s inherent fatality rate. The OCFR is affected by various factors at different stages of human infection, such as the capacity for detection and screening, active infection (e.g., vaccination), and the enhancement of immunity due to repeated passive infections. While the WHO mandates the inclusion of asymptomatic infected individuals in the case fatality rate calculations, the deficiency in early screening capabilities across different countries and regions resulted in an overestimation of the OCFR’s actual impact on mortality. Conversely, the OCFR tends to underestimate the true mortality rate of the strain when there is an improvement in immunity during later stages. Consequently, this introduces a certain degree of uncertainty.

Last, the model is calculated on the basis of short-term economic losses. However, the long-term economic impact of COVID-19 lockdown measures is complex and profound. The economic pressures imposed on society and households by these measures often result in increased drug abuse, mental illness, domestic violence, and even suicide. Given the significant individual variations in these outcomes, our research team is currently tracking the long-term effects of COVID-19. However, we have yet to accumulate long-term cohort tracking data. In future research, we will consider this aspect using more sophisticated models.

Conclusions
This study shows that with the continuous enhancement of detection capabilities and the continuous formation of population immunity, the OCFR of COVID-19 decreases exponentially, and the half-life is about 8 months. In the infectious disease lockdown strategy model, there is a close correlation between the benefits of lockdown and OCFR. During the early transmission period of SARS-CoV-2, especially under conditions of high OCFR, the lockdown strategy in Wuhan brought huge health benefits to the population. However, as the OCFR decreases, these health benefits gradually diminish and eventually transition into losses. Although large-scale lockdown strategies may not be universally applicable for political reasons, they appear to be the least disruptive option in the early stages of an outbreak. The partial lockdown model mentioned in this study can provide a reference for various countries and regions. This study establishes a connection between saving lives and
protecting the economy, indicating that these 2 objectives are not opposites.

This study provides a critical scientific basis for policy makers, guiding the appropriate timing for the implementation or relaxation of lockdown measures. It offers essential insights for formulating public health management strategies related to COVID-19 and future pandemics, providing indispensable reference information for governments and decision-making entities. By integrating thorough risk assessments with economic impact analyses, our research aims to develop more effective and compassionate approaches to pandemic response, with dual objectives: to protect public health and safety and to minimize negative impacts on the socioeconomic landscape.

Abstract

Background: Target systolic blood pressure (SBP) levels for older adults with hypertension vary across countries, leading to challenges in determining the appropriate SBP level.

Objective: This study aims to identify the optimal SBP level for minimizing all-cause and cardiovascular disease (CVD) mortality in older Korean adults with hypertension.

Methods: This retrospective cohort study used data from the National Health Insurance Service database. We included older adults aged 65 years or older who were newly diagnosed with hypertension and underwent a National Health Insurance Service health checkup in 2003-2004. We excluded patients who had a history of hypertension or CVD, were not prescribed medication for hypertension, had missing blood pressure or any other covariate values, and had fewer than 2 health checkups during the follow-up period until 2020. We categorized the average SBP levels into 6 categories in 10 mm Hg increments, from <120 mm Hg to ≥160 mm Hg; 130-139 mm Hg was the reference range. Cox proportional hazards models were used to examine the relationship between SBP and all-cause and CVD mortalities, and subgroup analysis was conducted by age group (65-74 years and 75 years or older).

Results: A total of 68,901 older adults newly diagnosed with hypertension were included in this study. During the follow-up period, 32,588 (47.3%) participants had all-cause mortality and 4273 (6.2%) had CVD mortality. Compared to older adults with SBP within the range of 130-139 mm Hg, individuals who fell into the other SBP categories, excluding those with SBP 120-129 mm Hg, showed significantly higher all-cause and CVD mortality. Subgroup analysis showed that older adults aged 65-74 years had higher all-cause and CVD mortality rates according to SBP categories than those aged 75 years or older.

Conclusions: The SBP levels within the range of 120-139 mm Hg were associated with the lowest all-cause and CVD mortality rates among older Korean adults with hypertension. It is recommended to reduce SBP to <140 mm Hg, with 120 mm Hg as the minimum value for SBP, for older Korean adults with hypertension. Additionally, stricter SBP management is required for adults aged 65-74 years.

Introduction

The older adult population is growing globally at a faster rate than that in previous years [1]. The World Health Organization expects the number of older adults to rise from 1 to 2 billion between 2019 and 2050, and in 2050, 22% of the world’s population is expected to comprise older adults [1]. In Korea, the aging population is progressing more rapidly than in other countries; it is expected that the proportion of the older adult population will exceed 20% in 2025, 30% in 2035, and 40% in 2050 [2]. To maintain quality of life with longevity, managing chronic disease is important in this population.

Cardiovascular disease (CVD), such as myocardial infarction, stroke, and heart failure, is the leading cause of death worldwide [3], and hypertension is one of the primary modifiable risk factors for CVD mortality [4]. Hypertension is very common in older adults because their systolic blood pressure (SBP) tends to be elevated due to increased stiffness and decreased elasticity in the arteries with aging [5]. Epidemiologic research by the United States National Health and Nutrition Examination Survey has indicated that 76.5% of older adults aged older than or equal to 65 years have hypertension [6]. Moreover, older adults with hypertension are more susceptible to CVD than younger adults with hypertension [7]; therefore, controlling the blood pressure of older adults is extremely important to prevent CVD.

However, the guidelines for target blood pressure levels in older adults with hypertension are inconsistent across countries. In 2017, the American College of Cardiology and the American Heart Association (ACC/AHA) revised the guidelines for the diagnostic criteria of hypertension from 140/90 mm Hg to 130/80 mm Hg. They recommend a target SBP level of <130 mm Hg in older adults with hypertension [8]. These guidelines are equivalent to the 2022 Taiwan Hypertension Guidelines of the Taiwan Society of Cardiology and the Taiwan Hypertension Society for the management of hypertension, recommending that blood pressure treatment in older adults should be initiated when SBP is ≥130 mm Hg; the target SBP level is <130 mm Hg [9]. On the other hand, the European Society of Cardiology and the European Society of Hypertension guidelines of 2018 maintain the previous criterion of hypertension as >140/90 mm Hg and recommend a target SBP range of 130-139 mm Hg, while advising against lowering it below 130 mm Hg due to potential risks without additional benefits [10]. This is similar to the 2019 Chinese guideline for the management of hypertension in older people, which recommends a target blood pressure level of <140/90 mm Hg [11]. The differences in target SBP levels across countries are related to variability in the prevalence of hypertension and CVD mortality rates among different racial and ethnic groups or regions [6,12,13]. Therefore, the diagnostic and treatment guidelines of hypertension are different across countries, making it difficult to achieve optimal blood pressure management in older adults and leading to challenges in determining the appropriate interventions.

In Korea, the 2022 guidelines for the management of hypertension published by the Korean Society of Hypertension (KSH) still maintain the diagnostic criterion for hypertension as >140/90 mm Hg [14]. Additionally, they recommend lowering SBP to <140 mm Hg for older adults with hypertension [14]. However, the KSH guidelines have a limitation in that they are based on research findings that may not specifically include data from older adults in Korea [15-18]. Therefore, further studies are needed to explore the optimal blood pressure levels for older Korean adults with hypertension.

In addition, previous studies conducted to determine the optimal blood pressure levels for older adults with hypertension have been limited by not investigating the impact of age differences. The 2019 Japanese Society of Hypertension guidelines recommend different target blood pressures for different age categories—<130/80 mm Hg in patients aged younger than 75 years and <140/90 mm Hg in those aged 75 years and older. This is because lowering SBP to <130 mm Hg in individuals aged 75 years or older may potentially result in adverse health outcomes, such as renal dysfunction [19]. However, to the best of our knowledge, no studies have identified age differences in optimal SBP levels in older Korean adults. Analyzing the impact of age-related differences in SBP on all-cause and CVD mortalities among older Korean adults with hypertension is an important indicator of future blood pressure management. Therefore, this study aimed to investigate (1) the effects of SBP on all-cause and CVD mortalities in older adults with hypertension and (2) the associations stratified by age (65-74 years and 75 years or older).

Methods

Study Design and Sample

This retrospective cohort study used data from the National Health Insurance Service (NHIS) database. The NHIS is a single obligatory social insurance system covering health care service costs in Korea. The entire population residing in Korea subscribes to mandatory social insurance, and all medical care institutions claim medical fees. The claims include medical information, such as diagnosis, prescription, medication, and data collected from the NHIS database. Because the NHIS also provides general health checkups biennially for all insured adults (annually for nonoffice workers) and collects health checkup data, the NHIS database is useful for continuously observing the health status of the Korean population. The NHIS database was initiated in 2002 and we followed up data until 2020.

We included older adults who (1) were aged 65 years or older, (2) were newly diagnosed with hypertension (Korean Classification of Disease [KCD] code I10), and (3) underwent the NHIS health checkup in 2003-2004. We excluded patients who (1) had a history of hypertension or CVD, (2) were not prescribed medication for hypertension, (3) had missing blood pressure or any other covariate values, and (4) had fewer than 2 health checkups during the follow-up period. Characteristics of the study population are shown in Figure 1. A total of 68,901 participants were eligible and were followed up until 2020.
Ethical Considerations
Ethics approval was obtained from the institutional review board of Yonsei University Health System (4-2021-1277), and the study complied with the Declaration of Helsinki. The NHIS database was anonymized to ensure confidentiality, and informed consent was not required because this was a retrospective study using the NHIS database.

Measurement
The independent variable in our study was the mean SBP measured during the health checkups. Blood pressure was measured using an automatic blood pressure monitor placed in front of the examiner after the participant had stabilized for at least 5 minutes. If the SBP was >120 mm Hg or the diastolic blood pressure was >80 mm Hg, the blood pressure measurement was repeated after at least 2 minutes. In this study, we categorized the SBP into 6 categories in 10 mm Hg increments from <120 mm Hg to ≥160 mm Hg, and 130-139 mm Hg was used as a reference category.

The dependent variables were all-cause and CVD mortalities. The CVD mortality was defined as death from myocardial infarction (KCD codes I21-23), heart failure (KCD code I50), hemorrhagic stroke (KCD codes I60-62), or ischemic stroke (KCD code I63). Data on the dates and causes of mortality were obtained from Statistics Korea.

Sociodemographic characteristics, health behaviors, blood test results, and hypertension medications were included as covariates. The sociodemographic characteristics included age, sex, and BMI. Age was classified as 65-74 years and 75 years or older. Health behaviors included smoking status, physical activity, and the Charlson Comorbidity Index. Blood test results included fasting glucose, total cholesterol, aspartate transaminase, and alanine transaminase. Hypertension medications included renin-angiotensin system blockers (angiotensin-converting enzyme inhibitors and angiotensin receptor blockers), beta-blockers, dihydropyridine calcium channel blockers, and diuretics.

Statistical Analysis
Descriptive analyses were used to describe sample characteristics. Continuous variables were described as means (SDs), and categorical variables were described as numbers and percentages. Thereafter, Kaplan-Meier curves and Cox proportional hazards models were used to identify the relationship between SBP and all-cause and CVD mortalities after adjusting for other covariates. A subgroup analysis was performed to identify age-related differences in the risk of all-cause and CVD mortalities according to SBP. All statistical analyses were performed using SAS (version 9.4; SAS Institute Inc), and the significance level was set at P<.05.

Results
In total, 68,901 older adults newly diagnosed with hypertension were included in this study. We divided them into the following SBP categories: 5666 (8.2%) as <120 mm Hg, 17,236 (25.0%) as 120-129 mm Hg, 25,277 (36.7%) as 130-139 mm Hg, 14,299 (20.8%) as 140-149 mm Hg, 4663 (6.8%) as 150-159 mm Hg, and 1760 (2.6%) as ≥160 mm Hg. Among the participants, 57,831 (83.9%) were aged 65-74 years and 11,070 (16.1%) were aged 75 years or older. The general characteristics of the study participants are presented in Table 1.

Figure 2 shows the Kaplan-Meier curves for the cumulative incidence of all-cause and CVD mortalities according to the
SBP category. The incidence of all-cause and CVD mortalities varied between SBP categories; older adults with SBP 160 mm Hg had the highest mortality rate, while those with SBP within the range of 130-139 mm Hg had the lowest mortality rate.

Figure 2. Kaplan-Meier curves for all-cause and CVD mortality according to SBP. CVD: cardiovascular disease; SBP: systolic blood pressure.

Table 2 shows the results of the Cox proportional hazards models for all-cause and CVD mortalities according to SBP categories. During the follow-up period, 32,588 (47.3%) patients had all-cause mortality and 4273 (6.2%) had CVD mortality. Compared to participants with SBP within the range of 130-139 mm Hg, those with SBP <120 mm Hg had a significantly higher all-cause (hazard ratio [HR] 1.40, 95% CI 1.35-1.46) and CVD mortality (HR 1.42, 95% CI 1.27-1.58) rate. These results were similar in participants with SBP within the range of 140-149 mm Hg, 150-159 mm Hg, and ≥160 mm Hg, in that the participants falling into these SBP categories had significantly higher all-cause and CVD mortality rates compared with those with SBP within the range of 130-139 mm Hg. However, when compared with participants with SBP within the range of 130-139 mm Hg, those with SBP within the range of 120-129 mm Hg did not show a significant difference in either all-cause (HR 1.02, 95% CI 0.99-1.05) or CVD mortality (HR 1.00, 95% CI 0.92-1.09).

Results of the subgroup analysis for the effect of SBP on mortality stratified by age (65-74 years and 75 years or older) are shown in Figure 3. In both age categories, there was a significantly lower mortality rate in the 130-139 mm Hg SBP category than in the other SBP categories, except for the 120-129 mm Hg category. Moreover, those aged 65-74 years showed a higher HR of all-cause and CVD mortalities according to the SBP categories than those aged 75 years or older.

Discussions

Principal Findings

In this retrospective cohort study, the rates of all-cause and CVD mortalities were significantly lower in older adults with hypertension and SBP within the range of 130-139 mm Hg than in the other SBP categories, except for those with SBP within the range of 120-129 mm Hg. These findings suggest the importance of managing SBP within the range of 120-139 mm Hg to lower all-cause and CVD mortality risks in older adults with hypertension. The optimal target SBP level was 120-139 mm Hg in both age groups (65-74 years and 75 years of age or older), and the impact of SBP on mortality was generally higher in older adults aged 65-74 years, indicating that more stringent SBP control is required in these patients than in their older counterparts.

Our results are consistent with the SBP goal of the 2022 KSH guidelines of <140 mm Hg [14]. The 2022 KSH guidelines have limitations in that the target SBP level for older adults with hypertension was established based on the findings of studies conducted on non-Korean participants [15-18]. Additionally, 1 of the main reasons for the unchanged target SBP level of the 2022 KSH guidelines compared to the 2018 KSH guidelines is that there is still insufficient evidence regarding the optimal target SBP level [14]. Our study provides empirical evidence for the optimal SBP level of older adults with hypertension in Korea to reduce all-cause and CVD mortality rates.

This study showed the presence of a J-curved relationship between SBP and CVD risk, indicating that lowering SBP to below 120 mm Hg increased all-cause and CVD mortalities compared with SBP within the range of 130-139 mm Hg. This result was consistent with an international cohort study on 22,672 patients with coronary artery disease [20] and the data from 2 randomized controlled trials (RCTs) on 30,937 patients with high cardiovascular risk [21], which showed that SBP within the range of 120-139 mm Hg had the lowest risk of cardiovascular events, and the risk increased at SBP <120 mm Hg, with a J-curve pattern. Furthermore, 19,110 older adults aged older than or equal to 60 years in the Singapore Chinese Health Study showed that SBP <120 mm Hg tended to increase CVD mortality risk compared with SBP between 120-139 mm Hg, although the risk estimates did not reach statistical significance [22]. However, most guidelines for hypertension management, including the ACC/AHA and KSH guidelines, do not specify the minimal level of SBP. It may be appropriate to suggest the minimum SBP level when scientists and professionals update the hypertension management guidelines. Although several studies on the optimal target SBP level have been conducted, the results remain controversial across countries. The Systolic Blood Pressure Intervention Trial (SPRINT) in the United States showed that an SBP target of <120 mm Hg decreased major adverse cardiovascular events and mortality compared to an SBP target of <140 mm Hg in older adults with hypertension aged 75 years or older [15]. The Strategy of Blood Pressure Intervention in the Elderly Hypertensive Patients trial in China showed that an SBP target of 110-130 mm Hg significantly reduced major adverse cardiovascular events compared to an SBP target of 130-150 mm Hg [16]. The Berlin Initiative Study in Germany showed that SBP of <130 mm Hg is associated with increased all-cause mortality compared to SBP within the range of 140-149 mm Hg [23], whereas another cohort study in England showed that 6311 individuals aged 50-79 years and 1299 individuals aged 80-89 years had no significant associations between SBP levels and all-cause and CVD mortalities [24]. A possible explanation for the different results is ethnic disparities. The prevalence of hypertension and CVD mortality differs across countries [6,12,13]. Asian populations are known to be more vulnerable to hypertension because they tend to have an increased aortic pulse and stiffness than European populations [25], and Asians have a stronger association between blood pressure and CVD than Europeans [25]. Therefore, the target SBP level for hypertension may vary according to race and country.

The estimated risk for all-cause and CVD mortalities increased for every 10 mm Hg increase in SBP above 140 mm Hg, compared to within the 130-139 mm Hg range, regardless of
age group, although the impact of SBP on mortality was slightly higher in individuals aged 65-74 years. However, the relationship between SBP and mortality in older adults remains controversial. A total of 2 RCTs, involving patients aged 75 years and older in the SPRINT [15] and 80 years or older in the Hypertension in the Very Elderly Trial [26], showed that a lower SBP was associated with decreased cardiovascular events. However, several cohort studies suggested that there was no association in older adults 75 years or older [27,28], and some even showed a negative relationship between SBP and cardiovascular events [29,30]. The discrepancies between the RCTs and cohort studies might be that the participants of RCTs were healthier than the general population of the same age because of the restricted inclusion and exclusion criteria [31]. The reason our study revealed an association between increased SBP and higher mortality, unlike other cohort studies, could be attributed to our deliberate selection of healthy older adults who were capable of undergoing health checkups on their own and had no previous history of hypertension or CVD. Therefore, further studies targeting diverse populations (i.e., frail or multimorbid) are needed.

Limitations and Strengths
This study had several limitations. Because we included participants who underwent health checkups between 2003 and 2004, older adults who did not undergo health checkups were excluded. We adjusted for many covariates to alleviate bias, but potential age-related confounding variables, such as frailty, activities of daily living, and gait speed, remained due to data availability. In addition, adverse events of decreased blood pressure, such as renal dysfunction or orthostatic hypotension, were not considered in this study due to data limitations; therefore, we suggest that additional studies exploring optimal blood pressure should include adverse events as 1 of the outcomes. Finally, we used a conventional Cox hazard model with mean SBP measured during the health checkups as an independent variable to facilitate interpretation. However, since SBP is a time-varying variable, a time-dependent Cox model could also have been used. The strengths of this study included the use of the NHIS database, which is nationally representative and includes almost all Koreans, and a large sample size. Our results have sufficient statistical power and can be generalized to older Korean adults with hypertension. In addition, through a 17-year follow-up observation period, our study provided evidence that controlling SBP is crucial for long-term CVD-related health outcomes.

Conclusions
Controlling SBP in older adults with hypertension is important for improving overall and CVD-related health outcomes. However, hypertension guidelines regarding optimal SBP levels differ across countries; therefore, it is necessary to identify the appropriate SBP level among older Korean adults with hypertension. Our retrospective cohort study using national data showed that SBP within the range of 120-139 mm Hg was associated with the lowest risk of CVD and all-cause mortality in older Korean adults with hypertension; therefore, SBP should be controlled within this range in this cohort. Our study also suggested that lowering the SBP to below 120 mm Hg could increase all-cause and CVD mortalities, indicating that caution should be taken not to lower the SBP beyond 120 mm Hg. Additionally, SBP had a greater impact on CVD and all-cause mortality in older adults aged 65-74 years than in those aged 75 years and older; more stringent SBP management is thus required in the 65-74-year age group. This study provides critical knowledge that improves our understanding of the optimal SBP in older Korean adults with hypertension to reduce all-cause and CVD mortality rates. The KSH guidelines only recommend lowering SBP to <140 mm Hg; however, we suggest adding 120 mm Hg as the minimum value.

Abstract

Background: Sleep health is a multidimensional construct that includes objective and subjective parameters and is influenced by individual sleep-related behaviors and sleep disorders. Symptom network analysis allows modeling of the interactions between variables, enabling both the visualization of relationships between different factors and the identification of the strength of those relationships. Given the known influence of sex and age on sleep health, network analysis can help explore sets of mutually interacting symptoms relative to these demographic variables.

Objective: This study aimed to study the centrality of symptoms and compare age and sex differences regarding sleep health using a symptom network approach in a large French population that feels concerned about their sleep.

Methods: Data were extracted from a questionnaire provided by the Réseau Morphée health network. A network analysis was conducted on 39 clinical variables related to sleep disorders and sleep health. After network estimation, statistical analyses consisted of calculating inferences of centrality, robustness (ie, testifying to a sufficient effect size), predictability, and network comparison. Sleep clinical variable centralities within the networks were analyzed by both sex and age using 4 age groups (18-30, 31-45, 46-55, and >55 years), and local symptom-by-symptom correlations determined.

Results: Data of 35,808 participants were obtained. The mean age was 42.7 (SD 15.7) years, and 24,964 (69.7%) were women. Overall, there were no significant differences in the structure of the symptom networks between sexes or age groups. The most central symptoms across all groups were nonrestorative sleep and excessive daytime sleepiness. In the youngest group, additional central symptoms were chronic circadian misalignment and chronic sleep deprivation (related to sleep behaviors), particularly among women. In the oldest group, leg sensory discomfort and breath abnormality complaint were among the top 4 central symptoms. Symptoms of sleep disorders thus became more central with age than sleep behaviors. The high predictability of central nodes in one of the networks underlined its importance in influencing other nodes.

Conclusions: The absence of structural difference between networks is an important finding, given the known differences in sleep between sexes and across age groups. These similarities suggest comparable interactions between clinical sleep variables across sexes and age groups and highlight the implication of common sleep and wake neural circuits and circadian rhythms in understanding sleep health. More precisely, nonrestorative sleep and excessive daytime sleepiness are central symptoms in all groups. The behavioral component is particularly central in young people and women. Sleep-related respiratory and motor...
symptoms are prominent in older people. These results underscore the importance of comprehensive sleep promotion and screening strategies tailored to sex and age to impact sleep health.

Introduction

Sleep health is a multidimensional construct that includes objective and subjective parameters and is influenced by individual sleep-related behaviors [1] and sleep disorders, measurable by a set of techniques ranging from psychometry [2,3] to mobile devices [4,5]. Sleep health is not merely the absence of sleep disorder symptoms; it also includes factors such as sleep disturbance and satisfaction with sleep [6,7]. Moreover, sleep health considers the importance of sleep behaviors reinforcing both the homeostatic (duration of sleep) and the circadian (regularity and time of sleep) system that underpin sleep quality [8]. Good-quality sleep is important for overall health [9], but sleep is influenced both by age and by sex [10-12].

Sleep architecture evolves from birth to old age, with changes in the macro- and microstructure that are underpinned by neuroanatomical changes in both homeostatic and circadian systems [13]. More precisely, sleep evolves across the lifespan, with the development of a 24-hour circadian rhythm, a progressive reduction in daytime naps, and a gradual reduction in the quantity of slow-wave sleep (N3) in the early years. From the fifth decade onward, advanced sleep timing, longer sleep onset latency, shorter nighttime sleep potentially compensated by daytime naps, increased wake after sleep onset (WASO), increased fragmentation, a lower threshold for wake from sleep due to external stimuli, reduced N3, and consequently increased light sleep (N1 and N2) from the fifth decade are seen [11,12,14-22]. These later changes are accompanied by changes in the microstructure of sleep with a loss of the homeostatic drive expressed as reductions in slow-wave amplitude and density [23] and modifications in spindles and K-complexes [24,25]. Neuronal loss with age underpins changes in both homeostatic and circadian systems. Changes in spindles are potentially related not only to a loss of the hippocampal gray matter [26] but also to a loss of the functional integrity of corticothalamic loops [27]. A loss of suprachiasmatic nucleus (SCN) neurons, notably vasofactorial intestinal peptide (VIP)-expressing ones, may contribute to changes in the circadian rhythm [28].

Sex-determined differences in the sleep macro- and microstructure are detectable from an early age, with differences in sleep disorders increasing from early puberty onward [29]. Certain sleep disorders are more frequent in men (eg, obstructive sleep apnea syndrome) [30], while others are more frequent in women (eg, insomnia disorder) [31], and these differences modulate over the lifespan. Concerning the impact of sex according to age, biological sex markedly affects sleep, and differences are detectable in newborns, with increased divergence at puberty [29]. Changes in sleep with age are modulated by sex: the marked reduction in slow-wave sleep in men over 70 years does not affect women, although reductions in rapid eye movement (REM) sleep are seen in both [12]. Numerous sex-related differences are seen at an anatomical level: larger male-specific declines are seen in galanin-expressing neurons, orexin neurons, neuromelanin-sensitive neurons in the locus coeruleus (LC), and VIP-expressing neurons in the SCN. Women report subjective changes in sleep related to menopause, with increased insomnia and reduced sleep quality [32], although this is difficult to demonstrate objectively via polysomnography [33]. Biological sex also affects sleep disorders: obstructive sleep apnea is more common in men [30] and insomnia in women [31]. In addition, sleep behaviors may vary between men and women: as circadian timing is phase-advanced in women [34], women have earlier bedtimes [35] and an earlier chronotype, although this reverses after the age of 40 years [36].

The multifactorial components contributing to sleep health are adapted to network analysis for several reasons. First, unlike a certain number of other models limiting the number of variables analyzed (eg, due to an increase in the type 1 error), symptom network analysis offers an original way to model the interactions between numerous sleep-related clinical variables according to other sociodemographic ones. In this way, it offers a more holistic view of sleep health. Second, traditional studies often examine symptoms individually, looking at their interconnected impacts. This computational network analysis not only allows visualization of the relationships between these variables but also helps identify the strength of those mutual relationships. The analysis of these interactions seems particularly important in the context of sleep health, whose mutual influencing factors have been largely undetermined until now. Third, identifying the most influential symptoms across varying age and sex demographics, by considering a large number of variables and the interactions between them, provides a clearer roadmap for health care and public health interventions. Finally, symptom network analysis has the potential for sleep health promotion at both a local and a global scale by identifying screening strategies that are sensitive to the nuanced differences across populations.

In our previous work using a data-driven network analysis approach in a large data set including sleep disorders, sleep disturbances, sleep-related behaviors, and comorbidities as variables, the most central variables were a complaint of nonrestorative sleep, excessive daytime sleepiness, circadian irregularity, and chronic sleep deprivation [37]. The latter 2 variables are linked to the circadian system and the homeostatic system, respectively, whereas the complaint of nonrestorative sleep, or not feeling refreshed on waking, is a relatively little studied concept compared to its potential importance for patients...
Finally, the complaint of daytime sleepiness can be considered a consequence of poor sleep, and as such, its centrality is unsurprising, given its importance for sleep physiology and for its historical and methodological centrality in the construction of sleep classifications and its relevance in clinical practice [40-43].

Given the known influence of sex and age on sleep health, extending our analysis to consider these variables is highly pertinent as network analysis explores sets of mutually interacting symptoms. It can thus detect whether the differences between groups (eg, of sex or age) may or may not be explained by some specific symptoms. Thus, although group comparison based on frequency statistics only provides an index of difference (eg, a $P$ value), network analysis provides insight into which factors drive differences.

The objective of this work was to study the centrality of symptoms and to compare age and sex differences in the experience of sleep using a cross-sectional approach of comparative network analysis in a population that feels concerned by their sleep. First, we aimed to analyze the relationships between the components of these sleep networks between 2 populations, men, and women. Second, we studied these relationships according to different age classes. For these 2 analyses (sex and age), we studied the potential differences in centrality (ie, the importance), predictability, and connections between different factors related to sleep symptoms, sleep behavior, and the effects of sleep.

Methods

Data Collection

The Réseau Morphée is a nonprofit organization funded by the French government (regional health authority), aiming to improve patient care pathways in sleep health. In 2017, the new patient care pathway was launched, offering a comprehensive online questionnaire as the initial port of entry. The questionnaire looks at 5 domains: sociodemographic data (age and sex), symptoms of sleep disorders, sleep disturbances, sleep behaviors, and comorbidities [40]. In total, 39 variables were analyzed. We prioritized data extraction based on clinical relevance, guaranteeing it aligned with both clinical and public health relevance (and reinforcing by analysis of robustness). We also provided an example of the analyses by adding a variable (the BMI) in order to discuss such an addition and its implications. Data from 3 validated scales were included: the Epworth Sleepiness Scale (ESS; excessive daytime sleepiness score<10) [44], the Insomnia Severity Index (ISI; clinical insomnia score>14) [45], and the Hospital Anxiety and Depression Scale for anxiety (HADS-A) and depression (HADS-D) (scores>10 for each) [46].

Ethical Considerations

Patients were informed about the use of their data for epidemiological research when data were originally collected. Informed consent was obtained from all participants included in the study. The study was approved by the scientific committee of the Réseau Morphée and by 2 patient associations, the Sommeil et Santé and the France Insomnie. As a noninterventional study (MR004), this research was approved by the Commission Nationale Informatique et Liberté (CNIL; approval number: 8013081; date of approval: December 19, 2016). Only data from participants over the age of 18 years were included in the analysis. The anonymization of data provides confidentiality and total respect for the privacy of participants. No publicity was used to attract participation. No financial compensation was provided for participating in the study.

Participants

Participants were French-speaking members of the general population who filled in an online questionnaire aimed at people concerned about their sleep. This population does not present people who already experience sleep problems but rather people who are sufficiently concerned about their sleep to use the Réseau Morphée online questionnaire. They were not in contact with sleep services and thus did not have a formal diagnosis of their sleep problems. We included all respondents over 18 years old from March 1, 2017, to September 9, 2020. All participants in our study speak French, but all may not be currently residing in France. Regarding demographic data, we collected the sex and age of each participant. As specified later in the Limitations section, we considered the person’s sex as assigned at birth, not gender as defined by the person, and we chose to use the terms “men” and “women.” The entire sample was divided into 4 age groups: 18-30, 31-45 years, 46-55, and >55 years. Age group stratification was determined by known sociodemographic boundaries in France; the 18-30-year group is either still in education or in the early stages of their careers and less likely to have children (the mean childbearing age in France was 30.9 years in 2021 according to the [47]). Participants aged 31-45 years are settled in their careers and may have children. The 46-55-year group was chosen specifically to isolate the period of the menopause, during which sleep complaints in women markedly increase [32]. We provided the number of men and women (sex), the mean (SD) of age, and the BMI for the ESS, the ISI, the HADS-A, and the HADS-D, and we detailed these measurements by age group.

Network Estimation, Inferences, Robustness, and Comparison

The main aim of this network analysis was to analyze a set of 39 variables described by a large population divided into several subpopulations by age and sex to compare the subpopulations. To this end, 6 networks were constructed for comparison: a men’s network, a women’s network, and a network for each age group (18-30, 31-45, 46-55, and >55 years).

In this methodology, the correlations between items were understood as a network in which each item represents a node and where correlations between symptoms are connections (or edges) between nodes. A connection between any 2 symptoms was said to exist if those symptoms were present in the same individual. Symptoms of 2 different disorders were connected if the symptoms were present in different individuals. We followed the network guidelines for computational analysis of network properties [48].
Network Estimation

Network estimation was conducted with the Ising Model, which is, to date, the state-of-the-art network model used in psychopathology research for binary data (see Multimedia Appendix 1 [49-69] for details on symptom networks) associated with a regularization technique called graphical least absolute shrinkage and selection operator (LASSO) [59,60]. The final model was chosen by using the extended Bayesian information criterion (EBIC) [61].

The network was graphically represented according to the Fruchterman-Reingold algorithm, where variables with stronger or more connections are placed closer to each other [62]. Nodal predictability was calculated based on models derived from mixed graphical models (MGMs) [63,70] and graphically represented as a pie chart in the ring around each variable. Predictability has a value between 0 and 1, provided on the basis of the variance of the prediction error calculated according to the $R^2$ of the MGM. It refers to how well a given node in the network can be predicted by all remaining nodes. It thus shows how relevant edges are (eg, a node may be connected to many other nodes, but if these only explain only 1% of its variance, it is unlikely that this node is relevant). This has further implications: for example, designing an intervention to affect certain nodes or detecting where data are lacking (eg, when parts of the network are little influenced by related nodes and thus must depend on external factors). In clinical practice, the predictability of a symptom indicates “whether an intervention on that symptom through the symptom network is promising” [70]. The predictability of sexes and age groups is given in Multimedia Appendix 2.

In agreement with previous work [37] and the main international sleep-wake classifications [71,72], as well as to facilitate the reading of the graphic representations, we classified elements from the questionnaire into 8 groups: hypersomnia symptoms, insomnia symptoms, respiratory symptoms, motor symptoms, psychiatric symptoms, sleep disturbance, sleep behaviors, and comorbidities. These groupings had no impact on the main results of the study and were only given for data visualization purposes.

Network Inferences

The most clinically relevant network inferences correspond to centrality measures [64]. Centrality measures are important for identifying symptoms that play a crucial role in connecting all the symptoms of a network [65]. Nodes with high centrality index measures represent variables that are highly connected to other variables. Precisely, 4 measures are classically described: strength, closeness, betweenness, and expected influence [66]. The strength of a node computes the degree to which it is connected with all the other nodes of the network [67]. The 3 other centrality measures are described in Multimedia Appendix 1. The centrality strengths of age groups and sexes were plotted and are detailed in Multimedia Appendix 2. The color (red=0, green=1) and bar plot of each symptom provide visual insight into the $P$ value. Symptoms were sorted in descending order of strength and predictability.

Network Comparisons

The networks were systematically compared between men and women and between the 4 age groups (18-30, 31-45, 46-55, and >55 years). Cross-age and cross-sex networks were compared between each other with a network comparison tool, providing significance indices for the overall structures of the networks and allowing us to evaluate the differences between each network.

We used the network comparison test (NCT) [73], a 2-tailed permutation test that examines differences between 2 networks. This test analyzes the difference in terms of relationships between (1) variables connections (“Are the connections between variables different between the 2 networks?”) and (2) centrality measures, named global strength (“Is the centrality of the variables different between the 2 networks?”). The NCT therefore presented 2 results: a comparison of connections between variables and a comparison in terms of centrality. $P<.05$ was considered a statistically significant difference.

There is a potential risk of loss of power when the samples are not of equal size [61]. To deal with our unequal sample, we subsampled the larger data set to the size of the smaller data set 5 times. This meant we ran the NCT 5 times, with 2000 replications for each comparison [74]. We presented the average of the results without adjusting the $P$ values for multiple testing.

Moreover, to offer inferences on the comparison between networks at the level of each symptom, we computed the local symptom-by-symptom correlations between the nodes of the 2 networks, with a $P$ value resulting from the permutation test concerning differences both in global strength and in edges weights. Local symptom-by-symptom correlations ($P$ value based on permutations) between the strength by sex and by age are given in Multimedia Appendix 3. Local symptom-by-symptom correlations ($P$ value based on permutations) between connections by sex and by age are also given in Multimedia Appendix 3. The color (red=0, green=1) and bar plot of each symptom provide visual insight into the $P$ value. The symptoms were sorted according to the order of the figures in the paper. However, we only discussed the most relevant relationships rather than variables systematically significantly associated, which should only be interpreted according to all the other relationships of the network.

Network Robustness

To verify that the number of participants was adequate to perform such a network analysis, we studied the robustness of the network using bootstrap analysis (N=2000 iterations) [68,69]. The robustness of the results was tested on a centrality measure, the strength (ie, we checked the stability of edges and centrality measures). We used a case-dropping subset to assess the stability of this centrality measure, providing a centrality stability correlation coefficient (ie, correlation stability [CS] coefficient; we computed how well the order of centralities was retained after observing only a subset of the data): the CS coefficient (ie, the maximum proportion of participants that could be dropped, while maintaining 95% probability that the correlation between centrality metrics from the full data set and...
the subset data was at least 0.70). Based on a simulation study [68,69], a minimum CS coefficient of 0.25 was recommended.

All analyses and graphical visualizations were performed in R version 4.2.2 (R Foundation for Statistical Computing). Generative artificial intelligence (AI) was not used at any point.

**Results**

**Participant Details**

Table 1 provides details of the study sample. There were twice as many women (n=24,964, 69.7%) as men (n=10,844, 30.3%).

Sleep Health Network Analysis

**Network Estimation**

Each network contained 39 nodes (items) and 741 edges (connections), with a mean weight of 0.011 (SD 0.005). Figure 1 presents results of the sleep health network analysis related to sex groups, with negative edges. The predictability of sexes and age groups is given in Multimedia Appendix 2.
Figure 1. Sleep networks related to sex groups of a French-speaking adult population concerned about their sleep (N=35,808). (A) Women’s network. (B) Men’s network. Blue edges (connections) represent the positive associations between variables and orange edges the negative associations. The thickness of the line represents the level of correlation between 2 variables. The predictability of the nodes is depicted as a pie chart in the rings around the nodes: the area in the outer ring of a node represents the percentage of variance of the node that is explained by all neighboring nodes. Color groupings are only given for data visualization purposes. A higher-resolution version of this image is available in Multimedia Appendix 4.

Results of the sleep health network analysis related to age groups are shown in Figure 2. In the figure, the 2-to-2 relationships, conditional on all other relationships between nodes in the network, can be visualized.
Figure 2. Sleep networks related to the 4 age groups of a French-speaking adult population concerned about their sleep (N=35,808). (A) 18-30 years, (B) 31-45 years, (C) 46-55 years, and (D) >55 years. Blue edges (connections) represent the positive associations between variables and orange edges the negative associations. The thickness of the edges represents the level of correlation between 2 variables. The predictability of the nodes is depicted as a pie chart in the rings around the nodes: the area in the outer ring of a node represents the percentage of variance of the node that is explained by all neighboring nodes. Color groupings are only given for data visualization purposes. A higher-resolution version of this image is available in Multimedia Appendix 4.

We first deduced from the graphical presentation which node-by-node correlations were the most relevant. In the women’s network, it was interesting to see that nonrestorative sleep was strongly negatively associated with early insomnia ($r=-0.2$). Similarly, in the men’s network, excessive daytime sleepiness was strongly negatively correlated with wakefulness satisfaction ($r=-0.26$) but positively correlated with falling asleep while driving ($r=0.23$) or with naps ($r=0.2$). Across the different age group networks, a number of relationships were consistently found, for example, between the symptoms nonrestorative sleep and awakening difficulties ($r=0.39$, $0.39$, $0.36$, and $0.38$ in the 18-30–, 31-45–, 46-55–, and >55-year age groups, respectively, in ascending order), as well as weak relationships between breathing abnormalities observation and nighttime leg pain ($r=0.12$, $0.08$, $0.01$, and $0.1$ in the 18-30–, 31-45–, 46-55–, and >55-year age groups, respectively, in ascending order).

Predictability results (ie, if a given node could be predicted by adjacent nodes) were interesting when identifying relevant relationships. For instance, in the women’s network, the 6 most central nodes had the following centrality values: nonrestorative sleep, 2.50; excessive daytime sleepiness, 1.70; chronic sleep deprivation, 1.53; chronic circadian misalignment, 1.40; leg sensory discomfort, 1.08; and wakefulness satisfaction, 0.87, as shown in Figure 3. These symptoms were also among the most predictable: predictability values were 0.54, 0.40, 0.68, 0.36, 0.33, and 0.39, respectively (mean 0.26, SD 0.15). All the predictability measures (variance) are given in Multimedia Appendix 2. However, in the women’s network, for nearly identical centrality, chronic sleep deprivation had greater predictability (0.68) than chronic circadian misalignment (0.36), roughly two-thirds to one-third. This result illustrates the need to consider the first of these nodes as being highly predictable but also central to modifying other nodes.
Network Centrality

In terms of the local structure, 2 symptoms were found among the 4 most central ones, regarding all the centrality measures of all the networks (for all age and sex groups, see Figure S1 in Multimedia Appendix 1): nonrestorative sleep (belonging to the “sleep disturbances” type) and excessive daytime sleepiness (belonging to the “symptoms of sleep disorders” type). The value of the strength for each measure is given in Multimedia Appendix 2.

This means that these variables exhibited a high degree of connection in the entire sleep network (strength), a high degree of connection with proximal variables of the sleep network after considering negative correlation values (expected influence), the shortest path between 2 other variables (betweenness), and the shortest mean distance from other variables (closeness).

The differences in centrality for the 2 sexes are given in Figure 3. The 3 most important centrality measures for the women’s network were, in descending order, nonrestorative sleep, excessive daytime sleepiness, and chronic sleep deprivation; for the men’s network, these were nonrestorative sleep, chronic circadian misalignment, and excessive daytime sleepiness.

Figure 4 shows the strength (centrality measure) of the 4 age groups in the sleep health network analysis. The 3 most important centrality measures for the 18-30–year network were, in descending order, nonrestorative sleep, chronic circadian misalignment, and excessive daytime sleepiness; for the 31-45–year network, these were nonrestorative sleep, excessive daytime sleepiness, and leg sensory discomfort; for the 46-55–year network, these were nonrestorative sleep, leg sensory discomfort, and excessive daytime sleepiness; and for the >55-year network, these were excessive daytime sleepiness, nonrestorative sleep, and leg sensory discomfort.
Nonrestorative sleep and excessive daytime sleepiness were among the 3 most central symptoms in all 4 groups (strengths were 1.73-2.21 and 1.35-2.19, respectively). However, in the 18-30-year group, the 2 other most central symptoms were chronic circadian misalignment (strength=1.42) and chronic sleep deprivation (strength=1.27), particularly in the women’s network, belonging to the “sleep behaviors” type. Between the ages of 31 and 55 years, the 2 other most central symptoms were chronic circadian misalignment (strength=1.30 for the 31-45-year group and strength=1.32 for the 46-55-year group) and leg sensory discomfort (strength=1.54 for the 31-45-year group and strength=1.78 for the 46-55-year group, belonging to the “motor symptoms” type. In the older group of participants (>55 years old), leg sensory discomfort (strength=1.48) remained 1 of the most central symptoms, while breath abnormality complaint became among the 4 most central symptoms (strength=1.13, belonging to the “respiratory symptoms” type), becoming more central than sleep behaviors found in the youngest. In Multimedia Appendix 4, we provide and discuss the example of a network with its centrality, including the BMI. Finally, Figure 5 shows the differences in centrality between the ages according to sexes.
Figure 5. Centrality measure (strength) of the 4 age groups relative to the women’s and men’s networks, distinguished by sleep health network analysis: the 4 age groups for (A) women and (B) men. At the top of the 4 tables, nonrestorative sleep has the highest centrality for the 31-45–year group in men. At the bottom, diabetes disease has the lowest centrality for the 18-31–year group in both women and men. A higher-resolution version of this image is available in Multimedia Appendix 4.

Network Comparisons

Here, we present the 2 results of the NCT, comparing (1) the connections between variables and (2) the results concerning centrality (ie, global strength). All the comparisons between variable connections for the 2 networks (men and women) were significantly different ($M$ test: 0.100, $P<.001$). However, there were no differences in terms of centrality (global strength of the women’s network=15.27, global strength of the men’s network=13.34; $t$ test: 1.92, $P=.68$).

Table 2. Difference in connections between age groups ($M$ test and $P$ value) of the French-speaking adult population concerned about their sleep (N=35,808).

In the same way, as shown in Table 2, all the comparisons between variable connections for the 4 age networks were significantly different. However, as shown in Table 3, no significant difference in terms of centrality measures was found. Multimedia Appendix 3 presents the local symptom-by-symptom correlations ($P$ value based on permutations) between connections and strength on sexes and all age groups.

Network Robustness

The robustness of strength is shown in Figure S2 in Multimedia Appendix 1. Robustness was judged acceptable, with a CS coefficient for strength at 0.91 for the women’s network; at 0.75 for the men’s network, the 18-30- and 31-45-year networks; at 0.672 for the 46-55-year network; and at 0.75 for the >55-year network.

Discussion

Principal Findings

Our study built on initial work describing key variables in people’s experience of their sleep complaints, in a population that was sufficiently concerned about their sleep to use the Réseau Morphée online sleep questionnaire. We showed that in network analysis on clusters defined by sex or age, the symptoms nonrestorative sleep and excessive daytime sleepiness and an element of sleep behavior (circadian irregularity) remained central to all groups. There were no statistical differences in these elements between the groups, implying that the underlying processes that drive the network and the underlying symptom structure are the same in men and women and the same across different age groups. However, differences in internodal connections between the clusters mean that sleep complaints are not connected in the same way in each of them. This difference should be interpreted as a difference in terms of the structure and the hierarchy in interactions between symptoms. For instance, in the women’s network, the symptoms breath abnormality observation, breath abnormality complaint, and snoring are much less related than they are in the men’s network (see Figure 1).

Comparison With Prior Work

The elements identified as central to the network for both men and women across all ages are best understood as the impact of underlying processes on the experience of sleep. As discussed in the Introduction section, the basic neuroanatomy underpinning sleep is identical in men and women, and although sex-related differences exist and functions may diminish with age, the structure remains. This leads to an important conclusion about improving sleep at a population level. For interventions to be effective in men and women and across all age groups, it is necessary to target central elements with high predictability: high predictability means that interventions aimed at these variables have a high chance of influencing the variables around them [70]. Fortunately, all 3 central variables showed relatively high predictability: interventions aimed at the key sleep-related behaviors have thus a high chance of working in men and women of all ages and of positively influencing other elements of the network.

Excessive daytime sleepiness is due to hypofunction of the wake system. This may be due to neuroanatomical modifications (eg, neuronal loss in the elderly or in patients with narcolepsy) or due to the effect of sleep fragmentation (eg, in obstructive sleep apnea) with incomplete recovery of the homeostatic system. Excessive daytime sleepiness has been shown to be central in both the International Classification of Sleep Disorders, Third Edition (ICSD-3) symptom network [40] and in the sleep-wake disorders symptom network of the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) [41]. Although sensitivity to sleep need may decrease with age and excessive daytime sleepiness is more common in women [75], the centrality of excessive daytime sleepiness as a consequence of impaired sleep or the wake system or both remains across all clusters.

Nonrestorative sleep, defined as a “subjective feeling of being unrefreshed upon awakening,” is considered a result of poor-quality or unrestful sleep. This symptom is poorly understood and has been little researched [6]. Ohayon [38]
reported that nonrestorative sleep was present in 10.8% of a European sample and 11.4% of French-speaking respondents. Nonrestorative sleep is found to be more common in women and younger subjects, increased in patients with psychiatric disorders, and much more frequent in people dissatisfied by their sleep and those with difficulty getting started in the morning. It is also associated with excessive daytime sleepiness, which would confirm our findings related to the centrality of nonrestorative sleep and excessive daytime sleepiness. However, the relationship between these 2 elements differs with sex: there is a direct and positive link between the 2 elements in women, whereas in men, the 2 nodes are more distant from each other and less strongly linked. The link also varies with age, with excessive daytime sleepiness and nonrestorative sleep being closer together and more strongly linked in middle age compared to young age (18-30 years) and older persons (>55 years). It is tempting to see nonrestorative sleep as an element related to the homeostatic system, with a residual sleep need at wakening due to either sleep disorders or circadian misalignment. The maintenance of its centrality across the different clusters is interesting. It clearly underpins the experience of sleep, and further research on its nature and correlates is overdue.

Finally, a behavior-related variable, circadian irregularity, retained its centrality across all clusters. Circadian irregularity relates to irregular sleep timing, with the risk that the actual timing of sleep is out of phase with the circadian rhythm. This is termed “circadian misalignment” and has been recently identified as 1 of the early indicators of cardiometabolic and neurological disorders. It is interesting to note that the central common features reunite physiological elements that underpin sleep: the homeostatic system, behavior affecting the circadian system, and the consequences of poor sleep. However, the centrality of circadian irregularity is particularly important as it is a clear target for behavioral interventions involving sleep: programs encouraging regular sleep are likely to positively influence the experience of sleep across the population.

After the homogeneity of the 3 central variables, the clusters differed in the subsequent variables: sleep-related respiratory and motor symptoms are more frequent in the older age groups. Sleep disorders, notably sleep apnea, are known to increase with age [30]. In the younger age group, sleep-related behaviors are more central, with chronic sleep deprivation being particularly important in young women.

Although no overall differences were detected for centrality, there were clear differences in the connectedness of the networks, which implies that the links between the different nodes are different: that is, although the structure of the network may be the same, the strength of the links between the different nodes is influenced by age and sex. This is seen in the relationship between excessive daytime sleepiness and nonrestorative sleep, where the relationship is closer and more direct in middle age compared to young age or those >55 years old (eg, the $p$ value was highly significant between the 18-30– and >55-year groups; $P<.001$).

Global strength increased in women and also in the 45-55-year group. The increase in global strength relates to the fact that all the variables are more closely related. This indirectly implies increased connectedness in the network: sleep symptoms, sleep behaviors, and sleep disorders are all more closely interlinked in women than in men or in older or younger age groups.

**Limitations**

Our study has clear limitations. First, we did not consider gender but rather considered sex as assigned at birth, which, despite the lack of consideration for the choice of the person involved, can improve epidemiological comparability. Second, our population comprises French-speaking participants who were concerned about their sleep and is thus not representative of the general population. Despite the large size of our sample, we should therefore be cautious about the generalizability of these results to the general population. Due to anonymity regarding certain sociodemographic data, we cannot provide the location of the participants’ primary residence. The fact that the average ISI, HADS-A, and HADS-D scores exceeded their respective thresholds indicates that on average, participants in our study displayed elevated scores for insomnia, anxiety, and depression. These characteristics may limit the representativeness (eg, whether participants were selected or self-selected based on certain criteria) or overall interpretation of the results (eg, the need to create subgroups). Moreover, an increase in nonrestorative sleep was noted in patients dissatisfied with their sleep in a study by Ohayon [76], and the interpretation of our results should bear this in mind. Third, participants responded to an online questionnaire with a structured symptom and sleep behavior list rather than a validated questionnaire: although this limited comparisons with other studies, it did, however, permit the inclusion of items such as screen use, which are often lacking from older questionnaires [41]. Finally, network analysis is a new and powerful way of analyzing large data sets, but interpretation of results and, notably, centrality should be performed with care. Network analysis highlights the dense interaction between variables and their interdependence at a population level but not at an individual level.

**Future Research Direction**

The results of this study provided 3 main perspectives. First, at the clinical level, this research advances our understanding of sleep variations by age and sex, centering on symptoms rather than diagnoses. Second, at the methodological level, it explores an area often underrepresented in the literature but essential for clinical practitioners, providing a weighted visualization of symptom relationships of sleep health, which is important when considering treatments such as cognitive-behavioral therapies. Finally, the study helps promote public health strategies, emphasizing the importance of the underlying unity of sleep health, while promoting a tailored and precise strategy for specific subgroups.

**Conclusion**

To conclude, this symptom network analysis on sleep health across various age and sex demographics demonstrates the stability of sleep health across sex and age groups, while highlighting the centrality of nonrestorative sleep and excessive daytime sleepiness. More precisely, younger individuals, especially women, show a higher centrality of behavioral-related sleep issues, whereas the older group has more sleep-related
respiratory and motor symptoms. These findings emphasize the need for both general and tailored sleep promotion and screening strategies based on age and sex to effectively address and enhance sleep health in the broader population. Furthermore, it paves the way for health care professionals to adopt a more individualized approach in assessing and treating sleep disorders, thereby enriching the overall quality of patient care.

Abstract

Background: Delay in the diagnosis of neurodevelopmental disorders (NDDs) in toddlers and postnatal depression (PND) is a major public health issue. In both cases, early intervention is crucial but too rarely implemented in practice.

Objective: Our goal was to determine if a dedicated mobile app can improve screening of 5 NDDs (autism spectrum disorder [ASD], language delay, dyspraxia, dyslexia, and attention-deficit/hyperactivity disorder [ADHD]) and reduce PND incidence.

Methods: We performed an observational, cross-sectional, data-based study in a population of young parents in France with at least 1 child aged <10 years at the time of inclusion and regularly using Malo, an “all-in-one” multidomain digital health record electronic patient-reported outcome (PRO) app for smartphones. We included the first 50,000 users matching the criteria and agreeing to participate between May 1, 2022, and February 8, 2024. Parents received periodic questionnaires assessing skills in neurodevelopment domains via the app. Mothers accessed a support program to prevent PND and were requested to answer regular PND questionnaires. When any PROs matched predefined criteria, an in-app recommendation was sent to book an appointment with a family physician or pediatrician. The main outcomes were the median age of the infant at the time of notification for possible NDD and the incidence of PND detection after childbirth. One secondary outcome was the relevance of the NDD notification by consultation as assessed by health professionals.

Results: Among 55,618 children median age 4 months (IQR 9), 439 (0.8%) had at least 1 disorder for which consultation was critically necessary. The median ages of notification for probable ASD, language delay, dyspraxia, dyslexia, and ADHD were 32.5 (IQR 12.8), 16 (IQR 13), 36 (IQR 22.5), 80 (IQR 5), and 61 (IQR 15.5) months, respectively. The rate of probable ADHD, ASD, dyslexia, language delay, and dyspraxia in the population of children of the age included between the detection limits of each alert was 1.48%, 0.21%, 1.52%, 0.91%, and 0.37%, respectively. Sensitivity of alert notifications for suspected NDDs as assessed by the physicians was 78.6% and specificity was 98.2%. Among 8243 mothers who completed a PND questionnaire, highly probable PND was detected in 938 (11.4%), corresponding to a reduction of –31% versus our previous study without a support program. Suspected PND was detected a median 96 days (IQR 86) after childbirth. Among 130 users who filled in the satisfaction survey, 99.2% (129/130) found the app easy to use and 70% (91/130) reported that the app improved follow-up of their child. The app was rated 4.8/5 on Apple’s App Store.

Conclusions: Algorithm-based early alerts suggesting NDDs were highly specific with good sensitivity as assessed by real-life practitioners. Early detection of 5 NDDs and PNDs was efficient and led to a possible 31% reduction in PND incidence.

Trial Registration: ClinicalTrials.gov NCT06301087; https://www.clinicaltrials.gov/study/NCT06301087

https://publichealth.jmir.org/2024/1/e58565
Introduction

After birth, the mother-child dyad can be impacted by impairments that remain undetected or are detected too late. Among these impairments, a neurodevelopmental disorder (NDD) such as autism spectrum disorder (ASD) affects 1 in 166 children [1]. The average time to diagnosis is approximately 4 to 6 years, whereas consensus statements indicate that a diagnosis could be made as early as 12 or 18 months of age [2-6]. Interestingly, parents are the main contributors to the NDD screening of their children [7]. Other disorders that deserve early screening are dyspraxia, language delay, dyslexia, and attention-deficit/hyperactivity disorder (ADHD) [8-11]. It is crucial to provide parents with screening tools and to recommend that they consult the physician at the first symptoms to treat them as early as possible.

Postnatal depression (PND) in mothers is another example of an undiagnosed disorder with severe consequences. PND—an episode of depression occurring during the first year after childbirth—has a prevalence of 17% and may have a negative impact on the synchrony or receptivity loop that is crucial to the proper neurodevelopment of the baby [12,13]. All these disorders can benefit tremendously from early detection by electronic patient-reported outcome questionnaires for parents and their children, which would enable early intervention.

We thus developed Malo, an “all-in-one” multidomain digital health record electronic patient-reported outcome app for smartphones, aiming to facilitate early screening of NDDs in children from birth to the age of 10 years and PND in mothers. We previously reported the results of a first observational, cross-sectional, data-based study in a population of 4242 children in 2022, showing a sensitivity of the alert notifications of suspected NDDs (possible ASD, vision, audition, socialization, language, or motor disorders) as assessed by the physicians of 100%, and a specificity of 73.5%. We also reported an earlier detection of PND in 907 mothers showing an incidence rate of 16.6% [14]. Since these results, changes in algorithms were performed to improve the specificity of NDD screening to avoid false positive results and we added early and continuous advice and support programs after childbirth to mothers to reduce the incidence of PND.

We thus report here the results of the revised algorithm aiming to be more specific for the screening of 5 NDDs (ASD, language delay, dyspraxia, dyslexia, and ADHD) and to assess the impact of the app and support program on the reduction in PND incidence.

Methods

Ethical Considerations

We ran an ecological, observational, cross-sectional, data-based study. Our study was approved by the French National Health Data Institute (Health Data Hub approval 16562971), which ensures ethical conduct in human participant research regarding data confidentiality and safety. The approval number for our human participant’s review was F20210420115840. The study complied with good epidemiology practices defined by the Association for French-speaking Epidemiologists. All the users received written information on our primary data collection purpose and the ability to be included in a secondary analysis in a deidentified manner—as specified in the app’s general conditions and privacy policy. However, users did opt in explicitly to be included in this specific study. Data were deidentified and aggregated at the server level before being passed to the researchers.

Data collection was embedded in the app. Data were collected in a French-certified health data cloud, as requested by local laws. Respondents self-entered the age and gender of their infants. The app also allowed for the entry of the children’s height, weight, vaccination status, medical background, and ongoing or previous treatments. No identifying data were used to produce our analysis, with emails, names, and exact dates of birth being segregated in other databases. For instance, the date of birth was converted to the child’s age in days at the time of answer in the data set. No compensation was provided to participants in this study.

Population

Malo is a mobile health (mHealth) app available on iOS and Android—only available in France at the moment. The kick-off of the first version of the app was historically initiated by a French national media campaign that was disseminated through social media between November 11 and 18, 2021. Details of kick-off modalities are provided by Denis et al [14]. The places of recruitment were multiple—3 maternity units, a dozen daycare centers, 15,000 followers’ social media accounts, and some insurers’ marketing efforts.

For this study, we included 55,618 users matching the criteria and agreeing to participate between May 1, 2022, and February 8, 2024. Enrollment in the study was strictly optional. Recruitment was open with no exclusion criteria. The inclusion criteria were to download the app, to have at least 1 child at least 10 years of age, and to provide informed consent (in-app). We extended the inclusion age of children up to 10 years to allow assessment of the incidence of dyspraxia/dyslexia disorders that can occur during this period.
Data Collection

Questionnaires and scales, each containing 25-50 questions assessing neurodevelopmental skills, were automatically submitted every month from birth to 9 months, then at 11, 12, 16, 18, 21, 24, 30, and 36 months and every 6 months until 10 years of age. Questionnaires were focused on sociability, attention or activity, motricity, language of their infants, and possible ASD to screen for ASD, language delay, dyspraxia, dyslexia, and ADHD.

Questionnaires and notifications were based on French health authorities’ reports, international recommendations, and experts’ agreements [8,15,16]. The questionnaire for the screening of PND was submitted to mothers every 2 to 4 weeks for 7 months after childbirth, using a modified questionnaire of the Edinburgh Postnatal Depression Scale adapted for self-assessment.

Threshold-Based In-App Notification and Outcome of NDD Module of the App

Notifications were sent automatically to the user if some symptoms matched predefined criteria and a physician consultation was recommended. Regarding NDDs, once a threshold of concern was reached, a notification was sent recommending that the mothers discuss their symptoms with their general practitioner or pediatrician.

The main outcome of the study was the median age of possible NDD notification of infants. The secondary outcomes were, first, user satisfaction regarding app experience and the level of support in child follow-up and second, relevance of the NDD notifications assessed by physicians, using a specific optional survey asking parents the following questions: (1) “In the last month, did your doctor detect a developmental disorder in your child during a follow-up consultation? YES or NO”; (2) “If you had a notification from Malo, did you follow the recommendation of the app to visit a physician? YES or NO”; and (3) “Which of the following reflects the physicians’ reply? (A) The notification is not relevant, (B) the notification is relevant and a medical surveillance of the evolution of the symptom is needed, (C) the advice of an expert is needed, or (D) a treatment is indicated.”

Threshold-Based In-App Notification and Outcome of PND Module of the App

Regarding maternal PND, there were 4 grades of notifications sent to the mother—grade 0 (score lower than 25) was associated with a message indicating that everything is ok, grade 1 (score between 26 and 50) was associated with a recommendation to talk about symptoms with a close relative, grade 2 (score between 51 and 65) recommended that they quickly discuss their symptoms with a family doctor, and grade 3 (score higher than 65) recommended that they meet a family doctor as soon as possible. Grades 2 and 3 were considered a high probability for PND. This algorithm and questionnaire were the same as those used in our previous study [14].

To reduce PND incidence, we added, since 2022, a support program in the current version of the app with early and continuous advice after childbirth to lead parents to take care of their mental burden and to be aware of burnout and PND. We also provided them with the option of joining speaking groups and accessing testimonials from other mothers.

The last secondary outcome was the rate and the median time of the mothers’ PND notifications after childbirth and subsequently to the support and prevention program.

Analysis

The analysis was performed on the 55,618 users, matching criteria were assessable for analysis and at least 1 neurodevelopment disorder strongly requiring a consultation was observed in 439 children.

Sensitivity, specificity, predictive positive and negative values, and the Youden index of algorithms triggering notifications of suspected NDDs were calculated according to the physician’s feedback. A notification was considered relevant if a physician suggested specific medical surveillance of the disorder or the consultation of an expert or a therapist or initiated therapy.

The χ² test was used in 2×2 tables to assess the statistical association between the medical relevance of the notification (relevant or not) and the notification results (notification or no notification of a possible NDD). We also assessed the rate of probable PND of mothers having a score >50 in the survey and the changes in the rate of PND during the time after childbirth. The level of statistical significance was 5% for all statistical tests.

Results

Overview

Among 99,916 nationwide users of the app between May 1, 2022, and February 8, 2024, a total of 55,618 children met the inclusion criteria (Figure 1). The median age of assessable children was 4 months (IQR 9), and 344,640 questionnaires were analyzed. Data analysis was performed at the end of February 2024. Among children, 0.8% (439/55,618) had at least 1 possible NDD strongly requiring a consultation. The median age of notification for probable ASD, language delay, dyspraxia, dyslexia, and ADHD was 32 (IQR 24-42), 16 (IQR 5-43), 36 (IQR 12-75), 80 (IQR 77-86) and 61 (IQR 52-85) months, respectively (Figure 2). The rate of probable ADHD, ASD, dyslexia, language delay, and dyspraxia in the population of children of the age included between the detection limits of each alert was 1.48%, 0.21%, 1.52%, 0.91%, and 0.37%, respectively.

Nationwide number of users of the Malo app for a toddler (0-10 years of age) n=99,916

Nationwide number of children with at least one questionnaire filled for neurodevelopment screening n=55,618

Users who also filled in the questionnaire for screening of maternal postnatal depression n=8243

Users who filled in the survey about the relevance of neurodevelopment notifications and their satisfaction with them n=130

Questionnaires assessable for relevance of neurodevelopment notifications in users who met physician. n=125
Figure 2. Distribution of the notifications of possible neurodevelopmental disorders and their type according to children’s age.

Analysis of the Assessment of the Relevance of the Alerts by Physicians

A 1-week survey was done at the end of January 2024 concerning the physician consultation feedback to parents following notification of possible NDD and to assess the satisfaction of users. Among the 130 parents who agreed to answer the survey, 113 had no alert, and 17 (13.1%) had received an alert of a possible NDD, which suggested a visit to their physician. Among users who received a notification suggesting a visit to their physician for a neurodevelopmental issue, 70.6% (12/17) users answered “YES” to the question “If you had a notification, did you follow the recommendation of the app to visit a physician?”

As 5 users with notification did not meet their physician, they were not included in the analysis of the clinical relevance of the alerts assessed by the physician. Data of the 125 assessable users who met the physician after notification showed a sensitivity of notification of 78.6%, a specificity of 98.2%, a positive predictive value of 84.6%, a negative predictive value of 97.3%, and a Youden index of 0.77 (P<.001).

Among the 11 children with true positive notifications of a possible NDD suggested by the app, medical surveillance of the evolution of the symptoms was proposed in 6 (54.5% of relevant notifications) cases, the advice of an expert was needed in 2 (18.2%) cases, and treatment was immediately initiated in 3 (27.3%) cases.

Satisfaction Analysis

Among 130 users who filled in the satisfaction survey, 99.2% (129/130) found the app easy to use and 70% (91/130) reported that the app improved the follow-up of their child. Moreover, the app was rated 4.8/5 on Apple’s App Store with 990 votes and 4.7/5 on Android Stores with 1100 votes.

Screening of PND

Among 8243 mothers who completed a PND questionnaire, highly probable PND (grades 2 or 3) was suspected in 938 (11.4%). Grades 1, 2, or 3 were reported in 54.2% (n=4468) of mothers. The a median 96 days (IQR 86) after childbirth and the incidence of supposed PND was equivalent during the 7-month follow-up (P<.001).

Discussion

Principal Findings

Our study prospectively assessed, in a “real-world” manner, in over 55,000 users, the benefit of mother-child dyad follow-up via a dedicated multidomain familial mHealth smartphone app providing early detection of 5 NDDs and leading to reduced incidence of maternal PND.

The main result is that the median age of alert for 5 NDDs (ASD, language delay, dyspraxia, dyslexia, and ADHD) by this smartphone screening app containing a dedicated questionnaire for parents seems to allow earlier assessment than in historical data. It also appears that the relevance of notifications was confirmed by physicians consulted following notification with high sensitivity (78.6%) and high specificity (98.2%).

Optimization of the neurodevelopment follow-up of children is very important as the identification of the first symptoms of NDDs is usually done by parents (without a dedicated digital device) in 61% of cases and by a health professional in only 14% as reported in a recent French study [7]. In our study, the median age of notification for probable ASD, ADHD, dyspraxia, dyslexia, and language delay was 32.5 (IQR 12.8), 61 (IQR 15.5), 36 (IQR 22.5), 80 (IQR 5), and 16 months (IQR 13), respectively, while time to diagnosis in France is usually 78 and 120 months for ASD and ADHD, respectively, that is, 4-5
The incidence of each disorder suspected in our study was similar to those historically reported, strongly suggesting that our cohort was representative of the general population—0.21% for ASD in our study versus 0.6% in the literature [1], 1.48% for ADHD 0.4% versus 5% in the literature [19], and 0.91% for language delay versus 2% in France in the literature [20]. The rate of dyslexia was lower in our study (1.52%) than in the literature (3% to 6% [10,20]) as was the rate of dyspraxia: 0.37% in our study versus 3% in literature [20]. The lower rates of dyslexia and dyspraxia screening in our study are probably caused by a reduced sensibility of the algorithm.

We also performed an analysis of physician feedback after an alert about a possible NDD. Most users (13/18, 72.2%) followed the recommendation of the app to visit their family doctor or pediatrician after an alert. In our previous study published in 2022 with the older version of the NDD trigger algorithm, the rate of parents following the recommendation was 84.4% (54/64). Both results suggest a high level of confidence of parents in the notification [14].

The main modification of the algorithm and forms between the previous and current versions of the app consisted of reducing sensitivity to optimize specificity by displaying several sub-questionnaires over a more extended period (at least 1 month between early warnings and confirmation) for confirmation and investigation of suspicious symptoms on the main questionnaire. In this study, the sensibility of notification was reduced to 78.6% while it was 100% in the 2022 study, but the specificity was higher with new algorithms (98.2% vs 73.5%). This was a deliberate choice to improve specificity by reducing false positive alerts, as observed in the 2022 version of the app to reduce inopportune and anxiogenic alerts to parents. This is also associated with a high negative predictive value of 97.3% which is interesting to reassure parents in the absence of alerts. The high positive predictive value is also an important factor for the confidence of doctors confronted with an alert, delivered by the app. It suggested that 84.6% of notifications were considered relevant by a physician. Among these alerts, the physician triggered a specific medical surveillance in 54.5% of notifications initiated a treatment or recommended parents to an expert in 45.5%.

Although these data were declarative by users and were not directly confirmed by physicians, we assume that the specificity of the ASD notifications is close to the result of Pierce et al [6], showing overall stability or specificity of an autism spectrum diagnosis of 84% at earlier than 18 months of age through a universal screening program in primary care. In a recent diagnostic accuracy study including 13,511 children aged 11-42 months, Barbaro et al [21] showed 83% positive predictive value and 99% estimated negative predictive value of the Social Attention and Communication Surveillance-Revised tool for autism identification when it was used by nurses for children aged 12 months. Our results seem to be similar when parents perform a screening using our app.

The inclusion of efficient digital tools is important in the logic of care pathways because it promotes acceptability and relevance by families and professionals. Early screening allows for early diagnosis and interventions as reported by works on the efficacy of early treatments of cases among young children and recent promising studies on early interventions [9-11,22-25].

We also reported a lower incidence of maternal PND (11.4%, 938/8243) assessed in 8243 mothers than in our previous study performed in 2022 (16.6%, 157/907 assessed mothers). The form and algorithms were not modified for the part relating to maternal postpartum depression between the previous and current versions of the app. To prevent the PND rate, we added to the early PND screening a prevention program to be initiated by mothers after childbirth. PND is well known to disrupt the crucial mother-infant relationship on which optimal child development depends. It is the most common complication associated with childbirth, and it may exert harmful effects on children such as increased risk of ASD [26]. It is usually underdetected or detected after many months. The early treatment of PND is effective, avoids negative impact on child development, and does not necessarily require drugs to improve symptoms in the earliest stages [27]. Its prevalence in France is 18%.

In our previous study performed in 2022 with the old version of the app, we reported that 16.6% of mother users had probable PND and a median time of detection between 8 and 12 weeks after childbirth. We thus added a support program since 2022 in the new version of the app, consisting of advice, information, sensitization to PND, as well as access to speaking groups and testimonials of mothers. This study reported a lower rate of suspected PND of 11.4% (151/907), that is, a 31% reduction in PND incidence compared to the results of the 2022 study. There were no changes in the questionnaire; the same algorithm for PND detection was active in both versions of the app, but only the prevention program was added. Interestingly, the incidence of all grades of assessment (1, 2, or 3) was similar between both studies (56.7%, 515/907 mothers in the 2022 study vs 54.2%, 4465/8243), suggesting that a switch to lower grade symptoms was associated with the new support program which in turn was associated with a diminished incidence of PND. This is, as far as we know, the first time that a reduction in PND incidence can be observed through the use of a smartphone app.

The level of satisfaction was also high (between 70%, 91/130 and 99.2%, 129/130 according to the assessed domains) and contributed to the high rate of adoption.

Limitations
There are limitations to our study. First, it was an observational study without a control group. Therefore, even though our sample was very significant, we could only proceed to an indirect (historical) comparison when intending to assess the efficacy of the tool regarding the detection of mental problems. Sample selection bias is always possible in the absence of randomization, due to social media recruitment modalities and because using the mobile app requires possession of a smartphone. We could have asked users questions about their educational level, practice classification (rural or urban), technical experience, and marital status, but we designed the app to collect as little personal data as possible. However, the very high rate of smartphone penetration in France (92% in a...
2018 survey) in people aged 25-39 years led us to believe that the risk of a selection bias associated with smartphone use was low. Nonetheless, we do note that parents without smartphones cannot benefit from the app [28].

The second limitation is that the data were declarative by users without a comparative arm, but we found similar results to our previous study in terms of NDD incidence and time to the detection of benefit.

The third limitation is that NDD suspicions were not directly transmitted by physicians. As diagnostic confirmation takes time, prospective follow-up of patients can be interesting to assess if suspicion is confirmed and makes it possible to study the confirmation rate of suspicions.

Fourth, the attrition rate (ie, the discontinuation of eHealth app use) was not assessed, but it could be interesting to study whether the benefit of early detection of NDD is maintained over time, thanks to prolonged use [29]. We need further studies to improve the lack of follow-up rate which is usually high in real-life studies of eHealth instruments.

Conclusions
To our knowledge, this multidomain mHealth app dedicated to both the early detection of 5 NDDs in children and the early detection and prevention of maternal PND is the first app with real-life data of clinical relevance. Results based on a large population of more than 55,000 users confirmed previous results and suggested that a multidomain familial mHealth app is suitable and effective for regular use in the mother-child dyad follow-up.

Data Availability
The data sets generated and analyzed during this study are not publicly available due to the sensitive nature of the patient data and the risk for reidentification if analyzed with this study are not publicly available due to the corresponding author on reasonable request.

Authors' Contributions
All authors had full access to all data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. FD conceptualized and designed the study. All authors contributed to the acquisition, analysis, interpretation of the data, and drafting the paper. Critical revision of the paper for important intellectual content was done by FD, FLG, MD, and AG. FD, FLG, GF, and MD oversaw statistical analysis as well as administrative, technical, and material support.

Conflicts of Interest
FD reports receiving personal fees from AstraZeneca, Ipsen, Kelindi, Pfizer, Chugai, and Roche and has stocks in Kelindi and Institute for Smarthealth. FLG, AG, and MD have stocks in Kelindi. The other authors declare no conflicts of interest. JDZ is an investor in Wandercraft, Kiro, Sim & Cure, Posos, Tilak, Orakl, Kelindi, Intelligent Location, Healthcube, Medicaim, Savana medical, Brightheart, and Deeplife. Kelindi developed the tool around which this study has been conducted.

Abstract

Background: Suicide is a significant public health issue. Many risk prediction tools have been developed to estimate an individual’s risk of suicide. Risk prediction models can go beyond individual risk assessment; one important application of risk prediction models is population health planning. Suicide is a result of the interaction among the risk and protective factors at the individual, health care system, and community levels. Thus, policy and decision makers can play an important role in suicide prevention. However, few prediction models for the population risk of suicide have been developed.

Objective: This study aims to develop and validate prediction models for the population risk of suicide using health administrative data, considering individual-, health system–, and community-level predictors.

Methods: We used a case-control study design to develop sex-specific risk prediction models for suicide, using the health administrative data in Quebec, Canada. The training data included all suicide cases (n=8899) that occurred from January 1, 2002, to December 31, 2010. The control group was a 1% random sample of living individuals in each year between January 1, 2002, and December 31, 2010 (n=645,590). Logistic regression was used to develop the prediction models based on individual-, health care system–, and community-level predictors. The developed model was converted into synthetic estimation models, which concorded the individual-level predictors into community-level predictors. The synthetic estimation models were directly applied to the validation data from January 1, 2011, to December 31, 2019. We assessed the performance of the synthetic estimation models with four indicators: the agreement between predicted and observed proportions of suicide, mean average error, root mean square error, and the proportion of correctly identified high-risk regions.

Results: The sex-specific models based on individual data had good discrimination (male model: C=0.79; female model: C=0.85) and calibration (Brier score for male model 0.01; Brier score for female model 0.005). With the regression-based synthetic models applied in the validation data, the absolute differences between the synthetic risk estimates and observed suicide risk ranged from 0% to 0.001%. The root mean square errors were under 0.2. The synthetic estimation model for males correctly predicted 4 of 5 high-risk regions in 8 years, and the model for females correctly predicted 4 of 5 high-risk regions in 5 years.
Conclusions: Using linked health administrative databases, this study demonstrated the feasibility and the validity of developing prediction models for the population risk of suicide, incorporating individual-, health system–, and community-level variables. Synthetic estimation models built on routinely collected health administrative data can accurately predict the population risk of suicide. This effort can be enhanced by timely access to other critical information at the population level.

Introduction
Each year, over 4500 Canadians take their own life [1], and more than 700,000 people die because of suicide worldwide [2]. As such, suicide has become a major international public health challenge. To facilitate suicide prevention, mechanisms should be in place that enable policy and decision makers to make informed decisions and mobilize resources to high-risk populations at the right places before tragic events occur. To achieve this goal, methods of predicting the population risk of suicide are critical.

Many suicide risk assessment tools have been developed in clinical settings with the hope that identifying patients at high risk and providing needed mental health services would reduce an individual’s risk of suicide [3,4]. Going beyond individual risk assessment, one important application of risk prediction models is population health planning [4]. In the realm of population health, population refers to “a group of individuals, in contrast to the individuals themselves, organized into many different units of analysis, depending on the research or policy purpose” [5]. These different units may be geographic regions (eg, states, provinces, and cities), groups (eg, workplaces and schools), and policy-relevant subpopulations (eg, by sex/gender and ethnicity). The aggregate health of the populations in these units is the focus of policy and decision makers through population health planning and policy [5]. Suicide has a complex etiology and is a result of the interaction of the risk and protective factors at the individual, health care system, and community levels [6-13]. Therefore, policy and decision makers and mental health service planners can play an important role in suicide prevention. However, policy and decision makers need tools that allow them to identify communities/regions that are at high risk so that they can mobilize resources and complex population-based interventions to these high-risk regions in advance. Ideally, such tools are developed based on readily accessible and real-time data so that they can closely monitor the population risk and the effects of the interventions.

There is a paucity of prediction models for the population risk of suicide. Gradus and colleagues [14] developed sex-specific machine learning algorithms for suicide using data from eight Danish national health and social registries. Kessler et al’s [15] machine learning algorithms targeted US Army soldiers who were hospitalized. Predictive models for population risk may use not only individual data but also health system–level (eg, quality of mental health care and mental health budget) and community-level data (eg, unemployment rate and social deprivation levels in the community). Therefore, a limitation of these individual-oriented models is the lack of consideration of health care system– and community-level factors as well as the potential changes in the distributions of the predictors over time. Research [16-18] has shown that community-level social vulnerability and antidepressant use/prescription are significantly associated with suicide at the population level. Kandula et al [19] went further by building a model to predict county-level suicide mortality in the United States using county-level annual measures of socioeconomic predictors of suicide risk and state-level prevalence of major depressive episodes and firearm ownership. Kandula et al’s [19] model used data from a variety of US public data sources, which makes the application of the model highly feasible. However, health administrative data was not one of the data sources. Studies from different regions have shown that a large proportion of people contacted health services in the year before their death [20-23]. For example, Canadian studies found that 82% of suicide decedents contacted health services in the year before their death [24] and that over 50% specifically contacted mental health services [25]. Therefore, the role of health service use data in predicting suicide risk at the population level cannot be ignored. The objective of this study was to develop and validate sex-specific predictive models for the population risk of suicide based on individual-, health system–, and community-level indicators in Quebec, Canada.

Methods
Population and Setting
The target population is the general population aged ≥15 years residing in the province of Quebec, Canada. Health care in Canada is provided through provincial and territorial systems of publicly funded health care that are universally accessible. In Quebec, health services are planned and delivered through 18 health regions, 22 integrated health and social services centers, and 166 local community services centers. Budgetary decisions are made at the levels of province and health regions.

Data Sources
We linked 5 health administrative databases using residents’ health care insurance numbers and the Canadian Urban Environmental Health Research (CANUE) data by postal codes, including the vital statistics death database, the physician claims database, the hospital discharge database, the Insured Person Registration File, and the public drug plan. The data of these databases (eg, billing and service procedures codes and service dates) are routinely submitted by clinics and hospitals for billing and administration purposes. No self-reported data were collected from residents. These databases cover up to 98% of
the population in Quebec. Together, the 5 health administrative databases can provide information on individual- (eg, sex and age), program- (eg, hospitalization and emergency department visits), and system-level (eg, mental health and addiction budgets) indicators [8]. CANUE is a Canadian consortium database [26], which contains indicators for social deprivation, material deprivation, and built environment at the community level. The data linkage was performed at the Quebec Institute of Public Health (INSQP) where the health administrative databases and CANUE data are kept. This study was approved by the Health Sciences Research Ethics Board of Dalhousie University (2021-5913). The methodological details of this study can be found in a previous publication [27].

Study Design

Because the base rate of suicide in the population is low, we used a case-control study design to develop sex-specific suicide risk predictive algorithms. For the training data set, we included all death by suicide cases that occurred from January 1, 2002, to December 31, 2010. The control group was a 1% random sample of living individuals in each year between January 1, 2002, and December 31, 2010, from the Quebec physician claim database. Individuals in the control group were only allowed to be selected once. The cases and controls were not matched to allow for maximum variability in predictors. The health administrative data from January 1, 2011, to December 31, 2019, were used for validation.

Suicide

Death by suicide cases were ascertained by Quebec’s Coroner’s Office after investigation. The decision is registered in the Quebec vital statistics database.

Predictors

Individual, programmatic, systemic, and community factors (Multimedia Appendix 1) 5 years before the suicide event, or the index date for controls, were used as candidate predictors to develop the risk predictive algorithms. For example, we extracted the data about the diagnosis of major depression (an individual-level factor) in the past 6, 12, 24, 48, and 60 months as 5 separate candidate predictors. Similarly, we extracted the annual mental health and addiction budget of each health region (a systemic-level factor) in the past 5 years as candidate predictors. The percentages of missing values associated with the variables in the databases ranged from 0.87% to 4.12%. The initial selection of candidate predictors was determined by content knowledge (ie, known relationships between suicide or suicide behaviors and individual- and local area–level variables), clinical utility, and policy relevance through team meetings (Multimedia Appendix 1).

Model Development

We included all preselected variables in penalized least absolute shrinkage and selection operator (LASSO) regression. The LASSO penalization factor selects important predictors by shrinking coefficients for weaker predictors toward zero, excluding predictors with estimated zero coefficients from the final sparse prediction model. We performed a correlation analysis among variables selected by LASSO regression and identified variables that were strongly correlated (γ≥0.60). Correlated variables were discussed by team members, and the variables that have better policy implication and clinical utility were kept and became the candidate predictors for model development.

We used logistic regression to develop the sex-specific statistical models. The backward selection method was used to eliminate unpredictive variables and to identify the model with the best calibration and discrimination. The decisions of model selection were initially based on the changes in the values of the Akaike information criterion and Bayesian information criterion [28]. Prediction accuracy was assessed by the discrimination and calibration of the model. Discrimination is the ability of a prediction model to separate those who experienced the outcome events from those who did not. We quantified this by calculating the C statistic, analogous to the area under a receiver operating characteristic curve. C statistic ranges from 0.5 to 1, with a higher value indicating better discrimination. A C statistic of 0.7, 0.8, and 0.9 may be considered the threshold for acceptable, good, and excellent discrimination, respectively. Calibration measures how closely predicted outcomes agree with actual outcomes. We used the Brier score to measure calibration. Brier score is the mean squared difference between the predicted probability and the actual outcome. The lower the Brier score is for a set of predictions, the better the predictions are calibrated. Given that the program will be used to forecast population risk by policy and decision makers, we prioritized calibration over discrimination in model development.

The second step of model development was to estimate the synthetic proportions of suicide. A synthetic estimate is a prevalence estimate for a local area that is calculated by using descriptive or demographic data at the community level [29]. The model-based synthetic estimation consists of two stages. First, for each predictor, the proportion of individuals within each category of that predictor in the initial modeling was computed separately by region. For instance, if hospitalization due to a suicide attempt in the past 5 years is a predictor in the model, the proportion of individuals with this attribute in a specific health region is calculated. If age is a continuous variable in the model, the mean age of the population in a health region is calculated. As such, the synthetic model contained community characteristics as predictors. A syntax program was then developed to apply the regression coefficients to the corresponding proportions and means in the data set, and to calculate the logit estimates for each of the health regions. The resulting logit values for each of the health regions were then converted into probabilities (ie, the synthetic estimate of the risk of suicide in the health region).

Validation

The validation data set included all suicide cases and 1% of controls from January 1, 2011, to December 31, 2019. We first calculated the yearly proportion of suicide at the provincial and health regional levels for males and females (ie, observed proportion). We then applied the developed synthetic models to the validation data to estimate the yearly prevalence of suicide death at the provincial and health regional levels in males and females (ie, predicted proportion). We visually compared and calculated the absolute differences between the predicted and
observed risks; smaller differences indicate better calibration with the data and model accuracy. Additionally, we assessed the synthetic model performance using three indicators: mean average error (MAE), root mean square error (RMSE), and the proportion of correctly identified high-risk regions. The MAE is the average magnitude of the difference between the predicted and observed suicide death rate for each health region. The RMSE is the square root of the average magnitude of the difference squared and is, therefore, similar to MAE but penalizes prediction errors with greater magnitude. More accurate predictions will result in smaller MAE and RMSE. To assess the extent to which high-risk regions are correctly identified, the top 5 health regions with the highest predicted and observed suicide risks were identified. The proportion of health regions observed in the top quartile of observed suicide death risks that were rightly predicted to be in the top 5 was calculated.

Ethical Considerations

This study was approved by the Health Sciences Research Ethics Board of Dalhousie University (REB number: 2021-5913), which waived the need for informed consent. This study used existing data held by the INSPQ, which are routinely collected by the provincial government. Under provincial health information regulations, deidentified INSPQ data were used, as requested, in the context of epidemiological surveillance of suicide, with ethical approval. With the deidentified data, individual patients cannot be identified, and the results of this study were reviewed and vetted by the INSPQ before publication. No compensation was provided to individuals in the databases.

Results

The demographic and socioeconomic characteristics of participants in the training data are in Table 1. Between January 1, 2002, and December 31, 2010, there were 8899 suicide cases (6713 males and 2186 females). We included a 1% random sample of the Quebec general population as controls (316,574 males and 329,016 females). Most of the participants lived in urban areas. Participants were grouped by quartile values of social deprivation and material deprivation scores based on population norms.

The final models for males and females are in Tables 2 and 3, respectively. The model for males included 20 predictors, and the model for females had 22 predictors. The predictors in the models covered the levels of individual (eg, age and mental health physical diagnoses), health system (eg, hospitalization and mental health budget), and community (eg, material deprivation). The male and female models had common predictors (eg, age; living in rural area; hospitalization for suicide attempt; outpatient psychiatrist visits for mental health reasons; and presence of mood, anxiety, substance use, and personality disorders); some predictors are sex specific (in males: Charlson score, emergency and general physician [GP] visits for physical health reasons, and regional mental health budget; in females: material deprivation score and emergency and GP visits for mental health reasons). The sex-specific models had good discrimination (male model: C=0.79, 95% CI 0.78-0.79; female model: C=0.85, 95% CI 0.84-0.86) and calibration (Brier score male model 0.01; Brier score for female model 0.005). Figure 1 shows the visual comparison between the predicted and observed risk of suicide. The models calibrated well with the data, especially the model for females.

We converted the developed models into synthetic estimation models as described in the Methods section and directly applied the models in the development (from 2002 to 2010) and validation (from 2011 to 2019) data. We estimated the annual prevalence of suicide in Quebec from 2002 to 2019 and compared it with the observed risk in each year (Table S1 in Multimedia Appendix 1). During this period, the annual prevalence of suicide in males steadily decreased from 27 per 100,000 in 2002 to 20 per 100,000 in 2019, while the annual prevalence of suicide in females remained stable at around 6 per 100,000 to 7 per 100,000. The predicted annual prevalence of suicide in males and females based on the synthetic estimation models was very close to the observed proportions. Over 18 years, the synthetic estimation models had 1 per 100,000 over- or underestimation in 8 years for males and only in 3 years for females. For the rest of the years, the synthetic estimations were exactly the same as the observed proportions of suicide in the population. The good performance of the synthetic estimation models was also reflected by the small MAE and RMSE, with most of the RMSEs around 0.1. With the validation data from 2011 to 2019, the synthetic estimation model for males correctly predicted 4 of 5 high-risk regions in 8 years, and the model for females correctly predicted 4 of 5 high-risk regions in 5 years (Table 4).

To examine the accuracy and fairness of model prediction, we validated the synthetic estimation models by age groups and health regions using the 2019 data. As seen in Table S2 in Multimedia Appendix 1, the models performed well in different age groups. In 2019, the prevalence of suicide varied by health region, ranging from 14 per 100,000 (Montreal) to 275 per 100,000 (Nunavik) in males and from 4 per 100,000 (Laval) to 92 per 100,000 (Nunavik) in females. The models predicted the same regional variations in males and females with small absolute differences (Table S3 in Multimedia Appendix 1).

Discussion

Principal Results

The data showed a sex difference in the trend of suicide risk and considerable variations in suicide risk by health regions in Quebec. The suicide risk in males had decreased since 2002, while the risk remained stable in females. This study demonstrated the feasibility of integrating individual-, program-, health care system-, and community-level data to build accurate prediction models for suicide at the population level. The models performed well in predicting suicide at both the provincial and health regional levels. The absolute difference between the observed and predicted proportions of suicide ranged from 0 to 1 per 100,000. The RMSEs were under 0.2. The prediction models could correctly identify the health regions that were at the top risk level, and the models achieved good performance in different age groups and health regions.

Limitations

This study had several limitations. First, data about social determinants of health, medication use, the use of crisis hotlines, and access to lethal means were not available in the health administrative data. As such, we were not able to examine the extent to which these factors may improve the performance of the models. Second, although the predictors in the models were associated with suicide, causal inferences cannot be made. The goal of risk prediction models is to identify a key set of factors that in combination best predict the outcome. The models are not meant to test a hypothesis or make inferences about etiology. Third, the relationships between the selected factors and suicide are complex. The logistic regression model is a linear function. Although we found no evidence of interactions among the selected predictors, nonlinear relationships between some predictors and suicide are still possible. Future studies may test if models using machine learning techniques have a better performance.

Comparison With Prior Works

The many factors in the models (eg, older age, living in rural areas, hospitalization for suicide attempt, emergency department visits for mental and physical health problems, and diagnosis of a mood/anxiety or substance use–related disorder) were associated with increased risk of suicide, which was consistent with the literature [6]. Outpatient GP visits for mental health (in females) and physical health (in males) were negatively associated with suicide in multivariate models. Audits of suicide cases, if aggregated, pointed toward the deficits in the health, mental health, and addiction services systems [8]. The work conducted in Quebec by our group [30] recommended better detection and treatment of substance use disorders at the primary (GPs) and specialist medical care levels, access to GPs and psychotherapy for common mental disorders and substance use disorders in the primary care context, mobile crisis teams operating from the emergency room (ER), public campaign targeting men about depression and substance use disorders as treatable diseases, and increasing the specialist mental health and addictions services budgets. This may explain the
relationships between GP visits for mental health problems, patients with visits to their GP for endocrine or genitourinary system–related problems, dementia, and the decreased risk of suicide because these individuals have had the opportunity to be diagnosed with depression and be supported. Patients with infectious diseases secondary to comorbid substance use disorders may have been undetected and untreated, which may explain the negative association. Similarly, at the program level, deficits in the coordination of specialist addiction and mental health services for known patients seen at the ER were found in one-third of the cases, which may explain the negative association with ER visits. Finally, the increased mental health and addiction services was a key system-level recommendation by the Coroner’s Office to the provincial public-managed care system that can be implemented in the allocation of regional health budgets [31]. Although material deprivation was negatively associated with suicide in females, the association was not statistically significant. More granular data about socioeconomic status may provide more insights about the sex differences.

One unique feature that differentiates population risk prediction from individual risk prediction is the use of community-level characteristics as predictors. The data for estimating these community-level parameters may come from various sources. For example, Kandula et al [19] modeled county-level suicide risk in the United States using county-level predictors derived from 8 different sources (government programs, health surveys, and private organizations). For some predictors such as the prevalence of major depressive episodes, only state-level estimates were available and these estimates were extrapolated to the counties [19]. Hudson [32] explored the utility of a regression synthetic estimation model that incorporated individual data from the National Comorbidity Survey, census, and hospital administrative data to predict state-level prevalence of severe mental illness. The advantages of these population risk prediction models are the use of community-level predictors from existing sources or published research and the ability to adapt the models to the local context. Notably, our study used the regression synthetic estimation modeling approach. We used the provincial health administrative data and the CANUE indicators from a single source (ie, INSPQ). The use of a single data source may improve the efficiency of data analysis, data access, and eventually the decision-making process. On the other hand, the use of a single data source may miss some important information. In Canada, the provincial health administrative data are collected primarily for billing and administration purposes. It does not include granular data about social determinants of health (eg, race/ethnicity, poverty, employment, and housing quality), crime rate, social support, the use of crisis hotlines, access to lethal means, access to private health care, and medication use (except for children, youth, and seniors). These factors have been found to be associated with suicide risk, but pertinent data are collected and maintained by different organizations. Future studies should investigate how important data from different sources may be feasibly and efficiently integrated, which factors can improve the model performance, and the feasibility of local adaptation and implementation of the developed models.

One critical element of building risk prediction models is assessing model performance and model validation. This is to ensure that the developed model is accurate and has good performance in different populations or at different time periods. In this study, we developed the models using data from 2002 to 2010 and validated the models using the data from 2011 to 2019. Furthermore, we validated the models in different age groups and health regions. These models were designed to predict population risk and to identify high-risk regions/communities, not to be used by clinicians to identify high-risk individuals. Therefore, the focus of model performance assessment can be different. Specifically, the few existing population risk prediction models for suicide and mental illness focused on model calibration. Kandula et al [19] used symmetric proportional error (observed deaths – predicted deaths)/(observed deaths + predicted deaths) to quantify model calibration. Hudson [32] calculated the absolute difference between the predicted and observed prevalence of severe mental illness. In this study, we calculated the absolute difference between the observed and model-predicted proportions of suicide. Additionally, following the approach of Marks et al [33], we used the MAE, RMSE, and the proportion of correct identifications of high-risk regions as the indicators for model calibration. There is no consensus about the thresholds for absolute difference between predicted and observed proportions of correct identification. Consultations with knowledge users are needed to understand what indicators are informative about model performance and the level of the model error that is acceptable.

The results of this study are expected to have implications for population mental health planning. Few would deny that resource allocation should be partly driven by needs, and needs assessments typically require the knowledge of potential changes in prevalence estimates and in local population profiles (eg, their demographics, diagnoses, and mental health services use). The prediction models developed by this study will allow decision makers and mental health service planners to forecast the proportions of suicide in the years to come at the provincial (state) and health regional (county) levels based on the potential changes in local population profiles. Such profile changes may be estimated using health administrative data and national population census data. Additionally, region-specific risk estimates can help categorize health regions (eg, regions with relatively stable suicide risk, especially those that remained in the highest or lowest groups, or regions in which the largest year-to-year changes are observed) and hence help identify areas in greater need of preventive resources or, conversely, identify areas where interventions seem to be effective. Furthermore, if the data about the predictors are available on a more frequent basis (eg, monthly or biweekly), the models will support the development of nowcast suicide surveillance systems.

Conclusions

Accurate prediction of the population suicide risk can play an important role in suicide prevention. This information can allow policy and decision makers and mental health service planners to categorize regions/communities that are at high risk and to monitor changes in risk so that they may mobilize resources [31] and interventions to the right populations and the right
places at the right time. Using linked health administrative databases, our study demonstrated the feasibility and validity of developing prediction models for population suicide risk, incorporating individual-, health system-, and community-level variables. Routinely collected health administrative data are readily accessible to policy and decision makers and mental health service planners. Suicide risk prediction models based on health administrative data can provide useful information to policy/decision makers at the moment they need the information. This effort can be enhanced by timely access to other critical information at the population level. However, the methodology of population risk prediction should be further studied to enhance the validity and precision of population risk prediction.

Acknowledgments
This study is supported by a grant from the New Frontiers in Research Funds (NFRF) of the Tri-Council Secretariat, Government of Canada, and a Tier I Canada Research Chair in Health Data Science and Innovation from the Canadian Institutes of Health Research (CIHR). However, the NFRF and CIHR played no role in the study design, data collection, analysis, and interpretation.

**Abstract**

**Background:** Electronic health records (EHRs) play an increasingly important role in delivering HIV care in low- and middle-income countries. The data collected are used for direct clinical care, quality improvement, program monitoring, public health interventions, and research. Despite widespread EHR use for HIV care in African countries, challenges remain, especially in collecting high-quality data.

**Objective:** We aimed to assess data completeness, accuracy, and timeliness compared to paper-based records, and factors influencing data quality in a large-scale EHR deployment in Rwanda.

**Methods:** We randomly selected 50 health facilities (HFs) using OpenMRS, an EHR system that supports HIV care in Rwanda, and performed a data quality evaluation. All HFs were part of a larger randomized controlled trial, with 25 HFs receiving an enhanced EHR with clinical decision support systems. Trained data collectors visited the 50 HFs to collect 28 variables from the paper charts and the EHR system using the Open Data Kit app. We measured data completeness, timeliness, and the degree of matching of the data in paper and EHR records, and calculated concordance scores. Factors potentially affecting data quality were drawn from a previous survey of users in the 50 HFs.

**Results:** We randomly selected 3467 patient records, reviewing both paper and EHR copies (194,152 total data items). Data completeness was >85% threshold for all data elements except viral load (VL) results, second-line, and third-line drug regimens. Matching scores for data values were close to or >85% threshold, except for dates, particularly for drug pickups and VL. The mean data concordance was 10.2 (SD 1.28) for 15 (68%) variables. HF and user factors (eg, years of EHR use, technology experience, EHR availability and uptime, and intervention status) were tested for correlation with data quality measures. EHR system availability and uptime was positively correlated with concordance, whereas users’ experience with technology was negatively correlated with concordance. The alerts for missing VL results implemented at 11 intervention HFs showed clear evidence of improving timeliness and completeness of initially low matching of VL results in the EHRs and paper records (11.9%-26.7%; \(P < .001\)). Similar effects were seen on the completeness of the recording of medication pickups (18.7%-32.6%; \(P < .001\)).
Conclusions: The EHR records in the 50 HFs generally had high levels of completeness except for VL results. Matching results were close to or >85% threshold for nondate variables. Higher EHR stability and uptime, and alerts for entering VL both strongly improved data quality. Most data were considered fit for purpose, but more regular data quality assessments, training, and technical improvements in EHR forms, data reports, and alerts are recommended. The application of quality improvement techniques described in this study should benefit a wide range of HFs and data uses for clinical care, public health, and disease surveillance.

Introduction

Background

By 2021, over 67% of people living with HIV were from sub-Saharan Africa [1]. Rwanda, along with other East African countries, has made great progress in the care and treatment of patients living with HIV/AIDS, including improvements in the uptake of prevention of mother-to-child transmission services and reduction in the rate of loss to follow-up for patients receiving antiretroviral therapy (ART). In 2019, a total of 84% of HIV-positive adults in Rwanda knew their status, 98% of those who knew their status were receiving ART, and 90% of those receiving ART had suppressed viral loads (VLs) [2]. HIV care has been available in Kigali (the capital) approximately from 2002. In 2005, partly through a collaboration between the Rwandan Ministry of Health (MOH) and the health care nongovernmental organization Partners in Health and Inshuti Mu Buzima (PIH-IMB), among other global partners, including the Centers for Disease Control and Prevention (CDC) and Global Fund, work began to scale up treatment to the whole population in need [3,4]. This scale-up treatment was designed around a community-based model, including routine care provision by nurses. Furthermore, it included the training and deployment of community health care workers for home follow-up and support and directly observed therapy for some patients. Ensuring long-term high-quality care for chronic diseases like HIV/AIDS also requires effective documentation of enrollment and follow-up care, with reliable access to clinical data at the point of care and quality improvement processes and reporting [5,6]. In 2005, PIH-IMB deployed a web-based medical record system, the HIV–electronic medical record (HIV-EMR), that had been developed for HIV care in Haiti [5]. These initial strategies were coupled with task shifting and scaling of diagnostics and treatment across Rwanda, reducing barriers related to geographical and financial access to the management of HIV/AIDS.

Digital Health Electronic Health Records

In the last 5 years, Rwanda has initiated digital health as one of the 7 key pillars of the Smart Rwanda Master Plan, which involves the digitalization of different processes of health care delivery and management. Recently, significant efforts were made to deploy information systems and numerous digital tools to support various aspects of service delivery in the health sector [2] with the aim of reaching the one citizen, one record principle. The focus of building the national digital health enterprise architecture was to support seamless information exchange and the need to develop Rwanda Digital Health Interoperability Standards and Health Information Exchange, now known as OpenHIE.

Electronic health records (EHRs) are widely used for collecting, storing, viewing, analyzing, and sharing of clinical data. They address critical limitations in paper records that have been used for generations to support health care and are still relied upon in many lower-income countries. The potential benefits of EHRs over paper records include the following capabilities: unrestricted access to patients’ records for routine or emergency care, often in multiple locations; secure storage of data with backups; search and retrieval of patient records and key clinical data; clinical decision support to improve quality of care; generating reports; sharing data between facilities; disease surveillance; and clinical research. The success of these activities depends on the design and cost of the software; the availability of suitable hardware and infrastructure, particularly in low-income settings; and the ability and motivation of the staff to use the system [7-9]. Effective EHRs need to address important priorities of stakeholders (value of the system) [10,11] and be usable by staff as part of their routine work, which requires attention to the user interface, clinical workflow, and training [11-13] (ease of use). Regardless of the specific system in use, one metric is critical for creating value from the system in the form of data for decision-making processes: data quality [8,14]. If an EHR implementation cannot achieve and sustain good data quality, it is unlikely to create real value for stakeholders, whether they are clinical staff caring for patients, members of the health facility (HF) management, members of ministries of health conducting disease surveillance, or researchers studying questions such as disease incidence or management.

What constitutes good data quality depends on the use of the data: the principle of “data which is fit for purpose.” Clinical care requires data that are as complete and accurate as possible, but specific variables, such as medications, past medical history, or laboratory results, are often most important [15]. Missing data erode the value of the EHR and trust in the system. This typically leads to staff questioning the value of using the systems and keeping data up to date, which can lead to a downward cycle of deterioration and sometimes abandoning the EHR [9]. Conversely, a well-maintained system that is valuable for clinical tasks and reporting can incentivize better data entry. Many strategies have been used to improve data entry, including mapping the system’s workflow to the typical task order of staff, providing warnings of inappropriate values for a form field, and reporting values inconsistent with previous entries such as body weight or age. Training staff in system use and the importance
of complete and up-to-date data are also priorities [16]. One essential strategy is monitoring data entry and completeness and periodic audits of data quality. As noted previously, data quality and completeness are typically linked. A fall off in data entry, for example, may be due to a technical issue or a lack of staff but can lead to gaps in the records and potential falls in data quality. Conversely, catching a lack of data entry quickly can identify correctable technical issues and allow early intervention to maintain momentum and confidence [17].

Many of these issues are more challenging in low- and middle-income countries (LMICs). In addition, the loss of reliable EHR data may have a greater impact on patient care and health system performance in LMICs, given the frequent lack of alternative records or strong health systems. Previous studies have investigated the benefits of different data entry and quality strategies, often in a small number of HFs [6,18]. However, many of these questions are most relevant in EHR systems deployed at scale and in longer-term use rather than pilot projects and recent deployments. There are important unanswered questions on what strategies are most effective at improving data quality, and what factors related to HFs and staff can facilitate or impede data quality [14]. Hedt et al [19] studied the quality of data in paper records of patients with HIV in Malawi using a technique termed lot quality assurance sampling (LQAS). Their study revealed high levels of completeness and accuracy of these records, all of which were reviewed by a supervising team on a quarterly basis. Furthermore, they studied how accurately the overall data quality could be predicted from a random sample of 76 records in each of the 19 HFs. This sample accurately predicted the overall data quality when a threshold of 85% on quality metrics was used to indicate a low quality.

**EHR Data Use for Clinical and Public Health**

Routine clinical data, such as those collected from EHRs, are an important component of public health systems in high-income countries [20]. Moreover, the data in EHRs can help to understand the patterns of HIV distribution, the progress in achieving national and global targets, oversight of the risks and patterns in specific population groups, and the evolution of the infection in different circumstances [21,22]. EHR data shared across HFs may help to realize continuity of care as people move from one region to another. LMICs are increasingly adopting EHRs, with HIV care being in the vanguard in Eastern and Southern Africa, providing a test case for broader EHR adoption and use. The quality and timeliness of these data are a key factor in public health decision-making and management of programs to improve population health outcomes. EHR data are used for public health surveillance, patient to provider communication, quality of care monitoring, linkage of primary care and public health system such as notifiable disease reporting [23], and strategic policy direction [24]. Health Information Exchanges linking EHR and laboratory data, for example, have a growing role in population health and disease surveillance [25]. To maximize the benefits of EHRs for clinical and public health functions, they increasingly allow data collection on behavioral, social, and environmental factors that may affect patient and population health [26]. EHR systems in LMICs, such as OpenMRS, are able to interoperate with pharmacy information systems, laboratory information systems, and mobile health (mHealth) apps, including through the Health Level-7 Fast Healthcare Interoperability Resources (HL7 FHIR; Health Level Seven International) standard, creating more comprehensive views of patient care, population, and public health across a range of communities [27].

**The OpenMRS EHR**

Recognizing the need for a general-purpose EHR system, PIH in collaboration with the AMPATH project (Academic Model Providing Access to Healthcare) in Eldoret, Kenya; the Regenstrief Institute in Indiana, United States; and the South African Medical Research Council deployed a new open-source general-purpose EHR for HIV care in 2006 [28]. This system, the OpenMRS EHR, was subsequently scaled to 43 PIH-IMB-supported HFs in Rwanda. From 2011 onward, it was rolled out to >300 MOH-run HFs. OpenMRS presently supports comprehensive services in all departments of district hospitals. Furthermore, it supports care for maternal-child health, noncommunicable diseases, and oncology in some health centers and hospitals in Rwanda and other countries [7]. OpenMRS is used in >44 LMICs [7], including support for HIV care in >5000 HFs, primarily in Kenya, Uganda, Mozambique, Nigeria, and Rwanda, and will soon be deployed widely in Ethiopia and Haiti [29]. OpenMRS continues to be upgraded with recent improvements in the user interface, data analysis and export, standardized clinical decision support systems, and improved interoperability using HL7 FHIR [7,27]. Previous studies on data quality in OpenMRS have been conducted [6], but only 1 published study by Muthee et al [14] evaluated data quality at scale in >50 HFs.

**Rwanda OpenMRS Evaluation**

This study was part of a larger process evaluation and randomized controlled trial (RCT) of OpenMRS in Rwanda. The US CDC funded a process evaluation of the OpenMRS EHR system in use at scale in Rwanda. This included (1) a user survey, (2) key informant interviews, (3) monitoring of system use and technical stability, (4) a study of the costs of development and deployment of the enhanced EHR software, and (5) the data quality study described in this paper.

Furthermore, a cluster RCT on the impact of improving workflow and adding decision support tools on the quality of HIV care is currently being completed. Three types of alerts were implemented in the trial:

1. A warning if a patient newly diagnosed with HIV was not started on ART within 2 weeks (in the same clinic)
2. A warning for a missing VL result for patients after 6 months of HIV care and annually thereafter (with a 2-month window for test results to be returned and entered into the EHR)
3. A warning for abnormal VL results (>1000) suggesting virologic failure

A total of 112 HFs were included in the RCT, half of which (56/112, 50%) were randomized to receive alert 1; 28 (25%) of these HFs also received alert 2, and 14 (12.5%) of these also received alert 3. The alerts were triggered when clinicians opened the patient summary and were also presented as a report...
of all patients currently matching the rule. The end users were trained to interpret the alerts in the patient summaries and reports. The larger study design has been described previously [4].

We aimed to measure data completeness, matching, concordance, and timeliness and to evaluate factors influencing data quality and strategies to improve it. The data studied were sourced from OpenMRS, a widely deployed EHR system supporting HIV care in Rwanda for >15 years [7,30]. It builds on a clinical trial of the effects of clinical decision support tools on HIV care. Furthermore, it includes data on the characteristics of the HFs and the staff who work there, building on the results of an EHR user survey of the same group of facilities [4].

Methods

Overview

In this paper, we describe a cross-sectional study based on the LQAS approach used by Hedt et al [19]. A total of 50 (44.6%) HFs were selected from the 112 HFs included in the clinical trial, based on the power calculations for that study, selecting a random sample from both intervention and control HFs and a representative mix of larger and smaller HFs but not hospitals. Trained research assistants from the Rwanda School of Public Health visited the 50 HFs and collected data using Open Data Kit (ODK), an open-source mobile data collection software [31]. At each HF, depending on the patient volume, 48 to 76 charts were randomly selected from the set of patients receiving HIV care based on the LQAS protocol used by Hedt et al [19].

The deidentified data were uploaded to a study database housed at the University of Rwanda School of Public Health. Data analyses were partly based on the work of Hedt-Gautier et al in Malawi [19] and Rwanda on public health reporting systems and Muthee et al [14] on data quality analysis in the KenyaEMR OpenMRS-based system.

Analyses included the following metrics:

- Comparison of the paper records and EHR records for completeness of the data items
- Comparison of the paper records and EHR records for percentage of matching of the data items
- Concordance scores comparing the combined matches of 15 key variables
- Comparison of HFs that were recorded as having high EHR uptime and availability (in the previous user survey by Fraser et al [4]) to those with poor EHR uptime
- Comparison of HFs based on the duration for which staff have worked with the EHR and their level of technological experience
- Comparison of completeness of key variables in the EHR records of intervention HFs with those of control HFs, for records completed after the intervention was implemented

Data Processing and Analysis

First, the data were processed to identify any missing values. Values were regarded as missing if the field was blank, was coded with an answer indicating that the information was not available, and, for date variables, if the date reported was impossible (ie, either too far in the future or dates related to HIV treatment that predated any HIV treatment occurring in Rwanda). The latter category helped address the fact that “missing” dates were often recorded as January 1, 1980. Then, for all 28 variables in the data set, we counted the number of records that did not have missing data in either the paper file or the EHR and recorded that value as the number filled or complete. This value was divided by the total number of records to obtain the percentage that were complete. The data were scored as “high quality” if ≥85% of the records were complete based on the LQAS protocol [19].

Then, from the subset of records that were complete, we analyzed how many of them matched in both the paper file and the EHR. Before determining the number of matches, we performed basic data standardization. Specifically, drug regimens were sometimes reported as multiple combinations, for example, the medications could have been coded as Tenofovir (300) + Lamivudine (300) and Efavirenz (600) instead of Tenofovir (300) + Lamivudine (300) + Efavirenz (600); for these cases, we standardized the drug list to 1 standard code. For 22 data points (minus VL values), data were regarded as a match if the standardized value recorded in the paper file exactly matched the standardized value recorded in the EHR. Data quality for matches was regarded as “high quality” if 85% of the records that were complete matched in both the paper file and the EHR.

For each patient, we also collected the last 3 VL results and dates, if available. There were few “matching” records for VL results. Further analysis showed that this usually occurred when the paper file had 1 newer VL result than the EHR; therefore, the most recent VL result in the EHR exactly matched the second most recent VL result in the paper file. To account for this, we aligned the records based on date; for example, if the EHR had a record for May 1, 2019, this would be treated as being the same entry as a record from the paper file that was also dated May 1, 2019. VL results recorded with a date in the paper file that did not match the date of a recorded VL result in the EHR were counted as missing in the EHR and vice versa. Because we only had the last 3 records from each file, in any case where the paper record had newer data than the EHR, there were always at least 2 missing records. To account for this, we aligned records in the EHR and paper file based on date and produced 2 derived variables: “All Viral Loads,” which summarizes all VL records but counts matches based on date rather than position, and “At Least 1 Viral Load,” which examines whether the most recent value in the EHR matches one of the 3 values in the paper file. Data completeness for filled VLs was regarded as “high quality” if ≥85% of the records existed in both files.

After the date alignment was completed, we standardized values such that VL numbers with a small difference within 1 copy/mL were counted as a match. This helped address cases where VL
results were reported with additional precision (20.6 vs 20 or 19.2 vs 20), noting that the EHR system only recorded absolute numbers (ie, 20 instead of 20.6). For all filled VLs (VLs where the date matched in both the paper file and the EHR), we counted them as a match if the standardized VL numbers in both records matched. VL matches were regarded as “high quality” if 85% of the records matched in both the paper file and the EHR.

Subsequently, we performed the same analysis for the data broken down by individual health care facilities, allowing for the analysis of potential factors affecting data quality. First, we examined the correlations between the HF characteristics and the resulting data quality. Facility characteristics were obtained from the user survey collected at the same time as this data quality study [4]. We hypothesized that the relevant factors would be (1) whether the HF was an intervention or control HF, (2) the average time (years) that the clinical users and data managers had been working with the EHR, (3) the relative technology experience of the users, and (4) how available and stable the EHR was. We hypothesized that being an intervention HF, the length of time of working with the EHR, EHR uptime, and technical experience would be positively correlated with better data quality.

To measure overall data quality, we developed a concordance score based on the work of Muthee et al [14] who compared data quality in paper and EHR records in Kenya. We narrowed the number of variables to 15 by considering only the most recent VL and drug pickup results and by dropping the variables for the health center sector, district, and facility, as these were not patient-specific data. The dropped variables were highly correlated or had little data entered in the paper file or EMR. The concordance score was calculated per record as the number of variables that exactly matched in both the paper file and the EHR after the values had been normalized, following the approach of Muthee et al [14]. This differed from our above mentioned analysis in that if the data were missing in both the paper file and the EHR, the records were counted as concordant.

Therefore, the concordance score here is a number from 0 to 15, which is the count of the number of concordant variables in a single record.

The randomization list of the control and intervention arm HFs was used to label the HFs in this study as intervention or control. For the number of years of experience with the EHR, we used the arithmetic mean of the number of years the clinical users and data managers at each HF had been using the EHR (if there was >1 individual). Technology experience was determined based on answers to the survey regarding “outside of work” use of technology, which included how frequently they (1) sent SMS text messages, (2) used the internet on a mobile phone, (3) used a computer, or (4) accessed the internet. For each question, they received 1 point for each time they said they used the technology either “most of the time” or “always,” resulting in a score from 0 to 4.

### Statistical Analysis

The study metrics are summarized in Textbox 1. We calculated the correlation between the concordance score and each HF characteristic using the Pearson correlation coefficient with Bonferroni correction applied to adjust for multiple comparisons. Subsequently, we sought evidence for the hypothesis that being an intervention site in the RCT would have a positive effect on the recording of VLs or drug dispensing episodes in the EHR. VL results and drug regimens were standardized as described in the Data Processing and Analysis section (due to different ways of recording the same data) and then counted as a match when the data were not missing and matched exactly. We could only compare data from after the intervention had been rolled out in July 2018. We then evaluated whether there was any association between the variables using a simple chi-square test to determine whether there was a correlation and using a Pearson contingency coefficient to estimate the effect size (for simple data such as a 2x2 contingency square, Pearson contingency is equivalent to both the phi coefficient and Cramer V). Data analyses were performed using R software (R Foundation for Statistical Computing).

Ethical Considerations
The study was approved by 3 institutional review boards: Rwanda National Ethics Committee, Kigali (913/RNEC/2016), and the University of Leeds School of Medicine Research Ethics Committee, Leeds, United Kingdom (MREC16-176). This study was also reviewed in accordance with the US CDC human research protection procedures (approval no CGH HSR 2014-270a) and determined to be research. However, CDC investigators did not interact with human subjects or have access to identifiable data during this study.

Results
Overview
A total of 3467 records were reviewed in both the paper charts and the EHRs in the 50 HFs selected, with a mean of 69.3 (SD 8.8) records reviewed per HF. A total of 194,152 data items were collected using the ODK-based study tool. Three metrics of data quality were applied: (1) data completeness of EHR and paper records, (2) matching of the values of individual data types between EHR and paper records, and (3) concordance scores of matches for 15 regularly collected data items between EHR and paper records.

Table 1 presents all 28 variables collected from the paper and EHR records and the percentage completeness of each category. Few patients were on second-line drugs and possibly 1 was on third-line drugs (shown in the EHR only) therefore these 4 fields were not included in further analysis. Notably, paper VL records were 20% to 30% more complete than EHR records.

Table 2 presents the matching of variables between the paper records and the EHR records. Most nondate variables had fairly high levels of matching, although 5 were between 82% and 85%, just below the threshold set for high quality. Similar to the data completeness results, VL values had lower matching rates (59.5% for the most recent value and 65.8% for the oldest value). Few patients were prescribed second-line or third-line drug regimens (and their matching was low).

Additional analysis of date matches showed that for single-entry dates, such as “date of enrollment in HIV care,” matches were fairly high (60.2%-75%) compared to repeated dates, such as “date of last visit” or drug pickup date. For the “one-off” dates, most errors appeared to be mistakes in transcription (eg, small date differences and single character errors). Detailed analysis of the degree of error in these date fields showed that many incorrect one-off dates, such as “date of enrollment in HIV care,” were within 1 month of the correct value 34% to 38% of the time. Conversely, for regularly updated dates, only 10% to 13% of the errors were within 1 month of the correct value or 29% to 34% of the errors were within 3 months, suggesting that these items were not updated frequently in the EHRs.

aART: antiretroviral therapy.
bWHO: World Health Organization.
cThe only matching rate below 59% that was not a date was for regimen 2 drugs that had very little data (n=78).

Concordance Scores

The mean overall concordance score was 10.2 (SD 1.28) for 15 (68%) variables in all 50 HFs. Only 2 HFs were at or above the threshold of 85% concordance. However, 8 of the 15 variables in the concordance score (not including the date of birth) were dates (refer to Table 1 for the included variables). The concordance score would be higher if dates that match within 1 month were included.

Evaluation of Factors Associated With Concordance Scores in Each HF

Correlations between the concordance scores and most HF characteristics were not significant. For the survey response that “the EHR was available always or nearly always,” there was a positive correlation with the concordance score, with $r=0.16$ (95% CI 0.13–0.19; $P<.001$; Figure 1). There was also a significant (negative) relationship between user responses suggesting that they had higher technology experience, and concordance scores with $r=-0.11$ (95% CI –0.15 to 0.08; $P<.001$). There was no significant correlation between the concordance scores and users’ reported years of EHR use (Table 3).
Figure 1. Correlation between concordance scores and the reported electronic health record (EHR) availability or uptime (ranging from 1 to 5 Likert scale responses of EHR users).

Effects of Alerts in the Intervention HFs on Matching of Key Variables in EHRs and Paper Records

As the intervention was implemented in July 2018 and the data for the data quality study were collected in November and December 2018, there was a 4-month to 5-month window when the alerts were active. All intervention HFs had alerts for starting a new treatment, but few new patients were enrolled in the 5-month time frame. Therefore, there was insufficient data to study the effects of alert 1. However, there was sufficient data to compare the data quality metrics of the 11 intervention HFs that had alerts for missing VL results (alert 2) with the 39 HFs without these alerts. Figure 2 shows the concordance scores for each site color coded by intervention status. Figure 3 presents the effect of the VL alerts on overall data matches between the EHRs and the paper records, ranked by percentage matching of variables between the 2 sources. The HFs with the VL alerts (orange color) had a higher rank overall than the control HFs.

In HFs with alerts, 85 (26.7%) of 318 VL records in the EHR matched those in the paper records, but in HFs without alerts, only 120 (11.9%) of 1008 VL records matched (P<.001, chi-square test).

Furthermore, we compared the number of drug pickups in the EHRs that exactly matched with those in the paper file records, comparing the intervention HFs with VL alerts with HFs without such alerts. The results are shown in Figure 4. In HFs with alerts, 280 (36.2%) of 774 of the records of drug pickups matched, but in HFs without alerts, only 183 (18.7%) of 981 matched (P<.001). A second analysis using the chi-square test and Pearson contingency coefficient for the 25 HFs revealed χ² =67.5 (P<.001), indicating a strong effect (φ=0.20, 95% CI
0.15-0.24). Despite the significantly higher data quality at the intervention HF s, not all HF s showed this effect.

**Figure 2.** Mean concordance scores for all health facilities color coded by intervention status (maximum score=15).

**Figure 3.** Graph showing percentage data matches for viral load results between paper records and electronic health records for each of the 25 health care centers in the intervention arm, ranked by percentage of matches.
Figure 4. Graph showing percentage data matches for drug pickups between paper records and electronic health records among the same 25 intervention health facilities (HFs) as in Figure 3. The overall scores were higher than in Figure 3 but only 1 (intervention) HF score was more than the data quality threshold.

Discussion

Principal Findings

The results showed that the completeness of the paper records and EHR records was generally >85% threshold for good quality, with the exception of VL data collected in the 2 years before the study data collection (VL results 2 and 3). The completeness varied across the data items, with the best results (>99%) for EHR data seen in demographic data, date of enrollment in antiretroviral (ARV) care, date of first being prescribed ARV drugs, and date of last visit. The lowest completeness was seen in the second-line and third-line drug regimens, but very few patients were prescribed these regimens. There was clear evidence that the electronic records were not being updated in a complete and timely manner for some data items at most HFs (based on concordance scores), with only 2 HFs meeting the 85% threshold for good data quality. Furthermore, there was evidence that certain HFs were more effective in data entry and management. Using data from the previously published user experience survey by Fraser et al [4], we compared the measures of user experience with the EHRs in the same HFs included in this study. Facilities reported to have more consistent uptime and availability of EHRs showed significantly better data quality based on the concordance scores. However, HFs with higher “technology experience” scores had lower concordance scores, the reason for which is unclear.

A key scientific question for the overarching study was to determine whether the enhanced EHR in the intervention HFs improved both the usability and use of the EHR and the completeness and overall quality of key data items required to support effective HIV care. The second decision support alert (refer to the Methods section) was designed to warn if a VL result had not been uploaded to the system by 6 months after starting ARV treatment or by 12 months after the last VL result (allowing for up to 2 months transport and data entry delays). There was a 4-month to 5-month period with the intervention in place before we collected data for this data quality study, allowing the assessment of whether VL data were more complete in the EHRs from the 11 HFs that received this alert. Although data completeness and timeliness for VL data were overall <85% of the threshold, with only 11.9% completeness in the 39 control HFs lacking the VL alert, completeness was significantly higher (26.7%) in the 11 intervention HFs that had VL alerts. A similar effect was seen for drug pickup data, suggesting that the presence of VL alerts impacted the overall data entry processes or behavior and not just the specific data type in the alert. It should be noted that VL testing was infrequent before the start of the study, as the laboratory capacity was still being established, which may have affected data management and data entry in the EHRs, especially for older values. The metrics for overall data quality and completeness may have been higher if there had been regular data quality improvement visits to Rwandan MOH HFs, an effect seen in the study by Muthee et al [14] in Kenya. Another strategy for improving data quality and user experience is the implementation of EHR systems, allowing direct point-of-care data entry rather than entering data on paper and in the EHR, as observed for VL results in Kenya [32]. The findings in this study also indicate
that data quality and timeliness would have likely been improved more generally using automated tools to alert staff of missing data for key variables such as VL results, using form field validation to detect impossible values, and comparing date values with other data. The analysis of the degree of error in date fields showed that many incorrect one-off dates, such as “date of enrollment in HIV care,” were within 1 month of the correct values for approximately one-third of the times and therefore may have been adequate for the care of HIV patients seen every 2 to 3 months. Incorrect repeated dates such as “last clinic visit,” “drug pickup,” and “VL” were within 1 month of the correct date, ≤12% of the times, and therefore may be less fit for use in patient care. Overall, most data were considered fit for purpose, as confirmed by the user survey [4], which showed a reliance on the EHR data for clinical care and reporting. Regular monitoring of data quality metrics and intervention at poorly performing HFs would likely help address major deficiencies efficiently.

The implications of these results are much broader than just HIV care, which provided the environment for this study. Primary care EHR systems remain rare in LMICs, but recent progress with facility-based EHR systems, such as OpenMRS in Haiti, Sierra Leone, parts of India, and the Philippines, are laying the foundations for wider use [33]. Mobile-based and tablet-based systems that support care in communities and some HFs should provide a much wider range of data for clinical and public health use. The World Health Organization (WHO)—led Open Smart Register Project [34] has 150 million patients now, the majority being in Bangladesh. Other mHealth systems, such as CommCare [35] and ODK [31], are used in many LMICs [36]. All these systems have the ability to share data with EHRs, such as OpenMRS. They increasingly support interoperability standards such as HL7-FHIR [27] for interoperability with a range of other health information systems, including laboratory and pharmacy systems, radiology information systems, and the District Health Information System-2 [37]. FHIR-based Application Programming Interfaces and toolkits are also being built into the Apple OS and Android operating systems [36]. Projects using data science techniques and machine learning are increasing in LMICs and require high-quality data sets that are representative of all communities and groups to avoid biases or poor performance in vulnerable groups [38].

Comparison to Previous Work

Muthee et al [14] studied data quality in 53 HFs running the KenyaEMR OpenMRS-based system. They analyzed data from a data quality assessment (DQA), which had been collected by MOH lead teams that visited the HFs. They found ≥1 missing value in 735 (31%) paper forms and 747 (32%) KenyaEMR records, a higher missing rate than that in this study. Concordance scores were calculated in the same manner as in this Rwanda study, with a mean concordance of 11.9 (SD4.0) for 20 variables at baseline. Furthermore, they were able to compare the DQA results with a second DQA assessment of 27 HFs. They showed that HFs with previous DQA had significantly better data quality on the second visit, with missing data falling to 13% and concordance scores increasing to a mean of 13.6 (SD 4.2, difference in concordance scores P<.02). This result suggests that the process of measuring data quality and providing feedback to staff can have long-term benefits. The mean concordance scores of 13.6 (SD 4.2) for 20 variables (68%) at the second DQA were equivalent to those in Rwanda, which was 10.2 (SD 1.28) for 15 variables (68%). Abiy et al [39] studied data quality in an HIV treatment program in Ethiopia. They compared the paper and EHR versions of 250 records. Data completeness was 78% (95% CI 70.8%-85.1%) for paper records and 76% (95% CI 67.8%-83.2%) for the EHR. They used the κ statistic to compare variables in both records, with results ranging from κ=0.93 for demographics, κ=0.86 for WHO stage, and κ=0.83 for “general appearance.” Furthermore, Ngugi et al [40] studied the clinical use and completeness of data entry in KenyaEMR at 219 HFs in Kenya. They showed a wide variation in data entry per month in different HFs and noted that this was likely affected by “patients’ volume, frequency of patients’ visits (encounters), EHRs mode of use, and active use of the system during care.” Haskew et al [41] studied the quality of data collection and the effects of clinical alerts on HIV patient care in Western Kenya before and after the cloud-based implementation of an OpenMRS EHR. They showed that clinical alerts reduced missing data and improved the quality of care. Missing data were significantly reduced for key variables (before and after alerts implemented) including “patient source” (375 to 69 patients), “first CD4 count” (826 to 35 patients), and “first WHO stage” (2258 to 479 patients; all P<.001). The number of patients eligible for ART (based on CD4 count and WHO stage) but not yet started receiving it, fell from 1346 (29.6%) to 270 (6.2%; P<.001) [41].

A study of the health management information system in 16 health centers, 28 health posts, and 1 hospital in Ethiopia showed that training staff to fill out the data forms was significantly associated with improved data quality (odds ratio [OR] 2.253, 95% CI 1.082-4.692), and measures showing effective supervision and leadership were also beneficial [42]. A study of HIV clinical data collection systems at 21 HFs (18 in Africa) showed a reduction in missing data associated with training in data management (OR 0.58, 95% CI 0.37-0.90) and weekly hours spent by a data clerk working on the data collection system (OR 0.95, 95% CI 0.90-0.99) [16]. Previous studies suggest that poor completion or accuracy of key data items required for clinical care is likely to limit the benefit of EHR systems in day-to-day patient management, such as the functioning of clinical decision support system in this study and that reported by Haskew et al [41]. Furthermore, it impacts quality of care metrics (eg, in cancer care in the United States [43]) and efficient reporting of data for clinical teams, MOH, and funders [16,42].

Limitations

The study was limited to a subset of the MOH-run OpenMRS EHR systems for use in HIV care. The inclusion criteria for the 112 HFs in the larger study favored HFs with better information technology hardware and successful implementation of a server monitoring tool [4]. Although the intervention HFs appeared to show improved data quality and completeness for certain variables, this effect might change over time. Although the user survey showed that staff in the intervention and control HFs received similar amounts of training and were equally positive about their training, it is possible that differences in the type of...
training in the intervention HFs and emphasis on the importance of VL contributed to better data quality. More robust and longitudinal studies are needed to understand the effects of different technologies on the use of EHR, including variations within and across HFs and individuals.

Conclusions

The study found that there was generally high data completeness in both EHR and paper records in Rwandan MOH-supported HFs. The percentage matching and concordance scores for the EHR and paper records were lower, but this mainly affected the recording of dates. The considerable potential benefits of EHR systems for patient care for HIV and other diseases will only be realized with sufficient support, training and monitoring of data quality, and adequate technical support and infrastructure to ensure reliable systems. The use of “point-of-care” EHR systems rather than transcription of data from paper records can also improve user experience and data completeness. The results of this study show that automated alerts regarding data quality, completeness, and timeliness can significantly improve these metrics in remote HFs in a low-income country. However, to be fully effective, these alerts should be combined with other strategies to ensure high system uptime and a range of data quality improvement strategies, including training, regular supervision, and feedback. These improvements will likely help drive the much wider use of EHR data in LMICs for clinical care, reporting, data science, and machine learning. Furthermore, the data collected will support population and public health uses, including syndromic surveillance, notifiable disease reporting, real-time monitoring of disease burden, and forecasting resource requirements to meet care needs.

Acknowledgments

The authors would like to thank the clinic staff at the study health facilities in Rwanda for their participation in the data quality study, the staff of the Rwanda Biomedical Center and the Ministry of Health, and the informatics team at Partners in Health in Rwanda for technical assistance and advice. The authors would like to thank Dr Eric Green (Duke University) for assisting with the randomized controlled trial design and randomization. They would also like to thank Henry “Roo” Fraser for assisting with the creation of diagrams.

This research was supported by the President’s Emergency Plan for AIDS Relief through the Centers for Disease Control and Prevention under the terms of program grant U01 GH000782-01 awarded to the National University of Rwanda. Additional funding and in-kind support were provided by Brown University, Providence, Rhode Island, United States. HSFF was a Marie Skłodowska-Curie Fellow from 2015 to 2017, funded by the European Union’s Horizon 2020 Research and Innovation Program under grant 661289, “Global eHealth.”

Abstract

The use of innovative digital health technologies in public health is expanding quickly, including the use of these tools in outbreak response. The translation of a digital health innovation into effective public health practice is a complex process requiring diverse enablers across the people, process, and technology domains. This paper describes a novel web-based application that was designed and implemented by a district-level public health authority to assist residential aged care facilities in influenza and COVID-19 outbreak detection and response. It discusses some of the challenges, enablers, and key lessons learned in designing and implementing such a novel application from the perspectives of the public health practitioners (the authors) that undertook this project.

web application; digital health; communicable disease control; outbreak; surveillance; influenza; aged care; aged care homes

Introduction

Digital health technologies such as web- and mobile-based applications have proliferated over the last 2 decades [1]. Historically, these applications have been used in communicable disease surveillance and control [1-3]. However, the public health field is beleaguered by tools that are short-lived, duplicative, disconnected, of poor quality, or not suited to user needs [2,4,5]. There is also growing evidence that there are consistent barriers to effective implementation and adoption of digital health technologies [4]. Some of these include change management, stakeholder acceptance, training, supporting infrastructure, sustainable financial and human resources, and governance for quality and safety [1,4]. It is therefore critical for public health practitioners to recognize the broader set of necessary factors and considerations when planning, designing, and implementing innovative digital health interventions.

In 2017, the Sydney Local Health District (SLHD) Public Health Unit (PHU), a district-level public health authority, embarked on a digital health innovation project to design, develop, and implement a web-based application—the Influenza Outbreak Communication, Advice and Reporting (FluCARE) application—to assist staff in residential aged care facilities (RACFs) in the timely detection and response to influenza outbreaks. Early outbreak notification to the PHU has been shown to reduce outbreak duration and impact [6].

The application was launched as a pilot across the district in late 2019. In 2020, in response to the COVID-19 pandemic, rapid adaptations were made to FluCARE to incorporate COVID-19 monitoring, supported by additional procedures, guides, and training modules. FluCARE continues to be used by RACFs across the district. The purpose of this paper is to describe the design, development, and implementation of the FluCARE application, as well as key challenges, enablers, and lessons learned from the perspective of the public health practitioners (the authors) who implemented the application.

Setting and Context

FluCARE was undertaken in the SLHD, which encompasses a metropolitan area of Sydney, Australia, with a population of 640,000, of which approximately 80,000 (12%) are aged 65 years and older [7]. Within the district, there are 62 RACFs, which vary in size, care levels, and ownership, with over 4700 operational bed places in total [8].

The PHU is responsible for local communicable disease control and outbreak management within the SLHD. This includes assisting RACFs in responding to influenza outbreaks, which remains a high priority for public health due to the potential for
significant health impacts on older adult residents [6]. While RACFs are not mandated to report influenza outbreaks to the PHU, it is recommended in national guidelines [9]. The national guidelines also provide definitions for suspected and confirmed influenza cases based on their symptoms and laboratory results, as well as the criteria for declaring a potential or confirmed outbreak. Upon the notification of an influenza outbreak, the PHU assists the RACF by advising on response actions and by monitoring outbreak progress through daily line lists of cases submitted by the RACF.

### Design and Development of FluCARE

An overview of our application design, development, and implementation activity is shown in Figure 1.

**Figure 1.** FluCARE project timeline demonstrating the relationships between stakeholder engagement, design and development, and implementation support activities. Staging refers to a prelaunch phase of FluCARE testing within the SLHD hosting environment. *Web-based training modules were offered through the Moodle platform. Conceptual Design

Application scoping and conceptual design occupied a significant portion (8 months) of our project timeline due to the need to ensure that we had the appropriate type and level of functional capability included in the application. A variety of different stakeholder consultation sessions were held with RACF and PHU staff to understand design needs (see Table 1, item 6), and through the establishment and use of a working group, we were able to finalize and agree on a minimum viable product (MVP; see Figure 1).
Table. Description of the design and technical features of FluCARE as per the WHO Mobile Health Evidence Reporting and Assessment (mERA) criteria [10].

<table>
<thead>
<tr>
<th>Item</th>
<th>mERA criteria or feature</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>Infrastructure</td>
<td>FluCARE is a web-based application. User access requires internet connectivity and a web browser, which are typically available in the PHU and the RACFs in the district. The application is optimized for desktop and laptop computers but can also be accessed by tablet and mobile devices. Users also require access to an individual email account and/or mobile phone to receive MFA codes. While smartphone device ownership in Australia is 91% [11], their use by RACF staff at work may be limited by workplace policies and/or signal strength. The FluCARE application and associated databases were initially hosted on a local server maintained within the SLHD secure network. At the time of writing this viewpoint, the application was being transitioned into the Microsoft Azure cloud environment.</td>
</tr>
<tr>
<td>2</td>
<td>Technology platform</td>
<td>FluCARE is an ASP.NET Core MVC web application written in the C# language with the Razor View engine and Telerik controls. Sensitive data are encrypted and held in a Microsoft SQL Server database. SendGrid is used for the delivery of email notifications and MFA codes. Amazon SNS is used for the delivery of SMS MFA codes. FluCARE is hosted on IIS in a Windows environment.</td>
</tr>
<tr>
<td>3</td>
<td>Interoperability</td>
<td>FluCARE is not directly connected to any other local or state health information system. However, relevant reports can be generated and exported as a CSV file, which can be configured for upload to the NSW Notifiable Conditions Information Management System where PHUs are required to report and document RACF influenza outbreaks.</td>
</tr>
<tr>
<td>4</td>
<td>Intervention delivery</td>
<td>RACFs register for and access the FluCARE application via the application web page. The PHU promotes RACF awareness, access, and use of FluCARE via the PHU’s annual workshop on winter preparedness for RACFs, regular email reminders, and occasional update teleconferences.</td>
</tr>
<tr>
<td>5</td>
<td>Intervention content</td>
<td>FluCARE content and processes are based on the national CDNA guidelines for the management of influenza outbreaks in RACFs [9]. Application content was developed, adapted, and reviewed by a multidisciplinary working group.</td>
</tr>
</tbody>
</table>
Design and development

End-user engagement and testing were conducted at multiple points throughout the design and development process (see Figure 1):

- Initial RACF staff consultation via an open forum discussion and structured survey, and key informant interviews with PHU staff on their surveillance needs informed the conceptual design of FluCARE.
- Preproduction wireframes were presented to PHU and RACF staff (both at an annual winter preparedness workshop and in facility-based meetings) to seek feedback on user-friendliness, aesthetics, and functions prior to MVP launch (see Figure 1).
- Postproduction UAT was conducted with RACF staff focus groups (not reported in detail here).

User feedback

UAT conducted with a focus group of RACF staff found the application design to be user-friendly and accessible, the content informative, and the functionalities useful and likely to save time and reduce workload. Most importantly, the UAT found that most RACF staff users would access and use the application on their desktop, rather than on mobile devices at the bedside, which led us to optimizing the application for desktop use.

Access of individual participants

Access to the FluCARE application requires a desktop computer or mobile phone and internet connection either at work or home.

Cost assessment

Economic evaluations of FluCARE are yet to be conducted.

Adoption inputs/program entry

PHU and RACF users are required to complete training on FluCARE via either a 2.5-hour face-to-face training session or a set of web-based modules. User manuals are available within FluCARE. Designated PHU staff provide users with email and telephone support from initial registration to operational use of FluCARE.

Limitations for delivery at scale

Application development will be necessary to allow FluCARE to cater for multiple districts or jurisdictions. Currently, further scale-up of FluCARE is limited by our district’s IT infrastructure and human resource capacity to support an expanded number of RACFs and users. Implementation research is needed to inform and adapt strategies to support FluCARE implementation to other LHDs or PHUs.

Contextual adaptability

FluCARE was built as a proof of concept with a focus on influenza outbreaks in RACFs in our district. However, we believe it would be adaptable for other communicable diseases, settings, districts, or jurisdictions. For example, FluCARE was rapidly redeveloped to incorporate COVID-19 outbreak monitoring in RACFs.

Replicability

The FluCARE application and supporting processes, such as user manuals, training modules, and standard operating procedures, can be replicated for introduction into new districts or jurisdictions.

Through the RACF stakeholder consultation sessions (see Figure 1), the PHU identified 3 key barriers to effective influenza surveillance and outbreak response and, with the working group, designed a series of features that addressed these barriers, as shown in Table 2 below. The working group membership included clinical and epidemiological staff from within the PHU, geriatric care managers and senior information and communication technology (ICT) staff from across the district, and managers of respiratory diseases from within Health Protection NSW. The group met weekly to advise on the components or features of the application and together produced a comprehensive business requirements document from which only the essential elements for an initial MVP build had to be identified and agreed on (see Figure 1).

Development

Once the MVP was developed, a comprehensive audit of the application’s content, algorithm, and functions was conducted, as well as external user acceptability testing (UAT) with a focus group of self-volunteered RACF staff (see Figure 1). The UAT was designed as a guided, hands-on training session on FluCARE followed by a structured feedback session with comments obtained via moderated group discussion. This testing identified minor issues and potential improvements, such as changes to interface workflow. The MVP then underwent further cycles of testing and enhancement prior to pilot launch. After the MVP launch, an independent security assessment verified that the technical and architectural design of the application met governing standards (Table 1, item 15 and Figure 1). Further to this audit and to support appropriate local procedures in how FluCARE data were managed, the PHU underwent an internal security risk assessment and developed a risk management plan with our IT services prior to launch. This was particularly important as the application transitioned from the digital developer’s environment to being hosted by the SLHD ICT local servers (see Figure 1).

Even after launch, the FluCARE application underwent further refinements over time in accordance with PHU or RACF feedback. The most significant enhancement was a rapid 6-week
development in March 2020 to incorporate COVID-19 monitoring and outbreak detection (see Figure 1). At the time of developing the FluCARE application, there was no standardized and validated way to report the features of a web-based application, so the features of FluCARE have been described as per the World Health Organization checklist on Mobile Health Evidence Reporting and Assessment criteria above (see Multimedia Appendix 1 [10]).

### Implementation Process

Preparations for application implementation occurred in parallel to the development process, as illustrated in Figure 1. The authors designed the implementation supports based on 2 reviews of the literature [16,17] focused on the implementation and adoption of health technologies by health care professionals, as shown in Figure 3.

**Figure 3.** Overview of the FluCARE digital health implementation package as informed by Cresswell and Sheikh [16] and Gagnon et al [17]. FluCARE: Influenza Outbreak Communication, Advice and Reporting application; ICT: information and communication technology; PHU: Public Health Unit.

Existing engagements with RACFs, such as the annual winter preparedness workshop, as well as FluCARE-specific outreach, including the various UAT episodes (Table 1, item 6), were used to raise awareness and user buy-in of FluCARE (Figure 3; personal and social enablers). A range of training resources and sessions (described in Table 1, item 10; see Figure 1) were developed by the working group to support PHU and RACF staff onboarding. Operationally, a suite of policies and
procedures were developed to govern the use of FluCARE as well as to manage issues typically introduced by digital technologies, such as user management, data security, and downtime contingency plans (see Figure 1, items 1 - 8 and Figure 3; organizational enablers).

Internal IT infrastructure and operational support from the SLHD ICT Services were also critical. The SLHD ICT Services built the requisite highly available and secure server environment to host FluCARE and continue to provide services for maintenance and issues resolution (see Figure 3; technical enablers).

For ongoing monitoring, quality improvement, and safety, the PHU established a registry (issue log) to prospectively record technical or operational issues and any improvement suggestions (see Figure 1). These are routinely reviewed by the working group for further updates to the application (technical enablers). Further evaluation of the implementation of FluCARE through a feasibility study has been published [15], and effectiveness studies are planned.

Discussion

Despite substantial challenges related to the redesign of the application during the COVID-19 response, the main lessons learned across the entire design, development, and implementation time frame of FluCARE (as shown in Figure 1) were the importance of user-based design activity, information security and privacy, and organizational support (such as funding and IT infrastructure).

User-Related Lesson: User Engagement Is Critical and Should Be Embedded in All Phases of Design, Development, and Implementation

User-centric design is a well-understood principle in IT projects [3,5,18-20]. From the outset, we were mindful that FluCARE’s capacity to improve outbreak outcomes was dependent on its ability to be accepted and adopted by RACF staff. This is typically determined by factors such as an application’s perceived usefulness, reliability, and user-friendliness [5,21]. As such, input from RACF staff was pivotal. Beyond informing the core functions of the application, feedback from RACF staff via the various user engagement and testing episodes embedded in our design and development process (see Figure 1; 0-27 months) was valuable in answering key design questions encountered by the working group and digital developers, for example, whether to optimize the application for desktop versus mobile use. Lastly, while acknowledging the importance of user-based design in the development of a digital health tool, no one design approach is accepted as a gold standard [22]. However, we did not conduct our user-based design activity through a theoretical framework or research process and would have benefited from such a systematic approach.

Technical Lesson: Data Security Should Be Addressed With a Multifaceted, Risk Management Approach

Data security and information privacy is a central concern that must be thoroughly addressed to ensure user acceptability, and that ethical and professional obligations are met, particularly when dealing with personally identifiable health data [5,23]. Addressing all facets of security appropriately required not only an understanding of the legislation, policies, and procedures in place to secure and manage health data appropriately within New South Wales but also a practical risk management approach in order to mitigate any perceived risks to data breaches. Based on the recommendations from the independent security assessment, the working group developed a user access management policy and security risk management plan to help mitigate any inappropriate access or use of the application and to ensure the security of the personal health information within the application (Figure 1; 15 - 27 months). While much of the existing literature focuses on the technical aspects of security, it is important to recognize that data governance strategies, staff training, and incident detection and response plans are also essential for security [24-26]. This multifaceted security approach was applied for FluCARE, as detailed in Table 1 (item 14).

Organizational Lesson: Organization-Wide Support for Digital Innovation Should Be Fostered and Promoted

Supportive organizational culture and structures for digital health innovation are important enablers for successful design and implementation [5,27]. FluCARE development was undertaken within a forward-thinking organization where innovation in health care IT is a strategic priority [28]. The project received high-level support at initiation through the SLHD executive as well as at the PHU and IT departmental levels, which facilitated supportive resourcing from the IT department, including their de novo build of the required hosting environment for FluCARE. However, we may have potentially benefited from an organization-wide mechanism for pooling institutional experience and sharing resources across different projects, given that a number of other application developments were also occurring in the SLHD over the time period of the design, development, and implementation of FluCARE (see Figure 1). This has potential for leveraging economies of scale, reducing duplicative overhead costs, optimizing interoperability, and improving procedural efficiencies [5,29].

Conclusion

The translation of an innovative application idea into an effective public health tool is a multifaceted process, which importantly includes early and ongoing user engagement, considered but practical data governance and security measures, organizational support, and dedicated resources and IT infrastructure to support maintenance over time. From our experience, these elements are essential to ensure user-friendly and security-conscious design as well as successful application implementation and uptake.
Acknowledgments

The initial development of the Influenza Outbreak Communication, Advice and Reporting (FluCARE) application was funded by winnings from the Sydney Local Health District (SLHD) “The Pitch” innovation challenge. This project was also supported by a grant to Sydney Health Partners (MR9100001) from the Australian Government’s Medical Research Future Fund (MRFF) as part of the Rapid Applied Research Translation program. We also thank the SLHD Information and Communication Technology (ICT) Services and FAQ Interactive for their technical contributions in the development and implementation of the FluCARE application.

Combining Digital and Molecular Approaches Using Health and Alternate Data Sources in a Next-Generation Surveillance System for Anticipating Outbreaks of Pandemic Potential

Abstract

Globally, millions of lives are impacted every year by infectious diseases outbreaks. Comprehensive and innovative surveillance strategies aiming at early alert and timely containment of emerging and reemerging pathogens are a pressing priority. Shortcomings and delays in current pathogen surveillance practices further disturbed informing responses, interventions, and mitigation of recent pandemics, including H1N1 influenza and SARS-CoV-2. We present the design principles of the architecture for an early-alert surveillance system that leverages the vast available data landscape, including syndromic data from primary health care, drug sales, and rumors from the lay media and social media to identify areas with an increased number of cases of respiratory disease. In these potentially affected areas, an intensive and fast sample collection and advanced high-throughput genome sequencing analyses would inform on circulating known or novel pathogens by metagenomics-enabled pathogen characterization. Concurrently, the integration of bioclimatic and socioeconomic genome sequencing analyses would inform on circulating known or novel pathogens by metagenomics-enabled pathogen characterization. Concurrently, the integration of bioclimatic and socioeconomic data, as well as transportation and mobility network data, into a data analytics platform, coupled with advanced mathematical modeling using artificial intelligence or machine learning, will enable more accurate estimation of outbreak spread risk. Such an approach aims to readily identify and characterize regions in the early stages of an outbreak development, as well as model risk and patterns of spread, informing targeted mitigation and control measures. A fully operational system must integrate diverse and robust data streams to translate data into actionable intelligence and actions, ultimately paving the way toward constructing next-generation surveillance systems.

Introduction

Overview
The COVID-19 pandemic has illustrated the limited capabilities of existing surveillance systems worldwide and the need to maximize the use of data to inform public health decisions [1,2]. Among the lessons learned from the pandemic is the critical importance of leveraging early alert warning capabilities to detect and respond to emerging and reemerging pathogens before they cause widespread impact. Unfortunately, existing global surveillance systems are often fragmented, lack coordination and collaboration, and do not prioritize early alerts [3,4]. This has resulted in millions of lives lost due to outbreaks of infectious diseases that usually occur following spillover from contacts at the animal-human interface. Therefore, as governments, civil society, and private entities continue to recover from the losses incurred by the COVID-19 pandemic, it is crucial to sustain the momentum generated by this global crisis and prioritize efforts to elevate health surveillance to the next level.

Developing a system focused on early warning tools is a fundamental requirement to enhance pandemic preparedness and response [2,4]. By investing in disease surveillance systems and building resilient health systems, countries can better prevent, detect, and respond to infectious diseases and other health threats. In this endeavor, we should take advantage of the improvements in several branches of technology and science, in particular digitalization of health routine records, data science, and artificial intelligence modeling, for the rapid gathering and analysis of large amounts of diverse data streams [2,4,5]. Next-generation early-alert warning systems should prioritize sensitivity by integrating various data streams for syndromic surveillance, as opposed to relying on traditional case reports. Additionally, achieving specificity through molecular pathogen characterization is crucial for efficient preemptive actions (Figure 1A). However, the process of collecting and analyzing samples is complex and expensive. To optimize logistics and reduce costs, it is recommended to identify priority areas for sample collection through risk assessment based on syndromic surveillance.

To inform the development of next-generation surveillance systems, here we outline key principles and requirements that should be addressed for creating a comprehensive and effective approach to disease monitoring. We instantiate these principles into the Alert-Early System for Outbreaks with Pandemic Potential (ÆSOP)—a system under development in Brazil that aims to improve the surveillance capacity and pandemic preparedness of this country.
Preparing for the Next Pandemic by Harnessing the Power of Data

Many countries, Brazil included, have now established national digital systems that capture routine health information, such as clinical consultations at the primary health care (PHC) level, hospital admissions, and drug prescriptions, and the COVID-19 pandemic has also accelerated integration of these digital systems within health systems and networks [6-8]. The next generation of surveillance systems should leverage this existing and emerging rich data landscape and integrate health routine databases with alternate data streams.

In ÆSOP, early warning will be achieved by monitoring of clinical-related data, which enables the mining of potentially anomalous patterns, such as unexpected surges of respiratory diseases outside the expected seasonality or in atypical age groups or locations (Figure 1B). More specifically, PHC weekly visits coded by reason for encounter, as well as drug sales related to acute respiratory syndromes and social media interactions will be monitored. Brazil’s national PHC database, SISAB (Information System for Primary Health Care; in Portuguese, Sistema de Informação em Saúde para a Atenção Básica), harbors data on the majority of public-funded PHC encounters in the country [9], coded by either the International Classification of Diseases or the International Classification of Primary Care, with 5535 out of 5570 municipalities reporting to SISAB in 2020, corresponding to 98.5% of the total Brazilian population for that year. Complementary, drug sales data encompasses approximately 95% of all drug sales in Brazil.

Continuous monitoring of clinical-related data streams in ÆSOP will enable the system to detect shifts in patterns, which can signal potential outbreaks. By issuing anticipatory warnings to health authorities, the system aims to provide early and timely alerts, as severe cases are not expected to be reported until days or weeks after an increase in mild cases seeking PHC assistance [1,10]. A proof-of-concept evaluating the early-warning capability performance of the system was conducted in Brazil,
totaling over 589 million patient visits to PHC facilities between 2017-2020 in 97% of Brazilian municipalities [11]. Of these visits, 4.24% were associated with upper respiratory infections, and results showed that rises in patient consultation in PHC encounters for respiratory disease were able to anticipate increases of severe acute respiratory syndromes, with geographical variabilities [11]. In a retrospective analysis conducted with data from Bahia, a state with 14.8 million inhabitants in the Northeast region, PHC syndromic monitoring was able to detect COVID-19 entry in 20 out of 21 regions of the state at least 1 week before the rise in COVID-19 cases, showing feasibility for use of the system [12]. The system can also be adapted to the monitoring of other syndromes, such as dengue-like illnesses, by reparametrizing the codes for reason for encounter and drugs used to treat these diseases. This flexibility by design is a key feature that enables the system to be customized to the specific needs of different regions and populations.

Different modeling frameworks were developed and applied to health data aiming at the early detection of outbreaks [13-17], including statistical, mathematical, and computational methods. Although some of them are in use in the routine of health surveillance agencies [15,16], to the best of our knowledge none has been adopted as a gold standard of undoubtedly effectiveness. However, all methods have limitations, and further developments are still needed in this field [2-4]. The proposal described herein aims to combine several approaches in a systemic logical approach combining their strengths. Table 1 presents general features of traditional health surveillance in comparison to what we envision would make a next-generation surveillance system (exemplified by ÆSOP) that overcomes identified deficiencies which hamper pandemic preparedness and response.

### Table 1. Comparison of key features in traditional disease surveillance systems with next-generation approaches.

</tr>
</tbody>
</table>

This approach should overcome current public health response limitations, as digital health has been recognized as a critical element [18] and an emerging discipline to prepare for, prevent, and respond to pandemics [1,10], while the syndromic surveillance approach will allow for greater sensitivity [19]. It is also of great importance that this monitoring tool is built over existing systems, as we aim for cost-effectiveness, and no additional burden should be added to already overwrought health systems. The system aims to complement traditional surveillance methods, which in Brazil rely mainly on the mandatory notification of suspected cases of priority diseases listed by the Ministry of Health, a usually paper-based process that often incurs in notification delays.

**Combining Digital and Molecular Approaches for Achieving Both Sensitivity and Specificity**

Genomics-enabled pathogen discovery has been proposed as a game changer for infectious disease surveillance, which some—optimistically—refer to as “not yet a panacea” [20]. The genomics component of ÆSOP, however, leverages sequencing power to provide pathogen specificity for the system at a later stage, rather than initially. By building upon the existing digitally informed streams of syndromic surveillance, which allows for “broad, but swift” monitoring, and using its output to pinpoint areas for the pathogen identification strategy continuously, ÆSOP aims to eke out the costs associated with real-time event monitoring paralleled with targeted genomics.

With further reduction of DNA sequencing costs in developing countries, metagenomics may become a key epidemiological tool for rapid pathogen identification. Alerts generated by clinical-related data will be used internally to activate site-directed genomic analysis for pathogen identification. This will allow for optimizing the logistic strategy for obtaining and analyzing samples. For instance, once a signal of a potential outbreak is identified, field teams will collect clinical samples that undergo molecular characterization for pathogen identification over a small area (Figure 1C). A major challenge in the system is the timely transportation of samples to the processing sites. In large countries with logistic hindrances, it is important to have decentralized sequencing sites for shortening transportation delays. ÆSOP will leverage and use the capillarity of the existing Brazilian Genomic...
Network facilities, such as that induced by Fiocruz during the COVID-19 pandemic [21], the National Network of Health Surveillance Laboratories, and others to speed-up the identification of circulating pathogens. Similar networks have been established in other countries as well, including the COVID-19 Genomics UK Consortium [22], the Indian SARS-CoV-2 Genomic Consortium [23], and the Africa Pathogen Genomics Initiative [24], among others. These initiatives have proven to be valuable in the response against SARS-CoV-2, providing critical insights into the spread and evolution of the virus. As the number of COVID-19 cases continues to decrease in many countries, it is vital that these networks are strengthened and expanded to ensure that they can be used as an essential component of next-generation surveillance systems, allowing for identification of pathogens behind potential outbreaks.

This integrated approach combines both data- and hypothesis-driven disease surveillance approaches, enabling quick identification of anomalies through syndromic surveillance using a combination of bona fide health data and alternative data streams (data-driven approach); once anomalies are identified, targeted sample collection and modeling (hypothesis-driven approach) can be used to confirm the outbreak and determine appropriate actions. To generate risk maps, computational models will integrate socioeconomic, environmental, and mobility and transportation data. Additionally, mathematical models coupled with artificial intelligence and machine learning methods will enable the assessment of risk and routes of outbreak spread (Figure 1B and 1C).

Data Security, Privacy, and Trust

Another unique feature of ÆSOP is the use of a defined methodology for the collection, linkage, and use of relevant and appropriate data. We will use, extract, transform, and load protocols [25] for capturing and standardizing data from different sources, and machine learning methods for feature engineering and longitudinal multimodal data integration. To ensure the security and privacy of data, ÆSOP will follow strict legal and ethical guidelines established by the Center of Data and Knowledge Integration for Health, which has already implemented robust rules and regulations for working with health data, based on global best practices [26]. This approach will ensure that ÆSOP not only provides early warning surveillance for outbreaks of epidemic or pandemic potential but also protects the confidentiality of individuals’ health information.

To ensure the responsible use of data, all information collected will be subject to rigorous digital curation procedures and preserved according to established standards [26]. The resulting deidentified and aggregated data will be made available to health authorities and the scientific community through an application programming interface, allowing for integration with other relevant data sources. This comprehensive set of spatially integrated health, environmental, social, and contextual data has the potential to be a valuable resource for research and other purposes beyond outbreak surveillance.

Fit for Purpose

An essential aspect of ÆSOP is its development in close collaboration with stakeholders and end users, ensuring its adoption by health authorities and successful implementation in mitigating and preventing outbreaks. We have collected feedback and identified key requirements from end users to inform rapid response, by convening workshops and focused meetings. Ultimately, these will lead to creating and fostering local/regional communities of practice for surveillance that will involve end users and other stakeholders in the development and implementation of surveillance systems, inspired by previous experiences such as the US Centers for Disease Control and Prevention’s National Syndromic Surveillance Program [27]. These communities will provide a platform for sharing experiences, challenges, and best practices in surveillance, and will serve as a valuable source of feedback for improving the system. By engaging with end users in this way, we aim to create a sense of ownership and investment in the system, which is crucial for ensuring its long-term success and sustainability through adoption.

Balancing Surveillance Data Sharing Needs With Data Sovereignty Concerns Using a Federated Approach

A critical lesson learned from responding to the COVID-19 pandemic is the need to build trust between governments, organizations, and societies to facilitate the early sharing of accurate information for responsive global health surveillance [2,4]. However, individuals’ privacy and data sovereignty concerns cannot be ignored. While balancing these necessities is not trivial, we understand that finding a solution to safely share information to guide decisions and provide global health security is crucial. In this sense, federated approaches represent a feasible solution that balances the need for data sharing with the need to protect data privacy and sovereignty (Figure 2). By allowing data owners to maintain control over their data, a federated system can help encourage collaboration between organizations, with sharing occurring only on a need-to-know basis. This is particularly relevant in health surveillance, where potentially sensitive data are involved.

A subset of the federated approach, federated learning enables independently built models to be trained on distributed data sets without sharing of raw data; then, an updated model is sent back to a central server to be aggregated with other models, and by iteratively exchanging parameters a globally refined model emerges [28]. This allows for the development of a more robust and accurate model while preserving data privacy. Combined, federated approaches provide a powerful solution for meeting the swift exchange of information under the International Health Regulations while also ensuring compliance with local legislation on individual privacy. Common data models and standards are necessary to ensure that data can be exchanged, integrated, and analyzed effectively across different sites [29].
**Conclusions**

The COVID-19 pandemic, and those before it, evidenced the need for substantial improvements in pandemic preparedness and response, globally. We presented key features and essential building blocks of the ÆSOP system—a system being developed with a combination of data-driven and hypothesis-driven infectious disease surveillance approach for early-alert identification of areas with significant risk of reemergence of infectious disease outbreaks. ÆSOP aims to accurately anticipate an outbreak when compared to currently in-place surveillance systems. Moreover, ÆSOP’s reports should enable precision public health strategies, such as targeted early outbreak mitigation and response strategies, as well as site-directed sample collection for pathogen molecular characterization, thus improving logistics and enhancing responses. To ensure that next-generation surveillance systems will properly meet public health needs, and to obtain a broader perspective of possibilities and bottlenecks, active engagement and cocreation processes with stakeholders, end users, and multidisciplinary experts will be essential and key to building and refining enhanced surveillance systems. Final, we are aware of the revision of the International Health Regulations and the preparation of the Pandemic Treaty, for eventual adaptation of ÆSOP to these rules.

**Acknowledgments**

ÆSOP is under development by Brazil’s Fundação Oswaldo Cruz (Fiocruz) and the Federal University of Rio de Janeiro in a cocreation partnership with the Rockefeller Foundation’s Health Initiative. We acknowledge the representatives of the Secretariat of Health Surveillance (SVS-A, Ministry of Health, Brazil), the Brazilian Health Regulatory Agency (Anvisa), the National Council of Municipal Health Secretariats (Conasems), the Pan American Health Organization, and the Gorgas Memorial Institute for their thoughtful inputs during a Visioning Workshop held in Bahia. The initial concept development of ÆSOP was supported by Fundação Oswaldo Cruz (Fiocruz). The System Visioning workshop in Bahia was funded and co-organized by The Rockefeller Foundation. We thank Andres Marquez-Lara, Felipe Abreu, Jessica Fan, and Sarah Forrester-Wilson from UFacilitate team for inputs during the workshop organization and event facilitation. The valuable inputs from Krista Mizenko to the project are also
acknowledged. The funders did not interfere in the decision to submit the manuscript for publication. Figures were created with BioRender and are published under permission. Details are provided in Multimedia Appendix 1 regarding the “ÆSOP Collaborating Teams.”

Data Availability
Data sharing is not applicable to this article as no data sets were generated or analyzed during this study.

Authors’ Contributions
MB-N is responsible for the conceptualization and coordination of ÆSOP. PIPR wrote the original manuscript draft with input from IM, AIB, KvdH, and MB-N. All authors reviewed and edited the manuscript for intellectual content. All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest
None declared.

Abstract

The recent SARS-CoV-2 pandemic underscored the effectiveness and rapid deployment of digital public health interventions, notably the digital proximity tracing apps, leveraging Bluetooth capabilities to trace and notify users about potential infection exposures. Backed by renowned organizations such as the World Health Organization and the European Union, digital proximity tracings showcased the promise of digital public health. As the world pivots from pandemic responses, it becomes imperative to address noncommunicable diseases (NCDs) that account for a vast majority of health care expenses and premature disability-adjusted life years lost. The narrative of digital transformation in the realm of NCD public health is distinct from infectious diseases. Public health, with its multifaceted approach from disciplines such as medicine, epidemiology, and psychology, focuses on promoting healthy living and choices through functions categorized as “Assessment,” “Policy Development,” “Resource Allocation,” “Assurance,” and “Access.” The power of artificial intelligence (AI) in this digital transformation is noteworthy. AI can automate repetitive tasks, facilitating health care providers to prioritize personal interactions, especially those that cannot be digitalized like emotional support. Moreover, AI presents tools for individuals to be proactive in their health management. However, the human touch remains irreplaceable; AI serves as a companion guiding through the health care landscape. Digital evolution, while revolutionary, poses its own set of challenges. Issues of equity and access are at the forefront. Vulnerable populations, whether due to economic constraints, geographical barriers, or digital illiteracy, face the threat of being marginalized further. This transformation mandates an inclusive strategy, focusing on not amplifying existing health disparities but eliminating them. Population-level digital interventions in NCD prevention demand societal agreement. Policies, like smoking bans or sugar taxes, though effective, might affect those not directly benefiting. Hence, all involved parties, from policy makers to the public, should have a balanced perspective on the advantages, risks, and expenses of these digital shifts. For a successful digital shift in public health, especially concerning NCDs, AI’s potential to enhance efficiency, effectiveness, user experience, and equity—the “quadruple aim”—is undeniable. However, it is vital that AI-driven initiatives in public health domains remain purposeful, offering improvements without compromising other objectives. The broader success of digital public health hinges on transparent benchmarks and criteria, ensuring maximum benefits without sidelining minorities or vulnerable groups. Especially in population-centric decisions, like resource allocation, AI’s ability to avoid bias is paramount. Therefore, the continuous involvement of stakeholders, including patients and minority groups, remains pivotal in the progression of AI-integrated digital public health.

(JMIR Public Health Surveill 2024;10:e49575) doi:10.2196/49575
Introduction

The SARS-CoV-2 pandemic saw the broad roll out and application of the first digital public health intervention at scale: digital proximity tracing (DPT) [1]. The general idea of DPT smartphone apps consists of leveraging the capabilities of standard Bluetooth sensors to trace proximity contacts and to notify the exposed individuals of past proximity encounters in case of a confirmed SARS-CoV-2 infection. The development and wide-ranging use of DPT apps have been a success story on several different levels. Their speedy development and release early in the pandemic reflects the prosperous international collaboration and backing by many relevant organizations such as the World Health Organization or the European Union.

To maintain the momentum for digital public health, it will be important to extend the digital transformation of public health in the domain of noncommunicable diseases (NCD). Prior to the pandemic, approximately 80% of all health care expenditures and 63.8% of the premature loss of disability-adjusted life years were associated with NCDs [2]. The challenges, but also opportunities, of NCD digital public health are quite different from the public health response to mitigate infectious diseases such as SARS-CoV-2. This perspective paper will start with an overview of current definitions of digital public health. Furthermore, in addition to requirements for digital transformation, we will explore different aspects that can guide the identification of potential use cases for digital public health applications in NCDs. The paper will close with an outlook on challenges and conditions to make further inroads on digitally transforming NCD public health.

Key Functions of Public Health

Public health is defined as the science and practice to establish conditions so that people can live healthy lives and make healthy choices. It draws on methods and knowledge of multiple disciplines such as epidemiology, medicine, psychology, law, social sciences, and many others [3]. Textbox 1 illustrates the essential public health functions that should be implemented by jurisdictions to achieve equitable health and health system access. These functions can broadly be grouped into “Assessment,” “Policy Development,” “Resource Allocation,” “Assurance,” and “Access.”

The framework emphasizes that public health involves more than just securing access to or ensuring high-quality medical care for individuals and an adequate health care workforce. Generally, public health also has a strong focus on communities and touches on the foundations for healthy living (eg, living conditions, education, or economic aspects), as well as population-based preventive measures (eg, childhood vaccinations).
Textbox 1. Institutional framework of essential public health functions.

Assessment
- Assess and monitor population health status and well-being, factors that influence health and its social determinants, community needs and assets, and health system performance and impact.
- Investigate, diagnose, and address health problems and hazards affecting the population, including public health surveillance and control and management of health risks and emergencies.
- Promotion and management of health research and knowledge.

Policy development
- Communicate effectively to inform and educate people about health, factors that influence it, and how to improve it.
- Strengthen, support, and mobilize communities and partnerships to improve health.
- Create, champion, and implement policies, plans, and laws that impact health.
- Use legal and regulatory actions designed to improve and protect the public’s health.

Assurance
- Assure an effective system that enables equitable access to the individual services and care needed to be healthy.
- Build and support a diverse and skilled public health workforce.
- Improve and innovate public health functions through ongoing evaluation, research, and continuous quality improvement.
- Build and maintain a strong organizational infrastructure for public health.
- Social participation and social mobilization, inclusion of strategic actors, and transparency.

Resource allocation
- Development of human resources for health.
- Ensuring access to and rational use of quality, safe, and effective essential medicines and other health technologies.
- Efficient and equitable health financing.
- Equitable access to comprehensive, quality health services.

Access
- Equitable access to interventions that seek to promote health, reduce risk factors, and promote healthy behaviors.
- Management and promotion of interventions on the social determinants of health.

Note: The framework is based on The Public Health National Center for Innovation [4] and Pan-American Health Organization [5].

Levels of Digital Changes

Overview
In health care and public health the levels to which specific processes and workflows, can be turned “digital” varies drastically. These levels are commonly described as digitization (moving from analogic to digital data collection), digitalization (integration of digital tools into established processes and workflows), and digital transformation (redesigning processes and workflows around digital tools). For the remainder, we will use the more neutral term “digital change,” which is intended to encompass all 3 levels.

Digital change attempts to achieve an impact on public health and health care by enabling better, more efficient, and more cost-effective public health interventions [6]. Thus it mirrors the triple aim of health care: improving patient outcomes, enhancing patient experiences, and reducing health care costs [7]. As such, digital change may also help to steer public health’s directions toward the goal of the 4Ps: preventive, predictive, personalized, and participatory [8]. By harnessing the -omics revolution, but also digital technologies such as wearables, mobile apps, and artificial intelligence (AI), health care providers can deliver preventive care by identifying potential health issues before they become severe. Predictive analytics can help identify patients at risk of developing certain conditions, allowing for earlier intervention and treatment. Personalized medicine can also be delivered through digital tools that analyze patient data to create tailored treatment plans. Finally, participatory health care allows for greater collaboration among communities, providers, and individuals, enabling these groups to take a more active role in managing their health. Consumers and patients are increasingly empowered to collect their own data and access medical information, thus gaining confidence, and claiming a role in health decision-making.
Conditions for Successful Digital Change in Health Care and Public Health

On the technical side, system readiness, interoperability, technical application programming interfaces, and nontechnical interfaces are crucial for implementing digital public health. System readiness ensures that digital technologies are compatible with existing health care systems and infrastructure [9,10]. Interoperability is essential to enable different systems to work together seamlessly, enabling for exchange of information and data between different platforms [11,12]. Interoperability also fosters the ability to collect and analyze vast amounts of health data in real time, thus allowing public health practitioners, policy makers, and citizens to gain valuable insights into health outcomes, treatment effectiveness, and disease trends [13]. As such, AI-driven analytics may also foster participation and personalization, as postulated by P4 [8]. However, ensuring that data analysis is unbiased and AI fairness is maintained is essential to avoid automating inequalities driven by AI modeling [14,15].

A further critical element in digital change routes is the scalability of technical systems and processes as health care systems look to scale their operations, widen care to more patients, and enhance the democratization of health care and public health [16]. Cloud-based platform solutions can help those public systems achieve scalability while reducing costs and improving efficiency as well as reducing disparities in public health [17-19]. Scalability also pertains to practices that involve humans-in-the-loop. Therefore, preparing the health care and public health workforce for digital changes is an important avenue to fill the gaps in skills and digital literacy in the next generation of public health practitioners, hence ensuring that health care systems can fully leverage the benefits of digital technologies [20-23]. Training programs and courses should focus on various disciplines and domains, including the Internet of Things, data analysis, data stewardship, and AI. Other essential domains for training programs and courses include cybersecurity, data privacy, and regulatory compliance where health care operators must be trained to ensure that they can protect patient data and comply with relevant regulations and legislation. Training programs should also cover soft skills such as communication, teamwork, and problem-solving, ensuring that health care providers can work effectively in interdisciplinary teams and collaborate with other stakeholders.

Creating a favorable legal and ethical context is critical for successful digital changes in public health. Legal frameworks must provide clear guidance on data privacy, security, and ownership issues [24,25]. In addition to legal and ethical considerations, financial factors also play a significant role in digital transformation in public health. Advantageous financial incentives can encourage health care providers to invest in digital technologies, enabling them to deliver better, more efficient, and more cost-effective care. Reimbursement and remuneration systems must also be adapted to account for incentivizing the development and use of digital technologies, ensuring that technology and service providers are fairly compensated for these technologies [26]. These models must also consider the value of these technologies, such as improved health outcomes, reduced health care costs, and increased user (ie, citizens or patients) satisfaction [27,28].

Yet, it will also be essential to plan for unexpected events or circumstances that could derail digital transformation efforts. By establishing a robust risk management plan and building flexibility into digital transformation initiatives, health care providers can minimize the impact of unforeseen events and ensure that their digital transformation efforts continue to deliver value and benefits to patients and health care providers alike [29-33].

Digital Change + Public Health = Digital Public Health?

The explicit connection between “digital” and “public health” is quite recent and well summarized by Iyamu et al [34], who trace “digital public health” back to a report by Public Health England from 2017 [35]. This report essentially calls for a reimagining of public health using digital tools, thus calling for a digital transformation of public health, a view that has recently been shared by representatives of the European Public Health Association [34]. As part of the transformation process, some authors suggest not only focusing on the technical possibilities but also looking for inspiration from the start-up culture of the tech industry, with a stronger emphasis on experimenting and adapting (pivoting) rather than waiting until scientific evidence has solidified. Other definitions describe digital public health as an “asset” toward achieving traditional public health goals, for instance by leveraging new data, methods, and work processes that have been given rise by digitization [36]. Therefore, these existing definitions appear to differ mainly in the meaning and role of “digital” on the digitalization-digital transformation spectrum, as already pointed out by Iyamu. But all authors agree that a consequential digital public health goes way beyond the digitization of existing services and interventions—they require rethinking and redesigning full health care delivery and public health services pathways.

Considering the framework of essential public health functions (Textbox 1), there are likely some domains that lend themselves more easily to a digital change, because digital data acquisition and analysis are at their core. Matching public health functions with suitable goals and purposes of digital change processes is critical for reaping the benefits of digital technologies. One of the key areas where digital transformation can be leveraged is in complex data analysis [37,38]. By contrast, the “digitalization or digital transformation question” is less easily resolved for functions such as building a sufficient health care workforce or equitable health care access. This is visualized in Figure 1 as conditions and technologies for digital change. In the figure, the “Public Health Functions” (Textbox 1) are depicted in the inner circle, and possible examples of digitally changed essential public health function processes are shown in the outer circle. The size of the circles in the outer circle illustrates our broad assessment of the achievability of digital change for specific public health functions, by taking the bespoke conditions for successful change into account, namely technical readiness, reliance on human interactions, or market interest in existing public health function processes. In general, processes relying...
on data collection and analysis or digitally facilitated mass communication lend themselves more easily to digital changes, while the creation and maintenance of an adequate workforce for health care and public health will likely continue to depend on human factors in the foreseeable future.

**Figure 1.** Conditions and technologies for digital change and concrete examples based on the public health functions. AI: artificial intelligence.

---

**Goal and Purpose of Digital Change**

To make further inroads toward digital change in public health functions and NCD public health in particular, it seems sensible to distinguish between the goal and purpose of making these functions and processes more digital. By goal, we mean the high-level public health goals of broad health care quality, access, efficiency, and equity of health promotion and health care provision, which can be fostered by digital changes. For instance, in light of the shortage of mental health care providers in many settings, apps for mental health assessments may ease access to at least some basic level of mental health care. Indeed, 24 of the 54 reimbursable digital health apps [39] (as of August 30, 2023) in Germany address mental health challenges including stress, burnout, or depression.

By contrast, we consider the purpose of digital change as improvements in the public health or health care service delivery process by digital change. These process attributes can, for example, be defined in analogy to the “triple aim” of health care innovation whether digital change renders the process of providing and delivering existing or novel public health measures and health care in a more effective, efficient, or user-friendly manner.

An alternative view on process attributes that are influenced by digital changes is offered by Peter Diamandis’ 6Ds of exponential technologies [16,40]. This concept identifies 6 categories of process attributes—digitization, deception, disruption, demonetization, dematerialization, and democratization—which also outlines the desired trajectory of a digital change process. Initiating digital changes in the health care sector may initially elicit resistance in some actors, who may initially respond with incredulity about the potential benefits of these changes in the short term. As the proposed innovation begins to ramp up, it reduces inefficiencies and optimizes current systems, disrupting the same old processes. Demonetization occurs as health care costs shift away from the fee-for-service paradigm, requiring new ways to deal with the small costs of care. Dematerialization further changes the paradigm by enabling care access outside of formal settings, such as through mobile health apps for therapeutics. Finally, democratization widens health care access thanks to these new characteristics.

Therefore, digital changes in the health care and public health sector need to be particularly mindful of 1 particular 6D [16] the creation of a digital divide due to a lack of democratization, meaning that digital changes can impose high hurdles to health
promotion or health care access for subgroups of individuals with lower digital literacy or different language backgrounds. Very often, these are also individuals who may benefit most from prevention or health care. Such barriers can be overcome, for example, by making user interfaces as simple as possible and by providing personal support, which can also be assisted by digital means. Therefore, it is advisable to include equity aims in digital change processes, and to define the purpose of digital change as a “quadruple aim.”

**Examples of Leveraging Digital Advances in a Pragmatic Digital Public Health**

Some digital advances in public health are already contributing toward making health care more equitable to underserved populations in low- and middle-income settings. Telemedicine, for example, enables patients to consult with health care providers remotely, breaking down geographic barriers to care. Digital technologies have also enabled health care professionals to reach more patients with chronic conditions, offering remote monitoring and management tools that improve patient outcomes while reducing costs. Bringing a spotlight on sub-Saharan countries, these innovations in health care access also were driven by the application of drones in delivering medicines, vaccines, and diagnostics tests to remote areas [41,42]. Furthermore, drones have been seen playing an important role in identifying malaria-vector breeding sites in rural areas as an important tool for disease surveillance [43].

As another example yet focused on low- and middle-income countries, Reach Digital Health [44] is leveraging digital technology to transform patient care, streamlining care requests, check-ins, follow-ups, and symptom assessments for a more patient-focused approach. Key initiatives include MomConnect [45], a WhatsApp smart bot that provides maternal and child health information in local languages to pregnant women in Sub-Saharan Africa, and Young Africa Live [46], a digital platform that empowers youth to make informed decisions about their sexual health. These innovative interventions, aimed at making health care more accessible and proactive, highlight the transformative potential of digital health in addressing public health challenges globally.

Expanding these digital advancements for a global health perspective, a notable instance of this progression is the “Global Flu View” platform [47]. This tool, which provides real-time tracking of global influenza activity based on participatory surveillance, signifies a transition from traditional to digital epidemiology. It presents unmatched opportunities for early detection, timely intervention, and strategic planning, all of which are crucial for managing influenza outbreaks and potential pandemics. Beyond its data visualization capabilities for influenza-like illness trends, Global Flu View also promotes knowledge sharing among public health practitioners [48]. As such, Global Flu View can also act as a template for similar collaborations in the field of NCD by acting as a code lab repository for exchanging scripts and algorithms for data analysis, facilitating peer collaboration, and fostering continuous learning and skill development of researchers and health care professionals. Furthermore, these digital platforms do not just address immediate public health needs; they also provide a valuable resource for training future digital epidemiologists. Through hands-on interaction with real-time health data, trainees can develop skills to transform intricate health data into actionable public health interventions.

**Emerging AI Trends and Their Possible Role in Digital Public Health**

In addition to automating complex data analysis and predictions, AI-driven digital transformation can replace repetitive tasks in stable environments, such as administrative tasks and data entry [18]. This frees up public health professionals and health care providers to focus on personal interactions with citizens and patients. Along those lines, it is vital to identify which human interactions or tasks cannot be easily replaced by digital technologies and should be strengthened, such as counseling and emotional support [19]. AI can also provide citizens and patients with new tools to take a more active role in managing their health [49]. However digital health is not a replacement for doctors or other health professionals, but rather a companion to guide individuals through the health care system. By leveraging digital tools, citizens and patients can take a more active role in managing their health and accessing care. This can help to address some of the challenges associated with aging, such as chronic disease management, as well as promote health equity by improving access to care for underserved populations. Additionally, digital health can help to promote sustainability in health care by reducing the need for in-person visits and streamlining care delivery.

Recent advancements in large language models (LLMs) have the potential to greatly enhance public health interventions by providing tailored, accessible information at scale [50]. LLM technology facilitates the dissemination of health information in a way that can be easily adapted to a population’s education level, cultural background, or general preferences. This can be particularly beneficial in public health campaigns, where the goal is to effectively communicate with diverse audiences who may find traditional medical jargon intimidating or confusing [51]. LLM technology, through its natural language processing capabilities, allows for the analysis of population-level data, enabling the creation of public health recommendations and advice that are contextually relevant. It can help communities better understand their collective risk factors or prevalent health conditions, thereby promoting health literacy, preventive measures, and access to care. The capability of LLM to interact in a more human-like chat can also revolutionize how public health messages are communicated, making them more engaging and comprehensible. Moreover, with its ability to provide 24/7 service, LLM has become an efficient, ever-present tool for promoting lifestyle changes and mitigating noncommunicable diseases at the population level. There is already evidence from health care settings illustrating the benefits of LLM technology in enhancing patient interactions. Applying this technology on a broader scale could potentially have transformative impacts on public health communication strategies, risk mitigation, and health promotion. Given the long time horizon of emergence and living with chronic diseases, a knowledgeable, tireless, emphatic, efficient, and 24/7-available companion would be a highly welcomed tool to support lifestyle changes or health promotion to avoid NCDs.
The opacity of some AI models in how predictions are achieved (eg, in neural networks) is a common point of critique and reason for nonadoption. Explainable AIs enable public health experts, health care providers, and patients to understand how AI-based systems arrive at their decisions and recommendations [52-57]. This can help to address issues of bias and discrimination in health care and public health, which can arise when algorithms are based on flawed or incomplete data sets. By providing transparency and accountability, explainable AIs can help to ensure that health care automation is more equitable and unbiased, although this area is still underproof and requires more evidence to achieve its pledge [58,59]. Machine unlearning is another emerging area of research in digital health that has the potential to promote equity and fairness in health care automation [60-62]. Machine unlearning involves the intentional removal of certain data points or variables from a machine learning algorithm in order to correct biases or errors. For example, if an algorithm is found to be discriminating against certain patient populations based on race or ethnicity, machine unlearning can be used to remove those variables and correct the bias. By doing so, machine unlearning can help to ensure that health care automation is more equitable and inclusive.

However, while explainable AIs and machine unlearning can help to promote equity and fairness in health care automation, they also raise important questions about the role of humans, liability, and trackability in the digital health space. For example, who is responsible if an AI-based system makes a mistake or causes harm? How can we ensure that these systems are transparent, accountable, and auditable? And what role do humans play in overseeing and monitoring these systems? These problems are even exacerbated in any application of AI in public health decision-making or prediction at the population level. While problematic treatment decisions in health care will be spotted and corrected through close patient monitoring, similar monitoring for larger populations is much more complex. Furthermore, AI-driven public health decisions may impact specific population subgroups differently. Therefore, a decision of whether AI-supported decisions are good or bad requires a much more complex framework that includes considerations of equity, vulnerability, effectiveness, and efficiency. As such, it is important to consider not only the technical aspects of AI-supported public health, but also the social, legal, and ethical implications of these emerging technologies. By doing so, we can ensure that digital health remains an inclusive, equitable, and accessible space for all patients and that these new technologies truly serve as companions to guide individuals through the health care system.

Federated learning and swarm learning hold transformative potential for public health, providing a path to harness vast, diverse data sets while preserving data privacy and data ownership. Federated learning involves training machine learning models across multiple decentralized instances with a central trusted server [63]. This offers a powerful solution for public health systems grappling with the need to analyze large, varied data sets while respecting privacy concerns. Swarm learning, in contrast, uses a completely decentralized network of instances to collaboratively train machine learning models in a peer-to-peer manner [64]. This becomes especially valuable in public health contexts where data are highly decentralized and distributed across numerous devices and locations. Swarm learning allows public health practitioners to harness the power of distributed data to create more precise and effective machine learning models, ensuring data privacy and security. Adopting these approaches can have profound benefits for public health systems aiming to enhance their digital health initiatives [65]. By refining algorithms at the population level, as well as in specific subpopulations, public health systems can improve the precision of disease prediction and early detection. This also allows for the identification of opportunities for targeted interventions and treatments, which in turn can help reduce health care costs, enhance health outcomes, and promote health equity and accessibility. Moreover, federated learning and swarm learning provide tools for developing more effective public health policies and interventions. By analyzing patterns and trends in population-level health data, public health systems can identify high-risk groups and more effectively direct interventions. This ability can play a crucial role in preventing the spread of infectious diseases, reducing health care costs, and enhancing public health outcomes overall.

A Pragmatic Vision for Making Inroads to Digital Change of Public Health for NCD

Digital change offers an unprecedented opportunity to address the substantial burden of NCDs at scale. However, the application of digital technologies needs to be thoughtfully aligned with public health functions, goals, and broader societal implications. Digital platforms can serve as tools for better public health monitoring, decision-making, as well as public engagement, and education. On the individual level, prevention requires behavioral changes and continuous personal efforts. One of the key downstream factors in a micro-level (individual) perspective is the psychosocial mechanisms mediated by social support, social influence, and social engagement [66]. Having these aspects addressed might mean a successful impact on the digital change of public health. On one hand, personalized prevention strategies have proven effective but lack scalability. On the other hand, digital solutions, such as telehealth platforms and health monitoring applications, may offer more scalable approaches by improving efficiency, effectiveness, and user experience.

While digital change opens new avenues, it simultaneously poses challenges related to equity and access. Populations that are (1) economically disadvantaged, (2) geographically isolated, or (3) digitally illiterate are at risk of being left behind in the digital transformation journey. Any initiative must include a comprehensive strategy to ensure that these changes do not exacerbate health inequities but rather work toward eliminating them. Furthermore, effective digital and nondigital NCD prevention at a population level demands a societal consensus. It often requires a willingness by people not directly at risk to participate in a larger social contract. For example, the legislation of smoking bans and “sugar taxes” may affect individuals who do not directly benefit from such measures. Therefore, stakeholders, from policy makers to health care providers and the general public, need to have realistic
expectations about the benefits, potential harms, and costs of digital changes in health care or public health service delivery. Ongoing monitoring and evaluation mechanisms need to be in place to gauge the broader-scale implications of digital change.

Conclusions

Digital health and AI in particular have great potential to make public health and health care of NCDs more efficient, effective, user-friendly, and equitable: the quadruple aim. Digital change in any of the 5 essential public health function domains should be purposeful and bring improvements in at least 1 dimension of the quadruple aim while not significantly compromising the other dimensions. But ultimately the success of digital public health and AI-supported public health measures will require clear criteria, monitoring, and benchmarks on how to achieve benefits for the majority while not putting minorities and vulnerable groups at a disadvantage. As such, AI explainability and unlearning of discriminatory or biased decision-making will be even more crucial for population-level decisions (which are common in public health, eg, regarding resource allocation) than in individual-level health care. Therefore, the close involvement of stakeholders, including patients, citizens, and vulnerable and minority populations, will be crucial in the development, roll out, and monitoring of AI-powered digital public health.

Abstract

The pandemic provided a stark reminder of the inequities faced by populations historically marginalized by the health care system and accelerated the adoption of digital health technologies to drive innovation. Digital health technologies’ purported promises to reduce inefficiencies and costs, improve access and health outcomes, and empower patients add a new level of urgency to health equity. As conventional medicine shifts toward digital medicine, we have the opportunity to intentionally develop and deploy digital health technologies with an inclusion focus. The first step is ensuring that the multiple dimensions of diversity are captured. We propose a lexicon that encompasses elements critical for implementing an inclusive approach to advancing health care quality and health services research in the digital era.

Introduction

A Lack of Diversity Limits Health for All

As the health care industry undergoes digitization, leaders across the field have the opportunity to develop approaches that can advance access and increase equity and quality. To do this, we need to examine the source of health disparities in the current system: the underrepresentation of specific populations as participants in research and inadequate health care access for all patients. By recent accounting, less than 3% of published genome-wide association studies include data on people of African, Hispanic, or Latin American ancestry, and 86% of clinical trial participants are of European ancestry [1]. This type of exclusion and the accumulation of health disparities as a consequence of inadequate access to care are deeply rooted in systemic and structural racism [2].

The pandemic’s inequitable toll on public health and health care was fueled by knowledge gaps resulting from decades of exclusion and inadequate care for the most vulnerable populations. COVID-19 infection and death rates, one example of public health consequences of health disparities, highlighted the dire consequences of a lack of diversity in research. Groups historically underserved based on the dimensions of race and ethnicity are disproportionately affected and dying at higher rates than their distribution in the population. Additional dimensions of diversity, such as lower socioeconomic status and limited English proficiency, continue to influence health burdens, health outcomes, and overall quality of life [3-5].

Currently, federal policies driving diversity initiatives for patients in health care and participants in research focus on race and ethnicity [6-9] and are intended to encourage and support research that includes more racial and ethnic groups, as well as women. Some progress has been made; however, the focus has been narrow and incomplete. Attention to race, ethnicity, or sex is not sufficient to promote broad health equity. We propose widening the focus of health equity to better capture the many dimensions of diversity. Age, gender, sexual identity, socioeconomic status, educational attainment, physical and mental health, and a range of other factors contribute to disparities in health outcomes, including access to care, health behaviors, and the distribution of health care resources. By addressing these additional dimensions of diversity, we can work toward more equitable and inclusive health care systems.

(Access to the full article is provided by the publisher or through libraries.)
cognitive abilities, access to care, and geography also impact care and quality of life.

Social determinants of health (SDOH), that is, the conditions and environment in which people live, work, learn, and play, significantly contribute to health inequities [10]. When overlaid with the intersectionality of race, ethnicity, age, gender, and sexual identity, SDOH expands the categorization for diversity and populations underserved by health care [11]. The All of Us Research Program [12], which was developed to increase representation in biomedical research, expanded the criteria for diversity to reflect this intersectionality and interdependence of factors affecting health. Now, a similar expansion is necessary to account for the many factors that contribute to a lack of digital equity and inclusion, including SDOH [13], digital access and digital and health literacy [14-16], and community lived experiences [17].

Define Diversity to Promote Inclusivity

The digitization of health care and research has the potential to transform how we care for people and develop new medical products [18,19]. The Digital Medicine Society, in collaboration with the Center for Devices and Radiological Health of the Food and Drug Administration (FDA) and with guidance issued by the FDA [7,8], has been at the forefront of implementing cross-disciplinary approaches to advance the ethical, effective, equitable, and safe use of digital technologies to redefine health care and improve lives by addressing relevant evidentiary, security, ethical, regulatory, and legal issues [20]. It is with this cross-disciplinary, multistakeholder approach that we propose a complete lexicon of dimensions of diversity that must be considered to ensure inclusion in the digital era of health care. This lexicon is intended to support not only efforts to increase diversity and promote inclusion but also to ensure that health disparities are not exacerbated by these new technologies.

The COVID-19 pandemic emphasized 2 elements that are critical for equity in the digitization of health care and research. The first is the dire consequences of health care built on research with limited populations and confounded by the inequities of care caused by decades of structural racism [21]. Limited research with Black/African American and Hispanic people has resulted in less access to safe and effective medications and a higher underlying disease burden, which increased the risk of a more severe COVID-19 prognosis or higher rates of death [22]. The second is a glimpse at the potential of digital health solutions. However, as digital health solutions have accelerated the transformation of health care, the decades-long systemic barriers to health equity continue to hamstring the potential for effective care for all patients. We saw this for telehealth visits, which were higher among those identifying as White and earning at least US $100,000 [23], and low vaccine distribution and adoption due to early reliance on technology [24]. This underscores is a clear example of the need for inclusivity; it is not sufficient to implement technologies and to hope people will access and use them.

An intentional commitment to inclusion is critical during the development and deployment of digital health solutions to facilitate and advance equity. The All of Us Research Program definition of “underrepresented in biomedical research” [12] must be expanded to include digital inclusion to continue to address health disparities centered on demographics, as well as environmental and lifestyle factors.

New Dimensions of Diversity for Inclusion in the Digital Era of Medicine

Digital health is the umbrella term for the intersection of technology and health care [25]. Digital medicine is the field of evidence-based digital health tools that measure or intervene in the service of health to support the practice of medicine broadly. To advance health equity, we need to focus on inclusion in digital medicine [26].

Inclusion in digital medicine means (1) being cognizant of characteristics of different populations, and (2) tailoring solutions to ensure that digital health products meet the needs of and benefit, all individuals and communities. This entails not just addressing the needs of individuals who face barriers to digital technology use but also addressing the historical, institutional, structural, and discriminatory forces that created and continue to perpetuate the digital divide [27] and health inequality. We combined the dimensions of age, race, ethnicity, education, socioeconomic status, religion, ability, location, gender, sexual preference, language, ability, and digital technology access and literacy and propose a new, expanded lexicon of dimensions in diversity suitable for the digital era of health (Table 1).
Table 1. A newly expanded lexicon of dimensions in diversity suitable for the digital era of medicine.

aDefinitions adopted from Mapes et al [12]. The other definitions were developed by members of the Digital Health Measurement Collaborative Community [28].

Digital medicine can prioritize inclusion through a human-centered, fit-for-purpose lens; that is ensuring that digital products do what they claim for all intended users and serve all members of the populations who can benefit from them. A focus on inclusion will capture diverse populations and lead to more equitable solutions and outcomes for health care. This will also address a big challenge for digital health technologies: trust [29]. Trust is important for full participation; full participation leads to health equity—the state in which everyone has an opportunity to attain their highest level of health [30]. Mistrust of health care systems has been growing for years and has been amplified with the COVID-19 pandemic. Digital health product developers have also contributed to this mistrust, especially when people do not see technology designed for them. A clear example is the photoplethysmography (PPG) optical sensors used in many fitness trackers and pulse oximeters. While PPG sensors have been shown to be inaccurate in people with darker pigmentation [31-33], the technology persists in many widely available products. Developers are evolving fitness trackers [34] with PPG sensors to play a bigger role in collecting relevant health data; however, there are few indications that the limitations of this technology for inclusivity are being addressed.

In the digital era of health, digital access and literacy have emerged as defining factors for equity. Access to high-speed internet, reliable and secure Wi-Fi, and tools such as computers, tablets, and smartphones are greatly impacted by socioeconomic status [35]. Digital health literacy, from recognizing the relevance and value of digital health products in your care to having products in your native language, will dictate the type and level of care you receive. There are currently several limitations to inclusion including resource allocation, data and knowledge gaps, and education and training. A multistakeholder approach which includes health care institutions, policymakers, and research and education systems is required to overcome current limitations.

The proposed new complete lexicon for dimensions of diversity for the digital era of health can effectively support intentional approaches to digital health solution design and deployment [28] for inclusivity. The lexicon is designed to support the intersectionality of specific populations and communities that the field of digital health is intended to serve, allowing for some level of customization for each person. The dimensions of diversity complement Richardson et al’s [36] framework for digital health equity, which expanded the National Institute on Minority Health and Health Disparities Research Framework. Our lexicon provides a level of granularity that those developing or deploying (either in clinical care or research) digital health products should sufficiently represent to ensure an inclusive experience. The lexicon has been applied to the digital health measurement market opportunity calculator, which enables digital health measurement product developers to build a business case for incorporating inclusive practices into their research and development processes [37]. Users of the market opportunity calculator select a dimension of diversity, for a health condition, and receive an output estimating the increase in engagement size and potential increase in market value when that product is made with an inclusive lens for that dimension. The lexicon can also be applied to the Partner, Identify, Demonstrate, Access, Report equity framework for behavioral digital health interventions [38] to focus efforts on specific
diversity dimensions and define specific actions for each point of the framework. These equity frameworks provide a structure whereby our lexicon can be added for inclusivity. Together these can lead to transformational changes that will advance health equity.

**Insist on Action**

Health equity in clinical research was strengthened by the 2023 omnibus spending bill and the FDA’s diversity plan [39] and is projected to continue in the next year. In a recent Deloitte report, health care and life science leaders rank health equity as a top 10 priority [40]. Partnerships across health care, especially health care providers, communities, and digital health product developers will be instrumental in advancing equity and driving inclusion. A level of accountability will be required to demonstrate early progress; the lexicon for the dimensions of diversity can easily be customized in a dashboard [41] to track and inform strategies and resources for more inclusive digital product development and deployment.

The Digital Medicine Society is hosting the Digital Health Measurement Collaborative Community (DATAcc) [28]. Advancing health equity with collaborative communities is a priority at the FDA’s Center for Devices and Radiological Health for addressing health care challenges. DATAcc convenes industry leaders, academic and clinical researchers, patient and community organizations, health systems, and government/regulatory representatives to develop and demonstrate best practices to advance harmonized approaches to speed the use of digital health measurement to improve health outcomes and health equity. Building on the medical device product lifecycle [42], DATAcc created resources to action the expanded dimensions of diversity to drive inclusivity in both digital health technology development and deployment [37].

Recognizing that the efforts to drive inclusion falls on everyone in the health care and health research ecosystems, DATAcc also designed resources to guide clinical care and research teams in assisting patients with understanding complex concepts associated with digital health product use, such as data privacy and security, and end user agreements. With widespread use, validation, and verification inclusive product development and deployment resources can lead to industry-wide adoption and formalization of inclusivity in digital health care. Thereby, building digital medicine on the foundation of inclusion.

**Conclusions**

Leaders in health care are at a crucial juncture that will shape the future of digital medicine. We can develop technologies in a way that is more inclusive to ensure that advances in digital medicine are available and used by all populations. We also recognize that inclusive product development is necessary but not sufficient; end users (patients and research participants) need complete information and training on these products so they can be informed. This has to be an ongoing, ever-evolving process that can grow and change with the adoption of new, more complex technologies. The proposed lexicon offers leaders and organizations the granularity they need to demonstrate their health equity efforts. Inclusivity is the key to accelerating health equity so that diverse populations become more integrated and are better served by the health care system.

Abstract

Electronic data capture (EDC) is a crucial component in the design, evaluation, and sustainment of population health interventions. Low-resource settings, however, present unique challenges for developing a robust EDC system due to limited financial capital, differences in technological infrastructure, and insufficient involvement of those who understand the local context. Current literature focuses on the evaluation of health interventions using EDC but does not provide an in-depth description of the systems used or how they are developed. In this viewpoint, we present case descriptions from 2 low- and middle-income countries: Ethiopia and Myanmar. We address a gap in evidence by describing each EDC system in detail and discussing the pros and cons of different approaches. We then present common lessons learned from the 2 case descriptions as recommendations for considerations in developing and implementing EDC in low-resource settings, using a sociotechnical framework for studying health information technology in complex adaptive health care systems. Our recommendations highlight the importance of selecting hardware compatible with local infrastructure, using flexible software systems that facilitate communication across different languages and levels of literacy, and conducting iterative, participatory design with individuals with deep knowledge of local clinical and cultural norms.

Introduction

Information systems supporting electronic data capture (EDC) for research and clinical operations are crucial to the development, evaluation, and sustainability of population health programs, facilitating health improvements supported by data. In some low- and middle-income countries (LMIC), EDCs can trend health outcomes and inform decision-making, thereby improving the efficiency and effectiveness of health services [1,2]. EDC can support health intervention and policy development along with determining the allocation of critical resources [3]. With the expansion of internet services globally,
using EDC systems is a cost-effective way to increase the amount and quality of data that can be used in LMIC [4,5]. However, EDC will only be useful in promoting positive health outcomes when the system matches the required users, tasks, and environment [6]. Implementing EDC systems to monitor health indicators is a complex process. It requires that EDC systems be developed to (1) suit the needs of the local context, (2) support long-term sustainability, and (3) accommodate routine adaptations [7-9]. Barriers to successful development include limited financial capital for implementation, low utilization of local expertise, and narrow conceptualizing of EDC technologies while ignoring relevant sociotechnical factors that should drive EDC decisions [10].

Published information on health interventions in LMIC typically focuses on the results of the interventions themselves rather than the EDC used for population health surveillance. Therefore, guidance for developing EDC systems is limited [10]. One qualitative study, for example, evaluating the implementation of an EDC, described the lack of trained information system specialists, inconsistent definitions of variables, insufficient data validation, managers not valuing the data, and communication issues as the core challenges to EDC implementation [10]. One systematic review found 132 published studies that used health information systems for data collection in LMIC [3]. The study reported on data analysis methods and data quality, noting that data completeness was a commonly cited issue with EDCs and exclusion, followed by imputation, was the most common means for handling missing data [3]. These publications highlight a common pattern among studies regarding EDC in LMIC, that is, if they go beyond simply describing the impacts of the interventions, the primary focus involves data quality and completeness. Although quality and completeness are important elements to evaluate with EDC, there remains a gap in describing the nature of the EDC systems and how their components were assembled and implemented.

Due to this gap in evidence, the objective of this viewpoint is to provide practical recommendations for designing EDC systems for research and health operations to sustain data-informed population health interventions globally. We describe 2 exemplar cases in Ethiopia and Western Myanmar/Eastern India to illustrate how robust EDC systems may be designed to support population health surveillance, specifically during humanitarian crises (ie, civil unrest and the COVID-19 pandemic). The research activities related to these cases have been described in other publications [11,12]. In this viewpoint, we describe case descriptions using a sociotechnical conceptual model to determine barriers and facilitators of successful development and use of EDC. We used this model because it provides a comprehensive framework that can be used to guide and evaluate EDC design and implementation [13].

Context and Project Overviews

Ethiopia Case Description–The Saving Little Lives Initiative
As of 2019, Ethiopia had high ratios of neonatal mortality (33 per 1000 live births) and infant mortality (47 per 1000 live births) [14]. Globally, Ethiopia has the fourth-highest number of newborn deaths [15]. Further, the Sub-Saharan Africa region has the highest neonatal mortality ratio in the world [15].

Ethiopia-specific causes of neonatal death include respiratory distress (45%), infection (30%), and birth asphyxia (13%) [14]. To improve newborn and infant health, the Emory-Ethiopia Partnership began work in Amhara in 2011. This case description focuses on one of Emory-Ethiopia’s efforts in the region—Saving Little Lives (SLL). SLL is a flagship health program of the Ethiopian government that spans 290 targeted hospitals across 4 regions. SLL is an aggressive scale-up study designed to reduce population-level mortality by 35% through improved newborn care. SLL uses a package of targeted and synergistic interventions to promote survival. SLL consortium partners are supporting the regional health bureaus to scale up 5 key interventions, as follows: (1) respiratory support (including resuscitation for newborns with asphyxia and continuous positive airway pressure for respiratory distress), (2) kangaroo mother care (KMC), (3) sepsis management, (4) feeding support, and (5) cross-cutting quality improvement methods. The project covers a population of over 37 million individuals in 4 Ethiopian regions and 285 woredas (districts). Emory-Ethiopia is the lead partner for the Amhara region in this national SLL consortium. These SLL activities build upon the same consortium’s scale-up research on KMC conducted in the same regions [12,16].

As of September 2022, Ethiopia had nearly 500,000 confirmed cases and over 7500 deaths from COVID-19. In November 2020, following claims that a minority party, Tigray People’s Liberation Front, had attacked a federal army base, the majority party ordered a military offensive in Tigray [17]. This ongoing conflict has led to the forced displacement of over 2 million civilians and a food crisis affecting at least 9.4 million northern Ethiopians—primarily in the Tigray region [18]. Furthermore, the crisis has led to an increase in gender-based violence and a decrease in access to proper health services for women and children [18]. Research associated with this case was approved by institutional review boards (IRBs) in the United States and Ethiopia.

Eastern India and Western Myanmar Description–The Mobile Health (mHealth) and Mobile Ultrasound for Mothers (mMUM)
Western Myanmar has one of the highest maternal mortality ratios in Asia, ranking 148 out of 187 on the 2019 Human Development Index [19,20]. Among women of reproductive age, maternal deaths account for 1 in every 10 deaths, with 75% occurring during delivery or immediately after birth [19].

On February 1, 2021, the Tatmadaw (Myanmar’s military) seized control of the government in a coup d’État. Health care professionals across Myanmar have participated in the Civil Disobedience Movement in response to the overthrow of a
The various aspects of research associated with this case have been approved by IRBs in the United States and India.

**Information Infrastructure Design and Adaptations**

Sociotechnical conceptual models may provide a structure for discussing EDC considerations in LMIC—particularly those settings impacted by civil conflict. Figures 1 and 2 show the information infrastructure for each case using Sittig and Singh’s “sociotechnical model for studying health information technology in complex adaptive healthcare systems” [13]. Labeled boxes represent established components in the Sittig and Singh’s model, and the descriptions and symbols highlight how these components were operationalized in each context. Tables 1 and 2 further describe the actions taken to create and sustain these EDCs during dual humanitarian crises organized by the constructs in the Sittig and Singh’s model.

• Collected data primarily via tablet and used paper to list mothers and babies discharged for further follow-up on the 29th day of life.                                                                                                                                                                                                 |
| Clinical content                     | • Designed content and metrics to ensure information was relevant to the local context while promoting internal and external validity (eg, incorporating clinical cascade metrics for newborns and mothers into routine SLL data collection) [16,24].  
• Developed programs and data collection to adhere to and be evaluated against standard quality guidelines, such as BEmONC\(b\) quality or newborn cascades.                                                                                                                                                        |
| Human computer interface             | • Data collection forms developed with local partners and researchers based in the United States.  
• Embedded Amharic language into data collection (eg, patient consent forms).                                                                                                                                                                                                                                                                                       |
| People                               | • The SLL initiative funds government-based evaluation officer positions with responsibilities including primary data collection, data training, and ensuring facility-specific data are submitted to central database.  
• Implementation officers support the training and implementation of SLL at the facility.  
• Program learning officers collect qualitative information (eg, enablers and barriers) from different units and care providers.                                                                                                                                                                                                                   |
| Workflow and communication           | • Evaluation officers complete real-time data collection of project indicators; program learning team obtains qualitative information from families and clinicians for continuous improvement.  
• Existing government staff at hospitals collect and enter facility-specific data into the electronic national monitoring system (ie, DHIS2\(c\)).  
• Community-based health extension workers collect governmental surveillance, service provision data, and other community needs assessments using the community health information system. Community health workers record data on paper. These data are then submitted to their supervising health center, which, in turn, forwards them to the woreda (district) health office. The woreda health office aggregate these data electronically and shares them with the primary health care unit. These electronic data directly enter the national database, and the regional government can query this database for their region. |
| Internal and organizational policies, procedures, and culture; external rules, regulations, and pressure | • Funding embedded government staff members (eg, evaluation officers) enables the synchronization of SLL data collection with government health surveillance.  
• SLL deliberately involves university-based colleagues (eg, Emory University) so that the program may generate transferrable research findings in addition to its local public health and clinical impact.  
• All SLL-specific data collection and procedures were approved by 3 institutional review boards from Emory University, Addis Ababa University, and Amhara Public Health Institute.                                                                                                                                 |
| System measurement and monitoring    | • Leveraging DHIS2 surveillance data collected via the government’s Health Management Information System.  
• Qualitative and quantitative evaluation via government-embedded evaluation officers who collect real-time SLL data outside the government’s DHIS2 system.  
• Data collected by evaluation officers, program learning officers, health care providers, and health extension workers integrated by the Amhara SLL research team for comprehensive SLL program evaluation at multiple levels (eg, district, regional, or national levels).                                                                                            |

\(a\)ODK: Open Data Kit.  
\(b\)BEmONC: Basic Emergency Obstetric and Neonatal Care.  
\(c\)DHIS2: District Health Information Software 2.
The SLL Initiative (Ethiopia)—Initial EDC System

The EDC used to evaluate SLL’s progress stems both from government health systems and SLL-dedicated staff—the program learning team and evaluation officers (Figure 1). Health Information technicians and other care providers at health facilities routinely collect government data, including information on health service utilization and clinical outcomes (eg, newborn mortality and postnatal care uptake) using the government’s District Health Information Software 2 (DHIS2) [21]. Evaluation officers are government-based staff, funded by SLL, who capture information on SLL-specific quality indicators related to clinical care (eg, uptake of KMC and provision of skin-to-skin contact). Evaluation officers visit SLL facilities and enter these data in the KoBo Toolbox (described below) with measures aggregated in a centralized data warehouse [22]. As partners with the Ethiopian Ministry of Health, SLL partners have access to routine government data for their region from the DHIS2 system. The SLL program staff access both these routine DHIS2 data and SLL-specific program data. These multisource data facilitate the optimization of interventions using both internal and external data sources. Refinement and utilization of EDC procedures have also directly informed core content areas in the national Basic Emergency Obstetric and Neonatal Care guidelines [23].

The data collection platform for SLL has been developed using KoBo Toolbox and an Open Data Kit (ODK) tool. The KoBo Toolbox allows for open-source sharing of input forms and enables users to design data collection forms. Forms designed in the KoBo Toolbox can be imported into ODK, which provides support. The KoBo Toolbox allows for open-source sharing of input forms and enables users to design data collection forms. Forms designed in the KoBo Toolbox can be imported into ODK, which provides

| Hardware and software computing infrastructure | • Selected data collection tools (ie, ArcGIS and Survey123) that work in settings with limited internet connectivity or no internet.  
• Purchased chargers that worked with local power sources (ie, solar, due to insufficient access to electricity).  
• Selected software with mapping capabilities to locate, support, and track transient populations. |
| Clinical content | • Developed data collection content with local personnel to ensure clinical and social questions were asked in a culturally sensitive manner.  
• The content of the collected data was adapted to suit the situation in a new country with different infrastructure [25].  
• Added medical anthropologist to the team to provide insights into how clinical problems are perceived and communicated in the given setting. |
| Human computer interface | • Chose a tool that also supported icon-based communication to provide context clues to users with lower literacy.  
• Chose a tool that could provide an interface not only in multiple languages but also supported languages with non-Roman characters. |
| People | • Used iterative participatory design process to create a culturally appropriate user interface.  
• Worked with local stakeholders to devise a plan to motivate data collection, specifically building on the strong sense of community and crafting messaging regarding how data collection can support the community. |
| Workflow and communication | • Local teams and community health workers handled most of the data collection due to lack of regular government surveillance data that may be used to track outcomes.  
• Planned to complete research data collection with those who worked most closely with patients (local nongovernmental organization and community health workers) but also involved higher-level providers (eg, midwives) who would do more advanced procedures (eg, ultrasound).  
• Pivoted to work in tandem with government-funded community health workers in India but are focusing the local team’s efforts on refugee camps, where existing health workers are struggling to have the bandwidth to provide support. |
| Internal and organizational policies, procedures, and culture | • Had to determine explicit language and marking for ownership of data collection devices, such as phones and ultrasound machines.  
• Added security protections to data collection devices in case they were stolen or intercepted, including encryption, dual-factor authentication, and remote wipe capabilities. |
| External rules, regulations, and pressure | • Developed memoranda of understanding with local governments to conduct data collection and research operations.  
• Adapted goals and data collection procedures based on local laws. |
| System measurement and monitoring | • Developed a procedure for assessing data quality using plausibility ratings by local experts since there is no ground truth with which we can compare the data collected.  
• We have been and will continue to collect qualitative data regarding how research data collection may impact workflow and productivity.  
• used government-collected data in the new location [25] to assess the most pressing health issues (eg, anemia), identify areas of greatest need, and detect possible shortcomings in data collection. |
Evaluation officers collect SLL-specific data using tablets with the ODK interface and forms and submit the data to the KoBo server. Each of them has a power bank for charging and airtime to upload data into the web-based server. All the collected data are fed into a centralized database to support collaboration and evaluation at multiple levels (ie, district, regional, and national levels as well as for scientific analysis).

Evaluation officers also use a collateral data collection strategy. They have printed tracking sheets that include information such as the name of the mother, her address, her phone number, or family members’ phone numbers, allowing them to call and gather information on the status of the mother and newborn.

Table 1 describes the features of the SLL EDC infrastructure.

The mMUM Study (Western Myanmar/Eastern India)–Initial EDC System

To design the mMUM study’s EDC system, we selected the ArcGIS (Esri) mapping software coupled with a survey platform (Survey123) [26] allowing community health workers and local nongovernmental organization team members to easily collect data in areas with low internet connectivity or no internet (Figure 2). ArcGIS uses cloud-based data storage. This helped support the local data collection and analysis from team members not working at the local sites. However, the location of the entity providing the cloud storage (ArcGIS in this case, located in the United States) came into question during the local IRB approval process. Cloud data storage approval was eventually granted, as only coded data and not personal health identifiers would be saved. The data collection forms allow for the inclusion of different languages and pictures to facilitate form comprehension. The survey software supports mobile apps for field-based data capture. The mapping software facilitates aggregation and embeds data into high-quality geographical information systems for tracking transient populations (eg, displaced person groups).

Table 2 provides additional details regarding the EDC features for the mMUM study.

The mMUM study required further adaptations following the move from Myanmar to India, facilitated by the design of the EDC system in place, as highlighted based on relevant sociotechnical dimensions described below.

Clinical Content

Our team has worked with local organizations from Myanmar and those native to India to update the content of the questions asked to patients in the data collection instruments. For example, new questions related to refugee status have been added, and questions pertaining to access to health facilities have been omitted, considering the stability and well-established nature of health facilities in India.

Human-Computer Interface

Our selection of a tool that could be translated into multiple languages has been helpful in relocation efforts, as the materials had to be translated into an additional language to support the Indian health workers.

Workflow and Communication

Based on discussions with Indian government officials, local team efforts leverage the medical expertise of those who are also Burmese refugees. This enables them to collect data and provide interventions to pregnant refugees, a population the Indian health system has found challenging to support due to the large and initially unexpected influx of patients in need. The Burmese aid workers also have the linguistic and cultural competency to support the unique needs of the refugee patients.

External Rules, Regulations, and Pressure

Our efforts have involved gaining memoranda of understanding with state-level government health officials in both Myanmar (initially) and India (adaptation). We have also had to adapt our interventions slightly, as in Myanmar we had planned to use portable ultrasound to serve rural areas. Portable ultrasound, however, is illegal in India due to issues with unregistered devices being used for gender selection (ie, female feticide). Therefore, our team has shifted focus to ensuring women are aware of where they can access legal ultrasounds and have transportation. We also plan to implement additional interventions that leverage the information we are collecting to better support the needs of pregnant refugees.

System Measurement and Monitoring

Myanmar did not have enough frequent public health surveillance data to help inform and pinpoint our team’s efforts. However, the population health surveillance in India is much more robust (and publicly available), allowing us to use this information to determine which districts are most in need.

Discussion of Lessons Learned

Overview

The 2 cases discussed involve curating EDC, considering various interacting sociotechnical dimensions to design EDC infrastructure for population health surveillance. This infrastructure is aimed at supporting research and clinical activities in 2 LMIC. Robust system design allowed our team to continue operations and make adaptations in varied capacities through close collaboration with local partners. This provided crucial data-informed health information relevant to vulnerable newborns, women, and families in these 2 LMIC despite ongoing humanitarian crises. The ability of both the mMUM and SLL projects to continue despite the dual humanitarian-COVID-19 crises was facilitated by the design of sustainable EDC infrastructure, which provided a foundation for each project’s interventions. There are transferrable lessons on optimizing EDC design for research and public health or clinical practice in LMIC, emerging from these 2 cases.

Despite differences in context, common lessons may be drawn from the 2 exemplar cases. Table 3 provides recommendations synthesized from our collective experience to guide EDC development and implementation in LMIC in future cases, organized using the dimensions of Sittig and Singh’s framework [13]. Both cases had strong foundations based on technical dimensions (eg, hardware, software, and human-computer interfaces) that supported necessary social, cultural, and
organizational implementation. Multiple recommendations stress the importance of directly involving those with a deep understanding of clinical context, people (end users), and cultural norms in the EDC development and implementation process. These recommendations align with the current literature, underscoring the importance of leveraging an iterative design approach when developing EDC and involving local end users and experts [27-29]. Others have also described the benefits of KoBo’s ODK and its ability to support EDC in settings with low internet connectivity [28]. However, previous studies typically describe EDC in the context of a single, specific system implementation without describing general important considerations, as is done in this viewpoint. Both cases involved engaging with government officials and data, although the SLL team has greater integration with the Ethiopian government. The mMUM team has gained approvals to work with government-funded community health workers in certain districts and has been able to use government-collected outcomes for maternal and child health in India to guide EDC development and variable selection. However, direct integration, as accomplished by the SLL team, is more challenging due to the displacement of some team members from Myanmar.

\(^a\)DHIS2: District Health Information Software 2.  
\(^b\)SSL: Saving Little Lives.  
\(^c\)mMUM: mHealth and Mobile Ultrasound for Mothers.

Compared to SLL, the mMUM study required more extensive adaptations to continue the project. This may be due to several factors, including the project being in earlier phases and less well-established than SLL as well as the need to relocate to a different country altogether due to a national government coup. Myanmar also represents a particularly challenging context from the perspective of developing EDC systems, as the country was essentially closed to external global influence until 2014. Consequently, other global countries with more technology-related partner engagement may have further developed EDC systems at baseline compared to Myanmar.

### Conclusions

This viewpoint addresses a gap in the literature by providing concrete recommendations for the development and refinement of EDC in LMIC, supported by case descriptions from 2 projects. In each case, the EDC infrastructure developed allowed the teams to continue clinical and research-based operations through humanitarian crises, including the COVID-19 pandemic and civil unrest. Common themes from each case have been presented as a series of recommendations for future EDC development and implementation in LMIC. Local system descriptions and recommendations leverage Sittig and Singh’s “sociotechnical model for studying health information technology in complex adaptive healthcare systems” [13], suggesting this model may be helpful for LMIC settings in...
addition to its previous use in high-income countries. Key elements of our recommendations include selecting hardware that accommodates local infrastructure, selecting systems that allow for communication across language and literacy levels, conducting iterative design with those with deep local and contextual knowledge throughout the design process, as well as gaining approval and buy-in from governmental entities.

Abstract

The COVID-19 transmission in the Eastern Mediterranean Region (EMR) was influenced by various factors such as conflict, demographics, travel and social restrictions, migrant workers, weak health systems, and mass gatherings. The countries that responded well to COVID-19 had high-level political commitment, multisectoral coordination, and existing infrastructures that could quickly mobilize. However, some EMR countries faced challenges due to political instability and fragile health systems, which hindered their response strategies. The pandemic highlighted the region’s weak health systems and preparedness, fragmented surveillance systems, and lack of trust in information sharing. COVID-19 exposed the disruption of access and delivery of essential health services as a major health system fragility. In 2020, the World Health Organization (WHO) conducted a global pulse survey, which demonstrated that the EMR experienced the highest disruption in health services compared to other WHO regions. However, thanks to prioritization by the WHO and its member states, significant improvement was observed in 2021 during the second round of the WHO’s National Pulse Survey. The pandemic underscored the importance of political leadership, community engagement, and trust and emphasized that investing in health security benefits everyone. Increasing vaccine coverage, building regional capacities, strengthening health systems, and working toward universal health coverage and health security are all priorities in the EMR. Emergency public health plays a key role in preparing for and responding to pandemics and biological threats. Integrating public health into primary care and investing in public health workforce capacity building is essential to reshaping public health and health emergency preparedness.

(JMIR Public Health Surveill 2024;10:e40491) doi:10.2196/40491

KEYWORDS
COVID-19; integration; pandemic preparedness; primary health care; public health

Introduction

The World Health Organization (WHO) was first alerted to cases of pneumonia of unknown origin on December 31, 2019. By January 30, 2020, the WHO had declared the novel coronavirus outbreak a public health emergency of international concern [1]. The WHO’s Director General described this outbreak of COVID-19 as a pandemic on March 11, 2020 [2]. Since then, many countries have announced several restrictive public health measures to contain the virus, such as travel bans,
border restrictions, lockdowns, and mandatory quarantines [3]. As a result, global economic growth was severely impacted, with the global gross domestic product dropping by 6.7% in 2020 [4,5]. These measures, along with the strain on resources due to the care of those infected with COVID-19, have disrupted the access to and delivery of essential health services [6]. Even the strongest health systems were heavily impacted and overwhelmed by the pandemic.

In 2020, the WHO conducted a global pulse survey to understand the impact of COVID-19 on health systems. Almost 90% of the 105 engaged countries reported interruptions in different services, ranging from routine and elective service delivery to critical care, especially in low- and middle-income countries [6]. Financial constraints, supply chain disruptions, redirection of services to the care of patients with COVID-19, and workforce unavailability affected access to essential health services [5]. The pandemic revealed that no country was sufficiently prepared against biological threats. Many risks and gaps were identified in the current public health system that hindered countries’ capacities for response. These challenges and gaps called for increased investments and stronger political will to enhance health emergency preparedness [7].

In January 2020, the WHO activated its incident management system at all 3 levels of the organization (global, regional, and country levels), in line with the WHO’s emergency response framework [3]. This system safeguards the coordination of response actions during public health emergencies [3]. The WHO’s Eastern Mediterranean Region (EMR) Incident Management Support Team (IMST) for COVID-19 was activated on January 22, 2020, as a coordination mechanism providing technical, strategic, and operational support to EMR countries. It has been operational for over 2 years as the WHO’s longest-running IMST. On January 29, 2020, the first cases of COVID-19 were reported in the EMR, and by April 10, 2020, all 22 EMR countries and territories had reported COVID-19 cases [8].

The EMR is composed of 22 countries, categorized into 3 groups based on socioeconomic development. Group 1 includes Bahrain, Kuwait, Oman, Qatar, Saudi Arabia, and the United Arab Emirates (UAE), which have the most resources and are all high-income countries. Group 2 includes Egypt, Iran, Iraq, Jordan, Lebanon, Libya, Morocco, Palestine, Syria, and Tunisia, which have the next most level of resources and are upper-middle- or lower-middle-income countries. Group 3 includes Afghanistan, Djibouti, Pakistan, Somalia, Sudan, and Yemen, which have the least resources and are all either lower-middle- or low-income countries [9]. The diversity of country incomes, emergencies, cultures, and health system capacities in the EMR led to varying response capacities, COVID-19 knowledge and risk perceptions, and socioeconomic impacts, which have usually been substantial [10].

This viewpoint highlights the challenges that faced EMR countries and their achievements and lessons learned during the COVID-19 pandemic. It provides an overview of the unequal COVID-19 vaccination coverage in the region and discusses the methods and approaches of how to reshape public health in the region and strengthen health emergency preparedness, providing recommendations for the way forward.

### Challenges in the EMR

Over 50% of the countries in the region are affected by complex emergencies, either directly or indirectly. The EMR holds 9 major humanitarian emergencies, 102 million people needing humanitarian assistance (37% of the global total), and over 32 million refugees and internally displaced persons [8].

Political instability, fragile health systems in some EMR countries, multiple disease outbreaks, and poor accessibility and availability of basic health care services have hampered the effectiveness and efficiency of the strategies adopted to combat COVID-19 [11]. The COVID-19 response in the EMR was influenced by multiple factors affecting viral transmission, such as state fragility and conflict; demographics, as this region has a younger population than most; early applications of travel and social restrictions, which limited spread at the beginning of the pandemic; large numbers of migrant workers; mass gatherings; and pilgrimage. Saudi Arabia made an unprecedented decision to downsize Hajj and suspend Umrah, and other EMR countries implemented public health and social measures. However, as “COVID-19 fatigue” set in, many countries loosened their restrictive measures, which often affected the disease trend [10]. Although some countries used and built on past health emergency experiences and systems, such as Saudi Arabia applying lessons learned from the Middle East respiratory syndrome experience [12,13], other countries were poorly prepared. For example, 6 EMR countries still lack national infection prevention and control guidelines, and 5 (Afghanistan, Iraq, Libya, Palestine, and Tunisia) developed their infection prevention and control guidelines in the past year only, with the support of the WHO [14]. The COVID-19 pandemic has exposed gaps in the health systems at multiple levels globally, even in high-income countries with strong health systems. The Islamic Republic of Iran, for example, which had a strong existing health care system, witnessed the largest rate of infections and deaths [15].

The pandemic also highlighted the weak epidemiological capacity of the region [13]. Data were generated but were not always analyzed, interpreted, and used as evidence for action. Additionally, surveillance systems are fragmented, with many being old and paper based [16]. There is also an issue of trusting the shared information in the region because of the underreporting of some countries or their hesitancy to share data [17,18].

Several countries within the EMR encountered obstacles in addressing the COVID-19 pandemic. For instance, Pakistan struggled due to its fragile health care infrastructure, characterized by shortages of health care professionals, hospital beds, and essential medical equipment necessary for treating patients with COVID-19 [19]. Similarly, Iran encountered difficulties in delivering crucial medical and humanitarian supplies due to economic sanctions [20]. Additionally, Yemen and Syria faced difficulties managing the pandemic within the context of ongoing conflict, displacement, and the challenges of maintaining health care infrastructure and resources [21].
**Achievements and Lessons Learned**

Despite the abovementioned challenges, there are many successes and lessons learned. First, the EMR countries that succeeded in facing COVID-19 had high-level political commitment and high-level multisectoral coordination. Often, the heads of state or prime ministers led the multisectoral committees or crisis committees, and this is an example of leadership. Also, regional laboratories were quick to mobilize and build on previous infrastructure and systems, such as those dedicated to influenza, polio, and other communicable diseases [10, 22]. Polio response teams were used in the field and played major roles in COVID-19 vaccination and community mobilization [22]. Before the COVID-19 pandemic, the region had expanded its influenza network due to the influenza pandemic potential. The WHO supported the strengthening of influenza surveillance and testing for respiratory infections. As a result, most countries had the capacity to test for respiratory viruses in a timely manner, allowing the successful use of reverse transcription polymerase chain reaction (RT-PCR) tests for SARS-CoV-2 testing in influenza labs and national influenza centers [23]. RT-PCR capacity for SARS-CoV-2 was expanded quickly to subnational levels across all 22 EMR countries. The WHO ensured the quality of SARS-CoV-2 testing by encouraging all countries to participate in the external quality assessment program for national and subnational laboratories. The WHO’s logistics hub in Dubai, UAE, which is the WHO’s largest repository of medical equipment and supplies globally, was also an asset to the region as it moved thousands of tons of supplies to the world and the region, including millions of RT-PCR tests [24].

Due to a lack of high-quality data, epidemiologists had to consider a variety of indicators [25], including testing rates and measuring the burden on health systems-related indicators, such as hospital occupancy, intensive care unit occupancy, bed occupancy rates, and case fatality ratios. These indicators allowed the WHO to estimate the extent of the pandemic and the COVID-19 response. A very high case fatality ratio could mean that the country is not reporting all cases, has a weak testing capacity or strategy, is poorly managing cases, or may have different case fatality definitions. Therefore, it is important to not only report data but to also interpret it for evidence-based policy making [25].

Limited testing capacity, supplies, and infrastructure were other reasons countries did not provide accurate data [26]. For example, Somalia and Djibouti did not have RT-PCR capacity at the beginning of the pandemic; however, they managed to procure the needed equipment [27, 28]. Enhanced data reporting was significantly increased due to improved laboratory capacity in the region, both for testing and sequencing. The pandemic was an opportunity to build capacity in genome sequencing, enabling the monitoring of the circulation of SARS-CoV-2 variants. Almost 15 countries in the region have genome sequencing capacity and are able to support other countries without such capacity [16, 29].

The pandemic resulted in several innovations, including apps, telemedicine, hotlines, and e-clinics. More countries in the region used innovative solutions to improve data collection, analysis, and dissemination to build strong surveillance capacities and bridge information gaps. For example, using phone companies’ mobility data to measure whether social interventions are successfully implemented allowed for a better understanding of people’s mobility patterns [30]. Another innovation included oxygen production and supply, as some countries, such as Somalia, had no oxygen plants and no capacity to produce oxygen [31]. Since Somalia did not have electric power, especially at the subnational level, they built small solar plants and used solar power to generate oxygen [31]. Similarly, there was a lot of stigma around mental health in the region [32]. However, during the pandemic, 17 countries (Afghanistan, Bahrain, Egypt, Iran, Iraq, Jordan, Kuwait, Lebanon, Libya, Morocco, Pakistan, Palestine, Qatar, Saudi Arabia, Tunisia, UAE, and Yemen) incorporated mental health and psychosocial support within their emergency response plans by establishing hotlines, e-clinic consultations, and platforms to serve the remote areas [33-35].

A total of 17 EMR countries (Bahrain, Egypt, Iran, Iraq, Jordan, Kuwait, Lebanon, Oman, Pakistan, Palestine, Qatar, Saudi Arabia, Sudan, Syria Arab Republic, Tunisia, UAE, and Yemen) banned waterpipe smoking outdoors; however, this was temporary [36]. In terms of the next steps and moving forward, the region needs to take advantage of these innovations and opportunities to enhance preparedness because they are feasible if there is the right commitment and policies.

There was a need for epidemiological modeling to predict the potential impact of public health and social measures, so the WHO established a modeling support team and used data from countries that requested this assistance to help model the progression of the pandemic [37]. COVID-19 also increased interest in epidemiological studies on the ground, including seroprevalence studies to understand population immunity levels or risk factors. The WHO provides standard protocols for seroprevalence studies [38]. The WHO also worked with countries on vaccine effectiveness studies, and many countries took part in clinical trials on vaccines and therapeutics. Through this, countries built their capacities, which is helpful for preparedness [16].

The positive side of the COVID-19 pandemic was that it revealed many of the gaps and weaknesses in the public health system and how to bridge these gaps [7]. The gaps include the nonflexibility of the health systems, workforce shortages, health service fragmentation (primary care, secondary care, and public health), and designs of health facilities. Additionally, misinformation was a significant challenge during the pandemic, and the outdated “disease model” adopted by most health systems does not meet the current needs of the population [39]. Indeed, access and use of essential health services such as maternal and neonatal care and routine immunization were highly affected [40]. The WHO conducted 3 surveys [41, 42] to measure the global disruption of essential health services. The first, conducted between May 2020 and July 2020, showed that the EMR was the WHO region with the highest disruption in health services due to health center closures, stigma, and fear of transmission [41]. The WHO worked closely with countries and published guidelines to address the impact of the pandemic.
Community engagement and community trust are important and lessons learned that will benefit the EMR include the recommendations [47], but some of the key recommendations and lessons learned that will benefit the EMR include the following:

1. The importance of political leadership is what made a big difference in the countries that did better than others.
2. Community engagement and community trust are important to prevent the pandemic’s spread and major economic collapse.
3. “No one is safe until everyone is safe” is not just a slogan, because if any country does not implement prevention measures, the virus can travel to other areas of the world.
4. The return on investment in health security is immense. How long does it take to receive a return on your investment? How much do we need to invest in pandemics?

There were estimates done, and an early estimate of the cost of the pandemic was about US $11 trillion up to the middle of 2021; another US $10 trillion has been added since then. However, if you invest in preparedness, it will cost US $5 per person per year, so for a global population of 8 billion, it will only cost US $40 billion. To prompt action from policy makers, it is essential to present them with these monetary figures.

**Reshaping Public Health**

During the COVID-19 pandemic, different reasons have called on the EMR countries to reshape their public health. Many countries in the EMR are experiencing new dynamic population growth due to birth, migration, and aging populations. Additionally, the region is facing what is termed a “brain drain.” For example, Egypt has a shortage of doctors because 65% of Egyptian doctors leave the country to seek opportunities abroad. Additionally, the world is witnessing continuous technological advances in the biological, physical, and digital spheres [48].

The burden of the disease in the region should also be considered. The Institute of Health Metrics studied the number of deaths per 100,000 in 2019, per disease per country, and showed that besides the known causes of death such as communicable disease, noncommunicable disease, etc., the region has witnessed other causes of mortality due to violence, mainly in Iraq, Syria, and Yemen. Accordingly, in the region, the leading cause of death from 2000-2019 was related to collective violence and interventions [49].

Furthermore, there is no specific data on public health personnel in the region. Data are mainly available on medical health workers, and Saudi Arabia and Sudan are the only 2 countries with registered public health professionals in the Arab world. On the other hand, only a small proportion of the public health workforce (public health consultants) are qualified in public health but without structured training. Therefore, the public workforce in the region needs to be tackled in terms of skills, experience, and foundational knowledge [50].

Investments in primary health care to mitigate the risks of future pandemics and to maintain accessibility and delivery of essential health services during emergencies [40]; investment in the health workforce, including training, mobilization, and redistribution to sustain high-quality essential health services delivery; and data management and surveillance are key elements of a successful response [16]. These actions and initiatives can also expand and reinforce health system capacities, providing an opportunity within the COVID-19 response for countries to reshape their health workforce and services and improve health security for future health emergencies [7,40,51].

Integrating public health into primary health care is an essential approach to reshaping public health and achieving preparedness. Primary care is the first point of contact for the community with the health system; it must be available 24 hours a day and should provide services in a continuous, personalized, and holistic way. Unfortunately, in many settings, primary health care focuses on treating the illness rather than preventing it. Therefore, integrating public health functions into the primary health care system is highly significant to ensure disease prevention, health promotion and protection, and a proper response to threats [39].
Accordingly, 6 models were identified by the WHO technical series on primary care called “Closing the gaps between public health and primary care through integration” to attain the integration of public health into primary health care and provide a tool to help countries be prepared during threats and emergencies. This, in turn, focuses the services on the population’s needs, achieving a person-centered approach. These models can be applied either individually or in combination, depending on the flexibility of the health systems, and they are titled as follows [39]:

1. Public health services are integrated into primary care
2. Public health professionals and primary care providers are working together
3. Comprehensive and proactive benefit packages that include public health
4. Primary care services within public health settings
5. Building public health incentives in primary care
6. Multidisciplinary training of primary care staff in public health

With a focus on the first model, integrating public health professionals into primary care, where they are involved in many public health functions, can be easily achieved progressively. It is essential to understand that the primary health team is complex and should not only include family medicine and freshly graduated doctors; rather, it should include the public health workforce, such as Field Epidemiology Training Program professionals. Additionally, building the competencies of the public health workforce is crucial because, even though the region has 2 public health academies—the International Academy of Public Health and Weqaya Public Health Academy—most of the workforce is untrained [39,50].

Many aspects need to be considered when reshaping public health: (1) financial allocation and establishing an independent national body for public health; (2) investing in public health laboratories, whole genome sequencing, public health analysis such as artificial intelligence, real-world data, real-world evidence, research, and people; and (3) teaching for precision public health where people are the center of health.

A hard lesson learned from this pandemic is that countries should not be dependent on other countries to provide them with essential medicines and vaccines. It is of great importance to strengthen health systems and work toward universal health coverage and health security, as Dr Tedros Adhanom Ghebreyesus, the Director General of the WHO, says that “Health security and global health coverage are two sides of the same coin” [32]. Capacity building is the way forward, including capacity building in integrated disease surveillance and in ensuring the continuity of health services. Additionally, engaging all relevant stakeholders, accelerating vaccine rollout, prioritizing COVID-19 response, and investing in emergency preparedness and the health systems are essential.

**Conclusion**

The political instability and fragile health systems in some of the EMR countries have hampered the effectiveness and efficiency of the strategies adopted to combat the COVID-19 pandemic. The EMR IMST for COVID-19 pillars was critical to the WHO’s role in coordinating the response during the pandemic. Although multiple challenges affect the transmission of the virus in this diverse region, there were many successes, and it is of great importance to build on these successes and focus on building the human and regional capacities as a way forward. Furthermore, focusing on public health is a key factor in responding to pandemics and biological threats, with COVID-19 being a clear example. The current health system faces many gaps and challenges, which can be overcome by adopting different approaches—specifically, integrating public health into primary care as an essential approach to reshape public health in the region and be prepared against threats and emergencies.

**Recommendations and Areas of Improvement**

Several areas of improvement need to be taken into consideration at both the national and regional levels to improve the response to future threats and pandemics. Countries should develop and update a multisectoral emergency preparedness plan and enhance government and political leadership capacity toward biological threats. They must strengthen their health systems and work toward universal health coverage and security. This can be achieved by integrating public health into primary care as an essential approach to reshaping public health coverage and security. This can be achieved by integrating public health into primary care as an essential approach to reshaping public health through adopting 1 or more of the 6 models of integration identified by the WHO. Moreover, there is a need to invest in building human capacities, including epidemiologists; emergency responders; community health workers; health economists; communication specialists; and most crucially, health leaders. Countries should also work toward community engagement and community trust by assessing people’s needs and engaging them in the decision-making process because public health is about people, for people, and by people. Finally, analyzing and interpreting collected data and using it by policy makers is essential for action and decision-making.

On the other hand, different actions need to be taken at the regional level to effectively control the spread of the pandemic. As the COVID-19 pandemic demonstrated, certain countries have greater capacities than others in the region and must facilitate cooperation, solidarity, and support. High-income countries, for example, should ensure vaccine sharing, equity, and distribution with low-income countries. Moreover, countries in the region can implement twin programs where human resources can be shared across countries.

Untapped Potential of Unobtrusive Observation for Studying Health Behaviors

Abstract

Improving the environment is an important upstream intervention to promote population health by influencing health behaviors such as physical activity, smoking, and social distancing. Examples of promising environmental interventions include creating high-quality green spaces, building active transport infrastructure, and implementing urban planning regulations. However, there is little robust evidence to inform policy and decision makers about what kinds of environmental interventions are effective and for which populations. In this viewpoint, we make the case that this evidence gap exists partly because health behavior research is dominated by obtrusive methods that focus on studying individual behavior and that are less suitable for understanding environmental influences. In contrast, unobtrusive observation can assess how behavior varies in different environmental contexts. It thereby provides valuable data relating to how environments affect the behavior of populations, which is often useful knowledge for effectively and equitably tackling population health challenges such as obesity and noncommunicable diseases. Yet despite a long history, unobtrusive observation methods are currently underused in health behavior research. We discuss how developing the use of video technology and automated computer vision techniques can offer a scalable solution for assessing health behaviors, facilitating a more thorough investigation of how environments influence health behaviors. We also reflect on the important ethical challenges associated with unobtrusive observation and the use of these emerging video technologies. By increasing the use of unobtrusive observation alongside other methods, we strongly believe this will improve our understanding of the influences of the environment on health behaviors.

Keywords

health behavior; environments; context; unobtrusive observation; video technology; computer vision

Introduction

It is now widely recognized that features of the environment (eg, green spaces, transport systems, and land use) can shape human behavior [1]. This has led to increasing research and policy interest in the idea that environmental change can be used as an upstream intervention to influence health behaviors, such as physical activity, diet, smoking, and alcohol consumption [2]. Despite the intuitive appeal of this idea, there is a shortage of robust evidence on the effects of environmental interventions [3,4]. A key reason for this is that studies often rely on obtrusive methods for measuring health behavior, which require direct elicitation of information from participants through measures such as self-report (eg, questionnaires), wearable devices (eg, accelerometers), and clinical indicators of behavior (eg, heart rate).

In this viewpoint, we argue that increased use of unobtrusive methods, where measurement does not involve the elicitation of information from participants, is needed to accelerate progress in understanding how environments influence health behaviors. We make the case for unobtrusive observation and discuss the opportunities and ethical challenges associated with the application of video technology and automated computer vision techniques, which could unlock the untapped potential of these underused methods.
Limitations of Obtrusive Methods for Studying Health Behaviors

Studies on human behavior are dominated by traditional obtrusive methods that focus on understanding individual behavior, often overlooking the broader environmental context. For example, typical studies examining interventions to increase physical activity involve interventions delivered to individuals (eg, in primary care) and rely on obtrusive methods to measure physical activity (eg, self-report, pedometers, and accelerometers) [5]. These studies typically focus on individual behavior irrespective of location, rather than understanding how populations behave in environments, that is, place-based behaviors. However, if we are to effectively and equitably tackle population health challenges such as obesity and noncommunicable diseases, interventions must focus on changing the environmental determinants in populations instead of trying to change each person individually [6].

Research on 3 widely studied health behaviors (alcohol, smoking, and diet) illustrates the importance of focusing on environments. Studies using unobtrusive objective data on sales of alcoholic beverages [7], cigarettes [8], and unhealthy food [9] have tested the effects of policy and environmental interventions, often through evaluating “natural experiments,” that is, real-world interventions where the researcher has no control over the design and delivery of the intervention [10]. Fiscal measures (eg, taxation), policy and legislation (eg, smoke-free policies), and environmental changes (eg, food advertising) are all examples of population-level interventions for changing health behaviors that have been found to work quickly and are cost-effective based on studies using unobtrusive measures [11,12]. These studies have explicitly focused on how changes in environments affect population outcomes (eg, overall sales), rather than examining changes in individuals. However, there remains a skeptical attitude toward these kinds of population-level studies, reflecting the belief that associations on an individual level better reflect “true” causal relationships than those on a population level.

Studies of individuals using traditional obtrusive methods have also methodological biases, which arise because they rely on eliciting information from humans, all of whom have constraints in terms of time, attention, and capabilities. Even before a study has begun, the lengthy and burdensome recruitment process typically stretches from identifying and contacting potentially eligible participants, through eligibility assessment, to obtaining informed consent [13]. This substantial burden on participants reduces response rates and increases attrition, therefore producing sampling bias. Moreover, people from already disadvantaged populations (eg, ethnic minority groups and people with low literacy levels) are more likely to be deterred at each stage, albeit unintentionally [14]. This differential recruitment and attrition threatens the generalizability and equity of research findings.

Even if researchers manage to recruit individuals who are both willing and able to participate in research, obtrusive methods are prone to measurement reactivity. Reactivity effects of research participation include change due to being assessed, having views about the desirability of different possible research requirements, and deliberately or unwittingly trying to satisfy researchers [15]. Self-report, which has long been the dominant method for measuring human behavior, is particularly vulnerable to reactivity because it relies on introspection. Therefore, asking participants to self-report their behavior can lead to response biases from memory recall, cognitive difficulties, and social desirability [16]. Although these various biases are well known, researchers often overlook the extent to which research studies are unusual contexts and that participants may react in unexpected ways to what researchers ask them to do [17]. These biases, resulting from “research participation effects,” have the potential to affect study outcomes in ways that undermine the validity and representativeness of research findings.

Making the Case for Unobtrusive Observation

Unobtrusive methods have long been recommended to avoid these issues associated with humans taking part in research. In their influential book in 1966, Webb et al [18] argued that researchers rely too heavily on traditional obtrusive measures of data collection. They advocated for greater triangulation using both obtrusive (reactive) and unobtrusive (nonreactive) methods together to provide reassurance that research is robust to the different types of bias associated with each method of measurement. Webb et al [18] described four categories of unobtrusive methods: (1) physical traces, (2) archives, (3) simple observation (observing in natural settings), and (4) contrived observation (observing in controlled settings).

The method that we focus on in this paper is simple observation; specifically, nonparticipative observation of human behavior in the context in which it naturally occurs (hereafter referred to as “unobtrusive observation”). We have been involved in over 1000 hours of unobtrusive observation in natural experimental studies of built environment interventions (eg, a new sustainable park) on physical activity and other behaviors (eg, social interactions) [19-21]. Hence, our experiences derive from a positivist approach, producing quantitative data through systematic observation—a structured method of observation using a predefined coding system.

Unobtrusive observation has historically played a crucial role in various fields of study. For example, sociologists such as Whyte [22] and Jacobs [23] have used observation methods to investigate urban life and better understand how people socially interact in public spaces. Similarly, within urban design, unobtrusive observation has been a valuable tool to provide insights for designers to improve the quality of urban landscapes. This is exemplified in Gehl and Svarre’s [24] pioneering work where they observed public spaces and human behavior, and in studies on “desire paths,” which explore informal routes created by individuals seeking shortcuts rather than adhering to designated paths [25]. Ethnographic research on cultures, communities, and social practices also relies heavily on observation methods, often involving researchers immersing themselves in the communities they observe. Additionally, in ethology (the study of animal behavior), prominent researchers such as Lorenz [26] and Chivers and Goodall [27] have
conducted extensive field observations to uncover insights into animal behavior and social structures. In health research, unobtrusive observation has been used to assess a range of health behaviors, including physical activity [28], smoking [29], suicidal behaviors [30], handwashing in clinical settings [31], and social distancing [32]. A common theme across all these observation approaches is that behavior is intricately tied to the environment, and a comprehensive understanding of behavior requires consideration of this contextual influence.

A unique strength of unobtrusive observation, in comparison to other unobtrusive methods, is its ability for fine-grained analysis of variations in health behaviors directly within the environments, or places, in which they occur. This provides us with strong insights into how people’s behavior is influenced by the microenvironments to which they are exposed. As a result, unobtrusive observation is particularly useful for evaluating the effectiveness of environmental interventions aimed at changing health behaviors. For example, Petticrew et al [29] used unobtrusive observation to evaluate the before-and-after impact of a Scottish legislative ban on smoking in public places, which allowed for the assessment of smoking behavior in great detail (eg, quantifying characteristics and behaviors of the smokers or nonsmokers, signage, and positioning of smoking materials) and in different environmental settings (eg, bars, bookmakers, and restaurants). In contrast, other unobtrusive measures, such as archival data, typically involve aggregated measures that make it more difficult for researchers to understand how people are exposed to specific environments of interest.

Observations can be conducted in many public settings, such as green spaces, public highways, shops, and bars, therefore providing real-world contexts for studying health behaviors and the impact of interventions designed to change them. Such studies can provide answers to important questions for policy and decision makers, for example: What kinds of green spaces best encourage physical activity? How can healthier food choices be promoted by changing physical microenvironments (eg, by altering the availability of unhealthy foods)? And how can smoke-free policies in public spaces influence smoking behaviors and secondhand smoke exposure? There is currently a small evidence base for these types of environmental interventions, suggestive of potentially large effects on health behaviors, but with considerable uncertainty and limited understanding of processes by which these outcomes are brought about.

Furthermore, as unobtrusive measures do not require explicit recruitment of participants, observations allow studies in a wide range of populations and settings. Therefore, unlike most traditional research that often fails to recruit participants from underserved groups (typically referred to as “hard-to-reach” groups) [33], using unobtrusive observation can produce valuable evidence in underserved populations where evidence is lacking but the need to improve health is the greatest. This is particularly important given that intervention effectiveness may differ between socioeconomically advantaged and disadvantaged populations [34].

Despite these advantages, unobtrusive observation remains an underused method for studying health behaviors, even though it has been advocated for over half a century [18]. For example, in a recent systematic review of 116 studies that had an explicit focus on how public spaces influence physical activity, leisure activity, and social activity [35], one would expect that unobtrusive observation would be most appropriate because the focus is on the link between the environment (ie, public spaces) and behavior, rather than the person. Despite this, 95 (82%) of the studies included in this review used obtrusive methods, compared to 53 (46%) studies that used unobtrusive behavior observation. More importantly, of the 95 studies that used obtrusive methods, 57 (60%) studies relied on a single outcome measure to assess behavior, mostly relying on a questionnaire. This is particularly problematic because previous research suggests that relying on methods where participants complete measures in nonbehavioral contexts (eg, at home and in laboratories) may underestimate the importance of contextual factors [36]. Therefore, although this systematic review did not compare differences in findings between obtrusive and unobtrusive methods, relying on questionnaires may lead to inaccurate inferences about the relationship between these behaviors and environmental contexts. This example highlights the importance of triangulation between different methods to reduce the risk of threats to validity based on single-measure research. For example, unobtrusive observation is stronger at quantifying place-based behaviors to examine variation between different contexts (where the place is the subject of analysis), while obtrusive measures are necessary for individual-level longitudinal analysis and assessing intrinsic factors (where the person is the subject of analysis).

So why do researchers typically rely on obtrusive methods and overlook unobtrusive observation? An important factor is that unobtrusive observation does not conform to the traditional mainstays of ethical research that prioritize participants’ right to be informed and freely choose to participate in research. A decline in the number of observational studies reported in journals in several fields has been attributed, in part, to the impact of ethical regulation (eg, [37]). Researchers should, of course, always consider the ethical issues involved in the use of unobtrusive measures, balancing wider societal benefits derived from the research against possible harm to participants. Some specific guidelines have been developed to advise on the unique ethical issues raised by the use of unobtrusive observation (eg, [38,39]). These guidelines typically advise that observational research in public settings where those observed would expect to be observed by strangers, and from which no harm could be reasonably supposed to come, does generally not require consent. Nonetheless, researchers must engage with communities to understand any concerns specific to the sociocultural context they are studying and develop contextually specific solutions to minimize the risk of negative responses when conducting unobtrusive observation. For a more detailed discussion of these ethical challenges, see Clark [40].
Another barrier to the use of unobtrusive observation is the need to deploy in-person observers across multiple study sites, which involves substantial staffing, training, observation time, and data entry—all of which limit scalability. It is therefore perhaps unsurprising that researchers often choose the more convenient and familiar option of traditional obtrusive methods, such as questionnaires and surveys, which have become even more accessible with the rapid rise of digital methods.

**Opportunities in Using Video Technology**

With advancements in video technology, observation methods are beginning to use video recordings, which could help address the scalability issues associated with in-person observations and thereby increase the uptake of observational methods. Specifically, cameras can be used to collect video recordings in public spaces, which can then be watched and assessed (“coded”) by a researcher. Using cameras removes the need to recruit, train, deploy, and supervise in-person observers. Therefore, camera-based observations can overcome issues of observer availability, fatigue, and inattention; reduce risks to researchers from working alone and at night for prolonged periods during observations; reduce measurement reactivity associated with the physical presence of observers (JS Benton et al, unpublished data, 2024); and ultimately decrease costs. Furthermore, the ability to pause, rewind, and rewatch footage can improve the reliability of coding (JS Benton et al, unpublished data, 2024) and allow for more in-depth analysis compared with “live” in-person observations.

Although rare, there are examples of camera-based observation research, such as the use of closed-circuit television (CCTV) surveillance to assess bystander behavior in public spaces [41], traffic webcams to assess physical activity [42], drones to assess park use [43], and wearable video devices to assess behavior on sidewalks or streets [44]. The level of unobtrusiveness associated with these various camera-based approaches will depend on the research context. For example, a recent study found no evidence of participant reactivity to the deployment of fixed video cameras in public spaces where there was already existing CCTV surveillance (JS Benton et al, unpublished data, 2024). However, there may be an increased risk of reactivity in public spaces where cameras might be more conspicuous, for example, due to sociocultural norms.

It is difficult to ignore the emergence of new technologies, such as internet of things devices, artificial intelligence, laser tracking, and remote electroencephalography, which are opening up new avenues of unobtrusive measurement of human behaviors [45,46]. For example, researchers are beginning to capitalize on advances in computer vision to use deep learning models (a subset of machine learning) to automatically detect and recognize behaviors within video images. Examples of diverse applications for automated human behavior recognition include analysis of pedestrian behavior and crowds (eg, monitoring social distancing) [47], detecting when a person falls in a health care facility [48], and evaluating sports performance [49]. Developing such models for assessing health behaviors could dramatically reduce the labor, time, and cost needed to collect data at scale, over extended periods, and with increased consistency across video images compared with human observers.

**Ethical Challenges in Using Video Technology**

Capitalizing on these emerging video technologies creates new risks associated with recording images of people in public spaces, rather than just observing them. Privacy, consent, and confidentiality are all important challenges, which are entwined within data protection laws that researchers must comply with when processing video recordings of people in public spaces. Using computer vision models could address issues of privacy by eliminating the need for humans to watch video recordings once the models are developed and validated. However, less is known about the broader ethical and societal implications of this approach. Therefore, further work is required to establish responsible research practices for the use (and nonuse) of these techniques.

We recently attempted to provide recommendations on how camera-based research can be conducted ethically and in line with data protection requirements [50], drawing on our experiences in the United Kingdom of conducting 3 studies using fixed video cameras to assess observable health behaviors in public spaces. Examples of good practice include engaging with local communities to codevelop privacy and cybersecurity solutions to minimize the risk of negative responses; displaying privacy notice signs and participant information sheets to increase transparency and ensure compliance with data protection legislation; having clear reporting procedures in place for any observed illegal activities; and implementing robust cybersecurity measures to prevent personal data from being intentionally or unintentionally compromised (eg, using secure data storage solutions).

However, views on what makes this type of camera-based research ethical or not can change depending on the researcher’s positionality, context, and experience. For example, visual researchers in the United Kingdom are increasingly concerned about heightened ethical scrutiny and regulation [51], whereas in the United States, exemptions under the Code of Federal Regulations 46 allow for certain research activities to bypass extensive ethical oversight. It is therefore important to acknowledge differences in ethical standards across different jurisdictions and physical and sociocultural contexts, which will inevitably evolve over time in response to societal, technological, and cultural changes.

There are also important wider societal debates about the use of cameras in research, particularly concerning CCTV use, given its ubiquity in many urban spaces around the world. While the use of CCTV in research is on the rise [52], there are differences between using CCTV footage as an observational method in research and its broader application for public safety. A recent study explored the acceptability of using CCTV for research on suicide prevention, which found that there were positive public attitudes toward this approach [53]. Further research is needed to examine acceptability in different geographical and sociocultural settings and in other areas of health research.
Conclusions

Understanding how environments influence health behaviors requires a major change in research practices to address our overreliance on obtrusive methods that primarily focus on understanding individual behavior and that tend to overlook environmental influences. Unobtrusive observation can assess how environments affect the behavior of populations; yet despite a long history, it remains an underused method in health behavior research. Capitalizing on video technology and automated computer vision techniques could provide a scalable solution to increase the uptake of these methods. However, we must find a way to ensure that the scientific and societal benefits are maximized while protecting individual rights. By increasing the use of unobtrusive observation alongside other methods, we strongly believe that this will improve our understanding of the influences of the environment on health behaviors.

Abstract

The COVID-19 pandemic revealed that data sharing challenges persist across public health information systems. We examine the specific challenges in sharing syndromic surveillance data between state, local, and federal partners. These challenges are complicated by US federalism, which decentralizes public health response and creates friction between different government units. The current policies restrict federal access to state and local syndromic surveillance data without each jurisdiction’s consent. These policies frustrate legitimate federal governmental interests and are contrary to ethical guidelines for public health data sharing. Nevertheless, state and local public health agencies must continue to play a central role as there are important risks in interpreting syndromic surveillance data without understanding local contexts. Policies establishing a collaborative framework will be needed to support data sharing between federal, state, and local partners. A collaborative framework would be enhanced by a governance group with robust state and local involvement and policy guardrails to ensure the use of data is appropriate. These policy and relational challenges must be addressed to actualize a truly national public health information system.

Introduction

Dr Rochelle Walensky, director of the Centers for Disease Control and Prevention (CDC), has admitted that the national response to the COVID-19 pandemic was deficient in many respects, citing the use and dissemination of data as a principal problem [1]. Indeed, the US public often relied on private data sources, such as the Johns Hopkins Coronavirus Resource Center, as the “go-to data source” for COVID-19 data rather than official government sources [2]. Many of the challenges concerning the use and dissemination of data are not due to the need to collect missing data, nor due to the technical limitations in sharing the needed data. Rather, many of these challenges are due to policy barriers that impede the needed data flows between public health entities, including local, state, and federal partners [3].

While data sharing challenges exist across the public health surveillance and dissemination systems, here we examine the specific challenges faced when sharing data between state, local, and federal syndromic surveillance partners. These challenges...
have been explored from state perspectives, but we examine these challenges through a national lens and how federalism issues affect federal, state, and local partners and shape the data use agreements (DUAs) that govern the data sharing relationships [4,5].

**US Syndromic Surveillance and Federalism**

Syndromic surveillance refers to the process of sharing electronic data with health departments—often in near real time—to understand existing and emerging public health issues [6]. This process can include diverse data sources, including emergency department electronic health records (EHRs), environmental data, vital statistics, and laboratory data. The rapid nature of syndromic surveillance permits real-time situational awareness of emergent public health issues [6].

The United States began its investment in syndromic surveillance after the terrorist attacks of September 11, 2001, and a rash of anthrax-laced letters [7,8]. In 2009, syndromic surveillance was included as part of the US $20 billion EHRs incentive program created by the Health Information Technology of Economic and Clinical Health (HITECH) Act [9]. The Act incentivized hospitals to adopt, and meaningfully use certified EHR systems. The Act also accelerated syndromic surveillance nationally by incentivizing hospitals to report specific public health measures, including syndromic surveillance, to their local public health authorities [10]. Over this time, the national syndromic surveillance system, which was first developed by CDC, evolved from BioSense to BioSense 2.0 to the National Syndromic Surveillance System (NSSP), with the overall purpose of establishing a nationwide surveillance system to detect and assess potential health outbreaks throughout the United States [7]. Each of these evolutions has been impelled by technical, policy, and relational challenges between federal and state or local syndromic surveillance partners, including CDC, Council of State and Territorial Epidemiologists (CSTE), Association of State and Territorial Health Officials, and National Association of County and City Health Officials.

The community of practice, one of the defining aspects of the NSSP, aims to improve syndromic surveillance nationally through collaboration and knowledge sharing between federal, state, and local partners [11]. The community of practice offers a platform for public health professionals to collectively identify and use the optimal approach in syndromic surveillance. Through professional engagements, members collaborate to exchange knowledge, improve understanding, cultivate expertise, and address issues, to advance the practice of syndromic surveillance [11].

Currently, the NSSP stores all participating state and local syndromic surveillance data in a single repository maintained by the CDC [6]. While some federal employees have access to all syndromic surveillance to provide technical system support for state and local jurisdictions (eg, quality assurance, troubleshooting, and developing analytical tools), these data are not shared by default for federal public health uses [5]. The DUAs between state or local governments and the CDC prohibit any federal access to state and local data for public health purposes without the express consent of the jurisdictions [4,5]. Specifically, the default federal access to syndromic surveillance data for public health purposes is limited to the US Department of Health and Human Services (HHS) region level. For example, while federal NSSP personnel might observe an incidence increase within HHS Region 10 comprising Alaska, Idaho, Oregon, and Washington, they could not distinguish between (1) an isolated event in Washington; (2) unrelated, but similar, events in Washington and Alaska; or (3) related events in Washington and Oregon [5,12]. At the regional level, the federal government lacks awareness of interstate public health events. These policy data sharing limitations effectively hamstrung the federal COVID-19 response by not allowing access to vital data that could have been used to give a broader view to federal agencies in the context of a novel, rapidly moving and evolving virus.

The COVID-19 data sharing challenges cannot be understood without fully appreciating how US federalism shapes and affects the US public health system. In the United States, federalism consists of the sharing of authority between the national (federal) government and the state governments. At the onset, it is important to recognize that there is no express public health power that is explicitly outlined in the US Constitution. This means that federal public health actions must derive from one of the US Constitution’s enumerated powers. Typically, most federal public health actions are derived from the powers to tax and spend for the “general welfare” and the interstate commerce clause (ie, regulation of industries and activities that affect interstate and international commerce, including health).

The police power—the states’ power to regulate in the interest of public health, safety, and community values—is the fundamental governmental power that authorizes nearly all traditional public health actions [13]. Under the Constitution’s 10th Amendment, these powers are reserved for the states. This means that the states have the authority to set quarantines, restrict businesses, mandate isolation for those infected with a communicable disease, and impose primary public health responsibility [14].

In comparison, the federal government’s role is much more limited to providing support to state and local governments (ie, taxing and spending for the general welfare) or addressing those issues that have interstate impacts, like vaccine approvals (ie, interstate commerce). Consequently, state and local governments can be thought to have the primary public health responsibility within their jurisdictions while the federal government has less direct public health responsibilities and interests (ie, supporting state and local governments and interstate commerce).

These federalism nuances and the consequent relationships between local, state, and federal partners came under strain during the COVID-19 response. Specifically, the DUAs between the CDC and the states effectively impeded the response to the COVID-19 pandemic by restricting federal access to HHS region level syndromic surveillance data [15]. In early 2020, the White House COVID-19 Task Force obtained access to all COVID-19 NSSP data in an apparent exercise of emergency authority [4,5]. Although the federal government was able to bypass these policy...
barriers, the decision left some state and local epidemiologists feeling that the agreed-upon DUAs were “thrown out the window” [5].

While examining the US legal framework for data sharing within US federalism, Fahey [16] writes that data sharing is a rapidly expanding intergovernmental marketplace in many areas of government, including public health. She argues that in the absence of federal legislation, documents such as DUAs are the strongest legal policies [16]. The consequences and the reality of DUAs being discarded in the event of a national emergency are something that will only become more complex as data collection and data sharing increases. The power that federalism gives the states in these circumstances may become harder to define if clear policy regarding data is not codified through binding statutes.

**Improving the National Public Health Data System for Future Epidemics**

In the following sections, we derive important lessons learned about public health data sharing within the US public health system, derived from the findings from a 2021 study by CSTE and the NSSP [4,5]. The study involved several work group calls with 20-30 state and local epidemiologists in leadership or decision-making roles and 8 key informant interviews. In addition, the study cited 8 randomly selected state and local epidemiologists from the list of NSSP site administrators to provide feedback on specific policy options [5].

**Align US Public Health Data Sharing Policies With Ethical Guidelines**

An increasing number of public health ethicists assert that there are ethical obligations to share public health surveillance data in certain circumstances [17-19]. For example, the World Health Organization’s (WHO) ethical guidelines expressly state [18]:

> [w]ith appropriate safeguards and justification, those responsible for public health surveillance have an obligation to share data with other national and international public health agencies.

Surveillance data can be legitimately disseminated to enable public health response, improve the efficiency and effectiveness of public health activities, and inform resource allocation and other support [20].

By limiting federal access to state and local NSSP data by default, the DUAs between the CDC and the states create significant impediments to legitimate public health functions under the enumerated powers to regulate interstate commerce and to spend for the general welfare [13]. In the context of a rapidly spreading public health threat such as the COVID-19 pandemic, the burden on the federal government to seek consent from all affected jurisdictions, each of which are also burdened by local public health actions, is antithetical to the calls for increased public health data sharing from ethicists. These DUAs should be revised to eliminate data sharing barriers when there is a documented and communicated public health need and there are appropriate policy guardrails to ensure only appropriate public health uses them. Importantly, proper guardrails can also eliminate other data sharing barriers [21].

**Using Granular Data to Respond to Interstate Threats and Allocate Federal Resources Equitably**

The NSSP DUAs that restrict federal access to state and local syndromic surveillance data impede several legitimate federal interests and national public health objectives. The DUAs permit routine federal access only to HHS region level aggregations [5]. In order to have a national view of emerging public health threats, access to data at the state level or at a more granular level is required.

A national view of public health threats is essential for the federal government to fulfill its legitimate governmental role in national public health responses [5]. The federal government plays a critical role in providing support and allocating resources to state and local jurisdictions. However, allocating these resources equitably in response to national public health events requires broad situational awareness of the burdens faced by all jurisdictions. This type of assessment cannot occur when the federal government lacks the data at the required level of granularity. This proved to be one of the major challenges during the COVID-19 pandemic [22].

Moreover, several state and local epidemiologists expressed openness to increased federal access to state and local NSSP data to enhance their public health actions. For example, a commonly expressed benefit among key informants was having extra “eyes” on data to provide greater detection capacity. One epidemiologist stated, “I do think there’s also a lot of opportunity right now, [but] there’s not enough capacity...to look at local data” [5]. Other articulated anticipated benefits were more coordination between agencies and the generation of regular reports or visualizations based on agreed-upon queries of state and local NSSP data [5]. Additionally, enabling greater access to the CDC could permit the creation of national training programs to train and support a growing number of state and local epidemiologists in syndromic surveillance methods and techniques.

**State and Local Agencies Remain Essential Partners in Public Health Surveillance Activities**

Regardless of legitimate federal interests, state and local governments still need to play a central role in syndromic surveillance for several reasons. First and foremost, state and local governments retain the primary public health responsibility for the communities within their jurisdictions. As a result, the duty to use syndromic surveillance data to improve population health in their jurisdictions rests squarely with state and local jurisdictions. This fundamental responsibility implicitly carries an ethical duty to safeguard this sensitive information and to protect the confidentiality of their constituents. This duty has additional significance to the relationships with the health care providers because many health care providers that contribute...
their data do so voluntarily (ie, few states mandate syndromic surveillance). Moreover, state and local governments have a legitimate interest in ensuring the responsible use of these sensitive data.

These fundamental responsibilities and interests do not end when state and local governments share their data to enable federal agencies to fulfill their legitimate public health interests. Federal partners must keep their state and local partners abreast of their use of syndromic surveillance data and any dissemination of findings. There are important risks in interpreting syndromic surveillance data without understanding local contexts. As prediagnostic EHR data are automatically transmitted in near real time, syndromic surveillance data are messy by design. There can be local variations in submission intervals or health facilities’ data entry conventions that can lead to misleading artifacts in data analyses for the unaware. Additionally, local events—such as a festival drawing out-of-state visitors—could result in expected localized spikes in emergency room or urgent care visits that could be misinterpreted as an emerging public health concern if analysts are unaware of the local context [5]. If federal agencies make decisions from syndromic surveillance data without fully understanding the local context, it is possible that federal actions could interfere with state and local public health activities or create unnecessary communication burdens (ie, states forced to explain or reconcile federal data releases).

State and local health agencies also have important, and sometimes fragile relationships with health care facilities that often voluntarily contribute syndromic surveillance data. Throughout the CSTE study, state and local epidemiologists expressed concern that increasing federal use of granular syndromic surveillance data could endanger these facility relationships if federal communications stopped once the data are received from local agencies without further clarification before any decisions or actions based on these data analyses. Disclosure of a facility’s syndromic data also exposes that facility to certain risks. As 1 key informant said [5]:

\[
\text{we have an understanding with the facilities that contribute data that we're not just going to release data from a single hospital to the public. So, sometimes it seems like federal users are not as sensitive to that.}
\]

Facilities in rural areas are particularly vulnerable to these types of risks as disclosures of granular syndromic surveillance data in rural areas may inadvertently expose the sole rural provider in that area. One informant stated [5]:

\[
\text{I think that the [syndromic] data is just a little bit more fraught than other data, where issues with facility level disclosures...speaking poorly...about a community without knowing that you are, and that...cultural awareness...that might not be apparent from a federal level...I think that states can bring a lot of value too.}
\]

While state and local epidemiologists saw benefits to increased federal access to state and local syndromic surveillance data, access to those data comes with risks that are exacerbated without collaboration and cooperation between federal, state, and local partners [5]. For example, federal interactions with health care providers that bypass state and local partners could threaten local public health relationships with providers that often voluntarily contribute their data to syndromic surveillance programs. If so, these federal actions would also interfere with state and local governments’ fundamental public health mission.

**Intergovernmental Relationships are Critically Important to Data Sharing**

Due to the decentralized public health structure inherent to US federalism, strong interagency and intergovernmental relationships are essential for any national public health response. Data sharing between agencies is also critically important in these responses. Indeed, fractures in relationships can be potently data sharing barriers [23]. Relationships are established through time spent communicating and working with each other. Notably, these relationships require trust between partners, and that trust was shaken during the COVID-19 response [5]. One nonfederal key informant noted [5]:

\[
\text{There's been such a lack of trust that has been reinforced during this response. I think it's actually going to be harder rather than easier [to permit greater federal access to state or local data]. I say that anyway because I think the NSSP program itself, in its current form, and I think it's probably important that this gets documented, has been an amazing steward of the data, but the system around it has become less trustworthy and I think the system around it and the system, the way that the response has worked with the states, is now going to impact the program's ability to do its best work. So, in today's world, CDC has become less and less willing to really talk to states in pre-decisional ways and help states understand this data is driving this decision, and there's been a much larger tendency for CDC to make decisions and then just inform states about it in this response. And so, I think pre-COVID, it actually would have been easier rather than harder to implement some of these changes right now, in a way that the states felt good about.}
\]

Enabling a truly national public health information system within the context of US federalism requires federal, state, and local partners to forge stronger relationships that will enable greater use of public health data. Done well, collaborating around the use of public health data has the potential to increase communication, common understanding, and teamwork toward a common goal that could increase trust. Importantly, however, public health politicization likely creates additional data sharing barriers, as some governments equated the COVID-19 pandemic with successful or unsuccessful governance during a global crisis [24].
Establish a State and Local Syndromic Surveillance Governance Group

Several state and local epidemiologists suggested openness to creating an NSSP governance group with state and local constituents [5]. Such a governance group should have some decision-making capacities that are currently absent from the community of practice, which functions more as a sounding board or advisory council to the CDC. A governance group with some decision-making authority would create an important check on the expanded federal access to the state and local syndromic surveillance data.

A governance group could have several different benefits for national syndromic surveillance efforts. First, a governance group would be well-positioned to establish a collaborative framework and norms between the federal, state, and local partners. Second, a governance group could establish protocols to help improve transparent communications and collaboration with federal partners regarding ongoing or proposed uses of state and local syndromic data. Third, a governance group could help flag important issues for other state and local partners to monitor, such as proposed federal publications, communications, or policy changes. Finally, a governance group could be empowered to facilitate emergency access to appropriate state and local syndromic surveillance data, greatly reducing the current individual jurisdictional consent burden required in a public health emergency such as the COVID-19 pandemic [5].

The DUAs and other applicable laws should be revised to enable the governance group to function nimbly as public health circumstances necessitate. For example, DUAs could bind state, local, and federal partners to decisions by the governance group to permit expanded emergency access to state and local syndromic surveillance data (and restrict access when emergencies end). This would build flexibility into the DUAs to anticipate and accommodate emergency situations reducing transactional friction while all parties are managing a crisis.

Develop a Collaborative Framework Between Public Health Surveillance Partners

The US federalism created a decentralized public health system, so policies and agreements establishing a collaborative framework are needed to create a national public health information system, while still recognizing state and local authorities as the primary public health authority. Indeed, the CSTE study identified “improved cross-jurisdiction collaboration efforts” as an important benefit of federal access [5]. This framework would have to carefully establish expectations for federal, state, and local partners and ensure that the legitimate public health interests of all parties are respected.

The CSTE study identified several critical issues that should be addressed in this collaborative framework [5]. Perhaps the most important issue is establishing protocols for communications between syndromic surveillance partners. Currently, communications are not standardized in mode or content. Furthermore, it is not always clear to state and local health departments when the federal government expects responses to their communications (eg, an “FYI” communication vs an investigation inquiry; see Table 1).

Table 1. Example of a tiered approach to federal National Syndromic Surveillance System communication response expectations.

<table>
<thead>
<tr>
<th>Tier</th>
<th>Public health threat</th>
<th>Expected response from states</th>
</tr>
</thead>
<tbody>
<tr>
<td>Tier 3</td>
<td>Low or moderate but only affecting targeted jurisdiction</td>
<td>None</td>
</tr>
<tr>
<td>Tier 2</td>
<td>Moderate but interjurisdictional in nature or high but only affecting targeted jurisdiction</td>
<td>Acknowledge receipt</td>
</tr>
<tr>
<td>Tier 1</td>
<td>High and interjurisdictional in nature</td>
<td>Response is expected</td>
</tr>
</tbody>
</table>

Given the division of public health responsibilities within the US federalism, these communication ambiguities are additional strains on thin public health resources [5].

A collaborative framework must also (1) establish processes and support for state and local involvement in data analysis and methodological development, (2) provide appropriate acknowledgment, (3) standardize data requests, and (4) restrict federal syndromic surveillance communications with participating health care facilities without the consent of relevant state or local public health partners.

Establish Appropriate Federal Policy Guardrails for Syndromic Data That Are Shared With Public Health

While many state and local epidemiologists who participated in the CSTE study indicated benefits to greater data sharing with federal partners, many called for strong policy guardrails to ensure appropriate federal uses [5]. To be clear, there are substantial restrictions on syndromic surveillance data currently, but these restrictions prevent legitimate public health data use. If these existing restrictions are loosened to allow legitimate public health uses, then new guardrails need to be established to prevent data misuse and manage risks while still enabling suitable data sharing between agencies. Critically, these sentiments were shared by federal participants in the CSTE study [5]. State and local epidemiologists in the CSTE study indicated support for policies that would (1) establish audit and documentation processes, (2) implement standards and processes to remove access from federal users, and (3) protect sensitive data from public disclosure—such as Freedom of Information Act requests [5]. Additionally, there should be strict limits on sharing NSSP data for nonpublic health purposes. For example, the WHO ethical guidelines strongly advocate against sharing data with agencies that are likely going to take law enforcement action against individuals [19]. Similarly, the facilities that voluntarily contribute their data for the betterment of their...
communities should not have to fear that their syndromic data will be used against them. The DUAs that address these guardrails would foster stronger relationships of trust in state and local jurisdictions. The existing DUA did not address these issues considering the proposed expanded federal access to state and local data [15].

As data sharing continues to grow between agencies the policies that govern data use need to have well-defined guardrails. In the absence of statutory protections having these guardrails defined in DUAs becomes even more important. This will ensure data are being used in the manner it was intended.

Significance for Broader Public Health Data Sharing

Data sharing is a persistent challenge for public health agencies [23,25-27]. Although this analysis is limited to the challenges in addressing broader data access to US syndromic surveillance data, it provides insights into data sharing in other contexts. For instance, Aamer Ikram, the executive director of Pakistan’s National Institute of Health recently spoke of the need to support coordinated and integrated public health surveillance, noting that the lessons of the COVID-19 pandemic—good and bad—“must be immediately translated into strategies and policies” [28]. In a 2022 study, The International Association of National Public Health Institutes (IANPHA) identified several jurisdictions where decentralized public health surveillance has complicated the data sharing, coordination, and development of integrated public health data systems [29]. For instance, Mozambique, Canada, and Pakistan all face challenges with local, provincial, and national public health partners that complicate efforts to create integrated surveillance systems [30,31]. The IANPHA report finds that optimal data flow requires systems that permit local and provincial data to flow into compatible national infrastructures supported by formalized data sharing agreements [29]. Accordingly, lessons from this analysis—that deal with facilitating similar data sharing between US local, state, and federal public health partners—could be useful in other international settings.

Limitations

Our analysis derives from insights from national, state, and local informants based on their experiences in syndromic surveillance practice before and during the pandemic. By the CSTF study’s design, these perspectives skew in favor of the US state and local epidemiologist informants. Moreover, many of the data in the CSTF study are qualitative, which have inherent limitations (eg, representativeness). In our analysis, we sought to consider additional national and systemic considerations, but these additional inputs likely do not eliminate the state or local perspective biases implicit in the CSTF study data used in our analysis. Additionally, there could be additional legal, political, and practical considerations that were not observed within the scope of our analysis.

Conclusions

The history of US syndromic surveillance is pendular. Every iteration of US syndromic surveillance (ie, Biosense 1.0, BioSense 2.0, and NSSP) was impelled by existing challenges and concerns [7]. However, imperfect responses to those challenges created new issues [7]. For example, to support collaboration between states, BioSense 2.0 shielded syndromic surveillance data from CDC access by using servers operated by the Association of State Health Officials [32,33]. However, this prevented the CDC from assisting with quality assurance and technical assistance [7]. The development of NSSP addressed this issue by having CDC systems once again host syndromic surveillance data but governed by DUAs that established a default of nonsharing between federal, state, and local partners [4,7]. The federal challenges to accessing state and local syndromic surveillance data suggest that the iteration of US syndromic surveillance data will have to wrestle with the policy barriers to intergovernmental public health data sharing.

Broadly, the harsh realities exposed by the COVID-19 pandemic impelled new efforts to improve the national public health data infrastructure. Chief among these efforts is the “Data Modernization Initiative” [34,35]. The CDC’s strategic plan outlines 5 key priorities that are, building the right foundation, accelerating data into action, developing a state-of-the-art workforce, supporting and extending partnerships, and managing change and governance to support new ways of thinking and working [35]. These are important and laudatory goals; however, it is not clear that they will address the challenges that are inherent in the US public health system in the context of federalism.

Future public health challenges such as the COVID-19 pandemic will force the distinct components to once again provide a national response in a decentralized system. State and local governments—having the primary public health responsibility within their jurisdictions—will once again be tasked with the responsibility of collecting data. Federal partners—requiring a national perspective—will once again seek access to these data. Absent a new collaborative framework and data sharing policies, federal agencies seeking access to the needed data will be forced to navigate the governmental bureaucracies of 50 states and hundreds of localities one DUA negotiation at a time. This creates an enormous transactional burden on a public health imperative [19].

Notably, there are substantial efforts to fix these problems. The Coronavirus Aid, Relief, and Economic Security (CARES) Act awarded US $500 million to accelerate data modernization. Part of that funding was intended to upgrade surveillance systems throughout the United States [34,35]. This funding follows the HITECH Act which heavily incentivized public health reporting through the US $35 billion meaningful use program [36]. However, it is here that we must note that these challenges cannot be fixed with new technology or funding alone.

The NSSP is a highly sophisticated public health information system in comparison to other surveillance systems. Nearly all reporting is automated. Reports are transmitted in near real time. Nearly all jurisdictional data are sent to the same data repository.
The data sharing challenges are not technical or practical. The data sharing challenges derive solely from relationships between government agencies and policies. These are the challenges that must be addressed to actualize a modern public health information system benefiting the nation as a whole.

Abstract
We reviewed the tools that have been developed to characterize and communicate seasonal influenza activity in the United States. Here we focus on systematic surveillance and applied analytics, including seasonal burden and disease severity estimation, short-term forecasting, and longer-term modeling efforts. For each set of activities, we describe the challenges and opportunities that have arisen because of the COVID-19 pandemic. In conclusion, we highlight how collaboration and communication have been and will continue to be key components of reliable and actionable influenza monitoring, forecasting, and modeling activities.

disease burden; modeling; seasonal influenza; surveillance

Context
The COVID-19 pandemic disrupted the typical timing, intensity, and duration of influenza virus activity in the United States and many parts of the world [1,2]. These disruptions are likely due in part to the adoption of nonpharmaceutical interventions, such as mask wearing and physical distancing, which were deployed to prevent SARS-CoV-2 transmission and likely also reduced transmission of influenza viruses and other respiratory viruses [1]. Reductions in the use of nonpharmaceutical interventions in the United States during the 2022-2023 influenza season compared to what was observed during the 2020-2021 and 2021-2022 seasons may have contributed to a return of influenza virus activity more comparable to levels observed during some prepandemic seasons, which had annual estimates of 9 million-41 million illnesses, 140,000-710,000 hospitalizations, and 12,000-52,000 deaths between 2010 and 2020 [3]. The interim estimated burden of influenza for the 2022-2023 influenza season indicated that between 27 and 54 million illnesses, 300,000 and 650,000 hospitalizations, and 19,000 and 58,000 deaths occurred that season [4]. The 2022 and ongoing 2023 influenza seasons observed in the Southern Hemisphere winter (approximately May to September) were characterized by the circulation of multiple seasonal influenza viruses (ie, influenza A/H3, A/H1, and B Victoria) [5]; atypical timing patterns, including early and late seasons; or increased intensity compared to recent seasons during the COVID-19 pandemic. However, changes in care-seeking behaviors, testing practices, and general reporting practices due to the pandemic complicate the interpretation of influenza surveillance data.

The experience of the Southern Hemisphere in 2022 and 2023 [5] and the atypically early and rapid start to the 2022-2023
influenza season in the United States [6-8] serve as reminders that seasonal influenza remains a major public health threat. Influenza burden during the 2022-23 season was elevated compared to activity observed in the United States during the first 2 years of the COVID-19 pandemic [4,9], and early and high rates of influenza-associated hospitalizations were observed, particularly in children [7,8,10]. Over the past decade, the Centers for Disease Control and Prevention’s (CDC’s) Influenza Division has worked internally and with external collaborators to develop, validate, and improve forecasting, mathematical modeling, and analytical tools that help translate US influenza surveillance data into action by forecasting short-term influenza activity and characterizing the burden and severity within and across influenza seasons. With the decreased influenza activity observed in the 2020-2021 season, atypical activity and timing in the US 2021-2022 and 2022-2023 seasons, and the Southern Hemisphere’s 2022 and 2023 seasons, continued circulation of SARS-CoV-2, and the return of other respiratory pathogens (eg, respiratory syncytial virus [RSV]) [1,11], we summarize these activities to highlight how these tools can help inform influenza prevention and control efforts during future seasons in the postpandemic respiratory virus landscape.

Data From Surveillance Systems Provide the Foundation for Influenza Situational Awareness and Risk Communication

Multiple surveillance systems provide complementary information to create a comprehensive picture of influenza activity in the United States [6,12]. These information streams are fundamental for situational awareness, risk communication, and subsequent modeling and analysis. Types of surveillance data collated and distributed by the CDC include influenza hospitalizations (hospitalization rates by age, sex, and race or ethnicity, as well as clinical characteristics and outcomes) [9,13]; influenza-related mortality (the National Center for Health Statistics Mortality Surveillance Data and pediatric influenza-associated mortality); virologic (eg, percent positivity, influenza virus type or subtype, and genomic characterization of influenza viruses, which can be used to assess the match of circulating strains to vaccine components); and syndromic outpatient illness [12]. Maintaining these data sources requires coordination within the CDC as well as with international organizations, vital statistics offices, state, and local public health partners in both clinical and laboratory settings, hospitals, and health care providers.

Weekly FluView [6] reports provide systematic data updates and interpretation from the many influenza surveillance systems. These reports, related data updates, and visualizations provide a valuable resource for the CDC, external partners, and the public to understand and interpret influenza activity. Regular and rapid dissemination of surveillance data that is easily accessible and interpretable plays an important role in risk communication and promotion of prevention and mitigation measures, such as vaccination, testing, antiviral use, and nonpharmaceutical interventions.

Given the cocirculation of multiple respiratory viruses with the potential to cause severe illness, interpreting influenza virus data alongside complementary surveillance data for other respiratory viruses provides additional context to the added burden of influenza on the population and the health care system. Symptom-based surveillance for influenza has traditionally been complicated, due in part to overlapping symptomologies. Accordingly, data from the US outpatient Influenza-like Illness Surveillance Network, where outpatient visits are monitored for influenza-like illness defined as fever plus cough or sore throat, can include reports due to infection with cocirculating respiratory pathogens that may be clinically indistinguishable from influenza, including COVID-19 and RSV. In addition, changes in health care–seeking behavior due to the COVID-19 pandemic, both in terms of provider choice and timing relative to illness onset and severity, will be important to consider when assessing surveillance data collected from health care settings. Additionally, the expansion of remote or telehealth options will complicate surveillance, particularly for laboratory-based surveillance. The Influenza Division will continue to leverage the strengths of different surveillance systems to provide a comprehensive understanding of seasonal influenza virus activity. In addition, in order to better understand the burden of influenza in relation to other respiratory viruses like RSV and SARS-CoV-2, the Influenza Division has cosupported the development of multipathogen respiratory virus surveillance networks and developed publicly facing summaries that compare acute respiratory illness emergency department visits for laboratory-confirmed influenza, RSV, and COVID-19 [14] and weekly in-season rates of laboratory-confirmed influenza, COVID-19, and RSV-associated hospitalizations by age, sex, and race or ethnicity [15]. Influenza surveillance and communication efforts will continue to adapt in the uncertain and changing landscape of continued respiratory virus cocirculation.

Estimating Influenza Disease Incidence Using Analytic Methods That Account for the Underdetection of Influenza Provides a More Complete Picture of the Burden and Severity of the Influenza Season

Not all people seek medical care for respiratory illnesses, and not all of those who do will be tested to confirm infection with a specific pathogen. Even when an individual seeks medical care and is tested, this may not occur during the time window of their illness when a collected sample has the potential to test positive (ie, the pathogen or antibodies may no longer be detectable). A variety of viral and bacterial respiratory illnesses are clinically indistinguishable from one another, complicating diagnosis based on symptoms or clinical findings alone. Laboratory testing for specific pathogens can be more or less common in certain care settings, for different age groups, and at differing levels of disease severity. To account for the incomplete detection of influenza virus infection from clinical testing in health care settings, models used to estimate the disease burden incorporate information on health care usage and laboratory testing for respiratory viruses [16]. Each year,
the CDC uses mathematical and statistical models to estimate the broader disease burden from influenza in the US population; since 2018, this has been estimated weekly during the influenza season [17]. In the 2022-2023 season, the first preliminary in-season weekly influenza burden estimates were released in October [4], earlier than any other season due to the atypically high levels of influenza activity observed at that time of year.

The ongoing effects of the COVID-19 pandemic on health care usage and testing for respiratory viruses [18], including influenza, are unclear and will likely continue to evolve over time. Major changes to health care–seeking behaviors, including where patients are seeking care and the use of clinical versus at-home diagnostic testing, could influence trends observed in long-standing surveillance systems, impact ongoing efforts to forecast influenza activity, and introduce new biases into epidemiological and clinical studies that rely on the results of clinical testing. The CDC will continue to make estimates using the best available data, adapt to challenges presented by atypical seasonality, and assess developments in care-seeking behaviors and influenza testing [19]. Communicating in-season and end-of-season burden estimates through the CDC website and FluView reports will help promote public awareness and add to our understanding of influenza burden alongside COVID-19 burden. These ongoing activities will ensure that influenza burden estimation continues to be improved, using the best available statistical methods and data sources.

**Collaborative Forecasting Efforts Hosted by the CDC Use Surveillance Data to Look Ahead and Provide Quantitative Forecasts for Short-Term Trends in Influenza Activity**

Although these traditional surveillance systems and disease burden estimates are comprehensive, they measure influenza activity after it has occurred, which limits their utility to anticipate future trends and inform risk assessment, resource allocation, and health care preparedness. To address these limitations, the CDC has been collaborating with and supporting public health officials and researchers from academia, industry, and the government in open forecasting challenges since the 2013-2014 season [20]. This process has ensured that forecasting targets are relevant to public health, forecast data are openly available and communicated; and the evaluation of forecast performance across different targets, seasons, geographic locations, and methods is transparent [21-23]. This foundation helped lead to the rapid establishment of the COVID-19 forecast hub in early 2020 [24-26].

Building on 10 years of experience and working in collaboration with academic and industry partners, including 2 Centers of Excellence in Influenza Forecasting (the University of Massachusetts and Carnegie Mellon University), the CDC has regularly communicated short-term forecasts at the national, state, and territory level for the 2023-2024 influenza season for the weekly number of patients hospitalized with laboratory-confirmed influenza based on data from the National Healthcare Safety Network (NHSN) hospital admission system (previously known as the US Department of Health & Human Services (HHS) system HHS-Protect) [13,27]. This hospitalization-based forecast target was adopted during the 2021-2022 season when reporting of laboratory-confirmed influenza hospital admissions became mandatory in February 2022 at the state- and hospital facility- level and is different from the forecast target used before the COVID-19 pandemic, which was based on outpatient visits for influenza-like illness [20]. This shift was made because of changes in outpatient care seeking associated with the pandemic, the continued cocirculation of SARS-CoV-2 and RSV, which complicated the interpretation of influenza-like illness data, and the new availability of laboratory-confirmed influenza hospital admission data through NHSN for all 50 states. This centralized source of virus-specific hospitalization data may provide actionable and reliable information moving forward [28,29]. Experience from using the NHSN hospital admission indicator for influenza forecasting during the 2021-2022 and 2022-2023 influenza seasons [30], as well as during other forecasting and modeling efforts during the COVID-19 pandemic, indicates that the NHSN hospital admission data [13], which became available during the COVID-19 pandemic, are a robust source of timely information about the impact of influenza in US hospitals. Reported data include daily state-level counts of total hospitalized patients, previous day’s admissions, and total hospitalized intensive care unit patients each with a laboratory-confirmed influenza virus infection [13]. Insights from past forecasting efforts, including for the COVID-19 pandemic and past influenza seasons, can provide users of forecasts with valuable takeaways for interpreting influenza forecasts with appropriate levels of caution. First, forecasts are less reliable during periods of rapid change (eg, during periods of sharp increases in incidence or when activity is peaking). During these periods, forecasts are often unable to reliably predict changing trends, and interim evaluation of early season forecasts received during the periods of the 2022-2023 season when influenza activity was increasing rapidly or peaking indicated that more reported hospitalizations than expected fell outside of the forecast prediction intervals, indicating a lack of forecast reliability. Improvements in forecasting methodology are needed to ensure that periods of rapid change can be forecasted reliably. Due to the unreliability of forecasts observed in these periods, the Influenza Division did not start public communication of these forecasts until observed performance became more reliable (January 2023). To begin addressing this limitation, the FluSight challenge [27] piloted a set of new forecast targets for probabilities of observing categorical changes in hospital admission trends, such as increases and decreases above certain thresholds, at state, territory, and national levels and will continue the use of these targets in the 2023-2024 season. Second, ensemble models typically outperform individual model forecasts, making them a more robust choice for forecasts with dependable accurate performance [22-24,26]. Finally, forecast performance degrades as they predict farther into the future, as evidenced by the higher performance of 1-week ahead forecasts than 2-, 3-, and 4-week ahead forecasts [22], and the CDC may also pause communication of these longer-horizon forecasts in periods of rapid change. In addition to the challenges associated with rapid increases, atypical
seasonality, and new data sources for forecasting present additional challenges for forecasting influenza during and following the COVID-19 pandemic since many forecasting models rely on historical data to inform predictions of seasonal trends. Ongoing discussions with academic and industry partners that complement collaborations with the Council for State and Territorial Epidemiologists, including the pilot activities mentioned above, will help ensure that forecasting and modeling results are shared, discussed, and interpreted in a timely manner.

Additional Modeling Approaches Are Needed to Increase Our Understanding of the Potential Severity and Timing of the Upcoming Influenza Seasons

Inherent uncertainties in epidemiological conditions and the effects of interventions over longer time horizons require different modeling frameworks than forecasting alone. Therefore, the CDC started collaborating with the Scenario Modeling Hub to use a multiple-model approach to consider potential courses of the 2022-2023 influenza season, including 4 scenarios covering higher and lower rates of vaccine impact and different levels of preexisting immunity [31-33]. The simultaneous consideration of multiple scenarios (sets of assumptions) allows modelers to consider what could happen under a variety of different circumstances. Results from the first round of the influenza Scenario Modeling Hub suggested in September 2022 that hospitalizations in the 2022-2023 influenza season would be higher than in recent seasons [32]. Early in the 2022-2023 season, projections for scenarios with lower population-level immunity demonstrated the plausibility of peak hospitalizations comparable to those of larger prepandemic influenza seasons, while projections for scenarios with higher vaccine effectiveness and coverage were accompanied by substantial reductions in peak size and cumulative burden of hospitalizations due to influenza [32]. Subsequent rounds of the Influenza Scenario Modeling Hub undertaken in November and December 2022 reinforced these findings that projected peak hospitalizations could be comparable to those of larger prepandemic influenza seasons in the most plausible scenarios [32]. As demonstrated by several completed rounds of the COVID-19 Scenario Modeling Hub [34], these longer-term projections provide a useful information source for intervention planning, preparedness, and decision-making [35-38]. By continuing to engage with the Scenario Modeling Hub in weekly meetings, the CDC will be able to provide insight on which questions are of most interest for public health practice and preparedness during the 2023-2024 influenza season to help guide scenario development as well as lend expertise on data sets that may enhance modeling efforts. Results from the Influenza Scenario Modeling Hub may be used to inform potential peak timing and intensity. Additionally, influenza modelers within the CDC will continue to engage with the broader infectious disease modeling community. Information on changing influenza epidemiology and surveillance systems will be regularly communicated across forecasting groups, modeling groups, and data curators. This will be achieved in part through coordinated efforts with partners in the Models of Infectious Disease Agent Study Network [39].

Conclusion

The COVID-19 pandemic has changed many things that could influence trends observed in long-standing influenza surveillance systems. These changes have impacted ongoing efforts to describe influenza disease burden and forecast influenza activity and introduced new biases into epidemiologic and clinical studies that rely on the results of clinical testing. However, the pandemic has also provided opportunities for innovation that could better inform and support influenza efforts moving forward, including novel data sources such as the NHSN hospital admission data set, the ability to compare the impact of multiple respiratory pathogens in different clinical settings, and increased engagement with the public and external partners. Prepandemic approaches used to inform influenza prevention and control efforts, such as surveillance, burden estimation, and modeling, will continue to be reevaluated to ensure their reliability. State-level data may be used in the future to provide more spatially resolved estimates of burden beyond the national burden estimates that are currently provided. The US CDC Influenza Division remains committed to these key data and analytic activities, including the simultaneous monitoring of syndromic influenza surveillance with complimentary data sources, as well as providing a central platform for collaboration and communication across disciplines and institutions to ensure that information to inform influenza prevention, situational awareness, and control remains robust and readily available.

Abstract
The globe is an organically linked whole, and in the pandemic era, COVID-19 has brought heavy public safety threats and economic costs to humanity as almost all countries began to pay more attention to taking steps to minimize the risk of harm to society from sudden-onset diseases. It is worth noting that in some low- and middle-income areas, where the environment for epidemic detection is complex, the causative and comorbid factors are numerous, and where public health resources are scarce. It is often more difficult than in other areas to obtain timely and effective detection and control in the event of widespread virus transmission, which, in turn, is a constant threat to local and global public health security. Pandemics are preventable through effective disease surveillance systems, with nonpharmacological interventions (NPIs) as the mainstay of the control system, effectively controlling the spread of epidemics and preventing larger outbreaks. However, current state-of-the-art NPIs are not applicable in low- and middle-income areas and tend to be decentralized and costly. Based on a 3-year case study of SARS-CoV-2 preventive detection in low-income areas in south-central China, we explored a strategic model for enhancing disease detection efficacy in low- and middle-income areas. This model can improve the local epidemic detection efficiency, ensure the health care needs of more people, reduce the public health costs in low- and middle-income areas in a coordinated manner, and ensure and strengthen local public health security sustainably.

KEYWORDS
low- and middle-income country; LMIC; pandemic; epidemiological surveillance; universal public health; nonpharmacological interventions; public health; callable model; efficacy; COVID-19; public safety threats; effectiveness; China; detection; epidemic

Introduction
Globally, advances in epidemiological, behavioral, and pharmacological interventions have led to a decline in the incidence of sudden public health events. However, in some low- and middle-income countries (LMICs), large-scale outbreaks of various communicable or noncommunicable diseases have not been proportionately contained, and the burden on public health continues to rise [1].

Current interventions for epidemiological prevention are suboptimal and tend to be high-cost and decentralized. A typical recent manifestation of this is the fact that in the worldwide discussion of how to win the COVID-19 war, the rush to action has varied greatly from country to country, and even within
countries. The US government advises against parties of more than 10 people, but San Francisco, California, has ordered everyone to stay home. Italy, France, and Spain have sealed off their populations almost completely, with police or military patrolling the streets in some places. Even as major cutting-edge magazines continue to report on the health threat of COVID-19, pubs remain open in Britain, Germany’s schools close, and Sweden’s schools remain open to young children. The patchwork reflects the different stages of the epidemic, as well as differences in resources, cultures, governments, and laws [2]. However, there has long been controversy about what works best, and how to balance the necessary with the reasonable, which some of the strategies adopted by these countries are missing elsewhere: widespread testing to detect cases, mass tracking of their contacts to test or quarantine them, and encouraging or forcing infected people to quarantine themselves. It is discrete and not cost-effective. Conversely, there is a large gradient in the timing of the blockades as income statuses change, with LMICs initiating disincentives earlier than ultra–high-income or high-income countries [3]. In the case of India, one of the first countries to observe the health impacts of neocorona viruses and to adopt a containment strategy, the establishment of a comprehensive blockade strategy of varying degrees of severity was declared in 2020, but in April 2021, the second wave of the COVID-19 pandemic in the country inexorably shifted from the west and north to the east and south [4]. A study investigating the scale of the infection showed an increase in seroprevalence in India from just over 20% in January 2021 to 67% in June-July 2021 [5]. Initially, local scientists attributed the increase to a variant of the virus, but after several months of comparative studies, it was found that the variant was not more transmissible [6]. Although Indian public health researchers have stressed the need for continued vigilance and standardized genomic surveillance, there are no restrictions on major events in key states, especially elections or religious gatherings, where returnee positivity rates are very high. This has upset the balance of prevention systems in different states and cities, and the interaction of old and new problems has created huge economic gaps in the health systems of different regions. The concomitant shortage of resources due to drug abuse and declining drug resistance, as well as more cases of multiple comorbidities, seems to be a common problem in many low- and middle-income areas [7]. Another issue of concern is vaccination. Most countries use electronic registries, and despite the principle of harmonization, vaccination during pandemics has long been limited by availability. Moreover, unlike the excellent tracking of vaccination in high-income regions, there has been a major gap in the ability of low- and middle-income regions to estimate the magnitude of morbidity and mortality during pandemics accurately. Past mortality analyses suggest that socioeconomic deprivation during pandemics leads to more excess deaths [8], and this is only a preliminary assessment from regions with stronger health and data systems; some transitional regions or poorly informationalized tribes may be worse off than realistically predicted. The pandemic in India and the current state of vaccine distribution worldwide point the way to the future of pandemic prevention in LMICs—early signal detection, systematic identification and analysis of health systems and their supply chain preparedness, and protection of the ability to deal with not only emergencies but also other disease-care services, as well as the ability to collect, collate, integrate, analyze, and interpret in real time. The ability for data to be recycled so that resources can be appropriately allocated when needed and health systems can better aid in understanding the causes of both poor and favorable outcomes. In 2022, A research survey further reiterated that epidemiological surveillance tends to prioritize urban and adjacent rural communities, but it simply does not reach low-income or remote rural areas [9]. To address the current gaps in pre-epidemic surveillance and prevention, Mobarak et al [10] suggest creating a relatively complete and locally relevant general detection system, including individual and population-wide engagement strategies, in areas where the basic public health system lags relatively behind that of other higher-income areas, which would address some of the cost commonalities and resolve some social conflicts.

Nonpharmacological interventions (NPIs), as the most important part of the current epidemiological prevention and control system, are aimed at raising awareness of risk reduction activities at the individual level (eg, proactive wearing of face masks and promotion of social distancing, among others) and the group level through a range of public health strategies, as well as common actions assumed in response to public health outbreaks (eg, group testing and quarantine, among others). This decelerates the spread of disease and prevents larger outbreaks to ensure that hospitalization and mortality rates are manageable [11].

In fact, before the SARS-CoV-2 outbreak, many countries had made steady progress toward achieving Sustainable Development Goal target 3.4 (reducing premature mortality from noncontagious diseases by one-third between 2015 and 2030) [12]. Of note, influenza pandemics impede these successes, disrupt health systems, divert resources, and draw attention away from them. Therefore, an important fact about COVID-19 is that anticipating and being alert to viral risks in advance and building a strong public health system with supervision, detection, and timely responses is essential and will greatly benefit the rational allocation of resources to the district health system and provide it with a path for the future. However, in designing and operating a surveillance intervention system, consideration needs to be given to the interrelated structural factors that support or impede preventive actions and behaviors of individuals or groups. These structural factors can be variable or inherent to social patterns, such as socioeconomic and cultural conditions, political will (eg, cooperation, commitment, and funding), governmental priorities or policies, and conditions related to environmental factors (eg, reducing industrial pollution). Addressing these structural factors can improve the preventive effectiveness of public health and protect the health interests of more people, thereby achieving sustainable economic and health benefits [13].
**The Significance of Structured Disease Detection Systems in Low- and Middle-Income Areas**

About half of the people in LMICs live in rural or remote areas [14]. Livestock raised in remote rural areas accounts for about 25% of the agricultural gross domestic product of LMICs and supports the livelihoods of more than 600 million smallholder farmers [15]. Complex environmental pathogenicity and high prevalence of zoonotic factors are a major problem for not only local but also global public health. In fact, previous pandemics have fueled a revolution in global disease prevention, including one in LMICs. It is emerging as a global consensus that vaccinating populations in remote areas will lead to a reduction in the risk of new viral mutations worldwide [16]. In many countries, domestic distribution capacity can be established quickly, affordably, and cost-effectively. LMICs have accumulated extensive experience with mass immunization campaigns, which have resulted in high levels of vaccine coverage for children and older adults [17]. Several countries, including Ghana, Liberia, India, Pakistan, and Sierra Leone, have begun experimenting with the concept of “mobile vaccination teams,” which bring batches of vaccines to the places where people live to make vaccinations more accessible [18,19]. These can involve nurses, supported by community mobilizers, visiting remote villages with vaccines to raise the attention of local residents and leaders, and calling for effective vaccination. This model has also been used successfully in the past: the “outreach clinics” in the Gambia, which provide immunization services to difficult-to-reach subpopulations (eg, homeless individuals, stigmatized groups, and migrant groups, among others), are considered an important factor in the elimination of measles [20]. This is mutually beneficial to the systematic monitoring scalable model we proposed. An efficient disease detection system can provide precise regional control and tools for local public health management, more effectively decelerate the spread of diseases in complex pathogenic environments, alleviate social conflicts in NPIs, enhance the vitality of public health, and provide a more precise guarantee of public health security and economic development in low- and middle-income areas. However, policy decisions are usually time- and resource-intensive and require a multidisciplinary team to implement. While policy support mechanisms tend to be effective in high-income countries, they are often inadequately monitored in many LMICs. Inadequate monitoring is largely due to budgetary constraints, which limit the ability to plan and coordinate. The use of affordable digital technologies can facilitate real-time monitoring and feedback from individuals, service providers, and policy makers. On the other hand, the theory of “synergy” has always played an important role in social science research and is often combined with governance theory by management scholars to create a more effective theory of “collaborative governance.” Thus, to address structural and other barriers to disease prevention and control, there is a need for a timely and more flexible, public, and dynamic system in place, which emphasizes the use of the total of the many ways in which individuals and various public or private institutions manage their commonalities [21], and which promotes public policy support mechanisms to guide policy decision-making in disease prevention.

**What Should We Do to Achieve Efficient Detection?**

**Overview**

As we discussed earlier, there has long been controversy about what works best and how to balance necessity with rationality. A complex pathogenic environment remains, but the past history of overscaled, short-lived surge operations has been unsystematic and wasteful. It brings not only lower-middle-income areas economic disasters during the pandemic but also the same or even greater vulnerability of local public health systems to a new round of public health challenges. So, we have transferred and quantified the traditional thinking on disease prevention and control to develop a disease prevention–sharing model with the government as the protagonist and the participation of the population, the health care system, and the private sector, and we have provided a service architecture diagram about epidemiological surveillance in low- and middle-income areas (Figure 1). Adopting the 4 dimensions of human, financial, material, and labor as the object of assessment and apportionment, this or the next public health detection event comprises 6 recyclable phases, including preparation, assessment, action, tracking, reassessment, and improvement, as well as an additional phase, with the first 6 phases operating in a closed loop. The efficacy assessment of each of these stages is based on our analysis of epidemiological data from selected low- and middle-income areas of south-central China, a comprehensive and targeted intervention design that is effective in the management of infectious disease illnesses such as pneumococcal pneumonia. Furthermore, this approach also can be considered for the management of noncommunicable or other epidemics such as zoonotic diseases.
Phase 1: Every Part Is Ready

The primary aspect of improving disease detection efficacy in low- and middle-income areas is to strengthen the response mechanisms of various stakeholders and build a bundle with efficient linkages. Throughout the COVID-19 pandemic, everyone has been able to be a transmitter and everyone has been able to be a defender. In the face of the public enemy of humanity, all controversies and prejudices were temporarily set aside [22]. We have divided all participants into 4 categories: the first is the government or local governing body, the second is the public, the third is the medical organizations, and the fourth is the private organizations. Generally speaking, the connection between regional governments and regional medical institutions is very close, and most public health organizations always respond to the first call of regional governments to solve public health matters; private institutions also bear certain social responsibilities. Simultaneously, in their daily health business dealings, they cooperate with public medical units to lay a large stage of the contact mechanism as the preparation stage of the second response echelon. The response of the population is the slowest and most important presence in the whole detection system. The development of new media communication has greatly saved the time and material costs of health information dissemination, but given that a large portion of the population lives in remote rural areas, there is still a gap in the ability of...
these populations to perceive the message due to the variability of communication networks. To solve such problems, the Chinese government has set up small government-like management teams in each village, which are elected by the residents themselves. They tend to have higher education levels and political literacy, and a high degree of familiarity with the environment in which they are located, and the residents’ authority over them is even higher than that of other expatriates, so they can be more accurate and effective in delivering information and preventing risks in their localities. In addition, and more importantly, it is often much less costly to train them than it is to reach the general population. We may wish to use such a mechanism to achieve a more efficient detection and cost-saving pathway, combined with the effectiveness of new media communications to form a third echelon of the crowd response during the preparedness phase.

Thus, we can have a more linear public health emergency response pathway, and when the government issues instructions for the preparedness phase, the first and second response echelons can have a clearer preparation plan for material preparation and personnel control according to the different levels of demand of the third response echelon, which provides an introductory for later detection effectiveness tracking and cost analysis.

**Phase 2: Load Balancing of All Available Resources**

Recommendations have been offered for nongovernmental organizations, governments, donors, and future research including studying the organizational effectiveness and sustainability of these partnerships to deliver effective and efficient health outcomes to recommend universal best practices in health care [23]. In disease detection systems in low- and middle-income areas, the usage and translational benefits of limited public health resources have a direct impact on the continuation of detection efforts. Load balancing is a quantitative assessment and optimization of resource interchange based on all available human, financial, material, and physical resources that the local area has. The 3-level response echelon should combine the actual local public health resources with the epidemic burden, analyze the public health cost of safeguarding the most realistic population’s basic health care needs at the emergent stage, and then perform resource interchange. Specifically, we start from 4 dimensions, including human, financial, material, and productivity dimensions, based on off-epidemic control, and the load capacity of each dimension in different regions needs to be precise to unit order of magnitude. For example, the number of people served by medical centers at all levels, the number of local funds invested in public health, the maximum number of testing reagents that can be provided, the maximum number of patients that can be admitted locally, etc, to complement each other’s strengths, visually help make up for the public health shortcomings of different regions in terms of funds or talents, optimize short-term benefits, and continuously mobilize other potential resources to maintain a more regular and sustainable development strategy.

In the previous phase of preparation, we emphasized the importance of response mechanisms, where the participation of all stakeholders enhances the carrying capacity of regional pre–disease detection efforts. The quantification of load balancing can effectively stimulate the participation of stakeholders to meet the simplest health rights needs of the widest local population in the pandemic era. On the one hand, it is an effective way to stimulate the work capacity of government and other health personnel, and on the other hand, it is a way to give direction and assistance to other stakeholders who are willing to take more social responsibility, thus maximizing the potential local public health capacity. The government as the core of the work can establish a public mechanism after quantifying the load capacity, and a joint class of government personnel and media to disclose the progress and cost budget of disease detection and prevention and control work at each stage to the population so that the transformation among human, financial, material, and productivity can have more flexible possibilities due to the participation of more aspects.

**Phase 3: Detecting General Differences in Actions May Be the Key to Cost Savings**

The collaboration of stakeholders who have gone through the first 2 phases provides a clear framework and a more convenient environment for our next testing initiatives. We also need to take into account the general differences in population and environment when conducting disease detection in low- and middle-income areas. On the one hand, most people in low- and middle-income areas live in rural or remote areas and depend on the agricultural economy for their livelihoods, with low external mobility and relatively high levels of self-sufficiency. It is worth noting that these groups tend to have far more frequent contact with the natural environment (the novel coronavirus was originally identified as being carried by bats [24]). On the other hand, the degree of aging has always been at a high level in the rural population, so even though in the first phase of our preparation of the links to improve the attitude of the population, especially among older groups to cooperate and respond to the current disease, most of them are only motivated by the importance of their health care, while other disease-causing factors around them, such as food, domestic animals, work environment, etc, have a lower deficit of prevention awareness. General differences in population characteristics and the complexity of disease environments that are difficult to monitor have been important reasons underlying the difficulty of timely and effective control of outbreaks in low- and middle-income areas, and even higher disease mortality rates. Such a situation requires us to prioritize environmental and “special population” factors in the detection system, and governments, public health organizations, and other private institutions need to adopt a more appropriate multifaceted cooperation mechanism to achieve population and environmental biases of resources, effectively and precisely cut off the transmission of diseases, protect special populations, and thus save long-term testing costs.

Based on this, to achieve the efficiency and sustainability of the testing initiative, we suggest that the government could take the lead in responding to the third-tier government-like personnel and public health organizations in cooperation with private institutions to establish a special disease testing service site in each tribe of the low- and middle-income areas by
measuring the geographic population and demand differences. The site could be staffed by local government workers with village doctors, and the testing laboratory and testing reagents and other equipment could be outsourced by a third-party organization. Adhering to the purpose of prioritizing the health testing needs of special populations and maintaining the living environment, we can choose to prioritize the training of these government workers and village doctors on disease prevention knowledge about collecting the disease testing needs of local special populations and the environmental risks of suspected transmission routes that need to be urgently cut off, so that when risk factors are found in the NPI work process, they can be fed back promptly to the service station. The medical staff of the service station can then directly implement testing and intervention, thus changing the local passive testing prevention system.

**Phase 4: All Traces of Traced**

The main reason why, in the previous phase, each task needs to be divided so carefully is to achieve full pathway effectiveness tracking in this phase, thus reducing internal suspicion to a greater extent and achieving a relatively stable phase cycle. In low- and middle-income areas, a series of problems such as unprofessional medical personnel, unclear division of functions between government and other agencies, and simplistic and one-size-fits-all disease prevention processes have been running through the whole stage of disease outbreaks or suboutbreaks. This is resulting in the emergence and spread of sudden epidemics in low- and middle-income areas, once they are prone to difficult preventive measures and slow effectiveness of control means, and such recurrence has led many low- and middle-income regional governments to find it difficult to cope with the cost overlap, and this even causes them to choose to adopt the sluggish strategy of abandoning detection and relaxing preventive control.

**Phase 5: Another Small Revolution in Costs**

At this stage, we have a general framework for disease detection, and some cost-trimming is required. The government, as the main body of action, needs to, on the one hand, give new load ratios based on the standard costs, actual costs, and sunk costs of the testing process as fed back by the hospitals in conjunction with the initial assessment, and then develop appropriate financial subsidy policies and epidemic prevention regulations to adjust the targets and outcome outputs of the testing work of medical institutions. On the other hand, it is necessary to promptly assess the cost-effectiveness of the testing services provided by third-party institutions throughout the testing service phase and determine the effect of social responsibility, to delineate new testing service intervals.

**Phase 6: Time to Make Some Changes**

The first 5 phases provide the basis for creating meaningful improvements in the improvement phase. During the outbreak period, we have had the experience of the first round, the population detection strategy that can be adjusted to areas with high susceptibility or population mobility. With limited detectors, a deployment system that can be adapted to assign additional personnel to besiege high-incidence areas, the ability to abate the detection force of the extensive population, and prevent and control with precision, the government can redivide the areas and classify them to guide the medical institutions’ service bias. The work of environmental testing can also be based on the susceptibility of different objects to emphasize the transformation of responsibilities between third-party testing agencies and public health agencies, targeting biological testing with a higher effectiveness bias than nonbiological testing to prevent the emergence of new forms of transmission such as zoonotic diseases that cause more serious economic losses. In the small outbreak period or stabilization period, all aspects of the detection force need to return to the 3 stages of tracking link posts, narrowing the envelope, strengthening the regularity of detection laws, reducing the frequency, shrinking the detection object at the same time, according to the cost criteria assessed, gradually narrowing the envelope of disease detection, increasing the service station of other disease surveillance functions. Thus, the cost of testing is continuously reduced and economic pressure is released.

**An Additional Common Claim for Enhanced Disease Detection in Low- and Middle-Income Areas**

Maintaining a strong database on disease surveillance and building a professional public health team to safeguard the health rights of a broader population and preserve an otherwise fragile economic environment has been a rather genuine need in low- and middle-income areas [25]. This will require a long-term joint effort by several committed and highly professional scholars in epidemiology, accounting, social sciences, and other related fields, together with low- and middle-income areas [26]. Despite the methodical efforts of disease detection and prevention in low- and middle-income areas, they are still passively waiting and receiving policy guidelines or emulation from higher levels. Much of the collection, organization, storage, and analysis of self-reported data is based on templates from other developed regions, and the cost of the vicious cycle of such a model can be devastating to some LMICs [27].

**Conclusions**

Here we describe an integrated and comprehensive approach that covers structural, social, and personal strategies to optimize the epidemic surveillance system in low- and middle-income areas. This model can improve the local epidemic detection efficiency, ensure the health care needs of more people, reduce the public health costs in low- and middle-income areas in a coordinated manner, and ensure and strengthen local public health security sustainably. Although there are certain differences in the policies and environment of disease detection in each region, our framework is more intuitive and easier to understand. We hope to provide clear behavior paths and tracking paths for managers, public health workers, and participants in other collaborative events in low- and middle-income areas, and improve the possibility of all measures that can maintain local public health security.

Abstract
Geospatial data reporting from surveillance and immunization efforts is a key aspect of the World Health Organization (WHO) Global Polio Eradication Initiative in Africa. These activities are coordinated through the WHO Regional Office for Africa Geographic Information Systems Centre. To ensure the accuracy of field-collected data, the WHO Regional Office for Africa Geographic Information Systems Centre has developed mobile phone apps such as electronic surveillance (eSURV) and integrated supportive supervision (ISS) geospatial data collection programs. While eSURV and ISS have played a vital role in efforts to eradicate polio and control other communicable diseases in Africa, disease surveillance efforts have been hampered by incomplete and inaccurate listings of health care sites throughout the continent. To address this shortcoming, data compiled from eSURV and ISS are being used to develop, update, and validate a Health Facility master list for the WHO African region that contains comprehensive listings of the names, locations, and types of health facilities in each member state. The WHO and Ministry of Health field officers are responsible for documenting and transmitting the relevant geospatial location information regarding health facilities and traditional medicine sites using the eSURV and ISS form; this information is then used to update the Health Facility master list and is also made available to national ministries of health to update their respective health facility lists. This consolidation of health facility information into a single registry is expected to improve disease surveillance and facilitate epidemiologic research for the Global Polio Eradication Initiative, as well as aid public health efforts directed at other diseases across the African continent. This review examines active surveillance using eSURV at the district, country, and regional levels, highlighting its role in supporting polio surveillance and immunization efforts, as well as its potential to serve as a fundamental basis for broader public health initiatives and research throughout Africa.

Introduction
After a decades-long, global effort, wild-type polioviruses (WPV) 2 and 3—the cause of poliomyelitis (polio)—were eliminated worldwide in 2015 and 2019, respectively [1]. However, WPV1 remains endemic in Afghanistan and Pakistan, where mountainous terrain, armed conflict, and societal and political factors have impeded polio immunization and surveillance [1,2]. More than 95% of polio cases are asymptomatic or associated with only mild, cold-like symptoms.
Mature, however, ~1 in 200 infected individuals develop acute flaccid paralysis (AFP) and paralytic polio, which have case fatality rates of 2% to 5% among children and up to 15% to 30% among adolescents and adults [3,4].

Infected persons, including asymptomatic individuals, may shed the polio virus in nasopharyngeal secretions or stool for several days to weeks, increasing the risk of transmission of this incurable and potentially fatal disease [3]. A Pakistani lineage of WPV1 was recently found in Mozambique and Malawi, demonstrating that polio risk extends far beyond the communities where it is endemic [5]. In addition, circulating vaccine-derived poliovirus (cVDPV) may emerge in populations with low immunization rates due to the genetic instability of the live-attenuated viruses included in the oral polio vaccine [6,7]. These mutated, neurovirulent strains produce paralysis much like WPV-associated polio [7]. They also account for the vast majority of polio cases [8].

To stop the spread of polio, the World Health Organization (WHO) Global Polio Eradication Initiative (GPEI) advocates intensive efforts to identify AFP cases in children aged <15 years (ie, disease surveillance)—both routine immunization (coverage >95%) and immunization campaigns to boost vaccination coverage to >95% and enhance herd immunity—to eliminate the potential for cVDPV transmission, and the deployment of novel type 2 oral polio vaccine, which reduces transmission of cVDPV2, the most common cause of polio [2,9,10]. The complementary strategies of surveillance and immunization led to the African continent being declared indigenous WPV-free in 2020, and since GPEI efforts began in 1988, nearly 1 million polio deaths were averted [11,12]. However, disruptions in GPEI activities during the COVID-19 pandemic contributed to a resurgence in African polio cases [2]. Since 2020, >1000 polio cases have been documented, including >600 reported in Africa in 2022, which highlights the urgent and ongoing need for intensive disease surveillance and immunization to prevent the further spread of polio [8,12-14].

Geospatial data reporting from surveillance and immunization efforts is a key aspect of WHO GPEI polio-eradication efforts in Africa, which are coordinated through the WHO Regional Office for Africa (AFRO) Geographic Information Systems (GIS) Centre. To ensure the accuracy of field-collected data, the AFRO GIS Centre has developed mobile phone apps such as electronic surveillance (eSURV) and integrated supportive supervision (ISS) geospatial data collection programs. These forms, apart from reporting on unreported AFP cases, are currently being used to create a consolidated Health Facility Masterlist for the WHO AFRO, which is a repository database containing validated baseline data for all health facilities in the African region. The Health Facility Masterlist contains comprehensive listings of the names, locations, and types of health facilities in each WHO AFRO member state. Field officers are responsible for documenting and transmitting geospatial location information regarding health facilities and traditional medicine (TM) sites using the eSURV form during their visits to active surveillance sites. The functionality of these facilities, as described in the Health Facility Masterlist, goes beyond mere listing. It involves the integration of health facility data and traditional health sites to enhance disease surveillance capabilities, particularly for polio. The Masterlist is intended to serve as a dynamic resource for health workers, enabling better planning and targeting of health interventions, improving response times to disease outbreaks, and facilitating more effective deployment of resources. The consolidated Masterlist should support at the operational level health strategies and interventions by ensuring surveillance is done properly at health facilities, and by providing a comprehensive, accessible, and up-to-date database of health facilities across the WHO African region. This review delves into the use of current and comprehensive health facility lists at the district, country, and regional levels, highlighting their role in supporting polio surveillance and immunization efforts, as well as their potential to serve as a fundamental basis for broader public health initiatives and research endeavors across Africa.

**Master Facility List Program in Africa**

A master facility list (MFL) is a complete, up-to-date, authoritative listing of health care facilities in any given country. Each MFL includes the information needed to accurately identify each facility, including the name, unique identifier, location, facility type, ownership, operational status, contact information for key personnel, types of services offered, and number of beds. The MFL should be validated, continuously updated, and accessible to all authorized stakeholders [15].

To date, MFLs have been updated manually. This process typically involves the country team sharing new facility information as it becomes available or through the use of the “Other” option. When a facility is not found in the existing list and is subsequently added as an “Other” option, it necessitates a manual update of the list. The upcoming version of eSURV should, however, bring significant improvements. It will incorporate a health facility registry, which will streamline the process of adding new facilities and updating existing facility forms.

Several countries have successfully compiled and made their MFLs available online, marking significant progress in health care information accessibility over the past 5 years. Notable examples include Zambia [16], Botswana [17], and Kenya [18]. There are also broader initiatives such as the WHO AFRO Integrated African Health Observatory MFL database and the Geolocated Health Facilities Data Initiative, aimed at enhancing health care planning and delivery with a more comprehensive MFL.

Despite these advancements, challenges remain in ensuring the continuous updating and maintenance of these lists. While eSURV visits are conducted regularly at health facilities—including traditional sites such as those of traditional practitioners—to verify and augment existing MFLs with new or missing facilities, the objective of sustaining up-to-date MFLs relies heavily on the diligent efforts of field officers conducting active surveillance. This ongoing process is crucial for maintaining the accuracy and utility of MFLs over time.
MFL Resource Package and Training

Before the availability of electronic databases, African MFLs were beset by challenges common to all paper-based data management systems, including out-of-date information, omissions, inconsistencies, and inaccuracies [19]. In addition, updating or correcting paper-based files and sharing the information with stakeholders such as other government ministries, public health agencies, and charitable organizations could be slow and resource-intensive. To address these shortcomings, the WHO and the United States Agency for International Development developed a set of guidelines for the implementation of a software-based facility registry service that makes the MFL accessible to stakeholders such as insurance companies; charitable groups undertaking health interventions; researchers assessing health system performance; and personnel involved in health management information systems, disease surveillance, and supply chain management [15,20]. A training program was also developed to help country teams establish or improve their MFLs. The target audience for this program includes ministry officials, facility list managers, data curators, national and regional health ministry personnel, and staff from nongovernmental organizations. Participants are trained in the purpose and contents of an MFL, MFL assessment, governance, data content, incorporation of geographic coordinates, establishment of the data set and registry service, ongoing maintenance, and sharing of the MFL, with a final session devoted to crafting an action plan for MFL creation and implementation.

TM Sites in MFLs

An important component of modern MFL development is the inclusion of TM sites in the database. Traditional healers serve as first-line health care providers for most of the population in Africa, where there is only 1 medical physician for every 40,000 people, compared with a 1:500 ratio of traditional healers to African residents [21-23]. Although some TM practices are associated with misdiagnoses leading to missed cases and ineffective treatment, traditional healers can have a strong, positive impact on the health and wellness of the people they serve when their products and practice are properly regulated and integrated into health systems [22]. These practitioners are also an important resource for disease surveillance and immunization efforts and may be trained to conduct community disease surveillance in areas where there is a shortage of medical facilities and formally trained health care providers.

eSURV and ISS in Practice

About eSURV

eSURV was developed by the WHO AFRO GIS Centre as an electronic health solution to enable surveillance agents to use mobile phones to document active case searches for polio and other infectious disease cases in health facilities and the community. The app comprises an electronic form based on a checklist that records the geographic location of health facilities visited by data collectors based on the global positioning system software on the user’s phone. The tool is used in 46 WHO AFRO member states, where case search activity is automatically recorded on country-specific modules on the GIS servers. The accumulated data are used to identify outbreaks of not only polio, but also other priority diseases such as COVID-19 [24,25]. As a result of data being continuously transmitted to GIS servers in near real time, areas with little or no surveillance activity can be promptly identified and corrective actions can be taken.

About ISS

Supportive supervision fosters high-quality disease surveillance and immunization best practices through systematic visits to priority sites (health facilities and surveillance sites, including TM practitioner sites) by supervisory WHO and national health ministry personnel, where they conduct monitoring, evaluation, and on-the-job training of health workers. To document these activities, the supervisors use ISS, a mobile phone app consisting of an integrated electronic checklist used for the supervision of active AFP case finding and routine polio immunization [24]. Approximately 40% of checklist questions focus on case surveillance for AFP and other vaccine-preventable diseases, whereas the other 60% assess routine immunization practices. Through ISS, supervisors promote understanding and recognition of AFP among frontline workers and help them keep immunization records up to date [26]. In addition, ISS facilitates the detection of previously missed AFP cases (Figure 1 and Table 1).

To ensure uniformity and standardization, the ISS tool includes 4 question categories the supervisor can ask frontline workers. The ISS checklist includes questions about both AFP cases and polio vaccinations. The app also includes the eSURV checklist, consisting of questions only about active AFP cases. A third category covers only routine polio immunizations and a fourth focuses on COVID-19 case surveillance (Figure 2 and Table 2).

**Frequency of eSURV and ISS Visits to Health Facilities**

The WHO recommends regular surveillance and supervisory visits to health facilities, with the frequency of visits being dependent on the priority level of the site (Table 3). The guidance suggests weekly visits to high-priority sites, including 3 eSURV and 1 ISS visit/mo, a visit every 2 weeks (1 eSURV and 1 ISS visit/mo) to medium-priority sites, and 1 ISS visit/mo to low-priority sites.

In the past, the numbers of actual eSURV and ISS visits have been reported to be lower than recommended, even in countries where ISS visits are required for regional certification [26]. Adherence to visit frequency recommendations appears, however, to be improving. Between 2020 and 2021, active eSURV visits increased by ~25,000, which permitted the identification of ~4000 missed AFP cases (Figure 3).

**Geospatial Data Entry**

When a field officer visits a health facility, the geolocation data are automatically transmitted to that country’s eSURV and ISS database. Field-collected data are synchronized on the server, and the dashboard is viewable by WHO and country health ministry personnel.

One of the challenges is that a single site may have multiple names in the database, resulting in site identification mismatches or multiple sites recorded for the same geolocation (Figure 4). To address this problem, eSURV includes data entry constraints, with a dropdown menu of the country’s MFL from the health observatory facility list or, directly, an inventory of the health facility list from the country team, which helps prevent data entry and server synchronization errors [19]. To allow for the entry of previously unrecorded sites or those missing from the list, the program includes an “Other” option, whereby data collectors can enter new data.
**Contribution of eSURV and ISS to Polio Eradication Efforts**

The eSURV and ISS apps provide real-time georeferenced surveillance and immunization data that can be accessed by polio program staff and used to audit data and evaluate data collector performance and accountability. In the past, paper-based systems were found to be not only slow, but also susceptible to data fabrication and omissions [19]. In contrast, real-time data transmission with mobile phone apps increases surveillance sensitivity and transparent data management increases WHO GPEI confidence in program results. The Open Data Kit (ODK) app currently faces some compatibility issues with iOS users. A few mechanisms have, however, been implemented to facilitate access for iPhone users. An example of this is the introduction of GIC Collect, which is compatible with iOS, thereby addressing some of these constraints. GIC Collect works as a port for the ODK for use with an iPhone.

The data provided through eSURV and ISS contributed to the attainment of WPV-free certification for the WHO African region [24]. For example, these tools were essential in AFP surveillance and immunization of >40,000 children of nomads living in 62 high-risk districts in and around the remote Lake Chad region (Figure 5) [25]. The eSURV and ISS data facilitated the identification and location of at-risk groups, who continue to be monitored for AFP cases [27].

Multiple studies have documented improvements in African polio public health interventions after the implementation of eSURV and ISS [19,26,28-32]. A preliminary analysis of the transition from a paper-based system to eSURV showed that the average case-reporting time in Africa decreased by 90% from a mean of 87.6 to 8.7 hours [32]. The time from case identification to entry into a polio case tracking database was reduced by 72% from a mean of 30 to 8 days. Another analysis by the same author group showed that the completeness of data collected via eSURV and ISS was >95% across 5 countries in sub-Saharan Africa, with error rates that ranged from 0.01% to 0.03%. The authors attributed the low error and high completion rates to inherent aspects of the software, including data entry constraints, skip logic, and enforced validation, as well as real-time data sharing. The latter enabled supervision and monitoring of the flow of data that permitted supervisors to detect data fabrication and omissions, which have been documented with paper-based systems [19].

In another study, the implementation of ISS in Zambia improved the updating of immunization records in 7 of 9 provinces studied, with up to a 53% increase in the proportion of health facilities with updated immunization records [26]. In addition, ISS had a statistically significant, positive impact on knowledge of AFP case definition and documentation of AFP case files.
Development of a Consolidated Health Facility Masterlist—Integration of eSURV and ISS With MFLs

Despite improvements in the frequency and accuracy of data collection with eSURV and ISS, several challenges have been identified. First, the total number of health facilities and TM sites in Africa has not been fully documented. The lack of a denominator of known sites limits the ministry of health and WHO personnel’s ability to assess the completeness of surveillance coverage. In addition, the lack of a validation mechanism for the reference list of health facilities has the potential to contribute to database errors. To address these gaps, the consolidated Health Facility Masterlist was developed and is managed by the WHO AFRO GIS Centre in close cooperation with the respective health ministries of each member state.

The Health Facility Masterlist uses existing MFLs provided by each country as references, which are compared with health facility lists compiled from eSURV and ISS data. In a structured process that is still ongoing, WHO AFRO surveillance and GIS personnel cross-reference eSURV and ISS lists from each country against that country’s MFL and consolidate the information for health facilities (including TM sites) with ≥95% similarity. Facilities with <95% similarity are returned to each country, where a designated focal person validates the site information using a health facility validation checklist web app that was developed for Masterlist consolidation and validation. The validated facility uses a standard operating procedure, developed at the operational level by the AFRO GIS Centre and validated by the country surveillance and data management team, to agree on the nomenclatures of a health facility name and health facility type as they differ from one country to another. Validated facilities are then added to the consolidated Health Facility registry form as updates. As data collectors discover and record new facilities (e.g., previously unrecognized TM sites) using the Site Registry form, the in-country focal person validates the facilities using the MFL validation checklist. After verification by the in-country teams (ministry of health and WHO), the new facilities are added to the consolidated health facility registry. The AFRO GIS Centre, in collaboration with the surveillance team at the country level, conducts updates on a priority level twice yearly. The Masterlist includes the following variables: site name, location based on administrative boundary, geocoordinates, priority level, type of site, level of care, operating status, vaccination status, ownership, and auto-generated unique identifier.

Once the consolidated Health Facility Masterlist is complete, the data can be used by the WHO AFRO to more accurately evaluate the completeness of surveillance and immunization efforts, as well as assess the performance of health facilities (Figure 6).

The Health Facility Masterlist is specifically designed for use at the operational level. Any digital surveillance or data collection activities carried out at the health facility level can make use of the health facility registry as a valuable resource. The primary objective is to continually update and enhance the registry, aiming to benefit all countries in the WHO African region. Additionally, the registry will be maintained as a web service, enabling automated integration with various forms such as eSURV, vaccine management, and other ODK forms that are administered at the health facility level, facilitating a comprehensive and streamlined approach. The primary
limitation of the use of the Health Facility Masterlist lies in elucidating the core method for updating the health facility process after consolidation. At present, the AFRO GIS Centre is working on a well-defined system commonly called the “eSURV Companion App” for maintaining, consolidating, and validating health facility data with eSURV. This issue will necessitate further examination in subsequent research related to this paper.

To prevent stagnation in consolidating the Health Facility Masterlist, the primary strategy is to uphold a robust active surveillance system through the use of eSURV, which is currently used by 46 countries in the WHO African region for reporting active surveillance visits. The exclusion of even one country, however, remains a significant hurdle in achieving full consolidation. Furthermore, a key recommendation is to encourage the adoption of the latest eSURV Companion App by 2024, ensuring comprehensive maintenance of the consolidated Health Facility Masterlist over time.

**Conclusions**

The eSURV and ISS mobile health solutions have played a vital role in efforts to eradicate polio and control other communicable diseases in Africa. Data compiled from eSURV and ISS over the last 5 years are being used to develop, update, and validate MFLs throughout Africa. Moreover, the ongoing consolidation of health facility information into a single health facility registry that covers the WHO African region should further improve disease surveillance and facilitate epidemiologic research. These efforts will support not only polio eradication in Africa, but also public health efforts directed at other diseases across the continent.

Abstract

Background: Black men who have sex with men (MSM) experience disproportionately high HIV incidence globally. A comprehensive, intersectional approach (race, gender, and sexuality or sexual behavior) in understanding the experiences of Black MSM in Canada along the HIV prevention and care continuums has yet to be explored.

Objective: This scoping review aims to examine the available evidence on the access, quality, gaps, facilitators, and barriers of engagement and identify interventions relevant to the HIV prevention and care continuum for Black MSM in Canada.

Methods: We conducted a systematic database search, in accordance with the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist, of the available studies on HIV health experience and epidemiology concerning Black MSM living with or without HIV in Canada and were published after 1983 in either English or French. Searched databases include MEDLINE, Excerpta, Cumulative Index to Nursing and Allied Health Literature, the Cochrane Library, the NHUS Economic Development Database, Global Health, PsycInfo, PubMed, Scopus, and Web of Science. From the 3095 articles identified, 19 met the inclusion criteria and were analyzed.

Results: Black MSM in Canada consistently report multiple forms of stigma and lack of community support contributing to an increased HIV burden. They experience discrimination based on their intersectional identities while accessing HIV preventative and treatment interventions. Available data demonstrate that Black MSM have higher HIV incidences than Black men who have sex with women (MSW) and White MSM, and low preexposure prophylaxis knowledge and HIV literacy. Black MSM experience significant disparities in HIV prevention and care knowledge, access, and use. Structural barriers, including anti-Black racism, homophobia, and xenophobia, are responsible for gaps in HIV prevention and care continuums, poor quality of care and linkage to HIV services, as well as a higher incidence of HIV.

Conclusions: Considering the lack of targeted interventions, there is a clear need for interventions that reduce HIV diagnoses among Black MSM, increase access and reduce structural barriers that significantly affect the ability of Black MSM to engage with HIV prevention and care, and address provider’s capacity for care and the structural barriers. These findings can inform future interventions, programming, and tools that may alleviate this HIV inequity.

International Registered Report Identifier (IRRID): RR2-10.1136/bmjopen-2020-043055
Introduction

The Canadian publicly funded health care system aims to provide universal access to medically necessary services [1]. This equitable goal alludes to Canadian values of equity and fairness in the administration of health and social services and serves as a source of collective pride for many Canadians [1,2]. However, this narrative does not reflect the state of access to Canadian health care services and the poor health outcomes experienced by marginalized populations [3-10]. These gaps are demonstrated through the HIV inequities seen in Black (descendants of Africa, African diaspora communities in Canada and the Caribbean) communities in Canada. For example, although Black Canadians comprise less than 4% of the national population, according to the 2017 HIV Surveillance report, they made up 25% of new HIV diagnoses [11]. In Ontario alone, between 2012 and 2017, the proportion of new HIV diagnoses increased for Black men while it decreased for White men [12]. Moreover, HIV exposure for gay, bisexual, and other men who have sex with men (MSM) represents the most significant proportion of reported adult HIV diagnoses [11]. Black MSM exist at the intersection of these 2 populations that demonstrate disproportionately high HIV incidence in Canada. Thus, sexual behavior and racialization are significant factors to HIV transmission in adult male HIV diagnoses; this illustrates the relationships between social identities and HIV health inequities in Canada.

Black MSM experience systemic anti-Black racism in addition to the sexual minority stigma and homophobic discrimination [13]. As other high-income countries work to address these inequities, it becomes increasingly important to identify the drivers of HIV inequity through the intersectional experiences of Black MSM in Canada and develop effective evidence-informed intervention models [14-16]. Unfortunately, HIV surveillance by Canadian federal and provincial health agencies does not provide the necessary disaggregated data to elucidate HIV transmission patterns for Black MSM fully. For example, only half of the Public Health Agency of Canada reported cases of integrated exposure category and race data in 2016 and 2017, while the 2018 report did not report this [11,17,18]. Even so, the limited available data reveal that Black MSM are overrepresented in the new HIV diagnoses [11]. Canada aimed to meet the Joint United Nations Programme on HIV/AIDS global targets by 2020 and significantly reduce HIV transmission by 2030; to achieve this goal, Canada must develop a clear strategy to respond to the increased burden of HIV for Black MSM.

Socially constructed identities, including assignment to racial and sexual minority or gendered groups, are associated with inequitable and disproportionate HIV infections [19]. The factors that lead to poor health outcomes are linked to intersectional and systemic barriers, including inaccessible health care services for Black MSM. Additional factors driving poor health outcomes for Black MSM include precarious employment and housing, stress-related mental health challenges, low sexual health and HIV literacy, as well as poor psychosocial health and general health [20-22]. These factors also limit the ability of Black MSM to meaningfully and consistently engage with HIV health care services [23]. Moreover, Black MSM are exposed to anti-Black racism and homophobia within health care institutions, resulting in psychological trauma and medical trauma [13,21,24-27]. Thus, Black MSM are ultimately prevented from accessing HIV-related services by inequitable care, discrimination in health care settings, and systemic marginalization [13,23]. Yet, as these powerful barriers persist, evidence demonstrates that multilevel interventions have successfully mitigated HIV inequity by improving the accessibility to and quality of health care services [24,28,29].

The current HIV prevention and treatment interventions are considered as a continuum of services [30]. This provides a framework through which key points in prevention, care, and existing gaps are engaged [30]. Specifically, the HIV prevention, engagement, and care cascade models the steps to prevent HIV infection or receive treatment if diagnosed with HIV [30-32]. This cascade can be used to identify the gaps in HIV prevention and care and the necessary interventions. However, Canadian HIV surveillance and response effortsquantify the state of HIV transmission and service access by compartmentalizing gender, sexual minority status and sexuality, and race as individual factors. This approach does not accurately characterize the intersectional marginalization of Black MSM. Intersectionality, coined by Crenshaw [33] in 1989, established that singular identities could not explain the complex forms of oppression experienced by marginalized peoples.

Similarly, in the context of Black MSM, their experiences must investigate their gender, sexuality, and race holistically. This may then inform HIV prevention and care interventions and strategies to reduce HIV incidence for Black MSM effectively. This intersectional approach to HIV research, however, has not been widely examined [34]. The results from such investigation could promote access to and improve the quality of prevention and care along the continuums for Black MSM in Canada. Nonetheless, the limited availability of HIV interventions, research, and literature for Black MSM in Canada necessitated this investigation into past and recent HIV research as well as health care provision of HIV-related services for this vulnerable population.

This scoping review examines the state of HIV-related research and health care provision for Black MSM in Canada. Overall, this review aims to comprehensively evaluate and determine the state of HIV prevention and care for Black MSM in Canada as a public health topic while incorporating the lived experience of Black MSM that influence health care engagement. The primary objective is to assess the available literature regarding the influence, access to, and quality of HIV prevention and treatment for Black MSM living in Canada. Secondary
Objectives are to explore the facilitators and disincentives or barriers to HIV-related health care services for Black MSM and the mechanisms through which they influence retention and adherence to the HIV care continuum. Although this review is focused on Black MSM in Canada, its findings will be useful for ethnic minority MSM anywhere in the world.

Methods

Overview
The current investigation used a scoping systematic review methodology. Peterson et al [35] identified this approach as a methodology to advance emerging research topics. Standardized systematic reviews and scoping reviews differ in terms of the specificity of their topic of interest. Scoping reviews tend to investigate broad topics compared to standardized, systematic reviews, which examine a specific, detailed question.

Criteria for Including Studies
This review included evidence syntheses and qualitative, experimental (randomized or nonrandomized), observational (longitudinal and cross-sectional), and mixed methods studies. For inclusion in the review, studies must (1) include data on self-identified Black MSM living with or without HIV, (2) research HIV prevention and care among Black MSM, and (3) have been published in at least 1 of the 2 official languages in Canada—English and French.

For exclusion in the review, studies must not (1) focus on Black MSM outside of Canada unless Canadian data are analyzed separately and (2) be published before the 1983 formation of Canada’s AIDS National Task Force.

Objectives of Interest
The primary objectives of interest of this scoping, systematic review include (1) identifying existing literature that examines the HIV prevention and care continuum in Canada for Black MSM, including epidemiological trends, determinants of engagement, and health care experience and (2) determining health access and availability of specific health resources related to the Canadian HIV prevention and treatment interventions for Black MSM.

The secondary objectives of interest include (1) examining the effects of social determinants of health on the HIV prevention and treatment interventions for Black MSM in Canada, (2) consolidating research on unilevel and multilevel interventions that address the social determinants of health for Black MSM in Canada, and (3) identifying existing health promotion for Black MSM in Canada.

Patients and Public Involvement
There was no direct involvement of the public and patients or participants who are Black MSM in the study.

Ethical Considerations
The approval of the Research Ethics Board was not required. As a scoping systematic review, information was based on secondary published data and not on human subjects. Peer-reviewed manuscripts, conference presentations, and students’ rounds can be strategically used to disseminate study findings. The findings may also influence policy within government health agencies and local HIV or AIDS service organizations.

Search Strategy for Identification of Studies
A health sciences librarian conducted a comprehensive literature search of studies published through the Health Sciences Library in Toronto, Ontario’s St Michael’s Hospital, Unity Health Toronto. This occurred in April 2020. The list of our search terms included “Quality of Health Care,” “Health Status Disparities,” “Social Stigma,” “Human Immunodeficiency Virus,” “Same-Sex Intercourse,” “Blacks OR African OR Caribbean.” The complete search strategy can be found in the published protocol [36].

Electronic Searches
These searches were done on MEDLINE, Excerpta, Cumulative Index to Nursing and Allied Health Literature, the Cochrane Library, the NHUS Economic Development Database, Global Health, PsycInfo, PubMed, Scopus, and Web of Science.

Reference Lists
Related articles were searched for in the reference lists of all pertinent citations.

Gray Literature
Available thesis and conference posters were searched while reports from relevant organizations such as the African and Caribbean Council on HIV or AIDS in Ontario (ACCHO), Black Coalition for AIDS Prevention (Black CAP), Africans in Partnership Against AIDS (APAA), Committee for Accessible AIDS Treatment (CAAT), TAIBU Community Health Centre, Ontario HIV Treatment Network (OHTN), and Canada’s source for HIV and hepatitis C information were explored.

Screening
The studies were deduplicated in advance, and the web-based app Rayyan QCRI (Rayyan) was used to import and screen citations found using this search strategy [37].

A data collection form customized to reflect the inclusion criteria was pilot tested by 2 independent reviewers. These reviewers played a role in generating and using the given form. A total of 50 abstracts were used as a sample to create consistency of use and establish the instrument’s validity. Interrater reliability was measured using the Cohen κ statistic. The screening began upon the achievement of a 60% (n=979) agreement [38].

The study’s selection process began with title and abstract screening to identify potentially relevant articles. This was followed by retrieving the full text for detailed screening using the inclusion and exclusion criteria before the data extraction procedure. All screening and data extraction were completed in duplicate and blinded by JD, PD, FW, AY, and GRAB. Any disagreements were settled via consensus. However, a third author was available to arbitrate (SG) if an agreement could not be reached.
Data Extraction

Bibliometric information such as author names, journal, year of publication, the study location, design, number of participants, outcomes reported, outcome measures overall, and outcome measures in Black MSM participants were extracted. In addition, each outcome is reported through measures of magnitude mean (SD) or percent (95% CIs) where possible, comparing the effect of the intervention in Black MSM versus men in other racialized groups or Black MSW; (odds or risk ratios, mean differences, accompanied with 95% CIs) [39].

Assessment of Methodological Quality of the Included Studies

We did not appraise the methodological quality and risk of bias in the studies as this is not required in a scoping review [40].

Analyses and Reporting

Study findings were reported as per the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines [41,42] through the use of narratives and tables. This is outlined in Multimedia Appendix 1. Data were grouped according to outcomes, with the number of studies and their design displayed using tables. In addition, a narrative synthesis of the data was conducted to identify overlapping themes and knowledge gaps.

Results

Results of the Search

Overview

The literature search of the database identified 3085 studies, with 10 studies found through gray literature and other sources (Figure 1). Thus, a total of 1630 studies were screened after the duplicates were removed. A total of 1607 studies were excluded as they did not study Black MSM in Canada or did not include any data on HIV prevention and treatment interventions. Of the remaining 24 studies, 4 were removed during full-text extraction; among them, 2 were abstracts, 1 study reported Canadian and American Black MSM together, and the other 2 did not provide information on HIV. This left 19 studies that met the inclusion criteria and were included in the study.

Figure 1. PRISMA flowchart. MSM: men who have sex with men; PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

Characteristics of the Study

There were 8 cross-sectional descriptive studies, 3 qualitative studies, 2 mixed methods studies, 1 meta-analysis, and 5 organizational reports. The studies’ publication years ranged from 2004 to 2020. The study characteristics are summarized in Table 1. Further description of each study is provided in Multimedia Appendix 2.

aMSM: men who have sex with men.

**Reporting of Results**

The results of the studies included in the scoping systematic review can be grouped into 4 themes identified from the data and are discussed below. They are the engagement with HIV prevention and care cascades, experiences in HIV health care services, the effects of the social determinants of health on HIV prevention and care access, and interventions for Black MSM.

**Engagement With HIV Prevention and Care Cascades**

**Overview**

A total of 10 studies explored the engagement of Black MSM with the various steps in the HIV prevention and care continuum.

**HIV Epidemiology and its Driving Factors**

Multiple studies assessed HIV infections for Black MSM and their predictors. In Ontario, Black MSM reported the highest increase of HIV diagnoses among racialized MSM, compared to the decreasing HIV diagnoses for White MSM over 2009-2010 and 2011-2012 [43]. This disproportionate increase for Black MSM is supported in other studies in this review [44,45]. Moreover, 2 studies explored differences in HIV diagnoses and associated factors between Black MSW and Black MSM in Toronto. Black MSM demonstrated considerably higher HIV and syphilis prevalence compared to Black MSW [44,46]. Significant HIV diagnosis predictors were the number of male partners (6 or higher), older than 24 years of age, and syphilis diagnoses [44,46]. In addition, Black MSM showed higher transmission of sexual and blood-borne infections (SBBIs) as well, including chlamydia, herpes simplex virus (HSV) 1, HSV-2, and active hepatitis B (HBV) infection compared to other MSM [44,45].

**Factors That Influence HIV Testing**

HIV testing behaviors among Black MSM were also investigated. Generally, African, Caribbean, and Black MSM had lower HIV testing rates than other ethnicities [43,47]. Straight-identified Black MSM were more likely to have had an HIV test than gay-identified Black MSM [45]. Canadian-born Black MSM were less likely to get tested for HIV [48]. Several studies assessed factors that influence HIV testing for Black MSM. Black MSM were shown to have a stronger likelihood of being tested for HIV if they were older than 21 years of age, engaged in condomless sex, had a history of a chlamydia infection, or had relatives or friends who live with or died from HIV [44,48]. Caribbean- and African-born MSM were more likely to know someone who currently lives with HIV or know someone who died from complications due to HIV than Canadian-born Black MSM [49,50]. Nontesters commonly cite low perception of risk and practicing safe sex as reasons for not testing for HIV [48]. Overall, Black MSM are most likely to be tested through their family doctor [48].

**Preexposure Prophylaxis Use Among Black MSM**

It is important to highlight that preexposure prophylaxis (PrEP) is a highly effective oral antiretroviral medication used in the prevention of HIV [51]. While the implementation of PrEP through the Canadian guidelines remains controversial due to...
concerns about accessibility for Black populations. PrEP is identified as a promising tool to reduce HIV incidence in Canada [52,53].

This review finds that similar to the trends seen with HIV testing, Black MSM in younger age groups and Canadian-born were less likely to accept PrEP [54]. However, Black MSM were found to accept PrEP at greater rates than Black MSW and similar rates to other MSM populations [54]. As a whole, PrEP acceptance was not significantly associated with self-risk perception [54]. More than half of Black MSM could not accurately describe their actual risk for HIV acquisition [54]. For those who did not accept PrEP, the most popular explanations for not accepting PrEP were concerns about side effects and low perception of risk for HIV transmission [54,55].

Experiences in Health Care for Black MSM

Overview
A total of 4 studies assessed the specific experiences that Black MSM have while accessing HIV health care services in Canada and the quality of care in the context of their intersectional experiences as Black MSM.

Discrimination in HIV Health Care
Black MSM consistently reported discrimination and inequitable access to HIV care and preventative interventions like PrEP [55-57]. In general, Black MSM noticed that health care staff neglected them in favor of White patients [55,56]. Black MSM who self-identify as gay, bisexual, transgender, or queer (GBTQ+) felt that their Blackness remained a barrier to care [55,57]. Furthermore, upon entering Black-centered health care organizations, many Black MSM often did not feel comfortable disclosing their sexual practices [55,57].

Inadequate HIV Health Care Provision
Black MSM describe low-quality and uncompassionate care, which facilitates gaps in HIV care and disrupts retention of care [56]. In addition, health care providers often use scientific or medical terms that are too complex [56]. This contributes to a more prominent theme of depersonalized care, where health care providers appear neither genuine nor have investments in their sexual health [55,56]. Moreover, mental health and emotional well-being were not incorporated into the HIV care provided to Black MSM, especially when health care providers were disclosing HIV diagnoses [56].

Missed Opportunities for Linkage to HIV Prevention and Care
Health care providers fail to inform Black MSM about the HIV resources and the prevention and treatment interventions that they could access, despite health care providers being described as a key source of sexual health information [55,58]. Black MSM needed to advocate for their care in response to the negligence of their health care providers [55,56]. GBTQ+ Black MSM who seek sexual health services from queer-friendly providers often have long wait times for services, which affects HIV care adherence [55]. Furthermore, many Black MSM did not know about PrEP or had inaccurate knowledge about PrEP despite regular HIV testing [55].

Social Determinants of Health and HIV Health Care Access

Overview
A total of 10 studies reported various social factors as facilitators and barriers to HIV care and prevention services for Black MSM.

Stigma and Homophobia
HIV stigma and sexual minority stigma are significant stressors for Black MSM and impair HIV prevention and care access and engagement [56,59]. Also, Black MSM living with HIV fear stigmatization and rejection can reduce their likelihood of disclosing their HIV status to their sexual partners [56]. GBTQ+ Black MSM have an even increased stigma burden due to homophobia [45,57,58]. The fear of ostracization from their communities also prevents Black MSM from talking about their sexual practices and HIV as a whole [57]. HIV stigma and sexual minority stigma also affect their perception of risk for HIV acquisition [59]. Specifically, heterosexual-identified Black MSM internalize messaging that associates HIV risk with being gay, compromising their own perception of risk [56,57]. For instance, “PrEP stigma” is prevalent as many Black MSM associate PrEP with promiscuity [59]. This stigma translates to increased concerns about PrEP and decreased knowledge about PrEP [59].

Regardless of sexual identity, these stigmas make Black MSM apprehensive about disclosing their sexual practices and deter them from accessing critical HIV interventions [45,55,56,58]. This limits the providers’ ability to inform Black MSM about HIV prevention interventions usually promoted to MSM [55]. Black MSM are also concerned about judgment upon entering HIV health care organizations or having their privacy and confidentiality breached [45,56].

Employment, Income, and Housing
Black MSM experience hardship securing full-time and part-time work, and many report unemployment as a priority concern [50,57]. Black MSM in the MaBwana study had lower incomes than the average income of a sample of MSM living in Ontario [50]. This may contribute to difficulties with securing housing and poverty [57]. These disparities affect their use of HIV prevention interventions such as PrEP, which is the most significant biomedical HIV prevention intervention [49,60]. The cost was described as a significant barrier to PrEP use—even if Black MSM were willing to accept PrEP, they report that its unaffordability prevents them from discussing PrEP with their health care providers [55,59]. Nonetheless, while there are various ways to access PrEP through public and private insurance, many Black MSM are unaware of PrEP coverage to mitigate PrEP costs [55,59].

Immigration
Migrants have distinct experiences in accessing HIV prevention and treatment interventions. While many Black MSM favor Canadian health care, they also describe language barriers and stress with navigating complex immigration laws [56]. Without having the necessary immigration documentation, some Black MSM have been denied medication and HIV care [56]. Many
Black MSM born outside of Canada have low HIV prevention literacy and have experienced medical trauma [58]. Also, they may doubt the efficacy of PrEP by emphasizing its adverse effects [58]. Moreover, migrant GBQT+ Black MSM face anti-Black racism and xenophobia in White gay communities, where more people may be using or know about PrEP [50]. This leaves many migrant Black MSM without the HIV and PrEP knowledge other communities may have [50].

**Education and Access to Knowledge About HIV Prevention and Intervention Methods**

The MaBwana study demonstrated lower achievement of formal education for Black MSM than other MSM [50]. In addition, some Black MSM disclose low reading and writing skills, which limit their ability to learn about important sexual health and HIV information and interventions [56]. Even when they can meaningfully engage with educational institutions, Black MSM describe heteronormative sexual education and a significant lack of GBQT+ representation [58]. Thus, they do not learn about biomedical HIV interventions and prevention methods relevant to their sexual practices [58].

**Mental Health and Emotional Well-Being**

The stigmatization of the sexual practices of Black MSM by their cultural communities has a considerable effect on their mental health [57]. This ostracization can lead Black MSM to experience feelings of isolation, alienation, and internalized homophobia. It also contributes to higher levels of depression and psychological distress [49]. These factors can impair the ability of Black MSM to access HIV treatment and care [45,50,57,61,62]. These dynamics act as barriers for Black MSM to meaningfully engage with HIV biomedical preventative interventions and mitigate the transmission of HIV [49]. Furthermore, research on Black MSM in the United States has shown that the intersection of discrimination experiences related to race or ethnicity, sexual orientation, and HIV status can significantly mediate the relation between socioeconomic status and mental health concerns [63]. These findings suggest that having low socioeconomic resources could increase exposure to discrimination and worsen mental health.

**Canadian HIV Interventions for Black MSM**

**Biomedical Interventions**

Condoms remain the most accessible biomedical intervention for Black MSM [49,50,55]. Initiatives that promote condom use in settings where Black MSM engage in unplanned sex or with casual sex partners may increase condom accessibility [49,50]. The Black CAP provided condoms through their bathhouse outreach program and similar programs in other places frequented by Black MSM like clubs, barbershops, Pride, and other community events [64]. The Black CAP developed a partnership with a local sexual health clinic, Hassle-Free Clinic, to implement programming that provided quick and easy access to HIV and syphilis testing for Black MSM [65].

**Behavioral Interventions**

Several behavioral interventions identified through these studies aim to improve risk perception and HIV literacy, promote HIV prevention services, and adapt sexual behaviors to mitigate HIV transmission [49,50,59]. For example, a workshop was provided to Black-Canadian MSM and focused on increasing knowledge of sexually transmitted infections and factors contributing to their transmission and promoting sexual health service use [59]. The ACCHO campaign, “Keep It Alive,” was a multimedia initiative in 2006 that used postcards, posters, and popular gay media to increase HIV literacy and knowledge of HIV in Black communities, promote testing, and reduce HIV stigma. Likewise, the “Be Real” campaign by the Ontario Gay Men’s Strategy in 2006 had similar aims as “Keep It Alive” and used related dissemination methods. Black MSM described both campaigns as significant in providing information about sexual behavior habits and reducing the risk for HIV transmission [50].

Black CAP’s MSM Outreach program focuses on African, Caribbean, and Black MSM and aims to increase HIV awareness, HIV testing rates, and access to HIV resources and services [66]. They facilitate regular group discussions and sexual health education for Black MSM. This expands on their bathhouse outreach program, where they continue to distribute sexual health materials in bathhouses and Pride events as well as in webpages designed for GBQT+ Black MSM. Moreover, Black CAP’s Men’s Prevention Program provides culturally responsive HIV-focused workshops to Black MSM and includes homophobia, community support, and self-esteem. Also, they developed a resource to promote PrEP knowledge, use, and access for Black MSM in Toronto [65].

**Structural Interventions**

Black CAP reported initiatives that aim to reduce social inequity and other driving factors for HIV transmission for Black MSM [65]. For example, they linked Black MSM with support services that increased access to food, housing, income, and immigration aid. They also created an employment program, “Be Your Own Boss Series,” which educates Black trans-MSM on entrepreneurship and supports developing skills to develop and maintain a successful business.

**Discussion**

**Principal Findings**

Overall, the purpose of this study was to evaluate engagement with HIV services and interventions, identify the relevant facilitators and barriers via the social determinants of health, and determine the research and available interventions for Black MSM in the HIV prevention and care cascade through the lens of intersectional, overlapping identities. This scoping review presents a comprehensive evaluation of the state of the science as it pertains to HIV prevention and treatment interventions for Black MSM in Canada through available literature and reports. Through the 19 published studies and reports included, this review has identified critical points in the HIV prevention and care cascades, where Black MSM experience poor outcomes in knowledge, access, engagement, and quality of HIV care and prevention.

PrEP remains the most accessible and well-established biomedical intervention available in Canada. Yet, there were no identified PrEP delivery strategies that target Black MSM in this study. To inclusively reduce HIV incidence in Canada,
it is crucial to identify the factors that promote PrEP access and use. Motivations to use these prevention methods are characterized by the perception of HIV risk, adequate knowledge of the intervention and its benefits, and acceptability within the relevant sociocultural contexts for Black MSM. Limited discussion on HIV risk and prevention methods with health care providers contributes to the low-risk perception and PrEP motivation [55,56,58]. For instance, some health care providers refuse to discuss PrEP with their patients due to being uncomfortable discussing sex, sexuality, and sexual health with same-gender-loving patients [67,68]. Moreover, social stigmas including homophobia, racism, and xenophobia may affect motivation to seek HIV preventative services. These experiences can prevent Black MSM from disclosing their sexual practices, which providers need to assess HIV risk. Ultimately, these gaps expose the need for timely interventions for Black MSM [55,56,58]; priority areas include promoting the relevance of PrEP to health care providers, highlighting culturally responsive strategies, and generating space spaces actively for Black MSM to engage with providers honestly.

Access in the prevention cascade is influenced by numerous factors, including income, employment, proximity to health care facilities, housing, and other social determinants of health [64,69,70]. Many Black MSM describe precarious work and housing statuses, low income, issues related to poverty, and difficulty accessing formal education [50,57]. These disparities are associated with inadequate access to HIV prevention interventions, as high PrEP costs consistently reduce PrEP uptake [49,55,59]. More research is necessary to fully elucidate the mechanisms through which key factors influence health care engagement such as income, housing, and mental health and emotional well-being [71,72]. In the literature, MSM living with HIV experienced depression associated with physical, educational, social, financial, psychological, and short- and long-term health consequences [69]. People living with HIV who experienced depression are exposed to poor health outcomes like poor quality of life and worsening of their disease states. This could have even more consequences on Black MSM who are already impacted by other structural factors [70]. Therefore, if depression is untreated in MSM living with HIV, this can lead to risky sexual behavior, alcohol, and drug misuse and abuse, including suicide [73]. Poor adherence to antiretroviral drugs has also been associated with depression in newly diagnosed people living with HIV, resulting in poor immunological and virological outcomes.

To reduce HIV incidence for Black MSM, interventions that increase access might be beneficial including mass distribution and outreach programs, integrated health services, or legal changes that empower Black MSM to engage with HIV prevention interventions [74]. There is still limited research on intervention strategies to increase access to prevention interventions for Black MSM across Canada. Similar research in the United States investigated specific legislative and structural opportunities for Black MSM to successfully engage in HIV prevention [75,76]. Canada should commit to adopting effective programs in other countries or funding Canadian research that uses implementation science to address the identified challenges in this review for Black MSM.

While HIV prevention and care services exist along the same continuum, HIV care differs from the prevention cascade. People who remain at risk and test negative for HIV need to be linked to prevention services, but an HIV diagnosis requires a specific set of services to maintain viral suppression. The HIV care cascade models HIV testing and diagnosis steps as the starting point to viral suppression through a series of HIV health care services [30]. In comparison to other MSM, Black MSM demonstrate lower testing rates [43,47]. Still, this review shows various HIV testing behaviors among Black MSM dependent on age, sexuality, country of birth, religious affiliation, history of SBSI, and even personal relationships that have been affected by HIV [44,48-50]. Fortunately, this can inform the generation of testing interventions targeting Black MSM subgroups. For instance, many Black MSM were found to receive HIV testing from their family doctor, which can be used to build programming to link Black MSM to HIV tests directly from their primary care physician [48]. Outside of Canada, there have been many HIV testing interventions for Black MSM and other priority populations that have improved HIV testing and knowledge, testing access, and social support [77-81].

Moreover, HIV diagnosis rates are higher among Black MSM than other MSM and Black MSW [43-45]. Once diagnosed with HIV, Black MSM must be linked to HIV primary and specialist care services and antiretroviral therapy to achieve viral suppression [30]. While there were no studies on engagement at these stages by Black MSM, studies address the discriminatory barriers to access for Black MSM [55-57]. Nevertheless, the use of HIV care interventions is shown to be effective with other populations through improvements in retention of care, engagement with providers, and even condom use [82-85]. This review did not identify any HIV care interventions for Black MSM, which exposes the health care gap for Black MSM despite the epidemiological significance. Canada’s goal to dramatically reduce HIV incidence by 2030 is unachievable unless Black MSM are explicitly highlighted by service agencies.

The unilevel interventions mentioned in this study were reported in organizational reports. These are Black community–based initiatives driven by Black-focused organizations such as ACCHO, Black CAP, and APAA. Although they have a strong engagement and trust with Black communities, they are limited by a lack of research to support their ability to scale up including a focus on their effectiveness, feasibility, appropriateness, and vitality. Health care organizations, government, and research funding agencies need to invest in interventions led by community stakeholders to reduce HIV incidence in Black MSM. Black MSM in Canada are entitled to an equitable standard of care and should not be confined to select organizations outside of provincially mandated health service providers.

This review provides information that can be used to develop many interventions, including programs that provide support for mental health, immigration, housing, and employment; train providers to deliver culturally responsive HIV prevention and care services; and provide accessible and affordable HIV testing and PrEP services. Combining systems-level, provider-level, and patient-level interventions may be necessary for reducing
the effect of these factors, as evidence suggests these interventions improve HIV-related outcomes in Black and nonheteronormative communities [86-88]. Targeting critical points in the HIV prevention and care continuum may lead to improvements for Black MSM. Thus, there is a strong need for unilevel and multilevel HIV prevention and treatment interventions as well as more comprehensive clinical research studies that investigate the outcomes of these interventions across Canada for Black MSM.

Limitations
The findings of this scoping review are limited by the fact that all study interventions were conducted in the Greater Toronto Area, with English as the dominant language. This approach may not be practical for capturing the diverse experiences of Black MSM across Ontario and in other Canadian provinces and territories. In addition, as no French studies were identified in this review, the specific barriers that Francophone Black MSM experience may not be included.

Conclusions
MSM and Black communities are priority populations most affected by HIV in Canada. Black MSM experience disparities in HIV incidence and are disproportionately affected by the driving factors of HIV transmission, including stigma and discrimination. Singular-focused MSM or Black-specific interventions may not be effective for Black MSM, as they need intersectional intervention strategies that affirm their racial and sexual identities and sexual practices. This review demonstrates evidence that Black MSM experience structural discrimination, stigma, and poor quality of care and linkage to HIV services, and as a result, higher HIV and other SBBIs impact. There is some evidence of HIV interventions in Canada for Black MSM. Still, none of the interventions identified in this scoping review were assessed by randomized control trials to evaluate their effectiveness in alleviating HIV transmission disparities for Black MSM. Thus, an important next step is to develop evidence-based HIV interventions to reduce HIV inequities for Black MSM in Canada. The benefit of this review is that it provides a comprehensive overview of the barriers for Black MSM in HIV care from the individual to environmental, institutional, and structural. Additionally, this review has highlighted gaps in care that need to be addressed and sheds light on the intersectional interplay of identities in Black MSM care. This review can inform the development of these interventions for Black MSM and outline the factors that need to be addressed. Furthermore, community agencies and researchers can use these findings to create the necessary programming and tools to reduce HIV incidence for Black MSM.

Acknowledgments
This paper was supported by the Ontario HIV Treatment Network Applied HIV Research Chair in HIV Program Science with African, Caribbean, and Black Communities (#AHRC-1066) as well as the Yale University Centre for Interdisciplinary Research on AIDS, National Institutes of Health-funded program (P30 MH062294).

Authors’ Contributions
LEN, PD, and JD contributed to the study conception and design. Study screening was performed by JD, PD, AY, FW, and GRAB. The analysis was performed by JD. Reporting was performed and informed by JD, PD, DLW, LM, and SG. The first draft of the paper was written by JD and all authors commented on previous versions of the paper. All authors read and approved the final paper.

Conflicts of Interest
None declared.

Abstract

Background: Public health surveillance plays a vital role in informing public health decision-making. The onset of the COVID-19 pandemic in early 2020 caused a widespread shift in public health priorities. Global efforts focused on COVID-19 monitoring and contact tracing. Existing public health programs were interrupted due to physical distancing measures and reallocation of resources. The onset of the COVID-19 pandemic intersected with advancements in technologies that have the potential to support public health surveillance efforts.

Objective: This scoping review aims to explore emergent public health surveillance methods during the early COVID-19 pandemic to characterize the impact of the pandemic on surveillance methods.

Methods: A scoping search was conducted in multiple databases and by scanning key government and public health organization websites from March 2020 to January 2022. Published papers and gray literature that described the application of new or revised approaches to public health surveillance were included. Papers that discussed the implications of novel public health surveillance approaches from ethical, legal, security, and equity perspectives were also included. The surveillance subject, method, location, and setting were extracted from each paper to identify trends in surveillance practices. Two public health epidemiologists were invited to provide their perspectives as peer reviewers.

Results: Of the 14,238 unique papers, a total of 241 papers describing novel surveillance methods and changes to surveillance methods are included. Eighty papers were review papers and 161 were single studies. Overall, the literature heavily featured papers detailing surveillance of COVID-19 transmission (n=187). Surveillance of other infectious diseases was also described, including other pathogens (n=12). Other public health topics included vaccines (n=9), mental health (n=11), substance use (n=4), healthy nutrition (n=1), maternal and child health (n=3), antimicrobial resistance (n=2), and misinformation (n=6). The literature was dominated by applications of digital surveillance, for example, by using big data through mobility tracking and infodemiology (n=163). Wastewater surveillance was also heavily represented (n=48). Other papers described adaptations to programs or methods that existed prior to the COVID-19 pandemic (n=9). The scoping search also found 109 papers that discuss the ethical, legal, security, and equity implications of emerging surveillance methods. The peer reviewer public health epidemiologists noted that additional changes likely exist, beyond what has been reported and available for evidence syntheses.

Conclusions: The COVID-19 pandemic accelerated advancements in surveillance and the adoption of new technologies, especially for digital and wastewater surveillance methods. Given the investments in these systems, further applications for public health surveillance are likely. The literature for surveillance methods was dominated by surveillance of infectious diseases, particularly COVID-19. A substantial amount of literature on the ethical, legal, security, and equity implications of these emerging surveillance methods also points to a need for cautious consideration of potential harm.

Introduction

Decision-making in public health draws on many sources of evidence. The best available research evidence, local health issues and context, current community and political climate, and evidence for existing public health resources all contribute to an evidence-informed decision-making approach [1].

Population-specific surveillance data provides critical evidence to inform decision makers on contextually relevant health issues. Public health surveillance data have been used to directly inform policies like animal importation laws; food recalls due to contaminated food; and communication to the public, such as promoting awareness of emerging environmental threats such as Lyme disease [2,3].

Public health surveillance plays a vital role in decision-making for maintaining and promoting population health. While surveillance programs are most well-known for tracking infectious disease outbreaks, programs also include screening for noncommunicable diseases. In Canada, public health surveillance occurs at national, provincial or territorial, regional, and municipal levels. At the national level alone, nearly 30 surveillance programs, networks, and systems operate to monitor disease and illness across Canada—such as the National Enteric Surveillance Program which monitors the incidence of foodborne illness, and FluWatch, which reports on the spread of influenza [4,5]. There are also regional and local surveillance processes that collect data, including the Ontario integrated Public Health Information System, which allows for reporting and surveillance of several diseases including enteric illness and influenza [6]. The surveillance data collected through these programs inform public health planning, programming, and response.

The COVID-19 pandemic and subsequent public health response led to a pivot in public health priorities. As the urgency to understand and respond to COVID-19 transmission grew, many public health teams prioritized pandemic response including the redeployment of many staff to contact tracing and eventually mass vaccination. For example, over 500 contact tracers were recruited in Ontario alone over a 2-month period in late 2020 [7], and, health care workers in British Columbia were hired or redistributed to form the COVID-19 Immunize BC Operations Centre to coordinate the province’s vaccine response [8].

Non–COVID-19 disease surveillance programs were impacted by emergency public health measures as well as reallocation of resources. Measures including physical distancing and service shutdowns impacted existing programs that were not considered essential, such as cancer screening programs that were paused or deferred during the height of the pandemic [9,10].

Access to “smart” or networked technology has become ubiquitous both in and outside of public health, with nearly 90% of Canadians owning a smartphone and 75% of Canadians using social media regularly [11-13]. The progression of public health surveillance methods has reflected a similar integration of technology, seeing many changes since the prominent SARS-CoV-1 epidemic in 2003. Newer surveillance tools include electronic health records, advancements in wastewater surveillance infrastructure and technology, and digital health surveillance [14]. Electronic health records are the technological response to navigate the complex Canadian health care system by digitally housing individuals’ full health histories [15]. Digitization of records also allows for centrally tracking infectious diseases that may enter the country or region [14]. Prior to the COVID-19 pandemic, wastewater surveillance had gained popularity for tracking infectious disease dynamics and tracing the origins of foodborne illness outbreaks [16,17]. As it is difficult to estimate the true burden of disease of foodborne illnesses, wastewater surveillance has proven to be an accurate and relatively inexpensive way of collecting health data [17,18]. Similarly, digital surveillance can use internet search data to track where and when disease outbreaks occur [19]. More individually, connection to WiFi and GPS tracking can provide access to millions of smartphone users’ locations, enabling accurate and specific tracking of outbreaks and other public health issues [20,21].

Despite advances that occurred prior to the COVID-19 pandemic, the need for improvement of public health surveillance capacity and methods has persisted in Canada and internationally [22-26]. Existing barriers in public health include low-quality data and obstacles to data sharing, as well as political and professional barriers such as incompatible technical lexicons and territorial borders [26]. This adds to the pertinence in investigating how the COVID-19 pandemic impacted public health surveillance and how it may continue to do so [27]. For example, the singular worldwide focus on COVID-19 allowed for an unprecedented dedication of resources (time, money, and intellect) to leverage pre-existing surveillance processes, creating the opportunity to apply these learnings to non–COVID-19 disease surveillance contexts [28]. The severity of the COVID-19 pandemic necessitated a further push in the development of innovative surveillance methods to track and manage SARS-CoV-2 transmission [29,30]. As a result, there have been marked improvements in the ability to predict, track, and respond to COVID-19 outbreaks in Canada and around the world [31-34].

However, there is a need for ethical consideration to be at the forefront of these novel surveillance applications [18,35]. Although the ubiquity of personal technology like smartphones presents convenient and cost-effective disease surveillance opportunities, concerns around privacy and stigma through potential applications have emerged [36-39]. Digital surveillance tools that capture data through personal devices such as smartphones have the ability to capture personally identifiable information including race-based and health history data [35]. As digital surveillance itself is fairly novel there are few regulatory and legal frameworks in place to protect the misuse of this data [35]. Transparency, in terms of what information is
being collected and how it is being used, is an additional ethical consideration that has yet to be fully addressed [38].

The National Collaborating Centre for Methods and Tools’ Rapid Evidence Service [40] was established at the onset of the COVID-19 pandemic to conduct rapid reviews on priority public health topics. This review was requested of the rapid evidence service by the Public Health Agency of Canada to understand how public health surveillance was changed by the COVID-19 pandemic, resulting in a knowledge synthesis to inform future decision-making. This rapid scoping review investigates the question: What is known about changes to public health methods at the population level for governments globally due to the COVID-19 pandemic?

Methods

Study Design

A scoping review capturing literature on changes to public health surveillance in response to the COVID-19 pandemic was conducted and is reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [41]. Review methods were based on previously described rapid review methods [40], with adaptations to a scoping review framework [42]. Inclusion and exclusion criteria were defined based on population, concept, and context criteria rather than population, intervention or exposure, comparison, and outcome criteria. Findings from included studies were not extracted and studies were not assessed for study quality, since the review question focused on identifying a breadth of evidence, rather than individual study findings. Data were analyzed for overall trends and presented visually.

Information Sources and Search Strategy

The search was conducted on January 25, 2022. The following databases were searched: Medline, Embase, Emcare, Global Health Database, PsycInfo, MedRxiv, COVID-19 living overview of evidence, Web of Science, and the World Health Organization’s global literature on coronavirus disease. Each data were searched using combinations of the terms “monitor,” “surveillance,” and “coronavirus.” Additionally, international government websites were hand-searched for relevant gray literature. The full search strategy is included in Multimedia Appendix 1 [14,28-30,32-34,36,43-274].

Eligibility Criteria

Literature on population-level surveillance was included if surveillance was established in response to the COVID-19 pandemic, or directly impacted by the COVID-19 pandemic, through reprioritization of resources or public health restrictions. Studies and reports published between March 1, 2020 and January 25, 2022, were included. While the first cases of COVID-19 were identified in December 2019, the search was timeframe limited to March 2020 or after to allow for literature to capture changes in surveillance and reduce the overall results set for this rapid scoping review. English- or French-language, peer-reviewed sources, and sources published ahead of print before peer review were included. Gray literature was also included. Detailed criteria for inclusion and rationale are outlined inTextbox 1.

Studies were screened using DistillerSR software (DistillerSR). Titles and abstracts of retrieved studies were screened by a single reviewer (SN). Full texts of included studies were screened by a second reviewer (ECC) and reviewed by a third (MD). The screening was not completed in duplicate to maintain a rapid timeline.

Data Extraction

Data extraction was completed by a single reviewer (ECC or SH). Details on the surveillance method (eg, wastewater sampling and digital data collection), as well as surveillance subjects (eg, COVID-19 and population mental health) for each included source were extracted. The type of evidence source was also extracted (eg, syntheses, single study, and opinion).

Studies, critical reviews, editorials, and newspaper articles commenting on the ethics of surveillance methods that were captured by the search were briefly summarized. Details of the method of surveillance and the focus of the ethical implications (ie, ethics, security, legality, and equity) were extracted. Consistent with a scoping review approach, quality assessments of included studies were not completed.

Data Analysis

Sources were grouped by surveillance method and surveillance subject to identify overall trends in the literature. Papers presenting ethical implications of novel approaches to surveillance were grouped by the paper’s focus.

Findings are presented as overall trends in the literature [42]. Results are discussed narratively and summarized in tables. To visually depict overall findings, a Sankey diagram was generated pairing surveillance methods and surveillance subjects, using the software SankeyMATIC (SankeyMATIC). Sankey diagrams can represent the flow of material or ideas through a system. The scale of each section of a Sankey diagram is proportional to the amount of material flowing between stages [43,275-277].

Peer Reviewers

Involving patient and public partners in rapid reviews has emerged as a valuable addition to review methodology. Gaining perspectives from patients and public partners can help ensure that rapid reviews meet knowledge users’ needs and are relevant for decision-making [278,279]. The Cochrane collaboration, a world leader in systematic review methodology, has identified consumer involvement throughout the process of evidence production and dissemination as a vital component [280,281]. Given the more technical focus of this review, rather than seeking partners with lived experience from the general public, epidemiologists who worked closely with surveillance efforts during the COVID-19 pandemic were invited as peer reviewers through organizational connections. Partners were invited to provide feedback on review findings based on lived experiences working in the field. Specifically, they were asked to review the Executive Summary and reflect on their own experiences with shifts in public health surveillance during the COVID-19 pandemic, and to highlight gaps in the literature. Their perspectives are not presented as a source of objective data.
alongside review findings, but rather as contextualizing perspectives of the objective data found by the review. Both partners provided written feedback that informed the review’s conclusions.

**Results**

**Overview**

Database searching retrieved 36,791 records and scanning of key government websites retrieved 8 records. After removing duplicates, 14,238 records were screened by title and abstract, resulting in 1980 reports for full-text review. Of those 1980 records, 241 papers that described surveillance methods and 108 papers that discussed the implications of changes to public health surveillance programs from ethical, security, legal, and equity perspectives were included in the scoping review and underwent data extraction. See Figure 1 for a PRISMA-ScR flowchart illustrating the paper search and selection process.

**Study Characteristics**

Of the 241 papers that described public health surveillance methods, 80 were review papers or evidence syntheses and 161 were single studies. Literature was dominated by reports of COVID-19 surveillance (n=187), but other infectious diseases were also represented, including other respiratory and viral pathogens (n=3), and gastrointestinal (n=3), sexually transmitted (n=2) and zoonotic infections (n=4). There were several papers reporting on surveillance related to immunization, including vaccine efficacy (n=1), vaccine safety monitoring (n=4), and vaccine hesitancy (n=4). Some papers reported on cancer screening (n=5) during the COVID-19 pandemic. Surveillance of mental health (n=11) and substance use (n=4) were also described. One paper described surveillance of healthy nutrition (n=1) and other papers described surveillance of maternal and child health (n=3). Papers described monitoring of antimicrobial resistance (n=2). Several papers described monitoring misinformation on the web (n=6). Table 1 summarizes the number of syntheses and single studies by public health surveillance subject, organized by public health topic area. A detailed list of included studies is available in Table S1 in Multimedia Appendix 1 [14,28-30,32-34,36,43-274].

Singles studies were conducted in the United States (n=51), Europe (n=27), East Asia (n=17), United Kingdom (n=9), Canada (n=5), South America (n=4), Africa (n=3), Australia (n=3), South Asia (n=2), and Russia (n=1). A total of 12 studies were conducted across several countries, and 27 studies were conducted globally. Global studies were mostly digital surveillance studies using global data sets.

Of the 80 included evidence syntheses, the majority were nonsystematic literature reviews (n=61). Syntheses also included systematic reviews (n=10), scoping reviews (n=7), 1 rapid review, and 1 guideline.

**Surveillance Methods**

The Sankey diagram in Figure 2 illustrates the number of included papers that report on the various surveillance methods used for the target surveillance subjects, listed by public health topic area.
Most of the papers on surveillance of COVID-19 transmission described digital surveillance (eg, 130 papers on the use of big data through mobility tracking and infodemiology and 40 papers on wastewater epidemiology). Other methods for monitoring COVID-19 transmission were designed to supplement limited COVID-19 testing capacity, including analysis of data from various health care settings, for example, hospitals and blood banks (n=11). Strategies to track COVID-19 transmission and detect new SARS-CoV-2 variants through genome sequencing were also described (n=5).

Literature for select public health surveillance functions that operated prior to the COVID-19 pandemic, such as cancer screening, child health assessments, and sexually transmitted infection screening, indicated that these functions adapted to using technology for remote screening in response to mobility restrictions and physical distancing. For example, 2 studies described videoconferencing for remote autism screening in young children, and another study described a pilot program for remote sexually transmitted infection self-testing under the supervision of public health staff through videoconference.

Other public health surveillance programs took approaches similar to COVID-19 surveillance. For example, digital surveillance technologies were applied to monitor population mental health (n=8), misinformation (n=5), and zoonoses (n=2). In addition to COVID-19, wastewater surveillance was used to monitor antibiotic resistance (n=2), mental health (n=2), substance use (n=1), as well as other infectious diseases.

Artificial intelligence (AI) was used to augment digital surveillance of COVID-19 transmission (n=29), immunization (n=2), substance use (n=2), and misinformation (n=3; Table 2). Most of these used AI to comb through population-level cell phone mobility data, social media content, or search engine queries for indications of COVID-19 transmission. AI was also used to analyze social media content and search engine queries for indications of vaccine hesitancy, substance use, and misinformation. One paper described using AI to analyze global wastewater data for COVID-19 transmission pathways.
Several studies (n=4) described the development of standardized, digitized data repositories to enable interjurisdictional surveillance [44-47]. One of these described standardized electronic reporting for cancer screening to support central cancer registries [44]. A literature review described distributed data networks to monitor COVID-19 vaccine safety issues [45]. Two papers described data federation technologies for infectious diseases other than COVID-19. A literature review by Baker et al [46] described the standardization of data for malaria, and a pilot study by Colella et al [47] described the development of a biorepository platform to monitor animal-to-human disease transmission. These papers emphasized the interoperability of data systems to facilitate large-scale surveillance of public health issues.

One study used Indigenous methods to monitor COVID-19 through a community-focused COVID-19 surveillance program [48]. In this study, the Hopi Tribe, a sovereign nation in the United States, collaborated with the US Centers for Disease Control and Prevention to deploy community health representatives to every household in 2 Hopi villages [48]. Community health representatives screened household members for COVID-19 symptoms, exposures, and provided education, all in a culturally safe manner [48]. No other studies using Indigenous methods were found.

### Ethical Implications

In addition to papers describing public health surveillance methods, 108 papers exploring the implications of changes to public health surveillance programs during the COVID-19 pandemic, from ethical, legal, data security, and equity perspectives were retrieved. These papers focused on digital surveillance (n=104) or wastewater surveillance (n=4) and discussed potential consequences of surveillance in terms of ethics (n=80), data security (n=28), legality (n=28), and equity (n=21), noting that some papers covered more than 1 topic area. A detailed list of included studies is available in Table S2 in Multimedia Appendix 2 [37-39,282-386].

Aside from 2 systematic reviews, most of the papers discussing the implications of surveillance were critical literature reviews, conducted nonsystematically and written to express a clear opinion or bias (n=71). There were 36 editorials that did not cite or infrequently cited other literature and were published in academic journals (n=29) or newspapers (n=7).

### Perspectives From Public Health Epidemiologists

Two public health epidemiologists who worked in Ontario during the COVID-19 pandemic provided feedback on the findings of this review. They suggested that nearly every surveillance system or program was impacted by the COVID-19 pandemic; some paused due to resource reallocation. Several key metrics that were previously reliable indicators became difficult or not possible to interpret due to the impact of COVID-19. These changes may not be captured in academic literature featured in this review, as many public health professionals working during the pandemic simply did not have the time, energy, or academic support to publish their work.

Epidemiologists shared that the overall approach to surveillance of COVID-19 also changed over the course of the pandemic. While case counts were an early key indicator, there has been a general shift to measures such as hospital and intensive care unit occupancy, reflecting the change in priority from eliminating COVID-19 altogether to reducing and managing the health care system burden.

It was also suggested by epidemiologists that while data for equity has been limited, some governments have made efforts to improve measures of equity. For example, in 2020 the Ontario government amended the Health Protection and Promotion Act and augmented the provincial case and contact management tool to allow for the collection of social determinants (eg, race and income) for COVID-19 cases. Similar changes were made for COVID-19 vaccine surveillance data.

It was suggested that substantial resources are required to restore public health surveillance systems during pandemic recovery and improvements can be made by leveraging or investing in better data.
Discussion

Principal Findings

This scoping review provides a comprehensive overview of changes to public health surveillance methods for programs, systems, and strategies at the population level implemented since early 2020. The review includes 241 papers, including 80 evidence syntheses and 161 single studies describing surveillance methods, as well as 108 papers discussing the implications of changes to public health surveillance programs from ethical, security, legal, and equity perspectives. A Sankey diagram (Figure 2) illustrates the dominance of COVID-19 surveillance in this literature, particularly through digital surveillance strategies.

The heavy focus on COVID-19 in the surveillance literature reflects public health’s drastic reallocation of resources to the pandemic response [387,388]. As nearly all countries of the world entered some form of public health lockdown, unique research opportunities presented themselves [389,390]. Health researchers redirected efforts to contribute to global focus to understand and mitigate COVID-19 transmission and harm [391]. Additionally, academic journals expedited the publication process for papers on COVID-19 [392,393]. While other public health subjects, such as maternal and child health, chronic diseases, and infectious diseases other than COVID-19 were also represented in the surveillance literature, these subjects were largely overshadowed by COVID-19. As suggested by the public health epidemiologists included in this review, those working in surveillance for other public health topics likely did not have time or resources to publish during the pandemic.

Within the COVID-19 surveillance literature, a substantial proportion of papers discussed digital forms of surveillance. This was largely using sources of big data, such as social media posts, search engine queries, and mobility tracking. Prior to the COVID-19 pandemic, there had been a steady rise in publications on big data, as such the field was sufficiently established to contribute to COVID-19 tracking and analysis at the onset of the pandemic [394,395]. Publications were largely proof-of-concept, demonstrating if and how big data analysis correlated with levels of COVID-19 infections seen in communities. Following the interest and advancements in the analysis of big data, these methods are likely to continue to see novel applications in public health.

Wastewater surveillance emerged as a dominant method in the COVID-19 surveillance literature. Wastewater testing is an attractive option for disease surveillance as it is a cost-effective method to monitor populations without requiring active participation or invasive testing procedures [396-398]. Similar to the literature for big data analysis, much of the literature on wastewater provided proof of concept by correlating wastewater detection of the SARS-CoV-2 virus with reported levels of COVID-19 in the community. The impact of wastewater surveillance on public health decision-making is likely to grow [399]. Recently, the detection of vaccine-derived poliovirus in wastewater in New York City led to the addition of the United States to the World Health Organization’s list of countries with polio transmission [400]. To expand coverage across Canada’s population, the Public Health Agency of Canada invested in a pan-Canadian wastewater surveillance network for COVID-19, in collaboration with other federal departments; provincial, territorial, and municipal governments; and academic institutions [401]. While the focus for wastewater surveillance was largely on COVID-19, advances in wastewater monitoring capacity allowed for progress in wastewater monitoring of other conditions and issues, such as mental health and substance use. Given the investment in wastewater epidemiology and advancements in its applications, it is likely to emerge as a key indicator for public health post the pandemic.

In the context of COVID-19 pandemic lockdowns and physical distancing, it is not surprising that some public health services, such as childhood nutrition, cancer screening, and sexual health, were adapted to remote provision of services. While several papers describing the implementation of remote services were included in this review, it is likely that these papers represent only a small sample of public health efforts to continue service provision during the pandemic. As indicated by the public health epidemiologists consulted for this review, many changes to existing public health surveillance programs are likely not published in the academic literature, due to the demands on public health professionals’ time.

The COVID-19 pandemic also highlighted the importance of interjurisdictional data systems which can enable timely access to data across jurisdictional boundaries to inform public health functions. Several papers included in this review explored standardization of data to enhance the public health response, for monitoring zoonoses [46,47] or rare vaccine-related harms [45] at a population level. Solutions to the current limitations of data interoperability must be implemented in future public health surveillance efforts to improve access to essential data in real-time that can inform decision-making within critical health organizations and governing bodies.

While technology has enabled many advancements in public health surveillance, the findings of this scoping review also demonstrate the alarm caused by these changes. The ethical implications of digital surveillance, in particular, were discussed in 80 included papers. Since smartphones and the internet of things (a system of interrelated computing devices to connect people or things identified by unique identifiers), have only become widely used relatively recently, with the potential consequences of their use in public health surveillance not being fully realized yet. The COVID-19 pandemic accelerated the development and testing of digital surveillance, and the literature reflects that experts in these fields have cause for concern. The relative lack of literature discussing the impact of changes in public health surveillance on equity is also concerning. The pandemic exacerbated existing inequities, and care must be taken so that these emerging methods do not further widen equity gaps [402-406]. Data collection and analysis for equity-deserving populations must be a priority as the identification of inequities allows for mitigation. However, these data must be collected and handled with care and respect to avoid potential harm and stigmatization [407,408].
Limitations

Two public health epidemiologists who contributed their perspectives to this review raised that many changes to surveillance are not captured in the literature, primarily due to the lack of time and academic support for public health in publishing. This is an important limitation of this review, as the full scope of changes to public health surveillance is likely not represented. Academic partnerships and support for public health can help share innovations [409].

The peer perspectives shared in this review are also limited to 2 epidemiologists based in Canada, which may not fully represent the perspectives of those involved in public health surveillance worldwide. However, the epidemiologists involved provided contextual insights to the findings of this review.

This review is also limited to papers from March 2020 to January 2022. Studies published after January 2022 may be more likely to capture changes to public health surveillance that are not directly related to COVID-19. For example, examples of wastewater surveillance of pathogens other than SARS-CoV-2 may not have been captured by this search.

As a scoping review of the literature for changes to public health surveillance methods during the COVID-19 pandemic, there are limitations to the overall conclusions that can be supported by this review’s findings. Given the scoping review approach, findings for the effectiveness of surveillance methods and the quality of included papers were not evaluated. A systematic analysis of included papers, including the extraction of outcome data, rigorous quality assessment of included papers, and judgments of the certainty of evidence, is strongly recommended when considering the potential future implementation of any of the surveillance methods discussed in this report.

Conclusions

A considerable body of literature emerged related to advances in surveillance during the COVID-19 pandemic. Some areas have seen much more literature, such as wastewater epidemiology, while others remain sparse, such as health equity for racialized populations. Possible next steps include conducting systematic reviews in areas for which multiple studies have been identified. In other areas with sparse literature, more research is needed to advance surveillance in the postpandemic era. A large volume of papers expressing concerns about the potential ethical, legal, security, and equity implications of emerging surveillance methods indicates a need for a thorough assessment of the potential effects of large-scale implementation of these surveillance methods.

Acknowledgments

The authors would like to acknowledge epidemiologists Jasmine Song and Mackenzie Slifierz for sharing their perspectives on public health surveillance as peer partners in this review. The National Collaborating Centre for Methods and Tools is hosted by McMaster University and funded by the Public Health Agency of Canada. The views expressed herein do not necessarily represent the views of the Public Health Agency of Canada. The funder had no role in the design of the study, collection, analysis, or interpretation of data or in writing the manuscript.

Data Availability

The data sets used and analyzed in the conduct of this review are available from the corresponding authors on reasonable request.

Authors’ Contributions

ECC, LH, and MD designed the study. SN, SH, AK, and ECC completed screening, and data extraction. ECC, SH, and MD analyzed the study results. AK prepared the Sankey diagram. ECC, SN, and LH wrote the manuscript in consultation with MD. SN, SH, AK, LH, and MD provided feedback on all drafts and the final version of the manuscript.

Abstract

Background: Counseling supporting HIV self-testing (HIVST) is helpful in facilitating linkage to care and promoting behavior changes among men who have sex with men (MSM). Different levels of counseling support for MSM HIVST users may lead to variance in the linkage to care.

Objective: This study aims to synthesize evidence on counseling supporting MSM HIVST users and to conduct a meta-analysis to quantify the proportion of MSM HIVST users who were linked to care.

Methods: A systematic search was conducted using predefined eligibility criteria and relevant keywords to retrieve studies from the MEDLINE, Global Health, Web of Science, Embase, APA PsycINFO, and Scopus databases. This search encompassed papers and preprints published between July 3, 2012, and June 30, 2022. Studies were eligible if they reported counseling supporting HIVST or quantitative outcomes for linkage to care among MSM and were published in English. The screening process and data extraction followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. The quality of the included studies was assessed by the National Institutes of Health quality assessment tool. Data were extracted using random effects models to combine the proportion of HIVST users who were linked to care. Subgroup analyses and metaregression were conducted to assess whether linkage to care varied according to study characteristics. All analyses were performed with R (version 4.2.1; R Foundation for Statistical Computing) using the metafor package.

Results: A total of 55 studies published between 2014 and 2021, including 43 observational studies and 12 randomized controlled trials, were identified. Among these studies, 50 (91%) provided active counseling support and 5 (9%) provided passive counseling support. In studies providing active counseling support, most MSM HIVST users were linked to various forms of care, including reporting test results (97.2%, 95% CI 74.3%-99.8%), laboratory confirmation (92.6%, 95% CI 86.1%-96.2%), antiretroviral therapy initiation (90.8%, 95% CI 86.7%-93.7%), and referral to physicians (96.3%, 95% CI 85%-99.2%). In studies providing passive counseling support, fewer MSM HIVST users were linked to laboratory confirmation (78.7%, 95% CI 17.8%-98.4%), antiretroviral therapy initiation (79.1%, 95% CI 48.8%-93.7%), and referral to physicians (79.1%, 95% CI 0%-100%). Multivariate metaregression indicated that a higher number of essential counseling components, a smaller sample size (<300), and the use of mobile health technology to deliver counseling support were associated with better linkage to care. The quality of the studies varied from fair to good with a low to high risk of bias.

Conclusions: Proactively providing counseling support for all users, involving a higher number of essential components in the counseling support, and using mobile health technology could increase the linkage to care among MSM HIVST users.
Introduction

Background

Globally, the estimated median HIV prevalence among men who have sex with men (MSM) ranges from 5% in Southeast Asia to 12.6% in Eastern and Southern Africa [1]. The risk of acquiring HIV is 26 times higher among MSM compared with the general population worldwide [1]. In 2022, the proportion of new HIV cases attributed to MSM was 44% in Asia and the Pacific [2], 38.7% in Europe, and 70% in the United States [3-5].

HIV testing is one of the key strategies for controlling the spread of HIV [6,7]. Both the Joint United Nations Programme on HIV/AIDS (UNAIDS) and the Centers for Disease Control and Prevention recommend MSM to undergo HIV testing every 3 to 6 months [6,7]. The UNAIDS established its 95-95-95 targets in 2014 [6]. The aim was to diagnose 95% of all individuals testing positive for HIV, provide antiretroviral therapy (ART) to 95% of those diagnosed, and achieve viral suppression for those treated by 2030 [6]. High coverage of HIV testing was the first step in achieving the 95-95-95 targets. However, the overall HIV testing coverage among MSM was 86.2% in Africa and 89% in North America [8]. There is a need for further improvement. HIV self-testing (HIVST) could serve as an alternative strategy for enhancing HIV testing coverage. Systematic reviews have demonstrated that HIVST can overcome barriers faced by MSM when accessing HIV testing services, such as perceived stigma from providers and inconvenience [9-11]. Previous meta-analyses consistently showed that HIVST has doubled the frequency of HIV testing compared with facility-based testing [12,13]. As a result, the World Health Organization (WHO) recommends offering HIVST as an additional approach in addition to the existing HIV testing services [14].

On the basis of the presence of counseling support, HIVST can be categorized into assisted and unassisted HIVST. Several studies investigated the linkage to care in assisted and unassisted HIVST. Individuals who received positive results through unassisted HIVST faced more difficulties in accessing care than those who were identified by facility-based HIV testing and counseling [15]. According to a systematic review, <25% of unassisted HIVST users were able to complete the test without any errors, and many of them had difficulties interpreting the HIVST results [16]. A meta-analysis showed that the absence of assistance would lead to a 17% decrease in the linkage to care rate among HIVST users [12]. Across countries, studies have consistently shown that implementing assisted HIVST could increase linkage to care among different populations [17-19]. A very high linkage to care (99%-100%) was observed among users of assisted HIVST in the United States and Zimbabwe [19]. Therefore, the WHO recommends that counseling support be provided to HIVST users [20].

As recommended by the WHO, 8 essential components should be included in the pretest and posttest counseling of a standard-of-care client-initiated HIV testing and counseling. The pretest counseling should include (1) assessing the risks and window periods, (2) informing clients of the benefit of taking the test and the implications of both negative and positive results, (3) assuring the clients’ right to refuse to take the test, (4) encouraging the clients to anticipate the possibility of beneficial disclosure of serostatus status, and (5) providing preventive information and materials [21]. Essential components of posttest counseling include (1) interpreting testing results; (2) offering psychological support to individuals testing positive for HIV, facilitating beneficial disclosure of their positive serostatus, and referring them for further care and support services; and (3) providing HIV-negative individuals with preventive information and materials [21]. However, the level of counseling support varied across previous HIVST programs. Some programs proactively provided pretest or posttest counseling support to all HIVST users unless they refused [22]. This mode of counseling support was categorized as active counseling [23-25]. Providing active counseling increased ART adherence among people living with HIV who had an unsuppressed viral load [26]. Other programs did not provide active counseling to users. Users could report their results via a web-based platform and obtain optional posttest counseling [27]. This mode of counseling support was categorized as passive counseling [24,25]. In addition, the number of essential components involved in counseling support varied significantly. Some studies only involved a single essential component (eg, providing additional HIV care for HIVST users who received reactive results), whereas others provided more comprehensive support (eg, assessing the risks and window periods, delivering preventive information and materials, and providing additional HIV care for HIVST users who received reactive results) [26,27].

Objectives

Existing systematic reviews and meta-analyses have investigated the digital support [28], effectiveness [29], and acceptability of HIVST [30]. However, few studies have summarized the levels of counseling support for HIVST among MSM. It is also unclear whether different levels of counseling support would result in differences in the linkage to care among MSM HIVST users. To address this knowledge gap, we systematically reviewed global evidence on counseling support for MSM HIVST users. We also summarized the linkage to care under different modes of counseling support, including (1) the proportion of users who reported HIVST results; (2) the proportion of users with reactive results who were linked to laboratory confirmation, ART initiation, and physicians; and (3) the proportion of users with...
negative results who were given information related to sexual risk behavior reduction, related to pre-exposure prophylaxis (PrEP), and linked to PrEP initiation.

Methods

This systematic review and meta-analysis was registered with PROSPERO (CRD42022346247) and conducted according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Multimedia Appendix 1) [31].

Search Strategy

We searched the MEDLINE, Global Health, Web of Science, Embase, APA PsycINFO, and Scopus databases for studies (including both published papers and preprints) between July 3, 2012 (the date when HIVST was approved by the Federal Drug Administration), and June 30, 2022, in any country or setting [32]. Keywords were selected based on the PICOS (participants, intervention, comparison, outcome, and study) criteria to address the research question (where P=MSM, I=HIVST with counseling, C=none, O=linkage to care, and S=randomized controlled trial [RCT] or observational studies). The Boolean operator was used in the search strategy, with “OR” and “AND” used to link search terms, whereas the asterisk “*” was used as a wildcard symbol appended at the end of the terms to search for variations of those terms. Full search strategies are available in Multimedia Appendix 2.

Additional studies were identified through the UNAIDS and WHO websites. We also reviewed databases listing ongoing RCTs, such as ClinicalTrials.gov, the WHO International Clinical Trials Registry Platform, and the Pan African Clinical Trials Registry, as well as reference lists of published reviews, meta-analyses, and articles.

Inclusion and Exclusion Criteria

Inclusion and exclusion criteria are presented in Table 1. The exposure categories and outcomes of the study are presented in Textbox 1.

Textbox 1. Exposure categories and outcomes included in the review of linkage to care following HIV self-testing (HIVST), along with counseling.

**Exposure categories**

1. Studies that included HIVST along with active counseling support (eg, studies proactively provided pretest or posttest counseling to all HIVST users unless refused)
2. Studies that included HIVST along with passive counseling support (eg, studies provided certain level of counseling support to HIVST users upon request)

**Outcomes**

1. Reporting test results (defined as the proportion of men who have sex with men [MSM] who reported test results)
2. Laboratory confirmation (defined as the proportion of receiving confirmatory test among MSM with reactive HIVST results)
3. Antiretroviral therapy (ART) initiation (defined as the proportion of ART initiation among MSM HIVST users who are confirmed to be HIV positive)
4. Referred to physicians (defined as the proportion of seeking physicians among MSM HIVST users who are confirmed to be HIV positive)
5. Prevention strategies (defined as the proportion of MSM with negative HIVST results who received information related to sexual risk behaviors reduction, pre-exposure prophylaxis [PrEP])
6. PrEP initiation (defined as the proportion of starting PrEP among MSM with negative HIVST results who had the risk of HIV infection)

Data Extraction

Critical information from this study was extracted using a data extraction form, as outlined in Table 2. The study outcome was the proportion of MSM HIVST users who were linked to care. Two independent reviewers (SC and YF) assessed the eligibility, evaluated the quality, and extracted information from the
included publications. Any disagreements during the data extraction and quality assessment process were resolved by a senior reviewer (ZW).

Quality Assessment

The National Institutes of Health quality assessment tool was used to assess the quality of RCTs and observational studies [87]. The tool covers 14 domains for RCTs, observational cohorts, and cross-sectional studies, with a total score ranging from 0 to 14. Higher scores indicated better quality, and each study’s summary score was categorized as poor (0-4 out of 14 questions), fair (5-10 out of 14 questions), or good (11-14 out of 14 questions).

Data Analysis

Meta-analyses were conducted using random effects models to combine data and calculate pooled proportions and 95% CIs based on the generalized linear mixed effects method [88]. Heterogeneity was quantified using $I^2$ statistic. $I^2$ values <25%, 25% to 75%, and >75% indicate low, moderate, and high heterogeneity, respectively [89]. We used visual inspection to assess the asymmetry of funnel plots and the Egger test to detect potential publication bias [90]. Sensitivity analysis was conducted by removing one study at a time.

Subgroup analyses and meta-regression were conducted to assess whether the proportion of linkage to care varied and was predicted according to the values of the study characteristics. These included study year (we used 2016 as the cutoff as it was the year when the WHO started recommending HIVST) [91], study sample size (<300 vs ≥300), study countries (high income, upper middle income, lower middle income, and low income based on the new World Bank country classification) [92], HIVST counseling delivery modes (technology and mobile health vs peer and community), presence of pretest and posttest counseling (posttest counseling only vs both pre- and posttest counseling), and quality of counseling. Quality of counseling was measured by the number of essential components involved in the counseling support for MSM HIVST users.

Among all studies, we assessed whether the overall linkage to care varied by study characteristics (type of counseling support, study year, study sample size, study countries, HIVST counseling delivery modes, presence of pretest and posttest counseling, and quality of counseling) using the univariate meta-regression model. Factors with $P<.10$ in univariate meta-regression analyses were entered into the multivariable meta-regression model. Within studies providing active or passive counseling support, univariate and multivariate meta-regression were used to examine whether linkage to care varied by study characteristics. All analyses were performed with R (version 4.2.1; R Foundation for Statistical Computing) using the metafor package.

Results

Study Characteristics

A flowchart of the literature selection process is presented in Figure 1. The initial search yielded 1362 publications through databases and registers, and 55 studies met the eligibility criteria and were included in the systematic review [27,33-86]. All 55 studies were included in the meta-analysis to estimate the pooled proportion of linkage to care among MSM HIVST users, categorized by active and passive counseling support.
The characteristics of the included studies are presented in Table 2, and the results for studies that assessed linkage to care are presented in Table 3. All studies were published from 2014 to 2021, including 53 full-text manuscripts [27,33,34,36-51,53-86] and 2 conference abstracts [35,52]. The 55 included studies reported data on 45,147 MSM aged 15 to 73 years. According to the geographical location, 26 (47%) studies were conducted in the Asia-Pacific region, 16 (29%) in North America, 9 (16%) in Africa, 3 (6%) in South America, and 1 (2%) in Europe. Of the included studies, based on the study design, 43 (78%) were observational studies, including 28 (65%) cross-sectional and 15 (35%) cohort studies, and 12 (22%) were RCTs. Detailed results of the quality assessment of the studies are presented in Multimedia Appendix 3 [27,33-86].

Active Counseling Supporting HIVST

Overall, 91% (50/55) of the studies provided active counseling support for MSM HIVST users [33-49, 51-58, 60, 62-79, 81-86]. These studies were conducted in China (14/50, 28%), the United States (12/50, 24%), Brazil (3/50, 6%), Australia (2/50, 4%), Uganda (2/50, 4%), Vietnam (2/50, 4%), South Africa (2/50, 4%), Canada (2/50, 4%), Burundi (2/50, 4%), Thailand (2/50, 4%), the United Kingdom (1/50, 2%), Nigeria (1/50, 2%), Ghana (1/50, 2%), Lebanon (1/50, 2%), Indonesia (1/50, 2%), Myanmar (1/50, 2%), and Kenya (1/50, 2%). Most of these studies (38/50, 76%) were conducted in high-income and upper middle-income countries.

Moreover, 66% (33/50) of the studies used mobile health technology to deliver active counseling support [33-34, 36-39, 41, 45, 46, 48, 49, 51, 54-58, 60, 63, 64, 66-76]. Mobile phones and the internet (eg, telephone calls, SMS text messages, and emails) were the most commonly used technology (21/33, 64%), followed by social media apps or geospatial dating apps (eg, WeChat, QQ, Blued, and Grindr; 8/33, 24%) and HIVST-specific apps (eg, HIVSmart!, WeTest, and C5 apps; 4/33, 12%). Other studies (n=17) used sex partners (3/17, 18%) and nurses or physicians (14/17, 82%) to deliver [33, 38, 42, 44, 45, 52, 55, 56, 64, 76-83].

Essential Components Involved in the Pretest Counseling of the Active Counseling Supporting HIVST

In the pretest counseling, 32 studies proactively provided at least one essential component to MSM HIVST users (Multimedia Appendix 4 [27, 33-86]). Five studies provided only one essential component, such as informing users of the benefits of taking the tests (1/5, 20%), assuring users’ rights to refuse HIV testing (2/5, 40%), or providing HIV prevention information (2/5, 40%). Five other studies provided 2 essential components. In addition to informing the users of the benefits of taking the tests, these studies provided risk assessment (1/5, 20%), assured users’ right to refuse (2/5, 40%), encouraged beneficial disclosure of HIV serostatus (1/5, 20%), or provided HIV prevention information (1/5, 20%). Four other studies provided 3 essential components. In addition to informing the users about the benefits of taking the test, the combination of other components were (1) providing risk assessment and HIV prevention information (1/4, 25%), (2) encouraging beneficial disclosure of serostatus and providing HIV prevention information (1/4, 25%), (3) assuring users’ right to refuse HIV
testing and providing HIV prevention information (1/4, 25%), and (4) providing risk assessment and assuring users’ right to refuse (1/4, 25%). Another study provided 4 essential components: (1) informing users of the benefits of taking the tests, (2) providing risk assessment, (3) assuring the user’s right to refuse HIV testing, and (4) encouraging beneficial disclosure of serostatus status. The remaining studies (n=13) provided all 5 essential components.

In addition to these essential components, 15 studies provided other supplementary components. These components consisted of (1) the reason for HIVST (1/15, 7%), (2) stories addressing general health concerns of MSM (2/15, 13%), (3) the assessment of potential social support (4/15, 27%), (4) first-person stories about people living with HIV (1/15, 7%), and (5) local data, news, and policies regarding HIV and sexually transmitted infections among MSM (7/15, 47%).

**Essential Components Involved in the Posttest Counseling of the Active Counseling Supporting HIVST**

In posttest counseling, 50 studies proactively provided at least one essential component to MSM HIVST users (Multimedia Appendix 4). Six studies only provided one essential component, offering additional HIV care to MSM who received reactive HIVST results. Moreover, 24 studies provided 2 essential components. These combinations included (1) additional HIV care for users with reactive HIVST results and interpretation of HIVST results (23/24, 96%) and (2) additional HIV care for users with reactive HIVST results and HIV prevention information for users with negative HIVST results (1/24, 4%). The rest of the studies (n=18) provided all 3 essential components (eg, interpretation of testing results, HIV prevention information for users with negative HIVST results, and additional HIV care for users with reactive HIVST results).

**Passive Counseling Supporting HIVST**

Passive counseling support to MSM was provided in 10% (5/50) of the studies [27,50,59,61,80]. These studies were conducted in the United States (2/5, 40%), China (1/5, 20%), Indonesia (1/5, 20%), and Thailand (1/5, 20%). Three studies used mobile health technology to deliver counseling [50,59,61], whereas the other 2 studies used peers and communities to provide counseling [27,80].

**Essential Components Involved in the Pretest Counseling of Passive Counseling Supporting HIVST**

In the pretest counseling, 3 studies offered at least one essential component upon request. One study only informed the benefits of taking the tests. The other 2 studies included 2 essential components: informing the participants of the benefits of taking the tests and providing HIV prevention information. In addition to these essential components, one study provided local data, news, and policies regarding HIV and sexually transmitted infections among MSM.

**Essential Components Involved in the Posttest Counseling of the Passive Counseling Supporting HIVST**

In posttest counseling, all 5 studies provided at least one essential component upon request. Three studies provided one essential component, such as interpretation of the HIVST results (1/5, 20%), or provision of psychological support and referral to HIV care for users with positive results (2/5, 40%). The other 2 studies provided 2 essential components. In addition to the interpretation of HIVST results, these studies provided referral to HIV care for users with positive results (1/5, 20%) or HIV prevention information for users with negative results (Multimedia Appendix 4).

**Meta-Analysis of Linkage to Care Among MSM HIVST Users Along With Active and Passive Counseling**

The main findings of the meta-analysis of the linkage to care among MSM HIVST users are summarized in Figure 2.
Reporting Testing Results
Our meta-analysis comprised 45,147 MSM, using a random effects model (Table 3). Overall, 10 studies measured the proportion of users who reported HIVST results [41,50,51,56,64,66,67,73,75,76]. In studies providing active counseling support, the pooled proportion of reporting HIVST results was 97.2% (n=9; 95% CI 74.3%-99.8%; $I^2=100%$; Figure 3 [41,51,56,64,66,67,73,75,76]). Only one study providing passive counseling support reported a proportion of 77.7% for reporting HIVST results [50]. However, this study was not included in the meta-analysis owing to insufficient data.

Linkage to Laboratory Confirmation
In total, 40 studies assessed linkage to laboratory confirmation among users with positive results [27,34,36,37,39-47,49,51-53,56-63,65,66,68,69,71,73-75,78,81-83,86]. In the studies providing active counseling support, the pooled proportion of linkage to laboratory confirmation was 92.6% (n=35; 95% CI 86.1%-96.2%; $I^2=57%$; Figure 4 [34,36,37,39-47,49,51-53,56-86,65,66,68,69,71,73-75,78,81-83,86]). In studies providing passive counseling support, the pooled proportion of linkage to laboratory confirmation was 78.7% (n=5; 95% CI 17.8%-98.4%; $I^2=82%$; Figure 4).
Linkage to ART Initiation

Overall, 25 studies reported linkage to ART initiation among users with positive results [37,43-45,47,49,50,52,53,59-63,66,67,70,71,73,78,80-82,84,86]. In the studies providing active counseling support, the pooled proportion of ART initiation was 90.8% (n=21; 95% CI 86.7%-93.7%; $I^2=0$%); Figure 5 [37,43-45,47,49,50,52,53,59-63,66,67,70,71,73,78,80-82,84,86]. In studies with passive counseling support, the pooled proportion of ART initiation was 79.1% (n=4; 95% CI 48.8%-93.7%; $I^2=0$%; Figure 5) [50,59,61,80].
Figure 5. Forest plot of the pooled proportion of linkage to antiretroviral therapy among users who were confirmed HIV positive: (A) Studies were provided active counseling along with HIV self-testing and (B) studies were provided passive counseling along with HIV self-testing.

### Linkage to Physicians

In total, 30 studies reported linkage to physicians among users with positive results ([33,35,36,38,39,41,44-47,49,54,55-57,60,63,65,66,68-71,74,75,77,79,81]). In the studies providing active counseling support, the pooled proportion of linkage to physicians was 96.3% (n=28; 95% CI 85% - 99.2%; $I^2=0$%; Figure 6) ([33,35,36,38,39,41,44-47,49,54,55-57,60,63,65,66,68-71,74,75,77,79,81]). In the studies with passive counseling support, the pooled proportion of linkage to physicians was 79.1% (n=2; 95% CI 0%-100%; $I^2=91$%; Figure 6) ([59,61]).
Figure 6. Forest plot of the pooled proportion of linkage to physicians among users with reactive results: (A) studies were provided active counseling along with HIV self-testing and (B) studies were provided passive counseling along with HIV self-testing.

Linkage to Information Related to Sexual Risk Behaviors Reduction and PrEP and PrEP Initiation

Overall, 7 studies reported linkage to information related to sexual risk behaviors reduction and PrEP among users with negative results. In studies with active counseling support, the pooled proportion of linkage to sexual risk behaviors reduction was 100% (n=7; 95% CI 0%-100%; $I^2=0%$; Figure 7 [34,49,60,63,71,81,85]). The pooled proportion of PrEP initiation was 27% (n=6; 95% CI 10.2%-54.6%; $I^2=97%$; Figure 7) [48,60,72,81,84,85] in studies providing active counseling support. No studies with passive counseling support reported a linkage to information related to sexual risk behaviors and PrEP or PrEP initiation among users with negative results.
Publication Bias

Upon examination of the funnel plots (Figure 8; Table 3), there was a publication bias in studies reporting the proportion of linkage to laboratory confirmation ($P=.02$), referral to physicians ($P<.001$), and prevention strategies ($P<.001$). Furthermore, outliers were identified in studies reporting the proportion of reporting test results [51] and linkage to laboratory confirmation [73,82], ART initiation [63], physicians [35], and PrEP initiation [85] (Figure 8).
Figure 8. Funnel plots for assessing the publication bias among the included studies: (A) linkage to reporting test results; (B) linkage to laboratory confirmation with active counseling support; (C) linkage to laboratory confirmation with passive counseling support; (D) linkage to antiretroviral therapy (ART) initiation with active counseling support; (E) linkage to ART initiation with passive counseling support; (F) linkage to physicians with active counseling support; (G) linkage to physicians with passive counseling support; (H) linkage to information related to sexual risk behaviors reduction, and pre-exposure prophylaxis (PrEP); and (I) linkage to PrEP initiation.

Sensitivity Analysis

For studies providing active counseling support, the pooled proportion of reporting test results, and linkage to laboratory confirmation, ART initiation, physicians, information related to sexual risk behaviors reduction and PrEP, and PrEP initiation changed slightly after removing one study at each time.

With regard to the studies providing passive counseling support, the pooled proportion of linkage to ART initiation did not change after removing one study at each time. However, after removing the study conducted by Jin et al [50], the pooled proportion of linkage to laboratory confirmation changed from 78.7% (95% CI 17.8%-98.4%) to 55.5% (95% CI 27%-80.8%). As there were only 2 studies with passive counseling support that reported linkage to physicians, a sensitivity analysis was not conducted. Details of the sensitivity analysis results are presented in Multimedia Appendix 5 [27,33-86].

Subgroup Analysis and Metaregression

Subgroup analysis by study sample size (<300 vs ≥300) revealed different levels of linkage to reporting test results (98.5% vs 82.7%), laboratory confirmation (93.8% vs 85.6%), physicians (92% vs 86%), and PrEP initiation (35.6% vs 23.9%). The subsequent subgroup analysis (posttest counseling only vs both pre- and posttest counseling) also found different proportions of users who reported test results (87.1% vs 93.2%) and initiated PrEP (20.2% vs 53%). Subgroup analysis by other study characteristics did not reveal a large difference in the linkage to care.

Among all studies, univariate metaregression analysis demonstrated that the type of counseling (active vs passive), a smaller sample size (<300 vs ≥300), and a higher number of essential components involved in the counseling support were significantly associated with better linkage to care. Furthermore, the multivariate metaregression analysis confirmed that a larger sample size was linked to a lower linkage to care ($P=.03$). In contrast, mobile health technology counseling ($P=.05$) and a higher number of essential components involved in the counseling support were associated with increased linkage to care ($P=.04$).

In studies providing active counseling support, univariate metaregression analysis indicated a smaller sample size (<300 vs ≥300), provision of both pretest and posttest counseling (vs
posttest counseling only), and a higher number of essential components were significantly associated with better linkage to care. The findings of multivariate metaregression analysis revealed that a smaller sample size ($P = .03$) and using mobile health technology for counseling ($P = .05$) were associated with a higher linkage to care. With regard to different outcomes related to linkage to care, a larger sample size was correlated with a lower linkage to laboratory confirmation ($P = .03$) and prevention strategies ($P < .001$) with active counseling support (Multimedia Appendix 6).

**Discussion**

**Principal Findings**

This systematic review and meta-analysis aimed to summarize the global evidence on counseling support and synthesize the proportion of linkage to care among MSM HIVST users. We categorized counseling support in assisted HIVST into active or passive. More than 90% of the MSM HIVST users with reactive results were linked to laboratory confirmation and ART initiation in studies implementing active counseling support. Such a proportion was higher than that of the studies with passive counseling support (78.7%-79.1%). Therefore, the provision of active counseling support may be helpful in improving the linkage to HIV care and treatment for MSM HIVST users with reactive results.

Relatively few studies (7/55, 13%) provided information related to sexual risk behaviors reduction and PrEP for MSM HIVST users with negative results. One possible explanation was that most resources were used to provide support for users with reactive results, which was considered a priority for some HIVST programs [93]. Hence, there are constraints in resources to provide support for the large number of users with negative results [93]. In addition to identifying individuals testing positive for HIV, facilitating behavior changes is an important purpose of HIV testing and counseling. Future studies should consider providing more comprehensive support for MSM HIVST users with negative results.

The metaregression results identified some significant determinants of the linkage to care among MSM HIVST users. First, more essential counseling components were associated with better linkage to care, which aligns with findings from a previous study [94]. Incorporating a higher number of essential components would enhance counseling quality. Previous studies suggest that delivering high-quality counseling improves linkage to care, reduces risky behaviors, and prevents new infections [95,96]. However, our study found that only 26% to 36% of the studies provided all essential active pretest and posttest counseling support. As a result, future programs should consider offering comprehensive counseling to MSM HIVST users.

Second, a larger sample size was associated with a lower linkage to care among MSM HIVST users. Providing active counseling support for HIVST users was resource demanding. For example, it took 1 hour to prepare and implement one session of real-time pretest and posttest counseling support for each MSM HIVST user [49,71]. Therefore, it is challenging to provide counseling support to a larger number of HIVST users. Furthermore, mobile health technology counseling was associated with a better linkage to care compared with peer and community counseling. Our study found that mobile health technology counseling is the predominant method to support MSM HIVST users, which aligns with a previous study [28]. Owing to high smartphone ownership among MSM (>94%) [97], mobile health technology presents a viable strategy for counseling among MSM HIVST users. In addition, previous studies have demonstrated that using mobile health technology for counseling support reduces the workload of HIV testing administrators [28,98].

Stigma and discrimination against MSM impede access to HIV testing and counseling services [99]. Systematic reviews have shown that perceived stigma remained a significant obstacle to engaging in assisted HIVST [100,101]. Future programs should consider increasing the empathy of health workers who provide counseling to support HIVST. A previous study suggested that the negative effects of perceived stigma or discrimination on HIV testing use could be offset by increasing the empathy of service providers [102]. A recent study applied computerized programs (instead of people) to provide active counseling supporting HIVST [98]. Such an approach could also reduce the concerns of stigma or discrimination when using assisted HIVST among MSM.

**Limitations**

There are several limitations in this study. First, there was high heterogeneity among the studies that reported outcomes on linkage to laboratory confirmation, physicians with the provision of passive counseling support, linkage to PrEP initiation, and reporting test results. Heterogeneity pertains to the diversity observed in the design of studies, the effects of interventions, or the outcomes obtained across different studies. Persistent heterogeneity could not be resolved using sensitivity analysis. Second, publication bias was found in relation to the pooled proportion of linkage to laboratory confirmation, physicians, and prevention strategies, which could impact the validity and generalization of conclusions. Third, because half of the included studies were cross-sectional, a causal relationship could not be established. Furthermore, the use of nonprobabilistic sampling for MSM in all the included studies limited the generalizability of the findings. Finally, the small number of studies in the comparison group (those providing passive counseling) would result in bias when comparing the study outcomes between active and passive counseling support.

**Conclusions**

This study synthesized evidence on active and passive counseling support for MSM HIVST users and quantified the proportion of linkage to care. As compared with passive counseling support, active counseling support had a better linkage to care. Having a higher number of essential counseling components, a smaller sample size, and using mobile health technology to deliver counseling support were also associated with a better linkage to care. As our results showed, proactively providing counseling support for all users, involving more essential components in the counseling support, and using mobile health technology should be considered to increase the linkage to care among MSM HIVST users.
Acknowledgments
This study was supported by the AIDS Trust Fund (MSS349R). The funder of the study had no role in study design, data collection, data analysis, data interpretation, or writing of the manuscript.

Data Availability
All data generated or analyzed during this study are included in this published paper (and its Multimedia Appendix files).

Authors' Contributions
SC, YF, PM, and ZW conceptualized and designed the study. SC, YF, and ZW were involved in data curation and formal analysis. SC, YF, PSFC, JK, PM, and ZW verified the data. SC and ZW drafted the manuscript. All authors critically revised and drafted the manuscript for important intellectual content, including data interpretation in the broader context. All authors had full access to all the data in the study and had final responsibility for the decision to submit for publication.

Abstract

Background: Hypertension and diabetes are global health challenges requiring effective management to mitigate their considerable burden. The successful management of hypertension and diabetes requires the completion of a sequence of stages, which are collectively termed the care cascade.

Objective: This scoping review aimed to describe the characteristics of studies on the hypertension and diabetes care cascade and identify potential interventions as well as factors that impact each stage of the care cascade.

Methods: The method of this scoping review has been guided by the framework by Arksey and O’Malley. We systematically searched MEDLINE, Embase, and Web of Science using terms pertinent to hypertension, diabetes, and specific stages of the care cascade. Articles published after 2011 were considered, and we included all studies that described the completion of at least one stage of the care cascade of hypertension and diabetes. Study selection was independently performed by 2 paired authors. Descriptive statistics were used to elucidate key patterns and trends. Inductive content analysis was performed to generate themes regarding the barriers and facilitators for improving the care cascade in hypertension and diabetes management.

Results: A total of 128 studies were included, with 42.2% (54/128) conducted in high-income countries. Of them, 47 (36.7%) focused on hypertension care, 63 (49.2%) focused on diabetes care, and only 18 (14.1%) reported on the care of both diseases. The majority (96/128, 75.0%) were observational in design. Cascade stages documented in the literature were awareness, screening, diagnosis, linkage to care, treatment, adherence to medication, and control. Most studies focused on the stages of treatment and control, while a relative paucity of studies examined the stages before treatment initiation (76/128, 59.4% vs 52/128, 40.6%). There was a wide spectrum of interventions aimed at enhancing the hypertension and diabetes care cascade. The analysis unveiled a multitude of individual-level and system-level factors influencing the successful completion of cascade sequences in both high-income and low- and middle-income settings.

Conclusions: This review offers a comprehensive understanding of hypertension and diabetes management, emphasizing the pivotal factors that impact each stage of care. Future research should focus on upstream cascade stages and context-specific interventions to optimize patient retention and care outcomes.

Introduction

Noncommunicable diseases (NCDs) constitute a formidable global health challenge, accounting for approximately 80% of NCD-related deaths, and they include cardiovascular diseases, cancers, chronic respiratory diseases, and diabetes [1]. Hypertension is the most pivotal risk factor for cardiovascular diseases [2]. The prevalence of hypertension among adults aged 30-79 years worldwide is estimated to be 1.28 billion, with an alarming 700 million individuals unaware of their condition. Less than half of adults with hypertension are diagnosed and treated. Only approximately 1 in 5 adults with hypertension have their blood pressure controlled [3]. Similarly, the global prevalence of diabetes among adults has surged to 537 million in 2021, with nearly half of these cases (240 million) remaining undiagnosed. Moreover, the treatment rate for diabetes is suboptimal, with only 32.9% of patients receiving appropriate care and a mere 16.5% attaining treatment goals [4]. Evidence suggests that a substantial proportion of patients with hypertension and diabetes reside in low- and middle-income countries (LMICs), wherein the management of these conditions remains persistently low [3,5].

Hypertension and diabetes are often approached differently by distinct clinical subspecialties owing to their clinical complexities. However, it is essential to recognize that the management of these 2 conditions together can be highly beneficial owing to their shared risk factors and bidirectional interaction. The management of hypertension and diabetes also shares the same pathway, which includes early detection, appropriate treatment, and continuous monitoring. The health care systems and implementation strategies designed to ensure the continuity of care exhibit significant overlap and can be harnessed efficiently and effectively to support both hypertension and diabetes patients. The care cascade is a model for evaluating patient retention across sequential stages of care required to achieve a successful treatment outcome [6]. This model has sequential stages, including awareness, screening, diagnosis, appropriate management, and disease control, that patients navigate while accessing health care services. Acknowledging potential lapses at each stage, the care cascade model identifies critical stages where patients may disengage, hindering them from attaining disease control [7]. The care cascade model was originally conceived for HIV care [8]. It has since been extended to monitor and manage infectious diseases, such as hepatitis C [9] and tuberculosis [6], and has been more recently applied to NCDs [10].

The utility of studying the care cascade of hypertension and diabetes goes beyond the mere exploration of their clinical pathways. It encompasses a broader holistic perspective that includes not only clinical aspects but also the impact on health systems, the quality of life of affected individuals, and the efficiency of health care delivery. Cascade analysis for hypertension and diabetes can help understand the common factors that affect the care model in order to identify appropriate strategies to improve health care for these 2 conditions. However, there is limited evidence synthesis regarding the care cascade of hypertension and diabetes. Therefore, we performed a systematic scoping review with the goal of mapping and describing the current state of evidence on a global scale. We sought to understand the process of hypertension and diabetes management, identify the factors that influence each stage of the care cascade, and explore potential interventions that hold promise for improving care continuity. By synthesizing existing evidence, our findings seek to inform future research endeavors, propelling the advancement of management strategies for hypertension and diabetes.

Methods

Study Design

This scoping review was conducted following the stages of a scoping review by Arksey and O’Malley [11] and was reported in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews (PRISMA-ScR) [12].

Identifying the Research Questions

This scoping review focused on mapping the existing evidence on the care cascade of hypertension and diabetes. The specific research questions were as follows: 1. How the care cascade model has been applied in hypertension and diabetes research? 2. Which stage of the hypertension and diabetes care cascade has the current research in high-income countries (HICs) and LMICs primarily focused on? 3. What are the barriers and facilitators of hypertension and diabetes care cascade completion? 4. What strategies have been employed to improve retention in the hypertension and diabetes care cascade? 5. What are the key knowledge gaps that remain in the literature about the hypertension and diabetes care cascade?

Identifying Relevant Studies

To identify relevant studies, a systematic search was conducted in MEDLINE, Embase, and Web of Science, using terms pertinent to hypertension, diabetes, and the specific stages of the care cascade. The framework of population, concept, and context was used to identify core concepts related to the research question and inform the search strategy [13]. A complete overview of the search terms for each database is provided in Multimedia Appendix 1. The population of interest in this review was adults aged 18 years or older who had been screened for or diagnosed with hypertension or type 2 diabetes, as well as patients with hypertension or type 2 diabetes undergoing treatment or management. The key concept of the review was the hypertension and diabetes care cascade, with a focus on studies explicitly applying the cascade care model to one or more stages of screening, diagnosis, treatment, and control. Articles describing interventions targeting specific stages of the cascade or factors influencing interventions or outcomes of at least one stage of the care cascade were included. The review aimed to explore a broad range of influencing factors involving both barriers and facilitators, with all pertinent descriptions included, regardless of statistical associations. The contextual scope of this review was in both HICs and LMICs, where hypertension and diabetes care was provided. The timeframe for database searches spanned from January 2011 to January 2021.
2023 since the concept of the care cascade was introduced in 2011 [8]. There was no restriction on publication language, allowing for an inclusive evaluation of relevant studies worldwide. The eligibility criteria are shown in Textbox 1.

Textbox 1. Eligibility criteria for screening.

1. Population: Adults aged 18 years or older who had been screened for or diagnosed with hypertension or type 2 diabetes and patients with known hypertension or type 2 diabetes currently undergoing treatment or management.
2. Concept: Hypertension and diabetes care cascade, with a focus on studies explicitly applying the cascade care model to one or more stages from awareness to control. Interventions that impact patient outcomes and factors that influence implementation outcomes and service outcomes within at least one stage of the care cascade.
3. Context: No limitation. All clinical and primary care settings.
4. Language: No limitation.
6. Article type: Original articles and protocol papers, including cross-sectional studies, cohort studies, trials, and implementation studies published in peer-reviewed journals.

Study Selection

All identified articles were imported into Covidence, and duplicates were removed. Screening proceeded through 2 distinct stages, where titles and abstracts were assessed independently by 4 researchers (JW, FT, XY, and ZW) in pairs, adhering to predefined inclusion and exclusion criteria to determine potential eligibility. In the event of disagreements, a collaborative discussion within the research team swiftly resolved any discrepancies. Subsequently, full-text screening followed a similar process, again involving 4 researchers (JW, FT, YY, and ZW) in pairs. Articles were excluded if they were (1) observing outcomes unrelated to hypertension and type 2 diabetes health care; (2) case reports, conference abstracts, editorials, commentaries, or reviews; and (3) unavailable in full text. Any unresolved discrepancies in article eligibility were resolved by group discussion until a consensus was reached. Notably, to glean insights into ongoing or planned projects and to identify potential interventions and relevant factors, study protocols were intentionally retained and not excluded in the scoping review.

Charting the Data

A data-charting form was created in Microsoft Excel and pilot tested with 15 articles to establish clarity and consistency in data extraction variables across reviewers. Data extraction was performed by 4 researchers (JW, FT, YY, and ZW). The extracted variables included title, author names, year of publication, study countries, disease of interest (hypertension, diabetes, or both), study method (quantitative, qualitative, or mixed method), study design (cross-sectional study, cohort study, trial, or implementation study), sample size, mean age of participants, stages of the care cascade involved, interventions aimed at improving retention, factors associated with stage completion, and reported outcomes. The care of hypertension and diabetes was divided into multiple stages of the cascade, including awareness, screening, diagnosis, linkage to care, treatment, medication adherence, and ultimately, disease control. The world’s economies were classified based on the World Bank classification as follows: low income, lower-middle income, upper-middle income, and high income [14]. The outcomes were categorized into implementation outcomes, service outcomes, and client outcomes. Implementation outcomes encompassed aspects pertaining to the process of implementing interventions and services for hypertension and diabetes care. This included factors such as acceptability, adoption, appropriateness, cost, feasibility, fidelity, and sustainability of interventions to health care providers or patients. Service outcomes were those related to the quality and effectiveness of the health care services provided to patients with hypertension and diabetes, such as access to health care services, continuity of care, appropriateness of care, equity of service, and health care provider adherence to clinical guidelines. Client outcomes, on the other hand, delved into the impact of health services on patients’ health and clinical conditions, such as blood pressure and blood glucose control, reductions in cardiovascular risk factors, and improvements in overall quality of life. To ensure data accuracy and consistency, a senior researcher (XY) reviewed all extracted data. Any disagreements were resolved by consensus.

Collating, Summarizing, and Reporting the Results

Interventions and influencing factors were analyzed by cascade stages and focused diseases. Studies that reported multiple stages of the care cascade were included in the synthesis of each relevant stage. The resulting information was subjected to rigorous quantitative analysis, employing frequencies and percentages to elucidate key patterns and trends. Inductive content analysis was performed to generate themes regarding the barriers and facilitators for improving the care cascade in hypertension and diabetes management. The initial list of codes was grouped into categories and then themes against the supporting evidence. Throughout this process, subthemes and themes were discussed and refined within the research team.

Ethical Considerations

This review does not involve human subject information, primary data collection, or any form of experimentation on individuals.
Results

Characteristics of the Included Studies

Of the 1321 unique articles identified for the title and abstract screening, 222 were retrieved for full-text review. Of these, 128 were included in the analysis after excluding 94 articles for various reasons (Figure 1).

The 128 studies originated from 40 countries, with 42.2% (54/128) conducted in HICs (Figure 2). Of the 128 studies, 47 (36.7%) focused on hypertension care, 63 (49.2%) focused on diabetes care, and 18 (14.1%) reported on the care of both diseases. Most studies (104/128, 81.3%) employed quantitative methods. The majority were cross-sectional studies (70/128, 54.7%), followed by cohort studies (26/128, 20.3%). There were 24 (18.8%) trials evaluating interventions to promote retention in at least one cascade stage. Only 8 (6.3%) were implementation studies designed to systematically assess service delivery gaps and identify contextually appropriate solutions to address these bottlenecks. A total of 116 (90.6%) studies reported health receivers’ perspectives, and only 8 (6.3%) studies had health system perspectives. Most studies (83/128, 64.8%) reported client outcomes as primary outcomes, and they mainly focused on the measure of the effectiveness of disease control. Moreover, 16 (12.5%) studies reported service outcomes, and they mainly focused on the measure of satisfaction. Furthermore, 29 (22.7%) studies reported implementation outcomes, such as feasibility, cost, and adoption (Table 1). Detailed characteristics of the 128 included studies are summarized in Multimedia Appendix 2 [10,15-131].

Completion of the Hypertension and Diabetes Care Cascade

Only 3 studies documented all 7 cascade stages, with 2 of them focusing on hypertension management and 1 addressing both hypertension and diabetes [15,16,132]. They were all population-based cross-sectional surveys aimed to describe disease prevalence and quantify the unmet need for hypertension and diabetes care. The remaining studies included in our analysis examined specific stages of the care cascade. Among the studies focusing on hypertension, 13 highlighted increasing awareness and knowledge related to hypertension, 8 addressed the importance of screening through blood pressure measurements, 14 focused on the diagnosis of hypertension, 13 explored the linkage to care, 34 discussed the initiation of treatment, 16 emphasized medication adherence, and 26 explored blood pressure management and control. For diabetes care, 8 studies addressed the critical aspect of awareness, 16 concentrated on screening, 20 discussed the diagnosis of diabetes, 21 explored the linkage to care, 38 focused on treatment interventions, 23 examined medication adherence, and 37 investigated the factors impacting diabetes control. In addition, 18 studies adopted an integrated approach, encompassing care for both hypertension and diabetes. Among these studies, 6 addressed awareness, 1 addressed screening, 4 addressed diagnosis, 10 addressed linkage to care, 9 addressed treatment, 2 addressed medication adherence, and 10 addressed control (Table 2).

Interventions of the Hypertension and Diabetes Care Cascade

**Awareness**

Various interventions were identified to enhance the knowledge of disease prevention. Health education programs for hypertension and diabetes were emphasized as continuous efforts to support ongoing management and care [17]. The provision of comprehensive education was achieved through training classes and consulting at nutrition-based shared medical appointments [17-19]. Automated outreach call services with the integration of electronic health records emerged as effective approaches [20]. Out-of-hospital continuous nursing interventions and community awareness campaigns were used to augment the awareness [21]. Dissemination of awareness campaign information occurred through various channels, including the internet, public awareness events, and targeted home visits [22].

**Screening**

In the pursuit of enhancing the screening process for hypertension and diabetes, a diverse array of interventions has emerged. The Sustainable East Africa Research in Community Health (SEARCH) study implemented a community health campaign that offered universal adult screening, rendering screening services widely accessible [23]. Moreover, innovative approaches like home-based screening interventions empowered individuals by providing convenience and ease of access to early detection services [24]. Early diabetes detection was prioritized through specialized medical check-ups, facilitating timely intervention [22]. The Integrated Tracking, Referral, and Electronic Decision Support and Care Coordination (I-TREC) program incorporated cutting-edge technologies, including electronic case record forms and clinical decision support systems, streamlining patient information and offering guideline-based screening. Enhanced training for health care providers in NCD management and lifestyle interventions further fortified the screening process [25]. Lastly, efforts were made to strengthen health education and outreach services, particularly targeting individuals without symptoms, to foster a proactive approach to screening [26].

**Diagnosis**

Effective interventions have been deployed to enhance the diagnosis of hypertension and diabetes. Continuous and coordinated care among multi-level health institutions was emphasized to enable timely diagnosis and consistent follow-up for hypertension and diabetes. Telephone peer coaching provided personalized support through weekly calls, aiding in timely diagnosis and empowering patients to engage in self-care [27]. Patient-centered integrated care with advanced technologies, such as electronic case record forms and clinical decision support systems, streamlined patient information and referrals to deliver tailored guideline-based care. Enhanced training for primary health care providers further strengthened timely diagnosis among patients [25].

**Linkage to Care**

Follow-up within 6 weeks at NCD clinics for participants with hypertension, coupled with the use of diabetes self-management record sheets and telephone reinforcement, has shown positive
outcomes [133]. Additionally, 8-week training classes encompassing diverse self-care aspects have demonstrated effectiveness [18]. Mobile health applications [28], shared medical appointments [29], telephone peer coaching [27], and regular general practitioner contact [30] have proven to be successful strategies for ensuring a smooth connection to care. Furthermore, providing training in communication skills and self-care education to health providers, along with reduced workload and increased availability of competent diabetes specialist nurses, has contributed to enhancing the linkage to care [31]. Educational group programs, decision support tools, and feedback reports for primary care professionals further reinforced the process [32]. Institution-level continuity of ambulatory care [33], standardized “self-care” programs [22], and patient-held health records [34] have also played pivotal roles in promoting seamless linkage to essential health care services among patients diagnosed with hypertension and diabetes.

**Treatment**

Various interventions have been explored to improve the treatment process for patients with hypertension and diabetes. Lifestyle interventions, including physical activity promotion and heart-healthy diets, have shown promise in improving treatment outcomes [35]. Collaborative care models involving pharmacists and physicians demonstrated positive effects on medication therapy management and overall patient care [36]. Self-monitoring of blood pressure is vital for facilitating appropriate treatment [37]. Additionally, interventions targeting medication affordability [38] and continuity of care [39-41,134] play crucial roles in ensuring optimal treatment adherence. Telehealth and digital interventions, such as continuous remote care and mobile health applications, are being explored for improved treatment accessibility and engagement [28,135]. Integrated care models, employing multidisciplinary teams and decision support tools, have yielded promising outcomes in coordinating comprehensive patient care [20,136]. Targeted education for patients and health care providers can effectively enhance communication and self-care skills [31,32]. Moreover, financial incentive programs, like pay-for-performance schemes, have encouraged optimal health care delivery and reimbursement [42].

**Medication Adherence**

A range of interventions has been investigated to optimize medication adherence in patients with hypertension and diabetes. Community-based interventions with patient education, recall services, and reduced out-of-pocket payments have shown promise in promoting adherence [43]. Self-measured blood pressure monitoring and chronic disease management programs in primary care settings facilitated continuous and comprehensive patient care [38,44]. Telephone peer coaching [27], regular general practitioner contact [30], and continuity of care initiatives [39,40,45,46,134] have also demonstrated positive effects on medication adherence. Collaborative care models, which involve patient-centered coordinated care, referral systems, and diabetes education, have yielded favorable results [47]. Additionally, interventions, such as medication co-payment schemes, enhanced counseling, and training for health care providers in communication skills, have reinforced medication adherence efforts [31,48]. Patient and provider engagement programs, along with pay-for-performance initiatives, have also incentivized optimal medication adherence [32,42]. Integrating pharmacists into multidisciplinary care teams has enhanced medication management and adherence [136].

**Control**

Interventions, including multidisciplinary collaboration, patient education, and technology integration, were adopted to enhance hypertension and diabetes control. The integration of pharmacists into care teams and the transition to specialized diabetes physicians can optimize disease management [49,50,136]. For instance, pharmacist-physician collaborative practice models have shown promise through features like shared medical records, defined interprofessional roles, frequent follow-ups, and collaborative practice agreements [50]. Structured educational programs, both for patients and primary care professionals, offer essential knowledge and support, such as tailored SMS text message communication and telephone peer coaching [27,51]. Patient health records and electronic decision support were used to improve the continuity of care and enable tailored interventions [34]. Additionally, integrated interventions like the EMPOWER-PAR program, grounded in the Chronic Care Model, made contributions to advancing disease control, even in the face of challenges related to health care system constraints [137].

**Barriers and Facilitators of Completing Different Stages of the Care Cascade**

In the completion of the hypertension and diabetes care cascade, several barriers and facilitators were identified, encompassing patient-level and system-level factors (Table 3). Patient-level barriers included factors like low socioeconomic status, unhealthy lifestyle choices, and limited health literacy, hindering effective management. Misconceptions about disease and treatment, high treatment costs, and fear of diagnosis also impeded the care progress. At the system level, inadequate resources, heavy workloads, limited capacity in primary care, and a fragmented health system were identified as significant obstacles to effective care.

  • System-level: Trust between physicians and patients [98] | • Patient-level: Characteristics of individuals: male sex [56], ethnic minority [20], and low health literacy [96]; Lack of access to medical care and medications [50]; Using nonoptimized doses of antihypertensive medications [65]; Experiencing adverse events associated with medications [65] |
| LMICs                | • Patient-level: High income [15,54,60,74], older age [19,72], marriage [10,54], fewer complications [65], and health insurance [19,39]; Healthy lifestyle: adopting dietary modifications or engaging in regular exercise [54,99]; Receiving long prescribed medications for hypertension and diabetes [71]; Belief in treatment efficacy and having family support [67]; Timely monitoring of blood pressure and blood glucose control [71]  
  • System-level: Adequate medications [84]; High physician density [75] | • Patient-level: Age ≥75 years [74], male sex [15,55,59,68,100], overweight [59,66,100], low income [55,60,67], specific occupations [66], and low education level [55,68]; Coexisting chronic conditions [68,97]; Living in rural or resource-limited areas [55,60]; Unhealthy lifestyle: smoking and alcohol consumption [66,97,100]; Lack of family/social support [57]; Limited awareness of the lifelong nature of the condition [67]; Complexity of the intervention [68]; Insufficient patient education about the importance of clinical management [67]; Poor communication of treatment monitoring results [67]  
  • System-level: Long waiting times at clinics [67]; Negative staff attitudes toward patients [67]; Weak monitoring schedules [67]; Lack of medical resources [84] |

^aHIC: high-income country.  
^bLMIC: low- and middle-income country.

Conversely, various patient-level facilitators positively impacted the cascade. At the patient level, characteristics like high socioeconomic status, positive health behaviors, and strong belief in treatment efficacy played vital roles. Furthermore, timely monitoring of blood pressure and glucose levels, engagement in health programs, and partner involvement were found to be associated with improved outcomes. System-level facilitators included a well-trained health workforce, existing chronic disease management programs, and improved access to medications.

Notably, certain barriers and facilitators were context-specific, with diverse prominence in HICs and LMICs. For instance, lack of understanding and misconceptions were more prevalent in LMICs, while the influence of cultural beliefs and minority status was more pronounced in HICs. Physician density and adequate resources were often noted as facilitators in HICs, while social support and tailored diabetes education were emphasized in LMICs.

**Discussion**

This scoping review identified a substantial body of literature investigating the hypertension and diabetes care cascade in both HICs and LMICs. While most studies provided descriptive snapshots of each cascade stage, only a limited number of studies applied implementation cascade analysis to explore the barriers and facilitators of patient retention. Furthermore, there was a paucity of studies evaluating the effects of interventions to bridge gaps between cascade stages. In addition to analyzing the characteristics of the included studies, this scoping review comprehensively summarized key interventions, facilitators, and barriers associated with completing cascade stages. These findings provide critical insights into the existing evidence on hypertension and diabetes management, offering valuable directions for enhancing health care delivery for these chronic conditions.

The results of this scoping review have revealed a notable gap in the existing literature concerning the entire continuum of all stages in the hypertension and diabetes care cascade. The majority of studies predominantly focused on treatment and control for both hypertension and diabetes care. There was a relative paucity of studies examining the stages before treatment initiation despite evidence suggesting that over 50% of patients with hypertension and diabetes who could benefit from treatment never start medication [3,72]. These pretreatment losses accounted for a much greater reduction in effective care than nonadherence to medication [101]. Modeling studies showed that treatment losses earlier on can result in a greater overall reduction in the public health benefit of hypertension management [142,143]. Potential gaps exist in identifying problems and developing strategies to improve awareness, screening, and diagnosis of the 2 diseases. Based on microsimulation modeling, it is estimated that scaling up diagnosis, treatment, and control of diabetes to achieve a hypothetical 80% target for each component of the care cascade would be highly cost-effective [143,144]. Regarding interventions to improve retention across cascade stages, the review emphasizes the importance of awareness campaigns and health education programs to improve patient retention in care and medication adherence. Moreover, interventions targeting the health system (ie, multidiscipline collaborative care, training for primary health care providers, and increasing access to medications) showed promise in improving diagnosis and treatment outcomes. Other innovations in hypertension and diabetes service delivery have been developed and could further enhance quality, but they require further study and proof of effectiveness at scale. Examples include electronic case record–based clinical decision support systems and telephone

Abstract

Background: COVID-19 screening is an effective nonpharmaceutical intervention for identifying infected individuals and interrupting viral transmission. However, questions have been raised regarding its effectiveness in controlling the spread of novel variants and its high socioeconomic costs. Therefore, the optimization of COVID-19 screening strategies has attracted great attention.

Objective: This review aims to summarize the evidence and provide a reference basis for the optimization of screening strategies for the prevention and control of COVID-19.

Methods: We applied a methodological framework for scoping reviews and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist. We conducted a scoping review of the present publications on the optimization of COVID-19 screening strategies. We searched the PubMed, Web of Science, and Elsevier ScienceDirect databases for publications up to December 31, 2022. English publications related to screening and testing strategies for COVID-19 were included. A data-charting form, jointly developed by 2 reviewers, was used for data extraction according to the optimization directions of the screening strategies.

Results: A total of 2770 unique publications were retrieved from the database search, and 95 abstracts were retained for full-text review. There were 62 studies included in the final review. We summarized the results in 4 major aspects: the screening population (people at various risk conditions such as different regions and occupations; 12/62, 19%), the timing of screening (when the target population is tested before travel or during an outbreak; 12/62, 19%), the frequency of screening (appropriate frequencies for outbreak prevention, outbreak response, or community transmission control; 6/62, 10%), and the screening and detection procedure (the choice of individual or pooled detection and optimization of the pooling approach; 35/62, 56%).

Conclusions: This review reveals gaps in the optimization of COVID-19 screening strategies and suggests that a number of factors such as prevalence, screening accuracy, effective allocation of resources, and feasibility of strategies should be carefully considered in the development of future screening strategies.

Introduction
SARS-CoV-2 has resulted in >500 million cases of COVID-19 worldwide, causing >6 million deaths, and continues to threaten human health [1,2]. The Omicron variant has become the most dominant variant in the current pandemic, and its insidious transmission makes community spread a big challenge [3,4]. For example, the large-scale Omicron outbreak in Shanghai between March and June 2022 resulted in >600,000 infections, and approximately 90% of them were asymptomatic [5]. The global spread of the pandemic has had a tremendous impact on the health of susceptible populations. In China, where the older adult population exceeds 26.4 million [6], the vulnerability of the older adults is heightened, despite the overall low mortality rate of the COVID-19 Omicron subvariant [5,7].

Symptom surveillance and voluntary nucleic acid testing were ineffective in response to the insidious transmission of the Omicron variant. Proactive screening of COVID-19 is essential to identify asymptomatic infections and break the transmission chain in a timely manner [8]. Under the dynamic zero policy [9], residents in epidemic areas received nucleic acid screening tests regularly, and the scope and frequency of the screening were dynamically adjusted in accordance with the epidemic trend. Antigen testing is used as a supplement to nucleic acid testing to improve the screening efficiency [10]. COVID-19 screening has become a basic prevention and control measure in countries worldwide, although the scope of screening varies [11]. Different strategies have been developed for the general population [10], international travelers [12], and high-risk populations [13].

COVID-19 screening is the rapid identification of potentially infected individuals by testing a massive population to take appropriate measures, such as isolating the patient, providing treatment, and conducting contact tracing. COVID-19 screening primarily involves nucleic acid and antigen tests. Nucleic acid screening relies on polymerase chain reaction (PCR) testing techniques and is the gold standard for the confirmation of infection [14,15], and the test includes 4 steps: sample collection, preservation, transportation, and testing [10]. The entire process is labor and resource intensive, and each step is important for test accuracy. Antigen screening uses different detection techniques, such as colloidal gold immunochromatography, latex methods, and fluorescence immunochromatography, allowing for quick and easy self-testing. However, antigen testing is less accurate and is often used as a supplement to nucleic acid testing [16,17].

To develop a COVID-19 screening strategy, the target population and the timing and frequency of screening should be considered. For mass nucleic acid testing, a pooled sample testing approach is often used to reduce costs and improve detection efficiency. Factors that influence the cost-effectiveness of outbreak control should also be considered when optimizing screening strategies. In this scoping review of published research, we aimed to summarize the evidence and provide a reference basis for the optimization of screening strategies for the prevention and control of COVID-19.

Methods
We followed the methodological framework proposed by Arksey and O’Malley [18] and reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) [19]. The PRISMA-ScR checklist is available in Multimedia Appendix 1 [19].

Search Strategy
The search strategy adopted in this review was ((test* OR screen* OR detect*) AND (polymerase chain reaction OR PCR OR nucleic acid OR antigen) AND (COVID* OR SARS-CoV* OR Omicron OR Severe Acute Respiratory Syndrome Coronavirus 2)) NOT (diagno* OR clinic* OR Gene* OR cell OR protein OR laboratory OR patholog*).

The words related to “testing or screening” were limited to the title field. The words related to “testing methods,” “COVID-19,” and “clinical diagnosis or laboratory process technology or pathology” were also limited to the title or abstract fields. PubMed, Web of Science, and Elsevier ScienceDirect were searched for studies published as of December 31, 2022. The reference lists of eligible studies were reviewed to identify additional studies.

Selection Criteria
The inclusion criteria were as follows: (1) the literature language was English, (2) the disease studied in the publication was COVID-19, and (3) the research articles were related to screening and testing strategies for COVID-19 infection.

The exclusion criteria were as follows: (1) articles not related to COVID-19, (2) duplicates, (3) articles that did not involve screening detection strategies, (4) clinical diagnosis or pathological research articles, (5) technical articles on laboratory testing or testing reagents, (6) environmental detection research articles, and (7) basic theoretical articles on COVID-19 detection techniques. YL and YY screened the literature by reviewing the titles and abstracts. The full-text review was performed by JS, J Hong, KL, and MD, and then, the filtered document was checked again by 1 of these coauthors. Any discrepancies were discussed by YL and YY (Textbox 1).

Data Abstraction
ZZ, YL, and YY determined which variables to extract, and the latter 2 developed and tested the data-charting form using Microsoft Excel. We abstracted data on the last name of the first author, research design, research population, optimization design, testing method, screening strategy, evaluation index, and recommendation. All authors participated in the data abstraction and reconfirmation of the abstraction. YL and YY charted the data, grouped the studies according to the optimization directions of the screening strategies, and summarized the findings.

Results
Overview of Included Studies
A total of 4290 publications were found by the searches conducted, of which 1536 were duplicates, and the titles of the remaining 2770 publications were screened for relevance (Figure 1). Subsequently, 476 abstracts were reviewed, and 95 publications received a full-text review. Finally, 62 publications were included in the synthesis (the data-charting form is available in Multimedia Appendix 2 [20-46]).

The study populations of the publications were the general population (36/62, 58%), travelers or immigrants (10/62, 16%), people in an organization (8/62, 12%, including workers, health care persons, and students), infected people (3/62, 5%), contacts or suspects (3/62, 5%), vaccinated population (1/62, 2%), and people at gathering activities (1/62, 2%). The optimization designs involved screening the population (12/62, 19%); timing (12/62, 19%); frequency (6/62, 10%); and testing procedure (35/62, 56%), including scenarios for adopting a pooling strategy (10/62, 16%), pool size (19/62, 31%), and pooling approach (18/62, 29%), as shown in Figure 2.
Figure 1. Flow diagram of the search and study selection process following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews.

4290 records identified through database screening:
- 1134 PubMed
- 1245 Elsevier ScienceDirect
- 1911 Web of Science

16 additional records identified through other sources

4306 records identified

1536 records left after duplicates were removed

2770 titles screened

2294 records excluded:
- 85 computed tomography or x-ray test studies
- 678 detection technology studies
- 70 pathogen or pathology studies
- 13 storage and transportation studies
- 77 environmental studies
- 142 observational studies
- 649 comparison or evaluation of detection technology studies
- 11 screening or detecting reviews
- 197 clinical or diagnosis studies
- 57 other disease studies
- 80 commentary and editorials
- 20 articles in other language
- 187 irrelevant research topic
- 28 vaccine studies

476 abstracts screened

381 records excluded
- 5 pathogen or pathology studies
- 19 technical methods and processes
- 81 evaluation of detection technology
- 26 studies of economic, cost, or resource
- 21 clinical studies
- 161 screening effectiveness evaluation
- 18 screening or detecting reviews
- 50 commentary and corrigendum

95 full-text articles assessed for eligibility

32 full-text articles excluded
- 12 screening effectiveness evaluation
- 13 detecting effectiveness evaluation
- 6 detecting technology studies
- 2 literature without peer review

62 total studies included in the scoping review
Optimization of Screening Population

**Screening of People With Different Infection Risks**

Previous studies tried to optimize screening strategies according to infection risk levels indicated by infection probability, contact with an infected person, probability of exposure, or presence of COVID-19 symptoms (Table 1). Du et al [20] simulated COVID-19 testing in populations with different severities of clinical symptoms and age groups and compared infection rates and false-positive rates among groups with different strategies. They found that in settings of high infection rate and limited testing capacity, a greater proportion of tests should be allocated to symptomatic individuals. Conversely, in a surveillance scenario characterized by a low infection rate and sufficient testing capacity, the optimal strategy, which involved directing a higher allocation of tests to people aged >50 years, only required 51.5% of available tests [20]. Likewise, the research by Han et al [21] supported that symptomatic testing at health care facilities was more beneficial than asymptomatic testing in the community, until most symptomatic individuals had been tested. It was also suggested that conducting additional tests to screen for asymptomatic infections among household members yielded the greatest benefit after fulfilling the demand for symptomatic testing [21]. Berestizhevsky et al [22] compared total morbidity, testing efficiency, and infection probability under screening strategies such as no testing and no isolation, symptom monitoring combined with random sampling testing, and symptom monitoring combined with “greedy” testing. Testing and quarantine among symptomatic populations using optimized sampling, which is based on community graphs and population risk factors, results in a 30% to 50% reduction in overall prevalence [22]. Kumar et al [23] compared the effectiveness and cost of outbreak control by weekly reverse transcription-PCR (RT-PCR) testing in 100% antigen-negative vaccinated individuals in a high-income country (the United States) and in a low-income country (India). They suggested that in regions with resource-limited vaccination strategies, high-frequency testing is still needed to minimize subsequent outbreaks [23].

### Screening of People in Different Regions

Table 1 also shows the results of optimizing screening strategies in different regions such as medium-risk or high-risk regions and domestic or foreign regions. Zhou et al [24] compared the total number of infections and daily nucleic acid test loads among the screening strategies and found that the optimal strategy was to test people from medium- and high-risk areas using nucleic acid tests before they traveled. Wong et al [25] assessed infections based on attendance at an event by applying different strategies: no testing and quarantine in all areas, quarantine of attendees from foreign areas, testing of attendees from mainland China, and testing of all attendees at the event. They found that the strategies of quarantining the attendees from foreign areas and testing all (foreign or local) attendees were effective in controlling the number of infections, and they estimated that the total number of new infections was only 1% higher than the current local prevalence [25]. Baik et al [26] simulated the effectiveness of outbreak control in regions with limited resources, such as low- and middle-income countries.
They evaluated 3 screening strategies: using PCR to test symptomatic patients in outpatient settings, community-based screening with rapid antigen tests (RATs), and symptom-driven outpatient diagnostic testing using RATs. This showed that RATs would reduce transmission most efficiently when used to test symptomatic individuals in outpatient settings, and to avoid large numbers of unnecessary isolations, mass testing with lateral flow tests (LFTs) should be considered as a screening tool [26].

**Screening of Occupational Populations and Students**

COVID-19 screening strategies were assessed and optimized for some specific student and occupational populations (Table 1). Sandmann et al [27] compared the number of infections, number of tests, and duration of isolation between individuals with and without COVID-19 symptoms living in worker dormitories. Testing all the workers was associated with a reduced transmission of approximately 67 individuals per 1000 tests. However, screening workers with COVID-19-like symptoms in isolation only was associated with a higher risk of transmission in the workplace compared with the strategy of screening all workers [27]. Zipfel et al [28] simulated transmission in health care workers using 2 strategies: testing all when positive cases were detected and testing all periodically at predetermined intervals from 1 day to 7 days. The study showed that 38% of hospital-based transmission could be prevented if all staff were tested within 1 day when a positive case occurred, whereas 30% to 78% of transmission could be prevented if daily testing was performed [28].

Van Pelt et al [29] analyzed the number of RT-PCR tests required to identify each true-positive case and the true-positive rate in a student population using strategies such as symptom screening only, nucleic acid test screening of symptomatic students, and nucleic acid test screening of all students. Conducting RT-PCR testing for all students and retesting those with initially negative results can effectively identify cases with a correct rate of 86.9% [29]. Leng et al [30] further classified the student population by age and simulated the implementation of daily mass screening or screening after the occurrence of positive cases. The study found that mass antigen screening among students significantly reduced the likelihood of not attending class but often required a large number of tests [30]. Similarly, Colosi et al [31] analyzed strategies such as routine testing, symptom-based testing, screening, and quarantine when a positive case was detected and found that weekly testing of 75% of unvaccinated students would reduce the number of cases by 34% in primary schools and 36% in secondary schools.

**Optimization of Timing of Screening**

**Timing of Screening for Travelers**

To address the risk of outbreak caused by population movement, researchers compared the timing of screening of traveling people (eg, before, during, and after travel; Table 1). Chowell et al [32] simulated the impact of testing at different times before and after boarding a cruise ship on the cumulative number of infected cases. The study found that testing before boarding, daily testing on board, and maintaining social distancing significantly reduced the possibility of onboard transmission [32]. Johansson et al [33] found that PCR testing on the day of departure and isolation at the destination reduced the risk of transmission. Testing on the day of departure reduced the risk of transmission when traveling by 44% to 72% [33]. Steyn et al [34] assessed the transmission potential of SARS-CoV-2 and the number of infections by simulating PCR or LFT screening at different times, such as the day before departure, the day after arrival at the destination, and the fourth and fifth days after arrival. It was found that the combination of testing and home isolation could reduce the risk of community outbreaks to approximately 0.01, and using daily LFTs or a combination of LFTs and PCR testing could reduce the risk to levels comparable with or lower than those using PCR testing alone [34]. Kiang et al [35] evaluated the cumulative number of days of infection and the number of infections when travelers used PCR or antigen testing at timings such as 3 days before departure, the day of departure, and 5 days after arrival at the destination. The results indicated that nucleic acid testing 3 days before departure reduced the risk of infection during the travel, and the cumulative number of infection days was reduced from 8357 to 5401 days [35]. Jen et al [36] compared the morbidity, missed tests, and proportion of asymptomatic and presymptomatic individuals in travelers with different strategies such as PCR testing on arrival and quarantine for 5 days and quarantine for 14 days without testing. It was found that >82% of the cases would progress from the presymptomatic phase to the symptomatic phase during the 5-day quarantine period, and the quarantine time with 2 PCR tests depended on the risk, testing and quarantine strategy, and vaccination status of the country of departure [36]. On the basis of previous screening strategies for travelers, Lee et al [37] analyzed transmission potential, infection rates, and subsequent infections for strategies such as testing before traveling, after arrival, or at the end of quarantine and 14 days of quarantine without testing, with a consideration of vaccination factors. It was found that at an incidence rate of 0.4 and a time-dependent reproduction number of 16, testing with a sensitivity of ≥98% and specificity of ≥97% both before traveling and on arrival ensured lower expected transmission in vaccinated than unvaccinated individuals with a quarantine of 14 days [37]. For entry-exit pandemic prevention, Dickens et al [38] analyzed the number of unidentified infected persons using the strategies of isolation only; predetection combining entry testing and isolation; and predetection combining entry testing, isolation, and daily testing. The results showed that the risk of transmission was greatly reduced by adopting predetection, which combined entry testing and isolation. During the isolation period, if an RAT was performed every 3 days, only 3% of the infected individuals were unidentified at 7 days and 0.7% at 14 days [38].

**Screening Timing in Response to an Outbreak**

When an outbreak occurs, the appropriate timing of screening facilitates the identification of infected individuals and helps control the spread of the disease. Several studies have explored the impact of different screening timings on the spread of the pandemic (Table 1). Quilty et al [39] compared the impact of daily antigen testing of close contacts over 1, 3, 5, 7, 10, or 14 days on the spread of the epidemic. It showed that quarantining for 7 days with an antigen testing on the last day or daily antigen
testing for 5 consecutive days without quarantine was effective in reducing the potential for secondary cases [39]. Wells et al [40] evaluated the impact of screening timing, such as at the start or end of isolation and during the period of isolation, on the risk of continued transmission after isolation. It was suggested that PCR testing at the start and end of isolation could reduce the risk of continuous transmission and shorten the isolation period from 14 days to 7 days. However, testing only at the start of isolation had no notable effect on reducing the risk of transmission and shortening the isolation period [40]. Fonseca et al [41] simulated the screening of close contacts at different timing, such as days 1, 2, and 3 after exposure to an infector, and compared the expected days of infection during outbreaks. This suggested that antigen testing should be performed on days 1 and 3 for epidemic prevention and control. Two tests were sufficient to effectively prevent infection, and the effectiveness was equivalent to a 14-day isolation period when personnel compliance was 80% to 90%. If an additional test (PCR or antigen) was performed, it was equivalent to the 14-day isolation period effectiveness when personnel compliance was 90% to 100% [41]. Peng et al [42] conducted a similar study to assess the risk of spread after the end of the quarantine period for PCR testing at different timings, such as the days 1, 2, 4, 5 and 6 during the quarantine period. The results showed that PCR or antigen testing at different timings reduced the quarantine period to different degrees without increasing the risk of transmission. Combining testing with shorter quarantine periods is more cost-effective in terms of both time and expenses compared with a 14-day quarantine. For instance, using 3 highly sensitive RT-PCR tests along with a 6-day quarantine yielded a similar risk of transmission as the traditional 14-day quarantine [42].

Optimization of Screening Frequency

Screening frequency should maximize the effectiveness of screening testing and minimize the related costs. Studies on the impact of different screening frequencies on COVID-19 control in communities or high-density populations are also presented in Table 1. Kahanec et al [43] found that 14 days after 2 rounds of mass nucleic acid testing, the infection rate decreased by approximately 30% and the basic reproductive number decreased by approximately 0.3. In a simulation study, Koo et al [44] found that the influence of the test frequency was greater than the maximum test sensitivity (range 0.6-0.8) on the number of infections. The average reduction in infections per day between the 2 testing days was 2.2%, whereas each 1% increase in test frequency reduced infections by an average of 0.43% [44]. Baker et al [45] found that if the number of screening tests per day was slightly higher than the daily testing capacity, it would not cause a burden on testing, but more cases could be found and transmission could be reduced more effectively. Koo et al [46] assessed the impact of biweekly PCR tests or weekly RATs on the number of new infections and infectivity in areas with a high population density (such as workers’ dormitories) and found that biweekly PCR testing (39 new cases per month) was as effective as weekly RATs (33 new cases per month) and could prevent local outbreaks.

Optimization of Screening Procedure

The Importance of the Implementation of the Pooling Strategy

Given the huge demand for sampling and testing, it is important to optimize the screening procedure, and the pooling strategy (ie, collecting multiple samples in a pool for testing) has been frequently used. For example, the National Health Commission of China and the Centers for Disease Control and Prevention of America have issued guidelines for pooled sample tests [47,48]. Three issues related to the pooling strategy have been studied: scenarios for adopting the pooling strategy, pool size, and test procedure.

Scenarios for Adopting a Pooling Strategy

In general, the decision to adopt a pooling strategy is determined by comparing the average number of pool tests per person with a baseline number of 1 (Multimedia Appendix 3 [49-83]). A study demonstrated that when the prevalence exceeded 0.1, the average number of tests per person was >1 for pooled testing with a pool size of 32; such pooled testing was no better than the individual test [49]. The average number of tests per person varied with the pool size. Choosing an optimal pool size can minimize the average number of tests per person. In this case, when the prevalence was <0.07, the pooling strategy could save the need to perform more than half of the tests. When the prevalence was close to or >0.3, the number of pooled tests was close to or exceeded that of the individual test [50]. A prevalence of 0.3 may be considered as the threshold for performing pooled testing.

Pool Size

The optimal pool size can be calculated based on expected positive rate and detection accuracy with the objective of minimizing the number of tests, and the number of tests decreases with decreasing prevalence and increasing pool size. If the accuracy was 100% and the prevalence was 0.001, 0.005, or 0.01, the optimal pool sizes were estimated to be 32, 15, and 10, respectively [51]. There is a certain upper threshold value for the pool size that is limited by testing accuracy (Multimedia Appendix 3).

To estimate the optimal pool size, the prevalence (positivity rate or infection rate) must be assumed. It is also assumed that all individuals are independent of each other, and that the probability of infection is uniform. However, in practice, the prevalence remains unknown until the test results are available (Multimedia Appendix 3). Pikovski and Bentele [52] considered the prevalence to be a random variable uniformly distributed between the expected maximum and minimum values substituted in the calculation of the optimal pool size. An optimal pool size of 4, 3, or 5 was acceptable when the prevalence was uniformly distributed between 0 and 0.3 [52]. In addition, there is heterogeneity and correlation in the probability of infection among people. Fewer tests are needed when individuals in the same pool for testing are homogeneous in terms of age, sex, and other risk characteristics [53-55]. Libin et al [56] considered that combining pools with several families for testing was more conducive to home isolation. The propagation dynamics simulation found that a family-based pool size of 32 and testing
volume of 50,000 per day could achieve the weekly testing of the entire population in Belgium [56]. A larger optimal pool size is required considering the correlation of individuals in the pool [57], or even the social graph [58], in which an edge represents frequent social contacts between 2 persons. Furthermore, Augenblick et al [59] showed that if the pool size could be adjusted to be optimal with the infection rate at any time, screening with a high testing frequency could quickly reduce the infection rate. The final number of tests may decrease despite the high testing frequency owing to the increasing optimal pool size, that is, “frequency gain” [59].

Test accuracy, including screening sensitivity and specificity, also affects the optimal pool size and the upper limit of the pool size. Bish et al [60] found that the optimal pool size would modestly increase when the sensitivity of the pooled sample test decreased. In the PCR test, the sensitivity would decrease and the specificity would increase in a pooled sample test owing to the dilution effect [61], which needs to be considered in the calculation of the optimal pool size [62]. The maximum pool size recommended in previous studies varies from 8 to 30 [63-65]. The sensitivity of the individual test and the influence of the dilution effect of pooling on sensitivity are related to the specific techniques of sampling and testing (such as sampling tools, sample processing reagents, detection instruments, and standardization of operation); therefore, test accuracy is an important determinant for the selection of pool size.

**Pooling Approach**

For the original Dorfman pooling approach, each individual in a positive pool is tested separately. If a pooled sample is negative, then all individuals in the pool are regarded as negative. Several suggestions were made to optimize the pooling approach, which are summarized in Table 2.

First, sequential pooling may be used. A positive pool is divided into several subpools, and the samples in the positive subpools are tested individually [55,66]. Binary pooling divides people to be screened into 2 pools, and the positive pool is divided and pooled again until all positive individuals are found [67]. In the nested pooling strategy, the samples in a positive pool are divided into smaller pools with an optimal number of stages, and the optimal pool size of each stage is calculated according to various measures such as the predicted number of positives and time limit [68,69]. Ng et al [70] conducted simulations of a household-based sequential pooling approach to optimize a universal testing scheme in Hong Kong. They showed that the household-based sequential pooling approach could rapidly screen people in high-risk groups for COVID-19 infections and quarantine those who tested positive [70]. Although these approaches reduce the number of tests required, the operability of such strategies for time-critical epidemic control should be carefully assessed.

Second, repeated testing of the same pool of samples may be conducted to reduce false negatives of the pooled test [71]. Litvak et al [72] conducted a second pooled test after reordering and recombining the samples in the negative pools. For the sequential pooled test, some researchers allocated a part of the samples to 2 subpools to improve accuracy [73].

Third, a copy-link optimization strategy may be used to accurately link the results of the pooled test to the individuals in the pool. The primary “copy-link” strategy is matrix pooling [84]. Samples are arranged in the form of a matrix, with each row and column forming a pool, and each sample is tested once in the row pool and once in the column pool. Research on matrix pooling for COVID-19 has only mathematically simulated the number of tests and the accuracy of the pooled sample test. The Dorfman pool test may be more economical when the prevalence is extremely low, whereas matrix pooling may be more economical when the prevalence is relatively high [74]. Zilinskas et al [75] broadened the concept of matrices by dividing each sample into 2 pools to create as many links as possible between pools. Zhou and Zhou [76] applied the copy-link strategy in designing the Pentagram minipool test. Mutesa et al [77] expanded the 2D matrix to a 3D or multidimensional hypercube, where the number of copies of each sample was split into different planar slices of the hypercube. The subsamples on 1 planar slice of the hypercube were tested in a pool together. Investigators have demonstrated the feasibility of this “hypercube testing strategy” in the laboratory, and field trials are underway in Rwanda and South Africa [77]. Wu et al [78] improved the current hypercube testing strategy by calculating the prevalence, edge, and dimension because every edge had a best performance range, and hypercube pooling with edge=3 may not be the optimal strategy in different outbreaks. Daon et al [79] used a Bayesian model to determine the best combination of pool size, detection steps, repeat detection, and split sample detection to maximize the mutual information between the infection status and testing results. However, this is limited to a simulation analysis.
Table 2. Research on optimization of pooling approach in COVID-19 screening strategy.

Discussion

Principal Findings

Despite ongoing vaccinations worldwide, COVID-19 is still present and causing outbreaks, and screening remains important. First, SARS-CoV-2 has the potential to mutate, and the transmissibility, pathogenicity, and incubation period of the novel variant remain unknown. Screening facilitates the surveillance and tracking of SARS-CoV-2 novel variants, providing essential information for an appropriate response. In addition, screening helps protect vulnerable populations and reduce the pressure on the health care system. Therefore, the continuous optimization of screening strategies to improve cost-effectiveness and reduce resource consumption is still worthy of our attention in the current global situation of relaxed prevention and control. Furthermore, the development of strategies for screening COVID-19 provides a basis for the prevention and control of novel or re-emerging infectious diseases in the future, particularly respiratory infectious diseases.

In previous studies, researchers have been optimizing the screening strategy for COVID-19 based on the target population, timing, frequency of screening, and testing procedure and providing a scientific basis for COVID-19 screening. Specific strategies are designed and developed for different populations according to risk levels, regions, or occupations; different timing and frequencies (eg, before, during, and after traveling or entry and exit); and different testing procedures (eg, individual or pooled test, pool size, and polling approaches). The conceptual model for developing screening strategies is available in Multimedia Appendix 4. As there is a continuous emergence of new variants of SARS-CoV-2, further research is necessary to improve the current screening strategy by addressing the issues on the scale of screening, proper timing and frequency of testing, testing accuracy, and cost-effectiveness.

Dynamic Adjustment of Screening Strategies Based on Variations in Prevalence

The design and optimization of any screening strategy are based on disease prevalence during an epidemic as a hypothetical
condition. This determines the strictness of the screening strategy, including the screening frequency, time interval, target population, and testing procedures. For example, the selection of pool size in pooled testing depends on the prior prevalence. To apply the optimization plan in practice, the information on real prevalence is important for determining the screening plan at a specific time in a specific area, which may be obtained from the screening results at the same time. Nicholson et al. [85], Hamadeh et al. [86], and Chiu and Ndeffo-Mbah [87] explicitly estimated the real prevalence by statistically correcting the reported data, which can be used in the research and practice of optimizing and adjusting screening strategies over time. Additionally, pandemics are constantly evolving. Screening results can help policy makers and researchers understand current risk levels and trends as well as reflect past screening effects. A feedback mechanism should be created to dynamically adjust the screening strategy according to the screening results. When the number of cases increases rapidly, the stringency of screening should be increased to prevent a larger pandemic outbreak. For example, Yu et al. [82] set several alternative pool sizes and updated the pool size within an alternative range every week according to the changes in prevalence in a simulation study. A dynamic screening plan should be relatively stable, easy to implement, and adaptable to the changing trend of an epidemic or outbreak.

**Optimizing Screening Strategies by Combining Multiple Testing Methods**

Various testing methods have been developed. Some methods are more appropriate than others for different screening processes. Self-detection, such as the use of antigen tests, has been widely promoted. As a supplement to laboratory detection methods, such as PCR, it can effectively save the resources of medical workers for sampling and testing. It has been applied for the screening of both small and large populations. However, the accuracy of the current antigen test is lower than that of the PCR test, with an overall sensitivity of approximately 70% and a specificity of approximately 98%, and its accuracy for asymptomatic patients is lower than that for symptomatic patients [88]. Moreover, there are no guaranteed standardization of sampling for self-detection and compliance with self-isolation after diagnosis. Self-detection is often an alternative when professional testing capabilities are insufficient, and self-detection and laboratory testing complement each other. A few studies have compared laboratory tests with self-tests or combined antigen tests with PCR tests [35,38,39,42,46,86]. Yu et al. [82] found that the PCR pooled test tended to be more cost-effective at low prevalence because it allows more people to be tested with existing equipment and quarantines more patients with presymptomatic and asymptomatic infections to prevent future infections. However, a pooled PCR test would cause delays in results and would not facilitate timely quarantine of infected persons and interrupt transmission at a high prevalence. In contrast, high-frequency antigen screening may reverse the epidemic to obtain results quickly and quarantine infected people in a timely manner, despite the large number of false positives in the screening process [82]. Although the sensitivity of the PCR pooled test may be higher than that of the RAT, there is a problem with a large number of tests leading to delays in reporting. RATs are particularly useful in settings such as schools, workplaces, and mass gatherings with a high frequency owing to their characteristics of lower cost, rapid time to result, and increased accessibility. A combination of laboratory testing and self-detection may maximize the benefit under limited resources, which needs to be studied in the future.

**Accuracy of Screening Test**

Whether an infected person can be identified depends on their infection status after exposure because viral nucleic acid, antigen, antibody, and other biomarkers change with infection time. The accuracy of testing results may also change with time. These characteristics can help in the selection of the appropriate timing for screening and quarantine of close contacts and entry-exit persons with a definite exposure time [39].

Screening accuracy is affected by sampling quality and detection accuracy. In China, sampling quality is monitored based on whether human somatic cells are collected from the swab as a laboratory indicator [89]. As the dilution effect caused by pooling is likely to reduce test sensitivity, it is crucial to consider PCR testing with optimal sensitivity and the maximum pool size. The sensitivity may be affected by the sample handling method, selection of the detection kit, and standardization of the detection operation [90]. The accuracy of screening should be evaluated when designing pooling strategies, which is conducive to the selection of pool size and the credibility of the screening results.

**Optimization of PCR Testing Procedures to Improve Detection Capacity**

Optimizing the nucleic acid detection procedure for the pooled sample test using various approaches reduces the number of tests performed and increases the detection speed and capacity, which can improve the speed of obtaining results for quarantine-infected individuals. The primary Dorfman procedure has been implemented during COVID-19 screening in some areas owing to its convenience and operability. The pool size when screening the entire population in China was 5, 10, or 20 [48,91], and the US Food and Drug Administration authorized 5 pool tests with pool sizes ranging from 3 to 10 [47]. The optimal selection and dynamic adjustment scheme of the pool size need to be in accordance with the actual prevalence and detection accuracy. The pooling procedure has been improved using a multistage strategy and “copy-link” strategies for higher detection efficiency [81]. The multistage strategy reduces the number of tests while simultaneously increasing the number of test rounds. The turnaround time from sampling to result reporting may increase, but its operability has not yet been investigated. The “copy-link” strategy not only reduces the amount of testing but also requires only 1 testing stage to locate positive individuals. However, for this strategy, the laboratory requires more complex testing procedures and equipment. It is not feasible to apply “copy-link” strategy to an existing laboratory platform.

**Accurately Define the Scope of Screening Individuals**

A screening strategy for the whole population can effectively control the outbreak, but it also has a significant impact on health care resources and delays the time of transferring cases.
and contacts to quarantine [45]. Therefore, the occurrence of cases does not imply the need for screening the entire population. In China’s dynamic zero policy, screening of the entire population of an area is often initiated in the early stage of an outbreak and interrupts the spread of COVID-19 [92]. However, there is a lack of research on when and under what circumstances a full screening should be initiated, and whether specific thresholds for the number of cases or incidence are necessary in the decision-making process. High-risk populations are usually targeted for screening such as people from high-risk areas or countries or people with special occupations. Screening helps to isolate infectious sources to prevent COVID-19 outbreaks [93].

Consider the Implementability of Screening Strategies

Previous studies on the optimization of screening strategies have mainly focused on how to control an epidemic, reduce the risk of transmission, and shorten the isolation period. However, the design and implementation of screening strategies depend on the resources available, which vary greatly among countries or regions. A large-scale screening program is costly and may not only be sustainable owing to limited resources.

Larremore et al [94] raised the meaningful problem of whether the frequency of testing, time to obtaining results, or sensitivity is more important in new crown screening. Their study revealed that effective testing depends largely on the frequency of testing and the speed of obtaining results, whereas the sensitivity of the test is relatively secondary [94]. This means that the implementation of relatively low-sensitivity PCR pooled tests or antigenic tests can improve the speed of obtaining results, facilitate quarantine of infected individuals, and interrupt transmission. This may be appropriate in areas with high prevalence.

Methods of Comparing Different Screening Strategy

When searching for an appropriate screening strategy, the most commonly used method involved using model simulations to evaluate the effectiveness of different screening strategies. For the selection of models to compare different screening strategies, the appropriate model should be based on different situations, populations, and purposes. In addition, real-world disease data are always available during the pandemic, but very few studies have evaluated the effectiveness of different screening strategies from the perspective of real-world data. The conclusions of evaluating the effectiveness of screening strategies using real-world data are more realistic. Model simulations enable a convenient comparison of the effectiveness of different screening strategies for different situations, but they are based on a hypothetical theoretical setting. Furthermore, if the results from the model simulations can be validated using real-world data, the findings of these studies will be more reliable.

Regarding the comparison of different screening strategies, which is the best strategy depends on the actual situation. The selection of a screening strategy in realistic scenarios requires a balanced consideration of the economic costs and effectiveness of controlling the outbreak. Only a few studies reviewed in this paper analyzed cost-effectiveness in a cursory manner; for example, the simple indexes such as cost per test [74] or cost per infection reduced [82] were used. Furthermore, attention should also be paid to resource consumption, such as medical resources (eg, hospital beds) and quarantine resources (eg, hotel rooms), which determine the feasibility and sustainability of the strategy [95].

Limitations

First, we restricted studies to those publications in English and did not search gray literature and might have missed relevant studies published in other languages and in non-peer-reviewed journals and conference proceedings. Second, we restricted the search terms to the title or abstract field and might have excluded some studies that included the search terms as Medical Subject Headings terms or free text. Third, we did not perform duplicate screening of publications owing to time limitations. However, data extraction was performed by 9 investigators from our team, and 2 investigators in cooperation conducted quality assessments (YL and YY) to ensure consistency. Finally, most publications in this review were simulation studies using mathematical models, which lack accepted criteria for quality evaluation; therefore, literature quality assessments were not performed.

Conclusions

A well-designed and developed COVID-19 screening strategy is conducive to the rapid identification of infected individuals and the control of an epidemic. As new variants continue to emerge, screening strategies should be dynamically adjusted and optimized to achieve expected results. To identify and isolate infected individuals in a timely manner, a screening strategy must produce fast and accurate results. A program is sustainable only when costs can be controlled at the level of available resources. Some key elements for COVID-19 screening strategies are reviewed and discussed, including the screening population, timing and frequency of screening, detection methods, and procedures.

Abstract

Background: The COVID-19 pandemic has prompted the deployment of digital technologies for public health surveillance globally. The rapid development and use of these technologies have curtailed opportunities to fully consider their potential impacts (eg, for human rights, civil liberties, privacy, and marginalization of vulnerable groups).

Objective: We conducted a scoping review of peer-reviewed and gray literature to identify the types and applications of digital technologies used for surveillance during the COVID-19 pandemic and the predicted and witnessed consequences of digital surveillance.

Methods: Our methodology was informed by the 5-stage methodological framework to guide scoping reviews: identifying the research question; identifying relevant studies; study selection; charting the data; and collating, summarizing, and reporting the findings. We conducted a search of peer-reviewed and gray literature published between December 1, 2019, and December 31, 2020. We focused on the first year of the pandemic to provide a snapshot of the questions, concerns, findings, and discussions emerging from peer-reviewed and gray literature during this pivotal first year of the pandemic. Our review followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) reporting guidelines.
Results: We reviewed a total of 147 peer-reviewed and 79 gray literature publications. Based on our analysis of these publications, we identified a total of 90 countries and regions where digital technologies were used for public health surveillance during the COVID-19 pandemic. Some of the most frequently used technologies included mobile phone apps, location-tracking technologies, drones, temperature-scanning technologies, and wearable devices. We also found that the literature raised concerns regarding the implications of digital surveillance in relation to data security and privacy, function creep and mission creep, private sector involvement in surveillance, human rights, civil liberties, and impacts on marginalized groups. Finally, we identified recommendations for ethical digital technology design and use, including proportionality, transparency, purpose limitation, protecting privacy and security, and accountability.

Conclusions: A wide range of digital technologies was used worldwide to support public health surveillance during the COVID-19 pandemic. The findings of our analysis highlight the importance of considering short- and long-term consequences of digital surveillance not only during the COVID-19 pandemic but also for future public health crises. These findings also demonstrate the ways in which digital surveillance has rendered visible the shifting and blurred boundaries between public health surveillance and other forms of surveillance, particularly given the ubiquitous nature of digital surveillance.

KEYWORDS
digital surveillance; COVID-19; public health; scoping review; pandemic; digital technologies

Introduction

Public health surveillance has been described as one of the most critical functions and mechanisms of public health [1]. With a history dating back to Snow’s pioneering investigations into cholera epidemics in England in the 19th century, surveillance has long been leveraged as a tool for meeting the objectives of public health, including population health assessment, health surveillance, health promotion, disease and injury prevention, and health protection [1]. The Centers for Disease Control and Prevention describe public health surveillance as “the ongoing, systematic collection, analysis, and interpretation of health-related data essential to planning, implementation, and evaluation of public health practice” [2]. Other definitions include the World Health Organization’s conceptualization of surveillance as continued watchfulness and the monitoring of events linked to action [3]. More broadly, Lyon [4] has defined surveillance as “the focused, systematic, and routine attention to personal details for purposes of influence, management, protection or direction.”

One of the outcomes of the COVID-19 pandemic and the corresponding global response has been the rapid development and deployment of digital technologies used for public health surveillance. New and existing digital technologies, including mobile phone location tracking, mobile phone apps, drones, and closed-circuit cameras, have been used for surveillance purposes in supporting the detection and mitigation of disease spread and to enhance compliance with public health measures [5]. The accelerated use of these technologies during the COVID-19 pandemic has led to some scholars describing the COVID-19 pandemic as the first public health crisis of the “digital age” [6] and as a catalyst for a “digital revolution” in surveillance [7].

Despite the extensive use of a plethora of digital solutions for public health surveillance, their actual efficacy in predicting disease spread or supporting public health responses has been unclear [8,9], and there remain ongoing questions about the ethical dimensions of digital surveillance. For instance, the use of digital tools by the state, its agents, the private sector, and other actors has raised concerns around the potential consequences of surveillance, particularly for those who are most marginalized [10-12]. The rapid pace of technological development has also limited opportunities to consider the consequences of technology use or misuse and whether digital technologies are actually effective in mitigating the health-related, economic, and social effects of the pandemic [13].

The growing attention paid to digital surveillance during the COVID-19 pandemic has also offered an important opportunity to reflect on the function of surveillance within public health. For instance, the ubiquitous nature of contemporary modes of data collection enabled by digital surveillance technologies has prompted a reconsideration of pervasive health monitoring [14]. The collection of large amounts of data from sources that have not traditionally fallen within the purview of public health surveillance (eg, transaction monitoring, closed-circuit cameras, drones, and location tracking through mobile devices) presents an urgent need to contend with the consequences of surveillance and the potentially invasive and coercive aspects of public health. Likewise, the use of digital surveillance technologies by a range of actors and for a variety of different objectives throughout the COVID-19 pandemic signals an important opportunity to consider the blurred boundaries between public health surveillance and other forms of surveillance (eg, criminal–legal surveillance, commercial use of data) and how these modes of surveillance and their aims overlap.

This scoping review examined peer-reviewed and gray literature on the global use of digital technologies for public health surveillance during the COVID-19 pandemic to (1) describe the nature of digital technologies used for surveillance during the COVID-19 pandemic, (2) describe the witnessed and potential short- and long-term implications of using digital technologies for public health surveillance, (3) synthesize the peer-reviewed and gray literature regarding the use of such technologies for surveillance during the COVID-19 pandemic.

(page number not for citation purposes)
response, and (4) identify gaps within this knowledge base. To meet these objectives, the review was guided by two research questions: (1) What is known about digital technologies used for surveillance during the COVID-19 pandemic? and (2) What are the short- and long-term predicted and witnessed impacts of digital surveillance during the COVID-19 pandemic?

Methods

Study Design
The protocol used to conduct this research followed the 5-stage methodology described by Arksey and O’Malley [15] and Levac et al [16], which included (1) identifying the research question; (2) identifying relevant studies; (3) study selection; (4) charting the data; and (5) collating, summarizing, and reporting the findings. A summary of the study’s methodology is included below; for a complete description, refer to a previously published scoping review protocol [17]. The study’s reporting structure also conformed to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines and checklist (Multimedia Appendix 1 [18]) [19].

Data Collection

Peer-Reviewed Literature Search
In January and February 2021, the MEDLINE (Ovid), PubMed, Scopus, CINAHL, ACM Digital Library, Google Scholar, and IEEE Xplore databases were searched for peer-reviewed literature. Journals and reference lists of relevant papers identified by our interdisciplinary team of researchers were also reviewed for additional publications. Textbox 1 shows the search terms and strategy created with guidance from a specialist research librarian.

Textbox 1. Search terms developed with the assistance of a health specialist research librarian.

1. Population Surveillance or Public Health Surveillance, or surveillance.tw.
2. digital surveillance.tw.
3. biosurveillance.tw or Biosurveillance
4. epidemiological monitoring.tw. or Epidemiological monitoring
5. 1 or 2 or 3 or 4
6. pandemic.t.w. or Pandemics
7. disease outbreak.tw. or Disease Outbreaks
10. H1N1.t.w.
11. SARS.t.w. or SARS Virus
12. 6 or 7 or 8 or 9 or 10 or 11
13. Public Health or public health application.mp.
14. 5 and 12
15. 13 and 14

An initial broad search was conducted to capture all English-language publications on the use of digital technologies for public health surveillance during previous and current pandemics, epidemics, and outbreaks. Documents were retained if they were published between January 1 and December 31, 2020. This preliminary search yielded 18,449 publications for review. Following the removal of 8819 duplicates, 9630 unique documents were subjected to title and abstract screening by 2 researchers (LC and MND) to assess their fit with the study’s aims. In this initial search, the following inclusion and exclusion criteria were used during the title and abstract screening: (1) document title or abstract mentioned the use of a digital technology for public health surveillance, (2) digital surveillance focused on containing or limiting the spread of an infectious disease, (3) public health surveillance monitored humans rather than nonhuman animals, and (4) digital technology used explicitly for surveillance (eg, data collection).

Consequently, 2076 publications were retained for full review following title and abstract screening. Following a full-text review, 888 publications were retained for analysis.

To conduct a feasible review of the literature, the research team narrowed the scope of the review to focus on COVID-19-pandemic–specific apps of digital technologies for public health surveillance. During this secondary screening, documents were retained for analysis if they were published between December 1, 2019 and December 31, 2020, and if they explicitly included any of the terms such as “coronavirus,” “COVID 19,” “SARS-CoV-2,” or “severe acute respiratory syndrome coronavirus 2” in the title or the abstract. This period was chosen not only to obtain a manageable number of publications for review but also to focus our attention on the first year of the COVID-19 pandemic as a means of better understanding the questions, concerns, findings, and discussions that emerged from the academic and nonacademic literature during this pivotal time. This process led to a final study sample...
size of 147 unique documents. Throughout this process, in cases in which the 2 screening researchers disagreed or were uncertain whether a publication met the inclusion criteria, a third researcher read the text and discussed with the 2 researchers to decide whether to include the document for analysis.

**Gray Literature Search**

Our search of the gray literature was guided by our multidisciplinary team of researchers as well as a specialist research librarian, who assisted in identifying relevant organizational websites that explore the use of digital technologies for surveillance. These websites included the Ada Lovelace Institute, Human Rights Watch, and the Munk School. The websites of these organizations were searched to retrieve potentially relevant current and archived publications using the same protocol and search terms used to search peer-reviewed literature. Publications were retained for screening if their content related to the use of digital technologies for surveillance during the COVID-19 pandemic. The initial search of the gray literature yielded 141 documents.

Gray literature publications were screened using the same inclusion criteria used to screen peer-reviewed literature. After 2 rounds of screening, 74 documents were retained for analysis. Five conference proceedings identified while searching the peer-reviewed literature were also included as gray literature for a total of 79 publications.

Due to the breadth and depth of the literature relevant to this review, attention to the social and ethical implications of digital health surveillance for public health purposes during the COVID-19 pandemic response is the focus of this scoping review. A second paper describes the types of digital technologies used during the COVID-19 pandemic response and the factors impacting their effectiveness in public health surveillance [8]. Figure 1 shows the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) chart describing the study’s inclusion process.

**Figure 1. Study selection process.**
Data Analysis
Documents were analyzed through an inductive coding process to identify dominant themes and patterns [20]. Following an initial analysis of 10 documents and discussion among 5 researchers, an extraction table was developed and further refined upon analysis of 5 additional publications. Five researchers piloted the data extraction table to ensure consistency of analysis and collaboratively reviewed all retained peer-reviewed and gray literature documents for data extraction and analysis. The completed table was used by 5 reviewers to extract data from each publication related to (1) authors; (2) author locations based on affiliated institutions as identified in publications; (3) study aim or objective; (4) methodology and research design; (5) countries or regions identified; (6) types of digital technologies identified; (7) intended or stated outcomes of digital technology use; (8) target populations; (9) unintended (or not explicitly stated) outcomes and implications of technology use; and (10) theoretical analyses, arguments, discussions, and debates. The findings were reviewed and discussed among our multidisciplinary team of researchers to ensure a range of expert perspectives from nursing, medicine, public health, epidemiology, surveillance, geography, health information science, law, bioethics, policy, knowledge translation sciences, critical theory, and sociology of health.

Results
Overview
The peer-reviewed literature included commentaries (n=39), reviews (n=39), analyses (n=27), reports (n=8), empirical studies (n=24), legal reviews (n=3), and a policy analysis paper (n=1). The gray literature included commentaries and opinion pieces (n=33); video and audio recordings and transcripts of conferences, panels, and meetings (n=8); news reports (n=33); and conference proceedings (n=5). Identifying the institutional affiliations of authors of peer-reviewed publications allowed us to grasp the international breadth of the literature (authors of more than 1 publication were counted only once). Authors were affiliated with institutions from countries including the United States (n=156), the United Kingdom (n=91), India (n=40), China (n=28), Australia (n=28), Singapore (n=27), Spain (n=25), Italy (n=24), Germany (n=21), Brazil (n=20), Japan (n=19), the Democratic Republic of the Congo (n=16), Switzerland (n=16), Taiwan (n=15), Canada (n=14), Ireland (n=12), South Africa (n=11), and Iran (n=9).

Across the publications reviewed, the use of digital technologies for public health surveillance during the COVID-19 pandemic was identified in 90 countries and regions (Multimedia Appendix 2). Mobile phone apps (particularly apps to support contact tracing), mobile phone location tracking through Bluetooth and GPS technologies, drones, temperature-scanning technologies, and wearable devices were among those most commonly discussed. Digital technologies were most frequently used to support contact tracing (ie, to identify individuals with the disease or symptoms and those with whom they have been in contact) [10,11,21-173]; to inform decision making by public health agencies, states, and individuals [21,25,28,31,44,47,49,51-53,56-60,62,63,66,67,77,81-83,88-90, 94,97,98,102,104,121,129,157-159,167,170,171,174-204]; to monitor compliance with public health measures [21,23,25,28,30-34,38,41,42,44,45,54-58,60,61,63,71,83,85,86,89,91, 94,95,100-102,105,108,110,119,125-127,129,130,135,140,155,156,165,170, 174,182,185,188,190,197,198,205-215]; and to inform the provision of health care services [28,41,44,46,54,57,62,64,66,69,77,80-82,87,94,95,102,108,126,128,159,170,174, 177,182,183,187,191-193,197,198,201,202,216-224].

Thematic Analysis
Key considerations related to the use of digital technologies for COVID-19 public health surveillance were grouped into five themes: (1) data security and privacy, (2) function and mission creep related to digital surveillance, (3) consequences of private sector involvement in surveillance, (4) human rights and civil liberties and impacts on marginalized groups, and (5) ethical principles for digital technology design and use.

Data Security and Privacy
Many authors identified risks to data security and data privacy associated with the use of digital technologies for public health surveillance (n=138) [11,22-26,28,30,31,33-45,47,48,51, 53,55,57-68,70-77,79-81,83,84,86-92,94-98,101-110,114,116, 118,121-123,125,128-130,132,134,137,147-152,154-156,165,168,169,172-174,179, 185,187,191,192,195,198,201,203,204,207,208,210,212,216,221,225-232]. Several authors argued that digital surveillance may exacerbate risks to information privacy given that data gathered through digital technologies are increasingly granular and that health data privacy protections often do not adequately address the collection and use of data through digital technologies, such as mobile apps [22,25,37,42,98,110,132,156,162,164,179,228,229]. Others noted that most technologies used for surveillance are products of private companies, and they advised caution related to potential function creep and exploitation (eg, data monetization) of data intended for public health purposes. The idea of a capitalist data strategy is a relatively new aspect of disease surveillance for many public health systems [34,211], and several authors acknowledged that in many countries, including Canada and the United States, health data regulations generally apply to data collection by the state and its agents but do not necessarily extend to private companies [24,33,132,190,195,211]. Issues with data security were also found to present potential risks to data privacy, particularly with regard to technologies that were rapidly deployed without full consideration of potential security vulnerabilities [10,28,33,97,102,105,110,147,150,233]. The UK government, for instance, posted the code for its mobile contact tracing app for public review and received feedback that data logs were not adequately encrypted and risked revealing individuals’ personal information [150]. Likewise, in a review of 50 mobile apps, the authors of another study found that while 30 of the apps required access to features including contacts, photographs, media files, location data, the camera, and call information, only 16 of the reviewed apps indicated that users’ data would be made anonymous, encrypted, or secured [28]. A number of digital technologies used globally during the COVID-19 pandemic were identified as examples of privacy-
and security-compromising surveillance. A frequently cited example was the use of cell phone location tracking to support contact tracing and quarantine enforcement in countries including Israel, India, the Czech Republic, China, South Korea, Argentina, Bahrain, Kuwait, and Norway [30,36,42,54,61,89,115,155,190,204,225]. The use of thermal cameras to detect fever among potentially symptomatic individuals in countries including the United States, China, South Korea, Thailand, Singapore, Italy, and the United Kingdom was also identified as a form of surveillance that may reveal sensitive information about underlying health conditions (eg, pregnancy) or stigmatized behaviors (eg, substance use) [44,95,221]. While van Natta et al [221] found that thermal cameras are typically construed as minimally invasive, they cautioned that data regarding individuals’ health could be used by data brokers, advertisers, employers, and law enforcement agencies.

Several authors conceptualized individuals’ right to privacy as a trade-off between data privacy and security and public health. The decision by different states to use centralized or decentralized contact tracing databases, for instance, was frequently mentioned as an example of the tensions between mitigating disease spread, protecting public health, and ending public health measures, such as lockdowns, while also protecting individuals’ data privacy and security [31,34,35,46,112-114,120,121,123,137,139,152,163,211]. While data held in centralized databases can be more readily accessed and analyzed (eg, by public health agencies), they are also more vulnerable to data hacks, data leaks, and other security compromises. In contrast, Christou et al [35] provided an alternative perspective in suggesting that the trade-off between the right to health and the protection of fundamental rights, such as privacy, is a false dilemma. They argued instead that these objectives are intertwined and that human rights standards will strengthen global efforts to mitigate the COVID-19 pandemic because greater human rights protections will heighten users’ trust in surveillance tools. The authors challenged the dichotomy between public health and private information and argued that decisions to infringe upon individuals’ data privacy should be informed by wider discussions of social and political values [96].

**Function and Mission Creep Related to Digital Surveillance**

Several authors (n=30) noted that use of digital surveillance may lead to forms of "creep," such as mission creep and function creep [21,22,26,28,31,34,36,44,54,61,75,83,86,92,93,95,96,101,102,123,160,185,190,195,196,210,211,221,226,230]. Broadly, the concept of “function creep” has been used to refer to instances in which there is a slow, nearly imperceptible transformation in a data processing system’s proper or intended activity. Meanwhile, the term “mission creep” has been taken up to identify the expansion of a project or intervention beyond its original aim, particularly if an intervention continues to be used beyond the end of the crisis during which it was implemented. In the literature examined in this paper, discussions of “creep” tended to be largely speculative in nature, as authors pointed to historical instances of emergency surveillance that outlasted the initial crisis or led to the repurposing of surveillance measures (eg, surveillance measures deployed by the United States and other states following the 9/11 crisis) and considered the potential for similar forms of creep that may occur following the COVID-19 pandemic [26,44,55,74,190,226].

While some authors focused on the potential for some states to take advantage of the COVID-19 pandemic to entrench forms of surveillance that might otherwise be seen as extraordinary [28,31,36,115,135,196,210,226], others noted that digital surveillance justified by the need to mitigate the COVID-19 pandemic may normalize surveillance. In this way, civil liberties (eg, the right to privacy and the right to freedom of movement) ceded during the crisis may be difficult to reclaim. Likewise, interventions not normally accepted may be normalized over time [10,11,23,31,36,44,48,76,86,91,93,103,115,135,190,203,205,209,211]. For instance, Leclercq-Vandelannoitte and Aroles [86] drew on Deleuze’s concept of control societies to analyze the normalization of digital surveillance during the COVID-19 pandemic. The authors considered the ways in which digital technologies (eg, mobile apps to support contact tracing used in China, Australia, Denmark, and Singapore) enable “control societies” as they facilitate insidious tracking of individuals’ everyday activities, which may normalize ubiquitous surveillance.

In some cases, authors identified specific technologies and modes of surveillance that may outlast the COVID-19 pandemic and that may repurpose COVID-19 health-related data. For instance, Kitchin [44,190] referenced the Indian state-sponsored mobile contact tracing app, which may be repurposed for political purposes to monitor and discriminate against certain (unspecified) populations. French et al [45] identified historical examples of racial biases in algorithms and questioned whether COVID-19 health data gathered through mobile contact tracing apps might be used, in the future, by law enforcement against racialized and other vulnerable communities. McDonald [135] described vaccination efforts in Bangladesh that may lead to the establishment of a state-supported digital identity program, including a data directory of vaccinated individuals. Pakes [230] discussed “panic buying” of digital monitoring systems for at-home workers (eg, keyboard-tracking technologies, video-monitoring tools) by unspecified employers and argued that the use of these technologies may normalize surveillance that extends beyond the COVID-19 public health mandate and persists after the pandemic has ended.

Tracking disease and its spread is a core mandate of a well-functioning public health system and critical to mitigating the COVID-19 pandemic. The rapid and unprecedented number of technologies employed to contribute to disease tracking sets the COVID-19 pandemic response apart from all other infectious disease and pandemic responses [211]. As such, many authors (n=46) expressed concern regarding the lack of guidelines related to the collection and use of individuals’ information within contemporary digital public health surveillance practices. They also emphasized the tensions created by the omnipresence of digital public health surveillance technologies and the urgency of their employment, which prohibited full discussion of the impacts and implications of digital surveillance strategies on public understanding and acceptance of surveillance practices.
Concerns were also raised around the existence of national and international laws that justify forms of surveillance and contraventions of human rights during times of emergency that would not be acceptable otherwise. The European Union’s general data protection regulation was cited as an example of a data privacy and security law that allows for nonconsensual surveillance and restrictions on privacy to meet public health objectives during crises [35,55,75,98,196,234]. Several authors warned that states may take advantage of public health emergencies to introduce or expand nonconsensual forms of surveillance, as witnessed in states including India, Israel, South Korea, and Singapore, which framed COVID-19 as a threat that required extraordinary measures, including location tracking through mobile devices [30,31,35,42,55,75,98,210,234].

**Consequences of Private Sector Involvement in Surveillance**

Several authors (n=27) highlighted private sector involvement in digital surveillance for public health and how private interests may lead to invasive, inequitable, or harmful surveillance if data are collected and used for commercial purposes [21,23,24,29,31,35,44,45,58,60,75,86,93,114,115,122-125,162,173,185,190,195,204,211,213,230]. Many of the digital technologies identified within the literature were developed and deployed through private companies or private–public partnerships. These include mobile contact tracing apps developed by the private sector in partnership with governments and public institutions, such as the Apple–Google App Programming Interface designed to support mobile contact tracing [23,24,33-36,44,45,53,57-59,61,64,66,67,70,72,74,75,78,83,86,90,94-96,105-107,112,114,144,152,160,190,195,204,211,213,230], and the use of aggregated and anonymized data collected by private companies, including telecommunications providers [37,44,55,76,121,125,128,129,154,179,190,210].

Private sector involvement in data collection and use has led to the development of proprietary technologies that are not interoperable and that may contribute to a fragmented public health system [35,44,58,60,66,190]. Other potential harms are associated more broadly with surveillance capitalism, the widespread collection and commodification of personal data by corporations [235], and disaster capitalism, the exploitation of situational crises to establish practices and policies at a time when individuals are distracted (emotionally and physically) or otherwise inattentive and less likely to consider the implications of or offer resistance to newly proposed changes in practice or policy [236]. There is a risk, for instance, that private companies might wrongly profit from the ability to predict when outbreaks will occur (eg, artificially increasing the price of medication) [31,44,45,55,67,75,134,174,190]. Furthermore, the potential and witnessed consequences of digital surveillance identified in the literature were frequently associated with the rapid innovation of digital technologies and rushed implementation of these technologies. Newlands et al [75] argued that rushed innovation is often a feature of disaster capitalism, as private interests seek to profit from crises; in the case of the COVID-19 pandemic, they noted that rushed innovation may heighten the risk of emergency legislation passed to make exceptions for use of these tools without full consideration of the ethical or legal implications [31,33,35,44,75,79,86,113,116,164,207].

**Human Rights and Civil Liberties and Impacts on Marginalized Groups**

The impacts of digital surveillance on human rights and civil liberties were noted by many authors (n=58) [10,23,24,28-30,34-36,38,43,44,53-55,61,67,71,78,89,91,98,104-106,109,111,115,125,131,135,137,154,157,173,188,190,204,209,210,212,215,220,223,226,230,232,233,237]. The erosion of freedom of movement [29,35,41,98,134], freedom of expression [75,130], freedom of association [41,130], and freedom of the press [33] was identified as a potential implication of digital surveillance [36,43,203,204,220]. A number of digital technologies used globally for public health surveillance were identified as imposing on rights and liberties, including digital proximity tracking technologies used in South Korea, Singapore, India, China, Hong Kong, and elsewhere [24,29,61,129,130]; use of wearable technologies (eg, ankle bracelets and trackable bracelets) in the United States, Hong Kong, Bahrain, and India [155,198]; and new advances in digital technology, including biosensors, artificial intelligence, and the Internet of Things [220]. Through the expansion of existing surveillance capacities, Russia and China, for instance, were described as using surveillance technologies, including mobile contact tracing apps, location data from telecommunications companies, and mobile apps for quarantine enforcement, in ways that did not contribute to proposed COVID-19 public health goals and impeded on human rights [125].

In addition to the impacts on human rights and civil liberties discussed above, the implications of digital surveillance for marginalized groups were discussed in many (n=46) publications [10,11,23,31,35,43,45,57,58,62,74,83,86,89,90,93,95,100,111,116,119,124-126,130,133,137,139,145,146,154,173,183,188,197,205,207,208,210,213,223,226,231,237,238]. Hendel et al [90] summarized this discussion through the recognition that the COVID-19 pandemic has not impacted all people in the same way, and that in addition to the need for epidemiological data on inequities generated by the pandemic response, there is a need to consider the ways in which digital surveillance could exacerbate existing vulnerabilities. A frequently cited example pertained to the use of mobile-based emergency alerts in South Korea sent out by public health authorities. These messages included intimate details regarding people infected with COVID-19 and allowed for ease of surveillance could exacerbate existing vulnerabilities. A frequently cited example pertained to the use of mobile-based emergency alerts in South Korea sent out by public health authorities. These messages included intimate details regarding people infected with COVID-19 and allowed for easy surveillance and may fear an exacerbation of marginalization through COVID-19 public health surveillance.

Ethical Principles for Digital Technology Design and Use

Authors of peer-reviewed and gray literature publications proposed several recommendations for designing and using digital technologies for public health surveillance in ways that minimize harmful consequences.

Fit for Purpose and Efficacy

Technologies should produce expected outcomes that will lead to actual benefits for public health and fulfill the needs of public health authorities. There should be evidence of this efficacy, and the potential advantages of digital technologies should be compared with other, less invasive options or nontechnological solutions [10,34-42,57,116-119,122,130,132,133,137,148,190,223,231,238,239].

Proportionality

The potential harms associated with digital surveillance should be proportional to the predicted or witnessed threats. Proportionality should include consideration of the disproportionate impacts of surveillance on marginalized groups [21,23,24,29,35,39,90,92,95,125,126,129,149,154,162,173,196,223,232,239].

Transparency

All aspects of digital surveillance should be performed such that they are easily observable. Information about how data are collected, used, and shared should be not only readily accessible but also easy to understand [29,31,35,39,43,44,53,63,73,95,97,102,104,113,117,118,120,125,132,149,154,161,173,178,190,192,196,203,231,232,240].

Temporary

There should be deadlines for data collection, use, and retention, and these should be communicated and upheld. In the case of emergency measures, there should be clearly defined indicators of when the emergency will be considered resolved and when emergency measures will end [21,29,35,36,41,43,53,70,73,75,97,105,122,126,129,149,154,161,173,179,196,226,229,232,237].

Rethinking Consent

There is a need to rethink what “consent” means in the contemporary digital surveillance context. In particular, there is an urgent need for discussions of how to avoid illusions of consent—for example, mandating surveillance to access certain spaces or use of data collected in covert ways for health-related surveillance [22,53,55,75,83,89,97,110,118,123,129,149,162,188,196,210,226,232,234].

Purpose Limitation

Collection and use of data should be limited to public health purposes for mitigating infectious disease spread. Data should not be repurposed [21,22,28,29,31,34,35,41,44,104,110,115,123,125,126,128,149,159-162,173,190,195,196,210,226,230,237].

Privacy and Security

Privacy and data security should be protected through privacy by design and technical tools as well as legislation regulating data collection and use [29,31,34-36,42,53,70,75,83,90,92,96,98,104-107,110,174,190,192,195,196,204,228,229,234,241,242].

Accountability

It should be clear who is responsible for data collection and use. Those engaging in surveillance should be answerable to the public, and individuals should be able to seek redress for harms [29,31,35,44,53,68,83,124,149,160,190,203,230,232,237,240].

Civil Society and Public Engagement

Digital surveillance for public health should require ongoing participation by the public and input from those who will be under surveillance. All aspects of surveillance should be discussed and debated through a democratic process [29,31,53,111,116,118,132,205,220,230,239]. Several authors (n=30) raised concerns that the use of digital technologies for public health surveillance may have long-term consequences for governance, the state, and civil society [11,23,25,30,33,41,43-45,52,55,68,71,79,86,91,95,100,114,123,133,190,203-205,209-211,220,230].

Discussion

Principal Findings

In our review of the academic and gray literature published during the first year of the COVID-19 pandemic, we aimed to explore the use of digital technologies for surveillance; the predicted and witnessed short- and long-term consequences of digital surveillance; and the questions, concerns, findings, and discussions that emerged in this first pivotal year of the pandemic. We found that digital technology use was identified in more than 90 countries and regions for pandemic-related applications, including contact tracing, symptom monitoring, disease tracking, enforcing compliance with public health measures, and supporting the direct provision of health care. We also found a number of consequences related to digital surveillance identified in the literature, including implications for data security and privacy, the potential for function and mission creep, consequences of private sector involvement in surveillance, implications for human rights and civil liberties, and impacts on marginalized groups. Finally, we also discovered ethical principles for digital technology design and use proposed throughout the literature.

Concerns regarding the potential consequences of digital surveillance often intersected. For instance, risks to privacy associated with digital surveillance were discussed by framing privacy as a human right, which, if compromised, may also lead to the undermining of other rights, such as freedom of movement, expression, and association. Likewise, the potential for mission and function creep and the expansion of surveillance
were linked to concerns around governance during the COVID-19 pandemic and whether this state of exception will extend beyond the crisis. Notably, discussions regarding mission and function creep drew parallels between other historical instances in which surveillance both extended beyond the initial crisis and captured data for uses other than those originally intended, such as the 9/11 crisis. These discussions highlight the fact that there is significant overlap between public health surveillance and other forms of surveillance (eg, criminal–legal and commercial) in both their objectives and their mechanisms. The blurred line between public health surveillance and other forms of surveillance is rendered particularly visible by digital surveillance, as the use of digital technologies for data collection and analysis highlights the ubiquitous, ongoing, and increasingly normalized nature of surveillance, which is likely to extend far beyond the COVID-19 pandemic.

The associations between public health and other institutional relations and modes of surveillance are captured in the authors’ descriptions of the impacts of surveillance on individuals’ human rights and civil liberties. In South Korea, the use of mobile-based emergency alerts sent out by public health authorities led to stigmatization and discrimination against lesbian, gay, bisexual, transgender, intersex, queer/questioning, and asexual communities; while these alerts were deployed in support of the public health response to the COVID-19 pandemic, the objectives of reducing disease spread and protecting public health do not detract from the invasive and coercive nature of these alert messages, nor their impacts on marginalized groups. Likewise, many authors raised concerns about the capitalist exploitation of public health crises and the repurposing of data to serve private interests. These findings mark the importance of attending to the intersections between public health, public health surveillance, and other forms of social control. These discussions are situated within long-standing debates around freedom of choice and other human rights, the coercive character of public health, and ethical quandaries brought to light by digital surveillance, as explored in this paper.

Recent publications have underscored the urgency of attending to questions of human rights related to digital surveillance during the COVID-19 pandemic, particularly in the case of marginalized groups. Abdelrahman [243], for instance, describes the impacts of digital surveillance during the COVID-19 pandemic on vulnerable groups, including African minority populations in China who had surveillance cameras installed outside their homes by the state. Marshall explores the potential implications of increased digital surveillance during the pandemic for queer sex workers, as enhanced surveillance through closed-circuit television cameras and facial recognition reduced their ability to work anonymously and increased their risk of being criminalized [244]. Our scoping review contributes to these ongoing discussions through a thematic, qualitative analysis that identifies the “slippage” between public health surveillance and other forms of surveillance, including their impacts on marginalized groups, regardless of the stated objectives of surveillance.

One of the most interesting findings to emerge from our review is the emphasis on the differences between digital surveillance and other forms of public health surveillance. While surveillance (including global health surveillance) has long been a critical function of public health [245], the emergence of the COVID-19 pandemic as the first global pandemic of the “digital age” has meant that the uncertainty of navigating this public health crisis was exacerbated by the unprecedented development and use of digital technologies for surveillance [6]. Given the unique context in which the COVID-19 pandemic spread and in which digital technologies were used for public health surveillance, some authors drew on theoretical concepts (eg, Deleuze’s theory of the control society and Foucault’s concept of the panopticon) to analyze the normalization of digital surveillance during the pandemic as these technologies became increasingly ubiquitous [79]. The consequences of emerging differences between digital surveillance and traditional forms of public health surveillance (eg, the huge amount of data collected, the ubiquity and pervasiveness of surveillance, and evolving techniques of data analysis, including machine learning) remain to be fully explored [6,246]. Further research is needed to elucidate the impacts of the normalization and omnipresence of digital surveillance and the implications raised in this review, including data privacy and security, creep, private sector involvement, and human rights.

In light of the ramifications associated with digital public health surveillance, the value of these forms of surveillance must be carefully weighed. Recent publications have suggested that the wide range of digital technologies implemented during the COVID-19 pandemic for surveillance purposes faced a number of barriers preventing their successful implementation, and while many of these digital innovations have yet to be formally evaluated or assessed, there is significant uncertainty around their value [8,9]. It is difficult to determine the impact of digital surveillance on disease transmission, particularly given the challenges around technology uptake, implementation, and consistency. Likewise, it is equally difficult to draw comparisons between countries given the various technologies used, the public health and health care infrastructures in which they were deployed, and the varying objectives toward which these technologies were used, including commercial, criminal–legal, and state objectives. In the face of this uncertainty, it will be important to continue to carefully assess the value of digital surveillance and its intended and unintended consequences. Also critical will be a holistic approach to surveillance that accounts for the blurred boundaries between public health, public health surveillance, and other forms of surveillance and social control.

Our scoping review provides a snapshot of peer-reviewed and gray literature publications from the first year of the COVID-19 pandemic. The scope of the publications included in this review is global, and we included authors affiliated with institutions across diverse regions, signaling preoccupation with these topics worldwide. The large number of publications retained also points to the urgency of these concerns and interest in digital public health surveillance in both academic and nonacademic spaces. Ongoing discussions continue to explore and generate appropriate practices, policies, and legislation to address the challenges associated with digital surveillance [6,246]. The findings of this scoping review contribute to our knowledge of
digital technologies used for public health surveillance during the COVID-19 pandemic, the potential and witnessed implications of digital surveillance, and ethical principles for technology design and use. This information is critical for leveraging digital public health surveillance in ways that are ethical and that use data to improve health while minimizing potential marginalization associated with surveillance.

Limitations
While our review provides important insights into the use of digital technologies for public health surveillance, this study has some limitations. Most significant is the restriction of our focus to the first year of the COVID-19 pandemic, which excludes the use of digital technologies for surveillance after this first year of the pandemic and during other public health crises, including other infectious disease outbreaks. Limiting the review to English-language documents may have also limited our analysis of global digital surveillance. As the COVID-19 pandemic continues and other outbreaks, such as mpox, emerge, this publication represents an early appraisal of existing knowledge. However, the occurrence of new infectious disease outbreaks and the use of new modes of digital surveillance underscore the urgency of reviewing this literature.

Conclusions
This scoping review explored the potential and witnessed short- and long-term consequences associated with the use of digital technologies for public health surveillance during the COVID-19 pandemic identified in the peer-reviewed and gray literature published during the first year of the pandemic. The review found evidence of concerns raised around risks to human rights and civil liberties, the potential normalization of surveillance, the expansion of the state of emergency of the COVID-19 pandemic, and data security and privacy. The literature also included recommendations for more ethical digital surveillance, including transparency, limited retention and use of data, proportionality, and ongoing efforts to introduce adequate legislation to regulate surveillance.

Although this scoping review focuses on the COVID-19 pandemic, the findings have implications for digital surveillance during other infectious disease outbreaks. The rapid pace of digital technology use and development requires consideration of the impacts of rushed innovation and how legislative, public health, technological, and other mechanisms can be used in striving toward more ethical data collection and use. The consequences and potential harms associated with digital surveillance identified in this review raise important questions about the use of digital technologies for public health surveillance and how these technologies can support public health without impinging on rights, liberties, or democratic processes.

Acknowledgments
We would like to thank Meagan Stanley for her assistance in designing the search protocol for this review. This work was supported by the University of Western Ontario FHS Research Grant 2020. The funder had no role in the study design; the collection, management, analysis, or interpretation of the data; the writing of the report; or the decision to submit the manuscript for publication.

Abstract

Background: Finding individuals with drug-resistant tuberculosis (DR-TB) is important to control the pandemic and improve patient clinical outcomes. To our knowledge, systematic reviews assessing the effectiveness, cost-effectiveness, acceptability, and feasibility of different DR-TB case-finding strategies to inform research, policy, and practice, have not been conducted and the scope of primary research is unknown.

Objective: We therefore assessed the available literature on DR-TB case-finding strategies.

Methods: We looked at systematic reviews, trials, qualitative studies, diagnostic test accuracy studies, and other primary research that sought to improve DR-TB case detection specifically. We excluded studies that included patients seeking care for tuberculosis (TB) symptoms, patients already diagnosed with TB, or were laboratory-based. We searched the academic databases of MEDLINE, Embase, The Cochrane Library, Africa-Wide Information, CINAHL (Cumulated Index to Nursing and Allied Health Literature), Epistemonikos, and PROSPERO (The International Prospective Register of Systematic Reviews) using no language or date restrictions. We screened titles, abstracts, and full-text articles in duplicate. Data extraction and analyses were carried out in Excel (Microsoft Corp).

Results: We screened 3646 titles and abstracts and 236 full-text articles. We identified 6 systematic reviews and 61 primary studies. Five reviews described the yield of contact investigation and focused on household contacts, airline contacts, comparison between drug-susceptible tuberculosis and DR-TB contacts, and concordance of DR-TB profiles between index cases and contacts. One review compared universal versus selective drug resistance testing. Primary studies described (1) 34 contact investigations, (2) 17 outbreak investigations, (3) 3 airline contact investigations, (4) 5 epidemiological analyses, (5) 1 public-private partnership program, and (6) an e-registry program. Primary studies were all descriptive and included cross-sectional and retrospective reviews.
of program data. No trials were identified. Data extraction from contact investigations was difficult due to incomplete reporting of relevant information.

**Conclusions:** Existing descriptive reviews can be updated, but there is a dearth of knowledge on the effectiveness, cost-effectiveness, acceptability, and feasibility of DR-TB case-finding strategies to inform policy and practice. There is also a need for standardization of terminology, design, and reporting of DR-TB case-finding studies.

(JMIR Public Health Surveill 2024;10:e46137) doi:10.2196/46137

**Introduction**

With the emergence of *Mycobacterium tuberculosis* strains resistant to first-line antituberculosis drugs, strategies to control tuberculosis (TB) have become even more challenging [1]. It is estimated that almost half a million people developed rifampicin-resistant TB, of which 78% had multidrug-resistant tuberculosis (MDR-TB) in 2019 [2]. Although drug-resistant tuberculosis (DR-TB) is not as prevalent as drug-susceptible tuberculosis (DS-TB), it is more difficult to diagnose, treatment is longer and more toxic, outcomes are worse, and costs are higher.

Finding individuals with DR-TB and initiating treatment as early as possible is important to improve patient clinical outcomes and to break the chain of transmission to help control the pandemic. Despite new diagnostic technologies, only a third of the estimated number of people who developed DR-TB initiated treatment in 2020 [3].

TB can be detected after the patient presents passively to health services or follows one of several different screening pathways depending on the case-finding strategy of a TB program [4]. Pathways can also be enhanced through several activities such as health promotion in the community, improved access to TB diagnostic services, or training of health workers to identify presumptive TB at general health services. Multiple activities often result in complex interventions and heterogeneous trials that are difficult to meta-analyze in systematic reviews [5,6].

To our knowledge, systematic reviews assessing the effectiveness, cost-effectiveness, acceptability, and feasibility of different DR-TB case-finding strategies to inform research, policy, and practice, have not been conducted and it is unknown whether enough research exists to conduct such reviews. It is also unknown whether case-finding strategies are similar for DR-TB and DS-TB and whether we can draw on findings from DS-TB reviews to inform decisions on DR-TB case-finding strategies.

Scoping reviews are useful for scoping the literature and to clarify concepts [7,8]. We therefore conducted a scoping review to assess whether enough research exists for a systematic review, to identify priority questions for such a review, and to clarify which case-finding strategies exist for DR-TB specifically.

**Methods**

**Reporting Guidelines and Protocol**
The Arksey and O’Malley framework [9], Levac et al [10], and the Joanna Briggs Institute scoping review methodology [8] guided methods for this scoping review. The review is reported according to the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) [11]. See Multimedia Appendix 1 for the completed PRISMA-ScR checklist. The protocol for this review was published in *JMIR Research Protocols* [12].

**Defining the Research Question**
The question for our review was, what literature is available on DR-TB case finding and which case-finding strategies are described? We looked at studies that had sought to improve DR-TB case detection.

**Eligibility Criteria**

Textbox 1 lists the inclusion and exclusion criteria for participants, concept, outcome, context, and study design.
Textbox 1. Eligibility criteria.

Inclusion criteria

• Participants
  • Participate regardless of symptoms, for example, contacts, people living with HIV attending HIV care, whole communities
• Concept/Intervention
  • Strategies aiming to improve or enhance participants’ pathways to drug-resistant tuberculosis (DR-TB) case detection specifically
• Outcome
  • Patients diagnosed with tuberculosis (TB)
• Context
  • Community
  • Primary, secondary, or tertiary care
  • Study design
  • Primary studies
• Systematic reviews
• Qualitative studies, where the experiences of individuals who receive the intervention or those who provide the intervention are investigated
• Studies of diagnostic test accuracy if the study describes a DR-TB screening strategy
• Trials comparing different screening or diagnostic tools within a DR-TB case-finding intervention

Exclusion criteria

• Participants
  • Patients with TB symptoms seeking care
  • Patients diagnosed with TB
  • Laboratory samples/isolates
• Concept/Intervention
  • Intervention strategies aiming to improve TB case finding in general, even if they do report the yield of people with DR-TB
• Outcome
  • No report of patients diagnosed with TB
• Context
  • Laboratory based
  • Study design
  • Meta-reviews (review of reviews)
  • Narrative reviews
• Editorial
  • Opinion articles
  • Meeting summaries
• Guidelines
• Prevalence surveys, except if the survey includes an intervention strategy to find individuals with DR-TB specifically
• Conference abstracts

Identifying Relevant Studies

With assistance from an information specialist, we searched the academic databases of MEDLINE (PubMed), Embase (Ovid), The Cochrane Library, Africa-Wide Information (EBSCOhost), CINAHL (EBSCOhost), Epistemonikos, and PROSPERO (The International Prospective Register of Systematic Reviews) using no language or date restrictions. These searches were conducted on August 31, 2021, and after an initial peer review of this article, an updated search was conducted on January 11, 2024. The search string included combinations of the following 3 domains, that are (1) terms related to “TB”; (2) terms related to “drug resistance”; and (3) terms related to “case finding,”
“case detection,” “screening,” “contact investigation,” and “contact tracing.”

Search strategies from each electronic database are detailed per search date in Multimedia Appendix 2.

Study Selection
We used Rayyan systematic review software [13] to screen titles, abstracts, and full-text articles. Decisions were blinded, except when reviewing conflicts. Reviewers screened abstracts in duplicate for inclusion. Conflicts were resolved through discussion. Full-text articles were also screened in duplicate. Disagreements were resolved through discussion to determine final inclusion.

Charting the Data
We developed a data extraction form in Excel (Microsoft Corp). The data extraction form was applied to all primary research reports to collect standard information on each study. Textbox 2 lists the information that was collected.

One reviewer extracted data from included papers and a second reviewer (SSvW) checked the extracted data. Reviewers met regularly to determine whether their approach was consistent and in line with the research question.

Collating, Summarizing, and Reporting the Results
We provide a narrative report with supporting tables to summarize the data. Table 1 contains definitions we used in charting, collating, summarizing, and reporting our results. A systems-based logic model developed from a synthesis of DS-TB case-finding strategies (Figure 1) was used as a framework to describe different strategies and resulting pathways (care-seeking pathways or screening pathways).

Quality appraisal was not conducted, because this is a scoping review and our interest is in the existing evidence base, regardless of study design and quality.
Table 1. Definitions.

**Results**

**Overview of the Available Literature**

We screened 3646 titles and abstracts and 236 full-text articles. We identified 6 systematic reviews and 61 primary studies (Figure 2) for inclusion. We divided primary studies into 6 different categories (themes) and described each category in more detail below. Table 2 gives an overview of the categories and references to further detail.
Figure 2. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram.

**Systematic Reviews**

We identified 6 systematic reviews. Outcomes were descriptive and none of the reviews identified any randomized controlled trials. In 5 of the 6 reviews, the date of the last search was more than 5 years ago (Table 3). In reviews with the yield of TB disease as an outcome, the denominator was reported as the number of contacts evaluated or screened; however, specific definitions for “evaluated” or “screened” were not reported and the yield for a specific screening or diagnostic strategy is unknown.

### Primary Studies

We identified 61 primary studies that were not included in any of the above reviews. Primary studies were descriptive and included cross-sectional studies, prospective studies, and retrospective reviews of program data. No trials were identified. Thirty-four studies were close-contact or household-contact investigations, 17 were outbreak investigations, 3 were airline contact investigations, 5 were epidemiological analyses, 1 described a private-public partnership program, and I assessed the feasibility and acceptability of an e-registry program (Table 2). Case-finding pathways were seldom described clearly, for example, whether contacts were invited for screening regardless of symptoms (Figure 1, blue pathway), whether all contacts were screened for TB at home (Figure 1, orange pathway), or whether those who experienced TB symptoms were invited for further tests (Figure 1, black dashed pathway).

### Close-Contact or Household-Contact Investigations

Countries where contact investigations were conducted included South Africa (n=6), India (n=5), Pakistan (n=4), Australia (n=2), the United States (n=1), Ethiopia (n=2), Myanmar (n=2), Thailand (n=1), France (n=1), Vietnam (n=1), Papua New Guinea (n=1), Armenia (n=1), the United Kingdom (n=1), Spain (n=1), South Korea (n=1), Oman (n=1), and Tajikistan (n=1). Two multicountry studies were conducted in Botswana, Brazil, Haiti, Kenya, Peru, South Africa, and Thailand. Data extraction from contact investigations was difficult due to incomplete reporting of relevant information, such as the total number of source cases or the number of cases tested for drug susceptibility (Table 4). Screening and diagnostic tools were not well reported and often lacked consistent or standardized use. Although investigations focused on contacts who had been exposed to DR-TB, drug-susceptibility testing (DST) was seldom reported. Case-finding pathways were also not clearly described. Some contacts were followed up over 1-2 years and some were only evaluated at baseline. Lack of or inconsistent reporting of this relevant data results in an unknown or inconsistent denominator when calculating the yield of screening the contacts of individuals with TB and makes it challenging to pool results or compare different case-finding strategies. There was also little consistency in the use of definitions. Source cases were often defined as “registered MDR-TB or extensively drug-resistant tuberculosis (XDR-TB) cases” without knowledge of how they were diagnosed. Several different definitions for “close contact” or “household contact” were reported. Some definitions were broad, for example, “people living with or having regular daily interaction with the MDR-TB source case” [23], while other definitions were more specific, for example, “a person who had shared the same enclosed living space for one or more nights a week, or for frequent or extended periods of time during the day, with the index patient during the 3 months before the current treatment episode began” [24-26]. The latter definition was used more often. See Multimedia Appendix 3 for more details.

Outbreak Investigations

The Dictionary of Epidemiology defines an outbreak as “an epidemic limited to localized increase in the incidence of disease, e.g., village, town, or closed institution” [57]. In the included studies, it was not always reported whether the number of identified patients was more than expected over a particular period. It was not always clear if a study was indeed an investigation of an outbreak. Studies are summarized in Table 5. These were mostly in lower TB burden countries. They were all descriptive and focused on different aspects of an outbreak, for example, contact investigation and follow-up, preventive measures, and transmission chains.

**Airline Contact Investigations**

Three studies described airline DR-TB contact investigation. An der Heiden et al [75] investigated passengers and crew members after exposure to an individual with XDR-TB. The response rate was 83%. No secondary TB cases were reported and 1 individual with TB infection, probably newly acquired, was identified. Kornylo-Duong et al [76] evaluated passenger contacts of individuals with MDR-TB. More than 65% were lost to follow-up. No secondary TB cases were reported. Eight contacts tested positive for latent tuberculosis infection (LTBI); however, it was unknown if these contacts were recent converters as they might have acquired LTBI from their countries of residence. Glasauer et al [77] analyzed international contact tracing notifications received by Germany from other countries, with a focus on air travel. The high variability in the completeness of contact tracing information made analyses a challenge.

**Epidemiological Analyses**

Nitta et al [78], Anderson et al [79], de Vries et al [80], and Suppli et al [81] described transmission patterns of DR-TB in Los Angeles County (1993-1998), the United Kingdom (2004-2007), and the Netherlands (2010-2019 and 2018-2019), respectively. Intervention strategies to find those with TB disease are mentioned, but not described in detail. Villa et al [82] described a cluster of 16 pre-XDR and XDR-TB cases in Italy between 2016 and 2020 as well as the role of whole-genome sequencing in TB surveillance.

**Public-Private Partnership Program**

Joloba et al [83] described a program to improve MDR-TB detection by improving access to rapid and reliable DST, redesigning the TB specimen transport network, and training health care workers in Uganda. This study enhanced the care-seeking pathway (Figure 1, green dashed pathway) to specifically improve MDR-TB diagnosis and no screening took place.

**E-registry Program**

Naker et al [84] described a qualitative study in Mongolia to assess the feasibility and acceptability of an e-registry tool to simplify the systematic screening of MDR-TB contacts. Of 42 contacts identified, screened, and evaluated, when these contacts were screened at home or invited for screening at a health facility; however, except for target group differences, for example, contacts of DR-TB source cases compared with DS-TB source cases, and DST when presumptive DR-TB is identified, we did not note any differences between DR-TB case-finding and DS-TB case-finding strategies. Information on factors that may influence the yield of TB disease, like the number of contacts identified, screened, and evaluated, when these contacts were evaluated (baseline or follow-up), and which screening and diagnostic tools used [85] were seldom reported in detail.

**Discussion**

**Key Findings**

This scoping review charts the existing literature on DR-TB case finding. More than 60% of identified studies described DR-TB contact investigations. Included studies were all descriptive and no trials were identified. There is a lack of primary studies for inclusion in systematic reviews assessing the effectiveness, cost-effectiveness, acceptability, and feasibility of different DR-TB case-finding strategies. Case-finding strategies were not always reported in enough detail to deduce the specific pathways in our systems-based logic model (Figure 1), for example, whether symptomatic contacts were invited to a TB diagnostic service or whether contacts were screened at home or invited for screening at a health facility; however, except for target group differences, for example, contacts of DR-TB source cases compared with DS-TB source cases, and DST when presumptive DR-TB is identified, we did not note any differences between DR-TB case-finding and DS-TB case-finding strategies. Information on factors that may influence the yield of TB disease, like the number of contacts identified, screened, and evaluated, when these contacts were evaluated (baseline or follow-up), and which screening and diagnostic tools used [85] were seldom reported in detail.

**Previous Work**

Although conclusions about the most effective DR-TB case-finding strategy cannot be drawn, several reviews looked at the possible effects of active TB case finding (screening pathways in Figure 1) compared with passive TB case finding (care-seeking pathways in Figure 1) in general. Two Cochrane reviews failed to identify any studies for inclusion. Fox et al [86] aimed to compare the diagnostic yield of TB disease between active case finding and passive case finding in TB contacts but did not identify any trials for inclusion in the review. Braganza Menezes et al [87] also could not identify trials for inclusion in a review aiming to assess the effectiveness of novel methods, for example, social network analysis, of contact tracing versus the current standard of care to identify individuals with TB infection or TB disease. A review by
Kranzer et al [88] included observational studies and concluded that screening compared with standard care increases the number of patients with TB disease found in the short term, but that it is unknown whether it impacts TB epidemiology. This finding was underpinned by another Cochrane review. Mhimbira et al [5] found that active case-finding strategies may result in increased case finding in the short term, but long-term outcomes were lacking. Except for the unknown effect of TB screening on TB epidemiology, the effect of screening on individual outcomes had been studied by Telisinghe et al [89] and Kranzer et al [88]. These reviews found limited patient outcome data and no difference in treatment outcomes between active and passive case findings. While it is known that screening may increase the number of identified cases, it is unclear if TB screening makes a difference to TB epidemiology and individual outcomes compared with passive case finding.

**Implications for Research**

There is a need for standardization of terminology, design, and reporting of DR-TB case-finding studies, especially contact investigation studies. Future research should focus on clear definitions, methodology, and detailed descriptions of all intervention components. There is also a need for well-conducted randomized controlled trials assessing the effect of active case finding on individual outcomes and long-term TB epidemiological outcomes.

**Strengths and Limitations**

The strengths of our review included a thorough search strategy and the use of a systems-based logic model. Nevertheless, there were some limitations. We searched several databases with no date or language restriction, but we did not translate all full-text articles. Studies that were not translated (n=4) are reported in the list of excluded studies (Multimedia Appendix 4) and from the translated abstracts it seems that similar study designs were found to those of included contact investigation studies. Our review excluded patients with TB symptoms seeking care, patients diagnosed with TB, and laboratory samples or laboratory isolates because the focus of this review was on active case finding. It should therefore be noted that studies that investigated strategies to improve identification of DR-TB after clinical identification of presumptive DR-TB cases, or studies that screened laboratory samples were not part of this review. Furthermore, for collating, summarizing, and reporting the results, we initially envisaged using our systems-based logic model as a framework to describe different case-finding strategies and resulting pathways. However, reporting was incomplete and inconsistent, and we were not able to describe pathways in detail. Nevertheless, the logic model guided our interpretation of whether a case-finding study involved screening or not. Finally, for contact investigation studies, we included studies that reported on the number of individuals with TB disease diagnosed, even if the study focused on LTBI testing and treatment. This might be a reason why the screening and diagnostic pathways were not always reported in detail. However, it is important to note that in contact investigation studies, the active case-finding component and the LTBI treatment component are both important aspects of early case finding and prevention.

**Conclusions**

Existing descriptive reviews can be updated, but there is a dearth of knowledge on the effectiveness, cost-effectiveness, acceptability, and feasibility of DR-TB case-finding strategies to inform policy and practice. There is also a need for standardization of terminology, design, and reporting of DR-TB case-finding studies, especially contact investigation studies, to decrease a large amount of research waste and increase the number of studies that could be synthesized and meta-analyzed in high-impact systematic reviews in the future [90].

Abstract

Background: The COVID-19 pandemic rapidly changed the landscape of clinical practice in the United States; telehealth became an essential mode of health care delivery, yet many components of telehealth use remain unknown years after the disease’s emergence.

Objective: We aim to comprehensively assess telehealth use and its associated factors in the United States.

Methods: This cross-sectional study used a nationally representative survey (Health Information National Trends Survey) administered to US adults (≥18 years) from March 2022 through November 2022. To assess telehealth adoption, perceptions of telehealth, satisfaction with telehealth, and the telehealth care purpose, we conducted weighted descriptive analyses. To identify the subpopulations with low adoption of telehealth, we developed a weighted multivariable logistic regression model.

Results: Among a total of 6252 survey participants, 39.3% (2517/6252) reported telehealth use in the past 12 months (video: 1110/6252, 17.8%; audio: 876/6252, 11.6%). The most prominent reason for not using telehealth was due to telehealth providers failing to offer this option (2200/3529, 63%). The most common reason for respondents not using offered telehealth services was a preference for in-person care (527/578, 84.4%). Primary motivations to use telehealth were providers’ recommendations (1716/2517, 72.7%) and convenience (1516/2517, 65.6%), mainly for acute minor illness (600/2397, 29.7%) and chronic condition management (583/2397, 21.4%), yet care purposes differed by age, race/ethnicity, and income. The satisfaction rate was predominately high, with no technical problems (1829/2517, 80.5%), comparable care quality to that of in-person care (1779/2517, 70.5%), and no privacy concerns (1958/2517, 83.7%). Younger individuals (odd ratios [ORs] 1.48-2.23; 18-64 years vs ≥75 years), women (OR 1.33, 95% CI 1.09-1.61), Hispanic individuals (OR 1.37, 95% CI 1.05-1.80; vs non-Hispanic White), those with more education (OR 1.72, 95% CI 1.03-2.87; at least a college graduate vs less than high school), unemployed individuals (OR 1.25, 95% CI 1.02-1.54), insured individuals (OR 1.83, 95% CI 1.25-2.69), or those with poor general health status (OR 1.66, 95% CI 1.30-2.13) had higher odds of using telehealth.

Conclusions: To our best knowledge, this is among the first studies to examine patient factors around telehealth use, including motivations to use, perceptions of, satisfaction with, and care purpose of telehealth, as well as sociodemographic factors associated with telehealth adoption using a nationally representative survey. The wide array of descriptive findings and identified associations will help providers and health systems understand the factors that drive patients toward or away from telehealth visits as the technology becomes more routinely available across the United States, providing future directions for telehealth use and telehealth research.

(JMIR Public Health Surveill 2024;10:e51279) doi:10.2196/51279
Introduction

Telehealth refers to health care delivered through digital devices (eg, computers, tablets, telephones, or smartphones) and typically includes communicating with the health care providers via live chat over the audio or video format or asynchronous messages through email or a patient portal [1]. During the early COVID-19 pandemic, with the unprecedented “Stay at Home Order” in March 2020 in the United States, in-person office visits were extremely restrained, while the demand of health care significantly increased due to the widespread infectious disease outbreak. Telehealth quickly served as an essential alternative to the limited in-person care [2]. Many private and public health insurance plans promptly started to cover virtual visits to respond to these emergency situations in an effort to enhance the availability of telehealth access [3,4]. The majority of health care sectors, including oncology, psychology, and surgery, promptly provided telehealth services to address the care needs while avoiding unnecessary in-person exposure to the infectious virus [5-7].

Previous studies analyzing sociodemographic characteristics have shown lower telehealth adoption in some populations in the United States. A study using one primary care network reported that older adults, non-Hispanic Whites, and low-income individuals were less likely to utilize telehealth visits [8]. Women and Medicaid beneficiaries had low odds of using telehealth among cancer survivors [9]. Moreover, low English proficiency was also related to low telehealth adoption among New York residents [10]. However, previous assessments were conducted in limited population groups (eg, older African American individuals) [11], at a single medical center or academic institution, with a specific medical specialty area (eg, oncology surgery), or in one geographic area (eg, New York, Los Angeles) and solely examined trends of telehealth utilization [12] or the impact of parity payment laws on telehealth use [13].

However, many components of telehealth use, such as telehealth availability, motivations for using telehealth, and patient perceptions of telehealth visits remain unknown. Second, an analysis of sociodemographic factors associated with low adoption of telehealth among individuals in the United States has not been conducted at the population level. Third, prior studies were conducted in the early phases of the pandemic, which may not be representative of late pandemic and current telehealth practices. Thus, this study aimed to comprehensively assess telehealth use in the United States, including adoption, motivations to and purposes of use, satisfaction, and perceptions, and identify sociodemographic associations with low adoption of telehealth during the third year of the COVID-19 pandemic using a nationwide database. Our findings will advance knowledge of recent telehealth use in the United States and contribute to preparing targeted approaches to enhance telehealth among those with low adoption of it. Recent evidence suggests that telehealth could contribute to enhancing health care access in some marginalized subgroups [14]. Hence, the knowledge and effort will be timely because telehealth has now been grounded as an essential part of health care delivery, being promoted from an emergency alternative during the early COVID-19 pandemic [15].

Methods

Data Source

We used a nationally representative survey (Health Information National Trends Survey [HINTS] 6, 2022) for the study [16]. HINTS is a publicly available source of self-reported cross-sectional data. The survey was administered to noninstitutionalized civilians (≥18 years) in the United States who were selected by a random sampling of stratified addresses. HINTS 6 was offered as a paper or online survey and collected from March 2022 through November 2022. With a total of 6252 respondents, the response rate was 28.1% [17]. We applied the full-sample weights to account for the household-level base weight, nonresponse, and the person-level initial weight [17]. This study followed the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines [18].

Outcome

To evaluate telehealth adoption, the following question was used: “A telehealth is a telephone or video appointment with a doctor or health professional. In the past 12 months, did you receive care from a doctor or health professional using telehealth?” The response options were “yes” (received by video, audio, or both) or “no” (not received; see Multimedia Appendix 1).

To assess motivation, those who answered “yes” to the telehealth adoption question were asked to indicate reasons why they chose telehealth, with answer options including (1) the health care provider recommended or required it, (2) I wanted advice about whether I needed in-person medical care, (3) I wanted to avoid possible infection at the office, (4) it was more convenient than going to the doctor, and (5) I could include family or caregivers in my appointment. Answer choices included “yes” or “no.” To examine satisfaction with their telehealth visits, participants used a Likert scale (strongly agree, somewhat agree, somewhat disagree, strongly disagree) to rate the following items: (1) I had technical problems with my telehealth visits, (2) the telehealth care was as good as in-person care, (3) I was concerned about the privacy of my telehealth visits, (2) the telehealth care was as good as in-person care, (3) I was concerned about the privacy of my telehealth visits. To assess the purpose of telehealth use, participants also used a Likert scale (strongly agree, somewhat agree, somewhat disagree, strongly disagree) to rate the following items: (1) annual visit, (2) minor illness/acute care, (3) managing chronic condition/disease, (4) medical emergency, (5) mental health, (6) other. For this study, the responses to the latter 2 questions were then coded as a binary variable: agree (strongly agree, somewhat agree) or disagree (somewhat disagree, strongly disagree).
To evaluate their perceptions, those who answered “no” to the telehealth adoption question were asked to indicate the reasons why they did not participate in telehealth visits, answering “yes” or “no” to options including (1) a preference for in-person care, (2) privacy concerns, or (3) difficulty with use.

Covariates
We selected sociodemographic characteristics based on the social determinants of health conceptual framework from Healthy People 2030 [19], which includes age, birth gender, race/ethnicity, household income (<US $20,000, US $20,000 to <$35,000, US $35,000 to <$50,000, US $50,000 to <$75,000, ≥ US $75,000), education, marital status, employment status, health insurance, and rurality of residence (metropolitan, micropolitan, small town, rural) [20,21]. Additionally, health status factors included general health (excellent, very good, good, fair, poor) and chronic medical conditions (cancer, diabetes, high blood pressure, heart disease, lung disease).

Statistical Analysis
We performed weighted descriptive analyses to calculate the frequency (n) and weighted percentage (%) with the SE to illustrate the sociodemographic and health status characteristics of the study population. Weighted descriptive analyses were also conducted to present telehealth adoption (computed by prevalence), by mode, sociodemographic characteristics, and health status characteristics to identify subgroups with higher-than-average adoption, as well as motivations for use, the care purpose, satisfaction with recent telehealth visits, and perception of telehealth prior to its use. Differences by group were assessed using the Wald chi-square test. To further explore differences in purpose and satisfaction with recent telehealth visits by age, birth gender, race/ethnicity, education, and employment status, weighted descriptive analyses with the Wald chi-square test were also performed. To examine the factors associated with telehealth use, we developed a multivariable weighted logistic regression model to obtain odds ratios (ORs) and 95% CIs for the sociodemographic and health status characteristics related to telehealth use. The logistic regression model was adjusted for age, birth gender, race/ethnicity, education, income, marital status, employment status, health insurance, number of health care office visits a year, and general health status, which were selected because these were potential confounders in this study (eg, changed covariate estimates by more than 10%) or previously known confounders for telehealth use [8,9,11].

The range of missingness was 1.7% to 11.4%, and covariates with any missing values were imputed. We applied the Hot deck imputation method, which was used to account for nonresponse by HINTS [16]. For all the descriptive and regression analyses, the imputed data were used, and the statistical significance was determined at P<.05 in SAS 9.4 (SAS Studio) [22,23].

Ethical Considerations
This was a secondary analysis of publicly available national survey data (HINTS). This study did not involve human subjects or identifiable information. Given that the data were deidentified, this study was deemed exempt from review by the Institutional Review Board of Stanford University.

Results
Study Population Characteristics
Table 1 presents the sociodemographic and health status characteristics of the study population in the third year of the COVID-19 pandemic in the United States. Of the survey respondents, 78.6% (4045/6252) of the respondents were less than 65 years old, 50.5% (3733/6252) were women, 61% (3615/6252) were non-Hispanic White, 72% (4703/6252) had some or more than a college education, 62.4% (3558/6252) had an income of at least US $50,000, slightly more than one-half were employed (2980/6252, 54.1%), slightly more than one-half were married (3234/6252, 56.1%), 85.7% (5393/6252) resided in a metropolitan area, 89.2% (5709/6252) had health insurance, 83.2% (5134/6252) were in generally excellent or good health, and 37.1% (2798/6252) reported high blood pressure.
Table 1. Sociodemographic and health status characteristics of 6252 US adults in the third year of the COVID-19 pandemic (Health Information National Trends Survey [HINTS] 6, 2022).

<sup>a</sup>Covariates with any missing values were imputed; missingness of covariates from the sample of 6252 adults: age: n=98, 1.6%; birth gender: n=410, 6.6%; race/ethnicity: n=687, 11%; education: n=404, 6.5%; income: n=732, 11.7%; employment status: n=390, 6.2%; marital status: n=415, 6.6%; health insurance: n=126, 2%; general health status: n=234, 3.7%; diabetes: n=252, 4%; high blood pressure: n=244, 3.9%; heart disease: n=238, 3.8%; lung disease: n=234, 3.7%; cancer: n=370, 5.9%.

**Telehealth Adoption by Mode by Sociodemographic Characteristics**

Overall, 39.3% (2517/6252) of the respondents had adopted telehealth (Table 2). Video-only visits (17.8%) were more prevalent, followed by audio-only visits (11.6%). Table 2 illustrates telehealth adoption by mode and the differences by sociodemographic and health status characteristics. Video visit adoption was higher among those aged 35 years to 49 years (<i>P</i>&lt;.001), women (<i>P</i>&lt;.001), the employed (<i>P</i>&lt;.001), the insured (<i>P</i>&lt;.001), those with at least a college education (<i>P</i>&lt;.001), and individuals with a high income (≥US $75,000; <i>P</i>&lt;.001). Audio visit adoption was higher among the oldest age group (≥75 years; <i>P</i>&lt;.001), Hispanic individuals (<i>P</i>=.02), those with a low income (<US $35,000; <i>P</i>&lt;.001), and unemployed respondents (<i>P</i>&lt;.001).
Table 2. Telehealth adoption by sociodemographic and health status characteristics of 6252 US adults in the third year of the COVID-19 pandemic (Health Information National Trends Survey [HINTS] 6, 2022).

\(^a\)"Any" included video only (n=1110), audio only (n=876), and both (n=531).

\(^b\)Not applicable.

\(^c\)Telehealth adoption use was higher than the average.

**Telehealth Motivations, Satisfaction, Perceptions, and Purposes**

The primary reason for not using telehealth was the lack of an available telehealth option (2200/3529, 63%) or preference for in-person care if telehealth was offered (527/578, 84.4%; Figure 1). Provider's recommendation (1716/2517, 72.7%) and convenience (1516/2517, 65.6%) motivated people to use telehealth, and users were mostly satisfied with their telehealth visits, with no reported technical problems (1829/2517, 80.5%) or privacy concerns (1958/2517, 83.7%) and good care quality (1779/2517, 75%). Acute (600/2397, 29.7%) and chronic (583/2397, 21.4%) condition care were the most common purposes of telehealth use. However, the purpose of telehealth use differed by age (of those aged 18-34 years, 28.2% [99/381] used telehealth for mental health vs of those aged ≥75 years, 31.3% [93/292] used telehealth for chronic condition care), race/ethnicity (of non-Hispanic Asian individuals, 35.6% [41/124] used telehealth for acute care vs of individuals of other races/ethnicities, 29% [27/94] used telehealth for chronic condition care), and income (of those with an income <US $20,000, 27.5% [92/345] used telehealth for chronic condition care vs of those with an income ≥US $75,000, 34.9% [335/1085] used telehealth for acute care; Table 3 and Table S1 in Multimedia Appendix 2).

</table>
Factors Associated With Telehealth Use

Individuals who were younger (ORs 1.48-2.23, 18-64 vs ≥75 years), were female (OR 1.33, 95% CI 1.09-1.61), were Hispanic (OR 1.37, 95% CI 1.05-1.80; vs non-Hispanic Whites), or had at least a college education (OR 1.72, 95% CI 1.03-2.87; vs less than high school) had higher odds of using telehealth (Table 4). Unemployed (OR 1.25, 95% CI 1.02-1.54) or insured (OR 1.83, 95% CI 1.25-2.69) adults were more likely to use telehealth. Those who had 1 or more health care office visits in 1 year or had fair or poor general health had higher odds of using telehealth.

Discussion

Principal Findings

Our study used nationally representative data to study modern telehealth practices observed in the third year of the COVID-19 pandemic. We comprehensively investigated features of telehealth use including adoption, motivation for use, purposes of use, respondent satisfaction, telehealth perceptions, and associated sociodemographic and health status characteristics of US survey participants. Approximately 2 in 5 adults received telehealth care, motivated primarily by providers’ recommendations and convenience. Care for both acute and chronic conditions was received via telehealth, with high overall patient satisfaction. Additionally, we identified factors associated with telehealth adoption, including younger age, female gender, Hispanic ethnicity, higher education status, being unemployed and insured, previously visiting a health care office, and poor health status. The wide array of descriptive findings and identified associations will help providers and health systems understand the factors that drive patients toward or away from telehealth visits. We illustrated the importance of the role of health policy to support those with low telehealth adoption and of integrating patients’ perspectives [24], as well as how telehealth adoption may improve inequities in health care access for socioeconomically marginalized groups [14].

In the United States, 39.3% of the population adopted telehealth during the third year of COVID-19. Video-only visits were more prevalent than audio-only visits, yet the mode used differed by sociodemographic characteristics. The main users of video visits were younger, educated, employed, insured, or high income–earning (≥US $75,000) adults, while the primary users of audio visits were older (≥75 years), of Hispanic ethnicity, unemployed, or low income–earning (<US $35,000), which is aligned with previous findings [8]. Given that video visits require technology-enabling environments (eg, broadband Internet access, digital device) and health technology literacy, our findings highlight the existence of inequities in video visit access. Although video and audio visits could serve different care needs, it is apparent that efforts will be necessary to improve the accessibility of video visits for disadvantaged groups.

In this study, the biggest barrier to telehealth adoption was a lack of accessibility despite its recent popularity. Although telehealth users’ satisfaction was generally high, preference for in-person visits was still the main reason for not scheduling an available telehealth service. Interestingly, the ability of telehealth visits to include family members in patient visits was a major motivation for its utilization, highlighting the potential role of telehealth in improving the active engagement of patients and caregivers in clinical care, which could improve disease management [25]. Moreover, approximately one-third of participants mentioned that they used telehealth as a means of advice for in-person visits. This suggests that telehealth could help patients make informed health decisions and foster self-care practices, as telehealth could create an enabling environment for individuals to educate themselves using quality guidance for self-care [26]. As a preliminary visit, telehealth could reduce unnecessary office visits, potentially contributing to relieving health professionals’ burden and enhancing health care efficiency in addition to saving patients’ time and effort required to make a visit [27]. Further analyses on the cost-effectiveness of telehealth are suggested to examine the economic and efficiency impact of telehealth on the health care system.

Although acute minor illness care (eg, fever, sinus infection) was the most common purpose of a telehealth visit, telehealth use for chronic condition management (eg, diabetes, high blood pressure) was also high. The findings reveal that the scope of telehealth currently goes beyond acute care and is broadly used throughout multiple practice settings, which aligns with previous findings [28]. We observed the drivers behind telehealth use differed by age, race/ethnicity, and income. Notably, the youngest subgroup used telehealth mainly for mental health care. Non-Hispanic Black/African Americans, other ethnic groups, those with the lowest income, and older adults used televisits mainly for chronic conditions, while non-Hispanic White individuals, non-Hispanic Asian individuals, and those with the highest income used it for acute minor illnesses. The findings contribute to our understanding of how telehealth can improve different care needs for different subpopulations. Need-based targeted promotions could be considered to meet the observed care needs, including telepsychiatry for younger individuals or teleendocrinology and telecardiology for those with a low income or of older age. As the technology matures, we expect the features, implementation, and delivery of telehealth to vary based on specialty, care setting, and acuity. Our findings suggest that future development of telehealth tools may vary depending on the practice setting, including its use for behavior modification [29,30].
Younger individuals (18-64 years) were more likely to use telehealth than the oldest individuals (≥75 years), which aligns with the findings of a recent meta-analysis on telehealth use in cancer care [31]. Previously, older individuals had lower odds of using tablets and smartphones to communicate with providers [32]. Older adults’ low health technology literacy or hearing issues were identified as potential inhibiting factors for the use of health technology, including telehealth [33-35]. In this study, older adults (≥65 years) had higher prevalences of preferring in-person visits and difficulty using telehealth as reasons not to schedule available telehealth visits than their younger counterparts. Our findings suggest that targeted patient education, particularly in the context of health technology literacy or tailored care, could ensure smooth care delivery [35,36].

Women had 30% higher odds of using telehealth than men, which is aligned with existing evidence that women are more likely to make primary care visits [37]. However, during the early phase of the pandemic (March 2020-May 2021), men were nearly twice as likely to use telehealth than women in a surgical oncology center [9]. A notable observation from our study was that the reasons for telehealth visits differed by gender; there was a higher prevalence of telehealth use for mental health care among women (19% vs 12% for men; \( P=0.03 \)). Given that women had higher odds of poor mental health during the pandemic [38], we may need to further examine if telehealth could be a promising tool to address women’s mental health care needs.

Hispanic individuals were more likely to use telehealth than non-Hispanic White individuals. In contrast, during the early pandemic, Hispanic individuals were less likely to use telehealth than in-person office visits [10], and Hispanic cancer survivors were less likely to use email or the Internet to communicate with health providers compared with White cancer survivors [32]. One possible reason for the discrepancy in the findings from previous studies may be that Hispanic individuals were more impacted by COVID-19 infection than individuals of other race/ethnic groups during the early pandemic [39,40], which might have led them to using more hospital visits and less telehealth [10]. Another potential scenario for the high likelihood of telehealth use among Hispanic individuals could be that they may have health issues that could be appropriately handled through telehealth visits. Given that Hispanic individuals had a higher prevalence of other reasons (19%) for recent telehealth visits than non-Hispanic White or Black individuals (13%), further study is warranted to assess if there were unmet health care needs that could be categorized as other reasons in the Hispanic population and if telehealth can sustainably satisfy those [41].

Highly educated individuals (at least a college graduate) had increased odds of using telehealth than the least educated individuals (less than high school). Similarly, a lower education level was a known predictor of low adoption of health technology [42] and technology-based patient-provider communications during the early pandemic [32,43]. Although it is possible that other factors could be at play in this association, it is also possible that less-educated individuals’ concerns about the privacy of telehealth visits might have limited active telehealth use, as we witnessed in this study. Additional steps to ensure telehealth users’ privacy is protected may need to be taken, with continued efforts to secure health information safety.

Insured individuals had 80% higher odds of using telehealth than uninsured counterparts. Given that the major private health plans and Centers for Medicare and Medicaid Services started to cover telehealth since early in the pandemic [3], this is not surprising. Previously, an association was found between a lack of health insurance and low adoption of tablets or smartphones to communicate with providers [32]. Further discussions may need to be initiated on how to support and help uninsured individuals’ low telehealth use. Moreover, unemployed individuals were more likely to use telehealth than employed counterparts. Although there is limited evidence pertaining to this association in the literature, perhaps one interpretation could be that unemployed individuals had more health issues for which they could receive care through telehealth. We observed that unemployed individuals had poor health conditions and used telehealth visits for chronic condition care compared with their employed counterparts. On the other hand, it was notable that employed adults used telehealth primarily for acute minor illnesses than unemployed adults. Although further study is warranted to examine the purpose of telehealth visits by employment status to better understand the dynamics, our findings suggest that a tailored approach to enhance working individuals’ telehealth access and providing more telehealth options outside of regular office hours could be considered.

Individuals who had health care office visits at least once were significantly more likely to use telehealth than those without any office visits yearly, which aligned with the findings of a previous study that examined the relationship between frequent office visits and communicating through electronic health records with providers [32]. This association could also be interpreted as having more health issues and a poorer health condition. For example, individuals with frequent office visits (≥5 times a year) had higher prevalences of poor general health and of using telehealth for chronic condition care compared with those without health office visits. Our findings indicate that active telehealth users were those who were frequent in-person office visitors, rather than those who had been away from health care. Future assessments may need to focus on whether telehealth could accommodate individuals with long-term, consistent care needs as that could potentially reduce the burden on health care professionals particularly in the areas suffering from shortages of the health care labor force.

Limitations
This study had some limitations. First, the temporality and causality of associations cannot be confirmed due to its cross-sectional design. Second, selection bias could be possible given the low response rate of 28.1%. However, HINTS is considered a high-quality national survey, full sample weights were applied to be representative, and imputation was conducted to minimize the bias from nonresponse. Third, as the HINTS is a self-report survey, reporting bias could also be present (eg, general health status is subjective). Fourth, although our data reflect telehealth use in the middle of the pandemic (data collected from March 2022 to November 2022), there may be...
changes in telehealth adoption and the factors associated with low adoption during the postemergency pandemic era. Hence, we suggest future studies to assess if there are any additional changes during the postemergency pandemic era starting in later 2023 and onward. Fifth, we were not able to look at asynchronous messaging as a mechanism of telecare and teledelivery due to data unavailability. Given its substantial use in practice, future studies are warranted to assess its trends and use [44]. Last, we did not consider health technology–related factors, including a technology-enabling environment (eg, digital device ownership, Internet connectivity) and health technology literacy, which are likely associated with telehealth use [45]. We would suggest further investigations into multiple factors at play for telehealth adoption in the future.

Conclusions
Our findings from a nationally representative study of modern telehealth practices show that nearly 2 of 5 individuals in the United States used telehealth, motivated by providers’ recommendations and mainly for acute and chronic condition care, resulting in a positive experience. We identified that an age between 18 years and 64 years, female gender, Hispanic ethnicity, higher education, being unemployed, being insured, frequent health office visits, and poor health status were associated with telehealth use. Future research is warranted to assess the inhibiting factors for those with low telehealth adoption especially where telehealth could be an alternate for in-person care. Furthermore, we recommend evaluating if telehealth satisfies the care needs of those with several health comorbidities. These findings help providers and health systems understand the factors that drive patients to or away from telehealth visits as the technology becomes more routinely available across the United States beyond the needs of the pandemic, providing future directions for telehealth use and telehealth research.

Abstract

Background: Innovation in seasonal influenza vaccine development has resulted in a wider range of formulations becoming available. Understanding vaccine coverage across populations including the timing of administration is important when evaluating vaccine benefits and risks.

Objective: This study aims to report the representativeness, uptake of influenza vaccines, different formulations of influenza vaccines, and timing of administration within the English Primary Care Sentinel Cohort (PCSC).

Methods: We used the PCSC of the Oxford-Royal College of General Practitioners Research and Surveillance Centre. We included patients of all ages registered with PCSC member general practices, reporting influenza vaccine coverage between September 1, 2019, and January 29, 2020. We identified influenza vaccination recipients and characterized them by age, clinical risk groups, and vaccine type. We reported the date of influenza vaccination within the PCSC by International Standard Organization (ISO) week. The representativeness of the PCSC population was compared with population data provided by the Office for National Statistics. PCSC influenza vaccine coverage was compared with published UK Health Security Agency’s national data.

Results: The PCSC comprised 7,010,627 people from 693 general practices. The study population included a greater proportion of people aged 18-49 years (2,982,390/7,010,627, 42.5%; 95% CI 42.5%-42.6%) compared with the Office for National Statistics 2019 midyear population estimates (23,219,730/56,286,961, 41.3%; 95% CI 4.12%-41.3%; P<.001). People who are more deprived were underrepresented and those in the least deprived quintile were overrepresented. Within the study population, 24.7% (1,731,062/7,010,627; 95% CI 24.7%-24.7%) of people of all ages received an influenza vaccine compared with 24.2% (14,468,665/59,764,928; 95% CI 24.2%-24.2%; P<.001) in national data. The highest coverage was in people aged ≥65 years (913,695/1,264,700, 72.3%; 95% CI 72.2%-72.3%). The proportion of people in risk groups who received an influenza vaccine was also higher; for example, 69.8% (284,280/407,228; 95% CI 69.7%-70%) of people with diabetes in the PCSC received an influenza vaccine compared with 61.2% (983,727/1,607,996; 95% CI 61.1%-61.3%; P<.001) in national data. In the PCSC, vaccine type and brand information were available for 71.8% (358,365/498,923; 95% CI 71.7%-72%) of people aged 16-64 years and 81.9% (748,312/913,695; 95% CI 81.8%-82%) of people aged ≥65 years, compared with 23.6% (696,880/2,900,000) and 17.8% (1,385,888/7,700,000), respectively, of the same age groups in national data. Vaccination commenced during ISO week 35, continued until ISO week 3, and peaked during ISO week 41. The in-week peak in vaccination administration was on Saturdays.

Conclusions: The PCSC’s sociodemographic profile was similar to the national population and captured more data about risk groups, vaccine brands, and batches. This may reflect higher data quality. Its capabilities included reporting precise dates of administration. The PCSC is suitable for undertaking studies of influenza vaccine coverage.
Introduction

The range of influenza vaccines available for clinical use has grown; there are now live attenuated influenza vaccines and recombinant vaccines in addition to the long-established inactivated influenza vaccine [1,2]. Live attenuated influenza vaccines have also been widely introduced to children via intranasal administration [3,4]. There have also been many new formulations of inactivated influenza vaccine (IIV). IIV are now often quadrivalent (active against 2 influenza B lineages, as well as 2 influenza A subtypes) rather than trivalent (which has a single B lineage), and their effectiveness may be increased by the addition of an adjuvant or higher antigen dosages [4]. Cell-based manufacture of IIV has been introduced in addition to traditional egg-based methods. Recombinant influenza vaccines are also being introduced, although these formulations are currently less widely used [5,6]. The available evidence indicates additional benefits from the use of newer and enhanced influenza vaccine formulations [7].

The Joint Committee on Vaccination and Immunization (JCVI) provides UK-wide advice on vaccination policy, including for seasonal influenza vaccine. The JCVI has progressively updated its recommendations as new vaccines have been introduced. These include the use of adjuvanted trivalent inactivated influenza vaccine (aIIV3) and high-dose trivalent inactivated influenza vaccine (HD-IIV3) for use in the 2018-2019 season and the use of cell-based quadrivalent inactivated influenza vaccine (IIV4c) vaccine for the 2019-2020 influenza season [8]. IIV4c was approved for adults and children from 9 years of age in at-risk groups and was available for use starting in the 2019-2020 season in the United Kingdom [9]. For the 2021-2022 season, a non-egg–based quadrivalent vaccine based on recombinant technology was added to the recommendations put forward by the JCVI for adults aged between 18 and 65 years [7]. For adults aged 65 years or older, 2 vaccine formulations were recommended by the JCVI in the 2021-2022 season, namely aIIV4, which replaced the trivalent formulation; aIIV3; and high-dose quadrivalent inactivated influenza vaccine (HD-IIV4) [7].

Additionally, the JCVI advised that the relative effectiveness of different enhanced influenza vaccine formulations should be assessed. Comparative influenza vaccine effectiveness data are required, preferably from the same country over multiple seasons and with laboratory-confirmed influenza end points [7,10].

In the context of an ever-increasing range of influenza vaccine formulations, we report influenza vaccine coverage in the English Primary Care Sentinel Cohort (PCSC) in the 2019-2020 winter season. We describe the representativeness of the PCSC compared with the national population, the uptake of influenza vaccination within this cohort (differentiated by formulation and also compared with national data), and the timing of vaccine administration across age bands.

Methods

Study Design and Setting

In this study, we compare the PCSC with national data for population representativeness and vaccine uptake by formulation and provide a descriptive report by week of vaccine uptake. These elements were included because vaccine studies can either be analyzed at the national population level or run in representative samples. It is important to know if there is sufficient representation of the different influenza vaccine formulations and to understand the timings of vaccine administration for studies of adverse events of interest or those of vaccine effectiveness compared with known dates of cocirculating strains of influenza [11].

This study was conducted during the 2019-2020 influenza season. The 2020-2021 season was not used as it was considered by authors as atypical due to the COVID-19 pandemic and associated changes in vaccination schedules (inclusion of persons aged 50 to 64 years and an absence of circulating influenza as a result of stay-at-home mandates) [12]. This study was conducted using the PCSC of the Oxford Royal College of General Practitioners (RCGP) Research and Surveillance Centre (RSC). At the time of this study, the RSC was, and remains, one of the largest and longest-established primary care sentinel networks in Europe [13,14].

At the time of this study, the RSC had been recording respiratory conditions, including influenza and notifiable diseases, and had provided data to support clinical and public health research (most notably on vaccine effectiveness) for over 50 years [3,13-16]. Data from the RSC were, and still are, hosted within the Oxford RCGP Clinical Informatics Digital Hub, a trusted research environment [17]. The RSC as a whole comprises over 1800 general practices in England, and the total current registered list includes over 19 million people—approximately 32% of the national population (Figure 1).
The RSC adapted and grew over the course of the COVID-19 pandemic when it was divided into 2 divisions [18]. First, the PCSC is the long-standing sentinel group of general practices (n=693) that conduct virology sampling (n=240) and serosurveillance (n=273) [19,20]. This group of practices has a long history of receiving feedback about data quality, historically at an annual visit and, in recent years, through dashboards, webinars, and web-based visits [21,22]. They were recruited to be nationally representative [13]. The second group, the Syndromic Surveillance General Practices (SSGPs), was recruited to support the UK Health Security Agency’s (UKHSA; formerly Public Health England) syndromic surveillance [23]. These practices were recruited to complement other data sources and were not nationally representative.

Representativeness of the PCSC, Including Risk Groups

The study population included participants of all ages in England who were registered with a general practitioner (GP) in the PCSC between September 1, 2019, and January 29, 2020. We describe the demographic characteristics of the study population in terms of the following:

- Age, including the following subgroups: ≤1 year, ≥2 to ≤3 years, ≥4 to ≤17 years, ≥18 to ≤49 years, ≥50 to ≤64 years, and ≥65 years.
- Sex: male, female, and missing.
- Race: Asian, Black, White, mixed, and missing or other, using an ontology to maximize identification [24].
- Socioeconomic status using the quintile of the Index of Multiple Deprivation (IMD) as a proxy (a nationally available measure assigned based on postcode). This provides an overall relative measure of deprivation for each Lower Layer Super Output Area (LSOA). An LSOA is a small area with an average population of 1500 people. The overall deprivation scores are ranked for all LSOAs within a country and can be divided into 5 groups (quintiles), where quintile 1 represents the most deprived LSOAs and quintile 5 represents the least deprived LSOAs. The IMD is a score based on the area as a whole and not everyone within an LSOA necessarily experiences the same level or type of deprivation [25,26].
- Geographic location is defined according to National Health Service (NHS) region [27].
- Risk factors for influenza as defined by the Chief Medical Officer, include chronic pulmonary disease, asthma, coronary health disease, diabetes, liver disease, chronic kidney disease, neurological conditions, immunosuppression, asplenia, learning difficulties, severe mental illness, and obesity [28].

To evaluate the representativeness of the PCSC in terms of the demographic characteristics above, we undertook a quantitative comparison of the age, sex, and IMD profile of the PCSC against published data for 2019-2020 from the Office for National Statistics (ONS) for England [29]. We compared the ethnic profile of the PCSC against ONS ethnic population estimates extrapolated from the 2011 census [30]. We also compared the broad geographic distribution of the PCSC population in terms of NHS regions with the data from the ONS on the geographical distribution of the population by government office regions [27,31]. Last, we compared the distribution of people with risk factors for influenza defined by the Chief Medical Officer in the PCSC with data from the Quality and Outcomes Framework 2019-2020 primary care disease prevalence figures published by NHS Digital [28,32]. We made 1 near-match using the...
Influenza Vaccine Coverage
The exposure of interest was influenza vaccination. Influenza vaccination was either recorded as a clinical term for vaccine administration or as a prescription. A large number of doses of influenza vaccines are administered by pharmacies and other community health care workers, although the majority of these vaccines are recorded in the primary care computerized medical record (CMR). Where vaccination was recorded as a clinical term in the CMR, it may not have been specific to the formulation, brand, or batch; when vaccination was prescribed, it was brand and batch specific. Prescriptions were only issued for adult and high-risk children who were vaccinated in their general practice [34]. A list of Systematized Nomenclature of Medicine clinical terms used to identify influenza vaccinations from the CMR of patients in the PCSC is listed in Table S1 in Multimedia Appendix 1 [27,35].

Vaccine coverage in the study population was described by providing the count and proportion (expressed as a percentage) of the PCSC vaccinated against influenza overall and by the following:

- Number and percentage of vaccinated individuals.
- Number and percentage of vaccinated individuals by type of vaccine.
- Timing of vaccination by week and day of the week.
- Number and percentage of vaccinated individuals by geographic location.
- Risk factors for influenza as defined by the Chief Medical Officer [28].

We could not precisely match the geographic locations. Our nearest match was to add East and West Midlands government regions to be equivalent to our Midlands region; we also combined Yorkshire and the Humber and the North East to be equivalent to our North East and Yorkshire regions.

To evaluate the representativeness of influenza vaccine coverage in the PCSC, a quantitative comparison was made to the influenza vaccine coverage for the winter season—September 1, 2019, to January 29, 2020—reported by the UKHSA [35]. We compared the influenza coverage in the PCSC according to the following inclusive age groups reported in national data by the UKHSA: 6 months to 1 year, 2–4 years, 5–15 years, 16–64 years, and ≥65 years. For influenza coverage by type of vaccine, coverage in the PCSC was compared with national data from the UKHSA in the following age groups only: 16–64 years and ≥65 years. We again made some near-matches for at-risk groups: coronary heart disease is compared with chronic heart disease, liver disease with chronic liver disease, neurological disease with chronic neurological disease, and obesity with morbid obesity.

Influenza Vaccination Timing
In order to evaluate the timing of influenza vaccinations given in the PCSC, we calculated the vaccine coverage overall in the study population by week and day of the week and recorded this information in line with its relevant International Standard Organization (ISO) week number.

Statistical Methods
For categorical measures, we calculated the frequency and percentage of total study participants observed in each category. For continuous and count variables, we presented the mean, SD, median, and range.

For proportion counts, we calculated 95% CI using the normal approximation to the binomial calculation [36]. Paired 2-tailed t tests were used to compare populations [37].

Statistical analyses were undertaken using R (version 3.5.1; R Core Team) [38].

Ethical Considerations
This study was classified as a service evaluation (measuring what standard of care this service achieved) by the Medical Research Council/Health Research Authority decision tool [39], so it did not require formal ethical approval. It was reviewed by the RCGP Approval Committee on January 8, 2021.

Results
PCSC Population and Comparison With English National Population
A total of 7,010,627 people (male: n=3,488,789, 49.8%; female: n=3,521,838, 50.2%) were registered with a primary care practice from the PCSC that submitted data for this study (n=693) between September 1, 2019, and January 29, 2020. The study population had a greater proportion of people aged 18–49 years (2,982,390/7,010,627, 42.5%; 95% CI 42.5%–42.6%) compared with the 2019 midyear population estimates from ONS (23,219,730/56,286,961, 41.3%; 95% CI 41.2%–41.3%; P<.001; Table 1) [29]. Populations in the most deprived quintile, namely those in IMD quintile 1, were underrepresented in this cohort, and those in the least deprived quintile, namely those in IMD quintile 5, were overrepresented.

Influenza Vaccine Coverage in the PCSC Compared With National Data

A total of 1,731,062 (24.7%; 95% CI 24.7%-24.7%) out of 7,010,627 people within the PCSC received an influenza vaccine (male: 790,660/1,731,062, 22.7%; female: 940,402/1,731,062, 26.7%). We subdivided vaccine coverage in the PCSC population by sociodemographic characteristics (Table 2 and Table S2 in Multimedia Appendix 1) and calculated the proportion of the PCSC population who were vaccinated in each subpopulation stratum. For example, 72.3% (913,695/1,264,700; 95% CI 72.2%-72.3%) of people aged 65 years or older in the PCSC were vaccinated, whereas the national data showed that 72.4% (7,621,505/10,523,854) of individuals aged 65 years or older received seasonal influenza vaccine [35], with a coverage of 24.2% (14,468,665/59,764,928; 95% CI 24.2%-24.2%; \( P < .001 \)). National coverage data only provided information on limited age bands, making direct comparisons between cohorts challenging (see Table S2 in Multimedia Appendix 1). Coverage of risk groups was slightly higher in our study than in comparable national data; for example, 69.8% (284,280/407,228; 95% CI 69.7%-70%) of people with diabetes in our study received an influenza vaccine whereas 61.2% (983,727/1,607,996; 95% CI 61.1%-61.3%; \( P < .001 \)) of people with diabetes received an influenza vaccine according to national data (Table 3).

Timing of Influenza Vaccination in PCSC

During the 2019-2020 influenza season in the PCSC, influenza vaccination started in ISO week 35 and continued until ISO week 3. Peak of vaccinations occurred in ISO week 41 (Figures 2 and 3). Weekly peaks in vaccination coverage occurred on Saturdays, especially among those aged 65 years or older. People aged 65 years or older received their influenza vaccinations earlier in the season than other age groups, with a peak around ISO week 40.

Figure 2. Timing of influenza vaccination across all ages in the Primary Care Sentinel Cohort. ISO: International Standard Organization.
Discussion

Principal Findings

The population of patients in the English national PCSC is broadly comparable to the general population in terms of demographic features. However, there is a greater proportion of people aged 18-49 years in the PCSC, and people who are more deprived are underrepresented and those in the least deprived quintile overrepresented. It is possible this may result in denominator inflation in the younger half of the working-age population for any influenza vaccine coverage estimates.

Overall, influenza vaccine coverage is comparable in the PCSC to national data, although coverage of risk groups was higher in the PCSC than in comparable published national data. Influenza vaccine type was recorded for a higher proportion of vaccines recorded in the PCSC than available from national data, although there are still a substantial number of vaccinations in the PCSC for which no influenza vaccine type or brand information was recorded.

The timing of influenza vaccination during the 2019-2020 season showed that influenza vaccination started in ISO week 35, with people aged 65 years or older receiving their vaccinations earlier in the season than other age groups. Weekly peaks in vaccination coverage were seen on Saturdays, especially among those aged 65 years or older.

Implications of the Findings

Our study demonstrated the representativeness of the PCSC in describing vaccine exposure, including timing, vaccine type, and brand-specific exposure. However, although we took steps to avoid denominator inflation, it is possible that our findings may be affected by an inflated denominator in the younger half of the working-age population (age 18 to 49 years). Denominator inflation may be a result of systematic differences in PCSC practices versus those practices outside the PCSC that have not been possible to quantify in this study, including opening times, accessibility, range of services offered, and patient satisfaction.

PCSC data about individual vaccine exposure, if combined with data on infection status, could be used to estimate vaccine effectiveness. The timing of vaccination in relation to the start of the season would allow comparison of individual vaccine exposure with circulating influenza virus strains. Where a larger population is required for a study, we could also include the RSC’s SSGPs. As the aggregated PCSC and SSGP population is over 19 million (32% of the national population; Figure 1), their combined representativeness would support a national study for which a larger sample size was needed. The RSC could also link individual exposure data to clinical records or conduct enhanced surveillance to monitor adverse events of interest.

The PCSC data did not capture the influenza vaccine type and brand for all vaccinations. Steps should be taken to improve data quality to enable comparative influenza vaccine effectiveness studies to be conducted. Of note for researchers looking to collect further information at the time of vaccination, many general practices run their influenza vaccination clinics on Saturdays, particularly for older people.

Strengths and Limitations

Strengths of the study included its large sample size from a well-established sentinel network that includes primary care practitioners who have been recording information on influenza incidence and vaccinations for over 50 years [14]. Additionally, given the completeness of our data on influenza vaccine type, we were able to include a wider range of influenza vaccine types in the PCSC than comparable national data [35]. However, the limited amount of comparable national data also curtailed our quantitative comparison of influenza vaccine coverage. It was especially difficult to compare the proportions of those vaccinated within at-risk groups as there was no detailed...
information available in national data. We have presented the proportion of people in at-risk groups vaccinated against influenza as a proportion of all the people in the at-risk group who were registered that year. For example, 284,280 people with diabetes received an influenza vaccine versus 407,228 people with diabetes. Where we identified a higher proportion of risk groups, we think this likely indicated better data quality; however, this may be a statistical artifact of differences in disease prevalence. Finally, we could not precisely match some risk groups.

The COVID-19 pandemic has resulted in interruptions of health services since early 2020. The indirect effects this had on routine vaccinations in primary care may have also affected the results of this study. However, the influenza vaccination programs had largely been completed by early 2020, and we felt confident in including 2019-2020 in our analysis. That said, this limited us to including only 1 year of data in our analysis. Furthermore, a large number of doses of influenza vaccines are administered by pharmacies and other community health care workers [40]. Although the majority of these vaccines are recorded in the CMR, communications from pharmacists to GPs around vaccination records have been described as suboptimal, especially with regard to data on manufacturer or batch number [34]. This may have affected the completeness and accuracy of our data, specifically, incomplete data about influenza vaccinations provided by pharmacies and other community health care workers would serve to underestimate the vaccine coverage rate we present in this paper.

Comparison With Prior Work
Other authors have reported strengths and limitations in the personal demographics service (described in detail in our method) and NHS number as a unique identifier [41]. Although a national identifier is overall a great strength, we need to conduct further studies to explore whether there is any denominator inflation in the PCSC database.

Past work codifying COVID-19 vaccination records in primary care settings has shown a high level of completeness of vaccine brand recording for this vaccination program. The National Immunization Management Service has recorded 99.6% of vaccine administration details and electronically transmits brand information to every individual’s GP record on a daily basis [42]. This compares with between 43.8% and 81.9% of influenza vaccine records having vaccine type and brand information accessible in the PCSC, depending on age.

Influenza vaccine effectiveness assessment is increasingly stratified by vaccine type or even vaccine brand to enable comparisons of different formulations that help to inform public health decision-making [43,44].

The United Kingdom is a possible candidate country to source comparative data for the newer influenza vaccine formulations, as it has historically had high annual influenza vaccine coverage for those aged 65 years or older. Between the 2004-2005 and 2019-2020 seasons, average coverage ranged from 71% to 75%; these figures are relatively high compared with the rest of Europe [45,46]. The World Health Organization has set a vaccination coverage target of at least 75% in the older adult population and among risk groups [47]. Influenza vaccine coverage among at-risk groups <65 years of age, excluding pregnant women, in England has been lower—approximately 49% between the 2007-2008 and 2016-2017 seasons [48,49].

Conclusions
The English PCSC was broadly representative of the national population. It included high-quality routine data, in terms of sociodemographic risk groups, recording of risk groups, and influenza uptake compared with national data sources. However, although data quality was reported to be good, there were significant gaps in vaccine type and brand. Methods implemented to capture COVID-19 vaccine data and encode it within general practice CMRs should now be implemented for influenza vaccines. The PCSC of the RSC, and the UK health care ecosystem itself, provide favorable environments for conducting influenza vaccine benefit-risk studies.

Acknowledgments
The authors thank Oxford Royal College of General Practitioners Research and Surveillance Centre member practices who shared data as well as patients and their parents or caregivers for not opting out of data sharing; EMIS, TPP System One, In Practice Systems, and Wellbeing for their collaboration with pseudonymized data extraction; and James Mansi, formerly from Seqirus, for his initial help and advice. Abstract

Background: As one of the leading causes of child mortality, deaths due to congenital anomalies (CAs) have been a prominent obstacle to meet Sustainable Development Goal 3.2.

Objective: We conducted this study to understand the death burden and trend of under-5 CA mortality (CAMR) in Zhejiang, one of the provinces with the best medical services and public health foundations in Eastern China.

Methods: We used data retrieved from the under-5 mortality surveillance system in Zhejiang from 2012 to 2021. CAMR by sex, residence, and age group for each year was calculated and standardized according to 2020 National Population Census sex- and residence-specific live birth data in China. Poisson regression models were used to estimate the annual average change rate (AACR) of CAMR and to obtain the rate ratio between subgroups after adjusting for sex, residence, and age group when appropriate.

Results: From 2012 to 2021, a total of 1753 children died from CAs, and the standardized CAMR declined from 121.2 to 62.6 per 100,000 live births with an AACR of –9% (95% CI –10.7% to –7.2%; P<.001). The declining trend was also observed in female and male children, urban and rural children, and neonates and older infants, and the AACRs were –9.7%, –8.5%, –8.5%, –9.2%, –12%, and –6.3%, respectively (all P<.001). However, no significant reduction was observed in children aged 1-4 years (P=.22). Generally, the CAMR rate ratios for male versus female children, rural versus urban children, older infants versus neonates, and older children versus neonates were 1.18 (95% CI 1.08-1.30; P<.001), 1.20 (95% CI 1.08-1.32; P=.001), 0.66 (95% CI 0.59-0.73; P<.001), and 0.20 (95% CI 0.17-0.24; P<.001), respectively. Among all broad CA groups, circulatory system malformations, mainly deaths caused by congenital heart diseases, accounted for 49.4% (866/1753) of deaths and ranked first across all years, although it declined yearly with an AACR of –9.8% (P<.001). Deaths due to chromosomal abnormalities tended to grow in recent years, although the AACR was not significant (P=.90).

Conclusions: CAMR reduced annually, with cardiovascular malformations ranking first across all years in Zhejiang, China. Future research and practices should focus more on the prevention, early detection, long-term management of CAs and comprehensive support for families with children with CAs to improve their survival chances.

Introduction

As a diverse range of structural, functional, and metabolic malformations present at birth, congenital anomalies (CAs) pose a great burden to the families involved [1]. According to the World Health Organization’s latest estimate [2], more than 240,000 newborns die from CAs in the first 28 days of life every year worldwide, and another 170,000 newborns who survive then die from CAs in the following 5 years. Although the world has witnessed encouraging reductions in CA burdens with regard to both mortality and disability-adjusted life-years [1], mortality due to CAs still constitutes 9.4% of all deaths for children younger than 5 years and ranked fourth among all causes globally [3]. For regions such as southern sub-Saharan Africa, the under-5 mortality (U5MR) due to CAs showed no sign of decline; instead, it had an annual increase of 0.17% from 1990 to 2019 [4]. In China’s case, we have also observed an ongoing decline of both U5MR and CA-related mortality [5]. However, deaths caused by CAs remain one of the leading causes of child mortality [6], as observed in other countries [7].

Even if children with CAs survive from an early death, the long-term physical disability or functional disorder still leaves a great burden to both the family and society. It was estimated that the cost of birth defect–related hospitalizations in the United States was US $22.9 billion per year [8]. Although the total medical costs regarding all birth defects is not available in China, the median expenditure of surgery for congenital heart disease (CHD) in China was reported to be CN ¥67,867 (US $9839) in 2020 [9]. For newborns, the median cost was as high as CN ¥144,380 (US $20,931), which was 5.24 times of the median yearly per capita disposable income of the Chinese population in 2020 [9].

According to data issued by the National Bureau of Statistics of China, Zhejiang, a province located in Eastern China, ranked fourth among all 34 administrative regions regarding regional total gross domestic product (GDP) and eighth in GDP per capita in 2022. It has the best medical resources and public health services among the 28 provinces and autonomous regions in the country, excluding the other 6 administrative regions including Beijing, Shanghai, and Hong Kong due to the incomparable size of the targeted service population [10]. However, with the epidemiological transition of the death-cause pattern from infectious diseases to noncommunicable diseases across the whole society [11], little is known about the survival burden of CAs in children younger than 5 years in Zhejiang. Therefore, we conducted this study to understand the trend and burden of under-5 CA mortality (CAMR) in this more economically advanced province in China.

Methods

In this descriptive study, data from a long-existing mortality surveillance system in Zhejiang were used.

Mortality Surveillance

Mortality surveillance for children younger than 5 years in Zhejiang started in the early 1990s and is carried out by health workers from 3 levels (village, county, and city) of child health care institutes, mainly maternal and child health care hospitals and community health care centers. Out of the 90 administrative districts and counties, 30 were randomly chosen, and the vital status of children younger than 5 years is routinely monitored in these districts and counties according to the protocol designed by the National Maternal and Child Surveillance Office, as reported elsewhere [5].

Briefly, all deaths that occur in the first 5 years after birth are recorded in a structured, paper-based death report card (DRC) by a physician in a hospital or a community health care worker, depending on whether the death event involves medical treatments in a hospital. Information on the children’s demographics, obstetric status, hospitalization, and death is recorded in the DRC and submitted to the provincial-level surveillance office seasonally, together with a quarterly report including residence- and sex-specific number of live births and deaths in each village.

Quality Control

To ensure the accuracy of the children’s survival status and the information in the DRC, cross-checking with the local maternal delivery system, vaccination information system, household registration and cancellation system in the Bureau of Public Security, etc., is performed by village-, county-, and city-level health workers quarterly, semiannually, and semiannually, respectively. Provincial-level staff perform a field quality control investigation every year. To minimize information error, 2 experienced physicians were invited to review all DRCs in the data preparation process independently, and any disagreement were settled by a third senior physician.

CA Groups

Deaths due to CAs (ie, CAs as the underlying cause of death) were coded according to the International Classification of Diseases, 10th Revision (ICD-10) and recorded in the DRC. In this study, we combined them into 10 broad groups, which were nervous system malformations (Q90-Q97); congenital malformations of the eye, ear, face, and neck (Q10-Q18); circulatory system anomalies including CHD (Q20-Q28); respiratory system malformations (Q30-Q34); cleft lip and cleft palate (Q35-Q37); other digestive system malformations (Q38-Q45); urogenital malformations (Q50-Q64); musculoskeletal malformations (Q65-Q79); chromosomal abnormalities including Down syndrome (Q90-Q99); and other congenital anomalies (Q80-Q89).

Statistical Analysis

Three age groups were generated during analysis, that is, neonates (aged 0-27 days), older infants (aged 28-364 days), and older children (aged 1-4 years). In the analysis, year-, age-, sex-, and residence-specific CAMRs were calculated as the number of CA deaths in the corresponding year, age group, sex (male or female), and residential region (urban or rural) divided by the number of live births in that specific group. Urban and rural regions were defined according to the fifth digit of the 12-digit administrative code issued by National Bureau of Statistics, for which 1 represents an urban region and all other digits represent a rural region. All mortality data were then standardized by using sex- and residence-specific live birth data.

https://publichealth.jmir.org/2024/1/e53860

JMIR Public Health Surveil 2024 | vol. 10 | e53860 | p.427
(page number not for citation purposes)
from 2020 National Population Census of China. The average annual change rates (AACRs) of CAMR and the rate ratios (RRs) of CAMR for male versus female children, rural versus urban children, older infants versus neonates, and older children versus neonates were analyzed using the Poisson regression model after adjusting for age, sex, and residence when appropriate. All analyses were conducted in SAS (version 9.2; SAS Institute), and a 2-sided \( P < .05 \) was considered significant.

**Ethical Considerations**

The Medical Ethics Committee of Children’s Hospital, Zhejiang University School of Medicine approved this study (2023-IRB-0248-P-01). Since all mortality data were deidentified from the government-established death surveillance system, informed consent was waived by the Medical Ethics Committee.

**Results**

From 2012 to 2021, a total of 1753 deaths caused by CAs were reported and the proportion of CA deaths stabilized around 20% of all deaths (Multimedia Appendix 1). The standardized CAMR in Zhejiang dropped from 121.2 per 100,000 live births in 2012 to 62.6 per 100,000 live births in 2021, representing a 48.3% (58.6/121.2) decline in total with a 9% annual reduction on average (\( P < .001 \); Table 1). Compared with female children, the CAMR of male children was generally higher in each year of the last decade, and the adjusted RR in total was 1.18 (95% CI 1.08-1.30; \( P < .001 \)). Generally, the AACRs for female and male children were –9.7% (95% CI –12.3% to –7.0%; \( P < .001 \)) and –8.5% (95% CI –11.1% to –6.1%; \( P < .001 \)), respectively.

Table 2 shows that relative to children from urban areas, rural children had a 20% higher CAMR (RR 1.20, 95% CI 1.08-1.32; \( P = .001 \)). Moreover, rural children had a higher AACR than their urban counterparts and the AACRs for urban and rural children were –8.5% (95% CI –11.6% to –5.4%; \( P < .001 \)) and –9.2% (95% CI –11.3% to –7.1%; \( P < .001 \)), respectively.

CAMR declined annually by 12% (95% CI 9.6%-14.5%; \( P < .001 \)) for neonates and by 6.3% (95% CI 3.4%-9.2%; \( P < .001 \)) for older infants, but not in older children (\( P = .22 \); Table 3). Generally, neonates had the highest standardized CAMR compared to older infants and older children (47.2 versus 31.0 and 9.5 per 100,000 live births; Table 3). However, the CAMR gaps across age groups narrowed annually. For older infants, the RR versus neonates turned insignificant since 2018 (all \( P > .05 \)) and increased from 0.48 (95% CI 0.37-0.63; \( P < .001 \)) in 2012 to 1.03 (95% CI 0.65-1.62; \( P = .91 \)) in 2021. For older children, the RR versus neonates grew from 0.17 (95% CI 0.11-0.25) in 2012 to 0.35 (95% CI 0.19-0.66) in 2021 (\( P < .001 \) in all years).

<sup>a</sup>The annual average change rate (AACR) of under-five mortality caused by congenital anomalies in neonates from 2012 to 2021 was –12% (95% CI –14.5% to –9.6%; P<.001).

<sup>b</sup>The AACR of under-five mortality caused by congenital anomalies in older infants from 2012 to 2021 was –6.3% (95% CI –9.2% to –3.4%; P<.001).

<sup>c</sup>The AACR of under-five mortality caused by congenital anomalies in older children from 2012 to 2021 was –3.2% (95% CI –8.3% to 2.0%; P=.22).

<sup>d</sup>RR: rate ratio.

<sup>e</sup>RR of under-5 mortality due to congenital anomalies adjusted for sex and residence.

<sup>f</sup>The unit of standardized mortality was per 100,000 live births.

Although a 9.8% (95% CI 7.3%-12.3%; P<.001) annual reduction was witnessed in circulatory system anomalies and more than half of the decline (33.1/58.6 per 100,000 live births, 56.5%) in the CAMR was contributed by the reduction in CHD
mortality, it still ranked first across all years in the last decade. Apart from CHD, the CAMRs reduced annually for all digestive ($P<.001$), other ($P=.004$), neural ($P=.004$), and respiratory ($P=.001$) anomalies, whereas CAMRs for the other 4 CA groups remained stable (all $P>.05$). Among the 10 CA groups, the rank of causes of death attributed to chromosomal abnormalities changed the most: from the eighth in 2012 to the third in 2021, with a 0.4% (95% CI: −6.7% to 7.6%; $P=.90$) insignificant annual increase. Details of the mortality for the 10 CA groups and a few common CA subtypes every 3 years from 2012 to 2021 are depicted in Figure 1.

Figure 1. Ranking of standardized under-5 mortality caused by 10 broad congenital anomaly groups and certain common subtypes in Zhejiang from 2012 to 2021. All data in this figure represent standardized under-5 mortalities due to certain congenital anomaly groups or subtypes (unit: per 100,000 live births). Different shades of red and blue indicating the rank of mortality caused by the broad category of congenital malformations: the darker the red is, the higher the rank; and the lighter the blue is, the lower the rank. AACR: annual average change rate; CHD: congenital heart disease; NTD: neural tube defect.

Multimedia Appendix 2 shows that 944 (53.9%) and 1562 (89.1%) out of 1753 deaths were caused by CAs occurred during the neonatal and infantile period, respectively. Among all common CAs, some were more fatal, with more than 70% of deaths occurring in the first 7 days of life, such as neural tube defects (NTDs; 25/32, 78%) and multiple systems–involved malformations (60/81, 74%). Some were less fatal, with better survival chances over 1 year, such as Down syndrome (17/52, 33%) and biliary atresia (23/81, 28%).
Discussion

Principal Findings

In this retrospective study, we observed an annual 9% reduction of CAMR in Zhejiang, and the change was significant in male and female children, urban and rural children, and neonatal and older infants. Generally, CAMRs were higher in male versus female children, rural versus urban children, and neonatal versus older infants. Among all CAs, some are more fatal, with ≥70% of deaths occurring in the first 7 days of life, such as NTDs (78%) and multiple systems-involved malformations (74%), whereas some are less fatal, with more survival chances over 1 year, such as Down syndrome (33%) and biliary atresia (28%). Circulatory system malformations, mainly CHDs, caused the maximum deaths in children younger than 5 years. U5MR caused by chromosomal abnormalities, although insignificant, tended to grow in recent years.

Comparison With Prior Work

The CAMR we observed in Zhejiang was not only lower than most provinces in China [6] but also lower than that in high-income countries such as the United States [12] and European countries [7]. The rather low CAMR and an ongoing declining trend can be explained by several reasons. First, there has been a series of nationally covered maternal and children health programs with stable financial investment from the Chinese government [13]. Among them, some aimed at reducing the prevalence of certain CAs and adverse birth outcomes, such as providing free folic acid tablets to women of reproductive age [14], whereas others aimed at improving the survival and health of children, such as providing antenatal and postnatal health care and health management for children aged 0-6 years [13].

Second, the rapid development and universal application of prenatal and newborn screening is another potential reason for the continuous decline of CAMR in Zhejiang. In 2000, only 7.6% children with Down syndrome were identified prenatally in China [15]. From 2013 to 2017 in Zhejiang, 91%, 96.9% and 100% of Down syndrome, encephalocele, and anencephaly were identified through prenatal screening, respectively [16]. Along with the extensive application of prenatal screening was a ≥90% rate of early termination of pregnancy, leading to less live births with severe CAs [17]. Newborn screening, a well-established public health measure to reduce early infant deaths, is widely used in Zhejiang, and more than 400,000 newborns are screened every year [18].

Third, with the development of postpartum surgical and repair techniques, the survival chances of children with CAs such as CHD, cleft lip, and cleft palate improved greatly [19,20]. For example, although the birth prevalence of CHD increased continuously worldwide [21] as well as in China [22], mortality due to CHD decreased gradually [23]. According to a hospital-based study, in-hospital mortality for children who underwent CHD surgeries during the first month after delivery reduced from 16.4% in the period from 2004 to 2008 to 5% in the period from 2014 to 2018 [24].

Similar to previous studies [6,25], we identified a larger CA death burden in male children than in female children. Both biological and genetic factors may play a role. First, male children are more likely to be born prematurely, which signifies lower survival chances [26]. Second, the X chromosome carries more genes responsible for immune function, leaving male children with CAs more vulnerable to infections [27]. The mortality differences across age groups are mainly related to the type and severity of CAs. As mentioned above, most severe CAs such as NTDs would experience pregnancy termination, and less than half of live births with NTDs would survive over 1 year [28]. For CAs that are less fatal such as Down syndrome, the life expectancy has increased dramatically and reached 60 years in 2002 [29].

The high death burden caused by CHD in our study was prevalent globally [4]. Although great progress has been made, the elimination of CHD remains a great challenge. On the one hand, as a public health issue driven mainly by genetics, it is difficult to remove the genetic predisposition and other environmental contributors that once existed [30]. On the other hand, timely diagnosis and treatment is still an issue to be solved. In Western countries such as Norway, only 13% of infants were discharged without the identification of severe CHDs [31], whereas in China, this number was 52.5% and can be as high as 71% for neonates with asymptomatic critical CHD [32]. In addition, mortality from complex CHD is still higher than other CHDs [33]. Besides, the high medical cost and parental worries for children’s future quality of life might also affect parents’ decision-making on whether to take further treatment or not.

In our study, we also noticed an increase in U5MR for chromosomal issues. Although insignificant, several reasons may provide an explanation. First, the proportion of pregnancies with advanced maternal age, a well-established risk factor of chromosomal abnormalities in the offspring [34], almost doubled after the termination of the One-Child Policy [35]. Second, new genetic techniques promote the detection and correct categorization of chromosomal issues [36]. Third, although detectable, systematic treatment strategies for most abnormalities are still absent [37]. Considering the factors mentioned above, higher prevalence and mortality of chromosomal abnormalities are projected in the future, and more attention should be paid to this issue.

Limitations

There are mainly 3 limitations in our study. First, the miscoding of death cause might exist. However, we have invited 2 experienced physicians to independently review all DRCs in the data preparation process to minimize this type of error in addition to routine quality control measures. Second, detailed information regarding each live birth with CAs and their survival status in the next 5 years was not collected in our work, limiting further analysis and comparisons on survival chances for different CA subtypes and the associated factors. Third, the analysis for CAs as a contributory cause of study was necessary but not feasible due to the lack of information in this study. It was reported that only 70% of deaths in infants with CAs...
recorded a CA as the underlying cause of death [38], meaning that the actual burden of CAs is greater than what we found.

**Conclusion**

In our study, we observed an ongoing decline in the CAMR in Eastern China, with cardiovascular malformations ranking first across all years. Despite the remarkable achievements, we still face great challenges, and we hereby make the following suggestions: (1) researchers should perform more well-designed studies to understand CAs’ risk factors and take measure accordingly to lower CA incidence, similar to what have been achieved with NTDs; (2) we must strengthen in-service education and training of medical staffs to improve their skills and promote “early detection, early diagnosis and early treatment”; (3) more sensitive and population-wide screening techniques such as echocardiography for early identification of CHD should be developed and applied to the public for free to lower undiagnosed CA cases [39]; and (4) we should provide easily accessible educational, emotional, and financial support to families with children with CAs, as reported by Wray and colleagues [40], to increase families’ capabilities and confidence in caring for children with CAs and improve their survival possibilities.

Abstract

Background: This study updates the COVID-19 pandemic surveillance in the Middle East and North Africa (MENA) we first conducted in 2020 with 2 additional years of data for the region.

Objective: The objective of this study is to determine whether the MENA region meets the criteria for moving from a pandemic to endemic. In doing so, this study considers pandemic trends, dynamic and genomic surveillance methods, and region-specific historical context for the pandemic. These considerations continue through the World Health Organization (WHO) declaration of the end of the public health emergency for the COVID-19 pandemic on May 5, 2023.

Methods: In addition to updates to traditional surveillance data and dynamic panel estimates from the original study by Post et al, this study used data on sequenced SARS-CoV-2 variants from the Global Initiative on Sharing All Influenza Data (GISAIID) to identify the appearance and duration of variants of concern. We used Nextclade nomenclature to collect clade designations from sequences and Pangolin nomenclature for lineage designations of SARS-CoV-2. Finally, we conducted a 1-sided t test to determine whether regional weekly speed of COVID-19 spread was greater than an outbreak threshold of 10. We ran the test iteratively with 6 months of data from September 4, 2020, to May 12, 2023.

Results: The speed of COVID-19 spread for the region had remained below the outbreak threshold for 7 continuous months by the time of the WHO declaration. Acceleration and jerk were also low and stable. Although the 1- and 7-day persistence coefficients remained statistically significant and positive, the weekly shift parameters suggested the coefficients had most recently turned negative, meaning the clustering effect of new COVID-19 cases became even smaller in the 2 weeks around the WHO declaration.
From December 2021 onward, Omicron was the predominant variant of concern in sequenced viral samples. The rolling t test of the speed of spread equal to 10 became entirely insignificant from October 2022 onward.

Conclusions: The COVID-19 pandemic had far-reaching effects on MENA, impacting health care systems, economies, and social well-being. Although COVID-19 continues to circulate in the MENA region, the rate of transmission remained well below the threshold of an outbreak for over 1 year ahead of the WHO declaration. COVID-19 is endemic in the region and no longer reaches the threshold of the pandemic definition. Both standard and enhanced surveillance metrics confirm that the pandemic had transitioned to endemic by the time of the WHO declaration.

Introduction

COVID-19, the disease caused by the virus SARS-CoV-2, was first detected in Wuhan, China, in the fall of 2019 [1-6]. The Middle East and North Africa (MENA) reported their first 9 COVID-19 cases in the United Arab Emirates and Egypt between January 29, 2020, and February 16, 2020 [7]. Our research team first conducted an epidemiological assessment of the pandemic in MENA 1 year into the pandemic [8]. This study provides 2 additional years of updated surveillance and analysis for the region.

We adopt the World Bank's definition of MENA, which is based on economic development and geographical proximity, encompassing Bahrain, Iran, Iraq, Israel, Jordan, Kuwait, Lebanon, Oman, Qatar, Saudi Arabia, Syria, the United Arab Emirates, Yemen, Algeria, Djibouti, Egypt, Libya, Morocco, and Tunisia [9].

The World Health Organization (WHO) and Director-General Ghebreyesus declared the end of COVID-19 as a public health emergency of international concern on May 5, 2023 [10-12] based on the recommendation of the COVID-19 Emergency Committee [12]. We compared how the pandemic, as experienced in the MENA region, progressed before and after the declaration.

Epidemiological terms, such as pandemic, epidemic, outbreak, and endemic, are used to describe the occurrence and spread of diseases [13,14]. The distinctions between these terms lie in their scope, geographic extent, and severity. An epidemic refers to a sudden increase in the number of disease cases in a specific population at the subnational level. If the epidemic spreads across several countries or continents, it becomes a pandemic. An outbreak, on the other hand, describes a sudden increase in a concentrated setting, usually involving a more limited geographic area than an epidemic. Endemic refers to the constant presence of a disease in a particular geographic region or population, with no sudden increases in case volume [15,16]. Field epidemiology defines these terms based on transmission metrics and geographical distribution. All public health surveillance data suffer from incomplete case ascertainment, meaning that not all cases of a disease may be reported or captured in the surveillance system. Despite this limitation, public health surveillance is valuable because it provides a near real-time view of disease trends within a population. Surveillance is crucial for leaders to respond effectively to health threats, implement control measures, and allocate resources where they are needed most. In sum, although the data may not capture every single case, they serve as a critical tool for monitoring and tracking the spread of diseases and health events in a population [17].

Since conducting and publishing our initial research on the pandemic in MENA, much more has been learned about the SARS-CoV-2 virus and its transmission and prevention [18-24]. Additionally, disease control measures and their effects on medical, social, and economic well-being have been further studied in the interval period, with new emphasis on clear guidelines and effective communication strategies [18,19]. In parallel, there was increased focus on risk factors for COVID-19 infection and mortality, ranging from personal risk factors such as age and medical comorbidities to air pollution, climate, and population density [18,25-27]. The vast breadth and depth of new knowledge related to COVID-19 and public health gained in the past 2 years underscore the need for new analysis with updated data and historical context.

Public health surveillance is the “ongoing, systematic collection, analysis, and interpretation of health-related data essential to planning and evaluation of public health practice” [28]. Surveillance explains the burden of disease with transmission and death rates [29-43] and allows us to compare that burden between geographical regions and to understand which regions are most impacted. The impact can be measured through standardized population rates regarding how many people contract or die from a disease.

However, traditional surveillance carries several limitations that this study addressed. Traditional surveillance provides a snapshot of what has already happened [29-43], meaning surveillance is static. In the middle of a burgeoning pandemic, policymakers and public health practitioners also need to understand what is about to happen. Is an outbreak increasing? Will growth switch from linear to exponential? Are more people dying from that particular condition in one place than another? To inform health policy and practice, knowledge of what is about to happen is often more valuable than knowledge of what did happen. To that end, we developed enhanced surveillance metrics that reflect the dynamics of a pandemic and can inform...
imminent growth and, most importantly, where along the epidemiological outbreak curve a particular region is situated. We also included dynamic metrics about the speed of the pandemic spread at the national, regional, and global levels. We measured how acceleration of speed this week compared with last week, as well as how novel infections last week predicted new cases this week. We can think of the latter measure as the echoing forward of cases. These metrics were tested and validated in prior research [8,44-54]. For the purpose of this study, standard surveillance metrics explain what has already happened in MENA, while enhanced surveillance metrics speak to what is about to happen or where along an epidemiological curve a country may sit. We used both types of metrics to analyze the possible end to the pandemic.

This study had 3 objectives. First, we aimed to measure whether there was a pandemic expansion or contraction in the MENA region at the time the WHO declared the end of the COVID-19 pandemic as a public health emergency of international concern on May 5, 2023. At both the region and country levels, we used advanced surveillance and analytical techniques to describe the status of the pandemic in a 2-week window around the WHO declaration. From a public health perspective, we need to know whether the rate of new COVID-19 cases was increasing, decreasing, or stable from week to week and if any changes in the transmission rate indicated an acceleration or deceleration of the pandemic. Statistical insignificance is significant—it signals an epidemiological “end” to the pandemic if the rate of new cases is 0 (or very low) and stable, meaning the number of new cases is neither accelerating nor decelerating.

Second, we used dynamic and genomic surveillance methods to describe the history of the pandemic in the region and situate the time window around the WHO declaration. We included the ratio of COVID-19 deaths to the number of transmissions as a proxy for the population-level mortality risk from infection. We also included a historical record of genomic surveillance from sequenced viral specimens to identify the appearance and spread of variants of concern in the region.

Third, we aimed to provide historical context for the course of the pandemic in the MENA region. We addressed several questions. How did countries respond to the pandemic? How did the region fare in terms of disease burden? What social, economic, and political factors shaped the course of COVID-19 in the region? This context can provide important lessons for disease prevention and mitigation in future pandemics.

**Methods**

**Data Source**

This study conducted trend analyses with longitudinal COVID-19 data for the MENA region from 2020 through 2023. Data on COVID-19 transmission and death were sourced from Our World in Data (OWID) [55]. OWID compiles data on COVID-19 cases and mortality from multiple sources, including individual websites, statistical reports, and press releases. The MENA region was defined by the World Bank’s economic and geographical metrics [9], and the data comprised an unbalanced panel of 20 countries and territories from September 4, 2020, to May 12, 2023. Because several countries around the world switched from daily to weekly reports at various points in 2023, we used a cubic spline to interpolate daily new cases and deaths when any country had 4 consecutive periods of non-zero new cases interspersed by 6 days of zero new cases. A cubic spline is a statistical function used to assess the “smoothness” of data points and estimate missing or unclear data on a line given surrounding trends.

To identify the appearance and duration of variants of concern, we used data on sequenced SARS-CoV-2 variants from the Global Initiative on Sharing All Influenza Data (GISAID), which is an effective and trusted online resource for sharing genetic, clinical, and epidemiological COVID-19 data [56-60]. We used Nextclade nomenclature [61] to collect clade designations from sequences and Pangolin nomenclature for lineage designations of SARS-CoV-2 [62,63]. Nextclade nomenclature is an open-source tool for viral genome analysis, mutation identification, clade assignment, and phylogenetic mapping. Pangolin nomenclature is an open-source tool (Phylogenetic Assignment of Named Global Outbreak Lineages) used to track the transmission and spread of SARS-CoV-2 and its lineages. Metadata for the study period were collected on June 22, 2023. To avoid low frequency or potentially erroneous samples, the data set was further filtered to exclude months with fewer than 100 available samples, variant groups with fewer than 5 samples in a month, and variant groups representing less than 0.5% of the total samples in a month. The final data set consisted of 184,386 total samples available on GISAID [56-59].

**Measures**

This study provides updates of traditional surveillance data and dynamic panel estimates from the original study by Post et al [8,52,53,64-66]. The “speed” of spread of the pandemic is the rate of new COVID-19 cases per 100,000 population. Novel metrics go beyond speed to add acceleration, jerk, and 1- and 7-day persistence measures. Acceleration is the difference in speed from one week or day to the next. Acceleration identifies whether the number of new cases is increasing (positive acceleration), decreasing (negative acceleration), or at a stable inflection point (zero). “Jerk” is the change in acceleration from one time interval to the next, and its name is adopted from physics nomenclature. A positive jerk can indicate explosive growth in the spread of a disease. Finally, 1- and 7-day persistence measures capture the impact of the 1- and 7-day lag of speed on current speed. These measures capture the echo-forward effect of COVID-19 cases on future cases either 1 or 7 days later. They are derived from coefficient estimates on lagged transmission rates in an Arellano-Bond dynamic panel data model [67]. The model follows the general form of:

$$y_{it} = \rho y_{it-1} + \beta x_{it} + \alpha_i + u_{it}(1)$$

where the dependent variable is the rate of COVID-19 transmissions, the independent variables include weekend and recent week indicators, $\alpha_i$ denotes country fixed effects, and $u_{it}$ is the idiosyncratic error term. Please see the initial study for more details [8].

We further analyzed the potential “statistical end” to the pandemic with a 1-sided $t$ test for whether the mean of speed
of spread, defined as the rate of new COVID-19 cases per 100,000 population in a given time period, was equal to or greater than the outbreak threshold of 10. We ran the test on a rolling 6-month window over weekly speed for the region, and we plotted the P values from the test over time. All statistical analyses were conducted with the *plm* package (version 2.6-2) in R (version 4.2.1) [64,65].

**Ethical Considerations**

This study followed the guidelines of the World Medical Association’s Declaration of Helsinki: Ethical Principles for Medical Research Involving Human Subjects [68,69]. This research relied on publicly available data with no private, identifiable information. Thus, institutional review board review was unsolicited.

**Results**

Table 1 presents the dynamic panel estimates for the most recent time window. The Wald test for the regression was significant (P<.001), and the Sargan test failed to reject the validity of the overidentification restrictions (P=.99). Although the 1- and 7-day lag coefficients were statistically significant, suggesting a cluster effect in which cases on a given day impact cases 1 day and 7 days later, the coefficients were moderate in magnitude (0.310 and 0.586, respectively). Furthermore, the shift parameters for either of the 2 most recent weeks were both significant and negative, meaning the clustering effect had become smaller—in fact, negative—in the 2 weeks around May 5, 2023.

Static surveillance metrics for the weeks of April 28, 2023, and May 5, 2023, are provided in Table S1 of the Multimedia Appendix 1. Every country had a small number of new COVID-19 cases. The highest rate of new cases per 100,000 population was 8.90 in Qatar for the week of April 28, 2023, still considered a low transmission rate by the Centers for Disease Control and Prevention (CDC) [70]. This rate falls just below the informal outbreak threshold of 10 cases per week per 100,000 population [8,44-54]. Specifically, a “Low” transmission is considered no more than 10 cases per 100,000 people per week. “Moderate” transmission is 10 to 50 cases per 100,000 people per week, and “Substantial” transmission is 50 to 100 cases per 100,000 people per week [70,71].

The weekly transmission rate in Qatar also fell to 0 the following week. For the same week, no other country had a speed greater than 2.

Comparisons in Table S1 (Multimedia Appendix 1) demonstrate little to no change in surveillance metrics before and after the WHO declared an end to the COVID-19 emergency. Without question, Iran and Israel had the most cases of COVID-19 transmissions and deaths, but this rank is a function of population size. Thus, a better measure is the number of transmissions and deaths, but this rank is a function of population size. Thus, a better measure is the number of cases per 100,000 people. Iran reported 0.02 deaths per 100,000 population. When we controlled for a risk of death given the number of COVID-19 transmissions, we found that Egypt had the highest conditional death rate of 0.05 deaths per case. The next highest rate was 0.03 deaths per case in both Algeria and Tunisia.

Table 2 contains enhanced dynamic surveillance metrics for the 2 weeks before and after May 5, 2023. Speed of spread was low for every country except Qatar in the week of April 28, 2023, and acceleration was 0 or negative for almost every country. During this time, Qatar still remained well below the outbreak threshold (see Table S1 in Multimedia Appendix 1). Although positive, acceleration was small. The 7-day persistence effect on speed of spread was also very small in magnitude for the week of April 28, 2023, in every country, and the persistence effect fell to 0 or negative for every country the following week. These metrics suggest the pandemic may have indeed ended for the region. We note that the figures in Table 2 are not calculated as day-over-day averages across the week, as they are in Table S1 in Multimedia Appendix 1. Thus, the magnitudes of speed may not exactly match those in Table S1 in Multimedia Appendix 1.

Table 3 compares the 7-day persistence effect on speed for the 5 countries with the highest persistence for the weeks of April 28, 2023, and May 5, 2023. In each case, the effect had become either 0 or negative by the second week. Again, these metrics indicate that COVID-19 was well controlled in the region overall.

Figure 1 plots the regional speed of spread, acceleration, jerk, and 7-day persistence metrics from September 4, 2020, to May 12, 2023. The dashed grey line denotes the informal CDC outbreak threshold of speed equal to 10. The region experienced 3 outbreaks over the course of the pandemic. The first was brief, reaching a peak speed of only 13 in April 2021. The second saw a peak speed of 19 in August 2021. However, these 2 outbreaks can largely be considered 1, as speed dipped only slightly below the outbreak threshold of 10 between them. The third outbreak was the largest, with a peak speed of 33 in February 2022.

Figure 2 plots variant groups as a proportion of all viral specimens collected and sequenced in the region (and made available through GISAID) each month. The first 1 to 2 outbreaks referenced in the previous paragraph occurred just around the appearance of the Delta variant. The last outbreak was driven by the Omicron variant. MENA, like much of the rest of the world, saw a surge in cases amid the heightened transmissibility of Omicron [73]. Still, the outbreak was much smaller than in several other regions of the world, such as North America, Europe, and East Asia and the Pacific, which each saw peak speeds of over 200 amid Omicron outbreaks.

Another potential indication of the end to the pandemic was the continued dominance of the Omicron variant. Although the region saw a mixture of the ancestral, Alpha, Beta, and Delta variants prior to the arrival of Omicron in November 2021, viral sequences have almost exclusively returned as Omicron and its subvariants ever since.

Figure 3 plots the P values from a series of 1-sided t tests to determine whether speed for the region was equal to or greater than the threshold outbreak of 10. These tests were conducted...
on a rolling 6-month window of weekly regional speed. The dashed grey line denotes the least restrictive conventional significance level threshold of $\alpha$=.10. The only time the test rejected the null hypothesis in favor of the alternative occurred around the 6-month period ending in mid-August 2021. This period marked the extended, intermittent outbreak driven by (presumably) the Delta variant. From then on, the test failed to reject the null hypothesis, although $P$ values did drop again somewhat around the later Omicron outbreak. The test statistic became consistently insignificant from approximately October 2022 onward. This more recent lack of statistical significance is consistent with the end of the pandemic in the region, as the test clearly failed to reject the null hypothesis of outbreak threshold speed.

With the historical context of enhanced surveillance metrics, the MENA region appeared to be at the end stage of the pandemic. Speed had not been this low for this long since the start of the pandemic. Furthermore, speed remained well below outbreak status for over 1 year ahead of the WHO declaration. Figure 4 provides a timeline of the onset of COVID-19 in MENA as well as vaccination programs and major events that likely created additional challenges to disease control, such as the arrival of new variants of concern.

**Discussion**

**Principal Findings**

The principal finding to the stated objective of this study is that the MENA region meets the 3 criteria for moving from a pandemic to an endemic. First, the transmission rates before and after the WHO declaration of the end of the COVID-19 public health emergency of international concern on May 5, 2023, were well below the threshold of an outbreak. Second, the transmission and death rates approached 0 and remained extremely small and stable. Finally, the pandemic in MENA is no longer propagating forward. Our findings therefore signal that COVID-19 has changed from a pandemic to an endemic in MENA. Nonetheless, COVID-19 had profound effects on the region’s economy, political, and public health institutions since the pandemic began in spring 2020.
The MENA region saw several waves of infection over the course of the pandemic, with significant spikes driven by new SARS-CoV-2 variants and the rollback of COVID-19 restrictions. The region saw significant disparities in how effectively countries were able to enforce quarantine rules and contain the virus. During an initial wave in 2020, MENA countries with the economic, social, and political resources to institute quarantines were quick to respond to the pandemic and had substantially lower infection and fatality rates compared with countries in Europe and North America. This response allowed them to reopen their economies quickly. MENA governments similarly responded to later waves by reinitiating quarantine rules in focused areas. For example, Saudi Arabia, Kuwait, and Qatar each saw the number of COVID-19 cases drastically increase in May 2020 after restrictions were eased for Ramadan. These governments quickly reinforced strict lockdowns to control the spread of the virus [74].

Other MENA countries, which were already struggling with economic and sociopolitical instability, faced heightened crises as COVID-19 strained their already fragile societies. In Syria, which has grappled with internal conflict since 2011, COVID-19 created a health care catastrophe as the country’s already strained health care system was pushed to the breaking point. According to the WHO, only 50% of hospitals in Syria were fully functioning, and 25% were partially functioning at the start of the pandemic due to shortages of staff and medical equipment from years of war [75]. Refugee camps, which lacked proper medical staff and equipment, created grounds for the virus to spread quickly [76]. Yemen, which has dealt with a long and protracted civil conflict, faced its own crisis in the pandemic. Trade restrictions due to COVID-19 led to more than 50% of Yemen’s population facing food insecurity and hunger [77-79].

In economic impacts, the MENA region saw a 3.5% decline in gross domestic product (GDP) in 2020 driven by COVID-19 containment measures. However, as vaccines became more prevalent and countries began easing COVID restrictions, economies rebounded, with GDP growth of 4.5% in 2021 [80]. Some countries, such as Saudi Arabia, Kuwait, and the United Arab Emirates, also faced a secondary economic shock from a sharp decline in oil prices in 2020 [81].

Many countries in the region approved large fiscal packages to support struggling economic sectors. These packages typically included direct cash support for affected workers, tax relief for individuals and corporations, investment in strained health care systems, and economic investment in specific sectors. Saudi Arabia announced a SR 70 billion (US $18.6 billion; 2.7% of GDP) private support package, which suspended government tax payments and provided additional liquidity to the private sector. Kuwait allocated KD 500 million (US $1.6 billion; 1.5% of GDP) toward economic stimulus, which included the provision of full unemployment benefits for Kuwaiti nationals [81]. Many MENA countries began the pandemic with underfunded health care systems and had to drastically increase their health care expenditure and invest in personal protective equipment, ventilators, and other medical supplies. Egypt allocated £5 billion (US $103 million) toward the purchase of necessary medical supplies and funds for additional medical staff [81]. Overall, these health and social welfare packages required MENA countries to borrow substantial amounts of money, leading to increases in government debt [82].

Given prior experience with the Middle East respiratory syndrome (MERS), many countries in the region were quickly able to enact containment strategies. The backbone of these strategies consisted of masking, border closures, contact tracing, social distancing, quarantines, and lockdowns. However, there were significant disparities in how effective these measures were implemented given the large differences in economic resources, health care infrastructure, and the political stability between countries. The United Arab Emirates was one of the first countries to issue a COVID-19 alert before the WHO declared COVID-19 a public health emergency. Saudi Arabia, a deeply religious country, barred Muslims from conducting prayers inside mosques. Pilgrimages to holy sites such as Mecca and Medina were banned for foreigners [83]. Additionally, the United Arab Emirates and Saudi Arabia levied fines against any individuals or businesses that failed to adhere to mask mandate policies [84]. Saudi Arabia also built makeshift hospitals to increase their health care capacity and accommodate surges in COVID-19 cases [85]. Israel’s Ministry of Health implemented a containment strategy focused on early travel restrictions to countries reporting COVID-19 cases, and 14-day self-quarantine measures were imposed on anyone arriving from abroad [86]. More extensive lockdown measures were ultimately implemented, including the closure of schools, universities, and all nonessential businesses [87]. Another cornerstone of Israel’s containment strategy was the use of its extensive health care resources to test and quarantine patients at scale [88]. Israel also utilized mobile apps and spatial data collected from mobile phones to effectively perform contact tracing [88,89].

Some countries in the region lacked the health care resources to effectively fight the spread of the virus. At the start of the pandemic, Morocco had a hospital bed capacity of 1.1 beds for 1000 people, among the lowest in MENA [90]. Morocco therefore adopted an early, strict containment strategy to prevent straining their limited health care system. Policies included suspension of public events, suspension of international travel, and restrictions on intercity travel [18,21,25,90,91]. Additionally, the government created a “COVID-19 Fund,” which provided funding to increase hospital beds and intensive care unit capacity, purchase personal protective equipment, and increase testing capabilities [92]. Morocco experienced one of the lowest fatality rates in the region during the initial wave of infections [92].

Yemen faced difficulties implementing a comprehensive containment strategy given the violent civil conflict facing the country. Health infrastructure lacked the capability to properly test patients and track the virus [93]. In parts of the country controlled by the Houthis, faction, almost no COVID-19 restrictions were implemented [81,94].

As the pandemic continued, countries eventually relaxed their restrictions to stimulate the economy and only reinstated lockdowns when COVID-19 cases began to spike [22,95]. MENA countries focused on achieving herd immunity through widespread vaccination campaigns. The Pfizer-BioNTech
vaccine was the first vaccine approved in Saudi Arabia in mid-December 2020, with millions of vaccine doses being administered throughout the pandemic [96]. In July 2021, Saudi Arabia was also one of the world’s first countries to implement a large-scale vaccine mandate to combat a new surge in cases from the COVID-19 Delta variant. This mandate required proof of vaccination to enter public and private institutions, including schools, shops, malls, public transportation, and more [97]. The United Arab Emirates also mandated vaccinations for all people attending live events such as sports events and art exhibitions. Attendees also had to provide a negative polymerase chain reaction (PCR) test within 48 hours of the event [98]. Egypt announced that COVID-19 vaccinations were mandatory for people over the age of 18 years. The country banned all nonvaccinated people from entering public, governmental, and educational buildings to further incentivize vaccination [99]. In June 2021, Egypt also signed an agreement with Chinese vaccine manufacturer SinoVac to locally produce the company’s inactivated vaccine, CoronaVac [100,101].

There were large disparities in access to vaccines, with richer nations such as the United Arab Emirates and Saudi Arabia able to vaccinate their population much faster than less-resourced countries. For example, by early December 2021, the United Arab Emirates had one of the world’s highest vaccination rates at 90% of the population, while Yemen had just reached a rate of 1% [23,82].

One unique issue facing countries in the MENA region was the need for halal-certified vaccines. Many countries in the region have significant Muslim populations [102]. Islamic law requires that Muslims avoid using vaccines manufactured with certain types of ingredients (such as pork products) [102]. To avoid potential vaccine hesitancy, religious leaders in several MENA countries, including the United Arab Emirates and Egypt, declared vaccines halal and encouraged citizens to get vaccinated to prevent further spread of the virus [103].

Limitations

Limitations of our data analysis and resulting manuscript include the following. COVID-19 data had become less frequently reported around the world by the time the WHO declared an end to the COVID-19 Emergency of International Concern [104]. Additionally, more people began to use at-home tests as the pandemic evolved [105]. Because the enhanced surveillance metrics of speed, acceleration, jerk, and 7-day persistence are based on rates, not total counts, statistical bias caused by countries dropping in or out of the sample is mitigated, but to the extent that a nonincluded country is unrepresentative of the region in disease burden, the omission of a country or territory can still influence historical data comparisons. Viral specimen tests for variants of concern in GISAID are also dependent on testing and sequencing capacity, which varied by country across the region.

Conclusion

Overall, the COVID-19 pandemic had far-reaching effects on MENA, impacting health care systems, economies, and social well-being. Although the region fared better in disease burden than several others, many countries in the region continue to face challenges due to limited economic and health care resources [48,106-108]. Although COVID-19 continues to circulate in MENA, the rate of transmission remained well below the threshold of an outbreak for over 1 year ahead of the WHO declaration.

The concern about potential resurgences of the SARS-CoV-2 virus is valid [20,109-111]. As long as COVID-19 continues to spread and mutate, the possibility of new variants emerging remains. Variants could potentially be more transmissible, resistant to vaccines, or cause more severe illness. For example, 4 months after the WHO declared the end to the public health emergency, Omicron has further mutated into Omicron EG.5, incorrectly referred to as Eris and sensationalized in the media [112]. There is no evidence that this subclade results in more severe disease or death [113]. This underscores the importance, however, of continued vigilance, vaccination efforts, and global cooperation to control the spread of the virus [19,24,26,27,51,114-116].

Our findings underscore the importance of the following efforts on a country and regional basis: government investment in epidemiological surveillance and preparedness for future pandemics and public health emergencies; identification of barriers to access of key public health resources including care (including acute and preventative care [ie, vaccines]), education, and material goods and financial support; additional crisis management preparations in the social and economic spheres given their intersectionality with public health; regular assessment of social attitudes toward health crises, including both ongoing and potential future emergencies.

Abstract

Background: It is known that 24-hour movement behaviors, including physical activity (PA), sedentary behavior (SB), and sleep, are crucial components affecting older adults' health. Canadian 24-hour movement guidelines for older adults were launched in 2020, emphasizing the combined role of these 3 movement behaviors in promoting older adults' health. However, research on the prevalence and correlates of guideline adherence and its associations with health-related outcomes is limited, especially among Chinese older adults.

Objective: This study aimed to investigate the prevalence and correlates of meeting 24-hour movement guidelines among Chinese older adults. Furthermore, this study aimed to examine the associations of guideline adherence with older adults' physical and mental health outcomes.

Methods: Using a stratified cluster random sampling approach, a total of 4562 older adults (mean age 67.68 years, SD 5.03 years; female proportion: 2544/4562, 55.8%) were recruited from the latest provincial health surveillance of Hubei China from July 25 to November 19, 2020. Measures included demographics, movement behaviors (PA, SB, and sleep), BMI, waist circumference, waist-hip ratio (WHR), percentage body fat (PBF), systolic and diastolic blood pressure, physical fitness, depressive symptoms, and loneliness. Generalized linear mixed models were employed to examine the associations between variables using SPSS 28.0 (IBM Corp).

Results: Only 1.8% (83/4562) of participants met all 3 movement guidelines, while 32.1% (1466/4562), 3.4% (155/4562), and 66.4% (3031/4562) met the individual behavioral guidelines for PA, SB, and sleep, respectively. Participants who were older, were female, and lived in municipalities with lower economic levels were less likely to meet all 3 movement guidelines. Adhering to individual or combined movement guidelines was associated with greater physical fitness and lower values of BMI, waist circumference, WHR, PBF, depressive symptoms, and loneliness, with the exception of the relationship of SB+sleep guidelines with loneliness. Furthermore, only meeting SB guidelines or meeting both PA and SB guidelines was associated with lower systolic blood pressure.
Conclusions: This is the first study to investigate adherence to 24-hour movement guidelines among Chinese older adults with regard to prevalence, correlates, and associations with physical and mental health outcomes. The findings emphasize the urgent need for promoting healthy movement behaviors among Chinese older adults. Future interventions to improve older adults’ physical and mental health should involve enhancing their overall movement behaviors and should consider demographic differences.

(KEYWORDS: physical activity; sedentary behavior; sleep; cardiometabolic indicators; physical fitness; mental health; post–COVID-19 era; older adults; COVID-19; systolic blood pressure; diastolic blood pressure; depression; loneliness)

Introduction

The number of older adults (≥60 years) worldwide was estimated to be 1 billion in 2019, and this figure is expected to double by 2050, accounting for around 22% of the global population [1]. This demographic shift has been occurring at an unprecedented pace and may accelerate in the coming decades, and it will bring considerable challenges to worldwide societies, especially in developing countries [1,2]. As a vulnerable group, older adults have shown low levels of physical fitness and high levels of morbidity and mortality of infectious respiratory diseases, cardiometabolic diseases, and mental disorders (eg, late-life depression), which have worsened because of the outbreak and continuation of the COVID-19 pandemic [3-5]. The daily routines of older adults have been substantially altered [6]. They have been challenged by requirements to increase their time living at home, limits to physical and social connections with other family members and friends, temporary decreases or cessation of employment and recreational activities, loneliness, and fear of illness and death for themselves and others [3,6-8]. Therefore, promoting physical and mental health among older adults during the pandemic and beyond to achieve healthy aging is a public health and socioeconomic imperative globally [7].

It has been shown that 24-hour movement behaviors, including physical activity (PA), sedentary behavior (SB), and sleep, have prominent impacts on a wide range of physical and mental health outcomes among older adults [9-11]. For example, regular engagement in PA has been shown to be reliably associated with better health-related outcomes, such as BMI [12,13], percentage body fat (PBF) [12,13], waist circumference [14,15], waist-hip ratio (WHR) [15,16], systolic and diastolic blood pressures (SBP and DBP, respectively) [17], physical fitness [18,19], and depression and loneliness [20-22]. Similarly, adequate sleep duration has been shown to be associated with greater cardiorespiratory fitness [23,24] and decreased risks of metabolic diseases [25] and mental disorders [26] among older adults. In contrast, prolonged sedentary time has been shown to be a modifiable risk factor that negatively affects the physical and mental health of older adults [19,27-29].

Historically, most studies have focused only on the effect of one of these specific movement behaviors on health-related outcomes, whereas the interrelationship and joint effects of these movement behaviors were comparatively ignored [30,31]. In recent decades, an increasing collection of evidence has supported the combined effects on health among different populations, including preschool children [32], school children [33-36], adolescents [33,36], and adults and older adults [30,31]. Drawing on the theoretical underpinnings of time-use epidemiology and bolstered by recent empirical findings, the Canadian 24-hour Movement Guidelines for adults aged 18-64 years and those aged 65 years or older were established in 2020 [31]. These guidelines advocate for adults aged 18 years or older to engage in a minimum of 150 minutes of moderate-to-vigorous physical activity (MVPA) cumulatively per week. Additionally, they recommend limiting SB to no more than 8 hours daily, with recreational screen time not exceeding 3 hours, and maintaining a sleep duration of 7-9 hours for adults aged 18-64 years and 7-8 hours for those aged 65 years or older. Furthermore, the guidelines emphasize the importance of regular sleep and wake-up times.

The launch of 24-hour movement guidelines for adults has inspired relevant research interest in the combination of 24-hour movement behaviors among adult populations [37-42]. For instance, a national-level surveillance (2007-2013) found that Canadian adults (aged 18-79 years) who adhered to all 3 movement guidelines had more favorable BMI, waist circumference, aerobic fitness, and cardiometabolic biomarker levels (eg, C-reactive protein and insulin levels) [38]. A recent cross-sectional study indicated an inverse association between meeting 24-hour movement guidelines and mental health outcomes (eg, depression) among Chinese caregivers of preschoolers (mean age 35.5 years, SD 4.9 years) during the COVID-19 pandemic [41]. However, there is a lack of evidence among Chinese older adults.

Previous studies have found that meeting 24-hour movement guidelines was correlated with a range of demographic factors, such as sex, education level, marital status, health condition, and economic status among adult populations [37,38,42]. However, all the above studies focused on young individuals and middle-aged adults, while to the best of our knowledge, there is a scarcity of recent evidence on the correlates of meeting 24-hour movement guidelines among older adults (aged ≥60 years).

Therefore, this study aimed to (1) investigate the prevalence of meeting 24-hour movement guidelines among Chinese older adults; (2) investigate the correlates of meeting 24-hour movement guidelines among Chinese older adults; and (3) examine the association of adherence to 24-hour movement guidelines with physical (ie, BMI, waist circumference, WHR, PBF, SBP, DBP, and physical fitness) and mental (ie, depression and loneliness) health outcomes among Chinese older adults.
Methods

Participants and Procedure
Participants were recruited from the latest provincial health surveillance of Hubei China [43]. The HSHC is an ongoing consecutive cross-sectional surveillance that collects various health indicators on a representative sample of Chinese residents living in the Hubei province of China every 5 years [43]. A self-weighted stratified cluster random sampling approach was applied in the HSHC, where participants were randomly selected from 17 municipalities of Hubei province, stratified by communities, towns (villages), and districts (counties) for each municipality. In this study, eligible participants were required to meet the inclusion criteria, including (1) age of 60-79 years, (2) adequate language skills (ie, reading and writing capabilities in Chinese), and (3) no restriction of physical mobility (eg, passed the Physical Activity Readiness Questionnaire [PAR-Q]). Participants excluded from this study were those outside the specified age range, those unable to read and comprehend Chinese, those failing the PAR-Q, and those diagnosed with cognitive or sleep disorders. A total of 32,080 participants were contacted, and 27,826 agreed to participate in the surveillance (86.7% response rate). After eligibility checks, 4953 eligible participants were invited to complete data collection.

Eligible participants were further invited to complete the study measures at a multi-function stadium, lasting approximately 30 minutes per person. To ensure assessment quality, for each municipality, the data collection was conducted by a trained health surveillance team, which consisted of 15-20 qualified assessors who passed a competency examination, according to consistent standard operating procedures. Data were collected from July 25, 2020 (3 months after the lockdown was withdrawn) to November 19, 2020.

Ethical Considerations
This study followed the Declaration of the Helsinki World Medical Association [44] and the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) statement [45]. Ethics approval was obtained from the General Administration of Sport of China (CISS-2019-01-31) and Hubei Institute of Sport Science (HISS-2019-03-01). All participants who were interested in participating in the surveillance were asked to sign a written informed consent form before the study commencement.

Measures
Adherence to 24-Hour Movement Guidelines
The Chinese version of the International Physical Activity Questionnaire long form (IPAQ-LC) was used to measure PA, SB, and sleep (interconsistency coefficient [ICC]=0.79-0.87) [46,47]. For PA, participants were asked to report the frequency (days) and duration (minutes) of 3 intensities of PA (ie, light PA, moderate PA, and vigorous PA) during the past 7 days. Weekly time of PA was calculated using the following formula: frequency\times duration. For sedentary and sleep time, participants were asked to report the time (hours and minutes per day) they spent in these 2 behaviors on weekdays and weekends separately during the past week. Daily time of SB and sleep was calculated by dividing the weekly time of SB and sleep by 7 days. According to the Canadian 24-hour movement guidelines [31], participants were categorized as 0 (meeting none of the movement guidelines), 1 (meeting 1 of the movement guidelines), 2 (meeting 2 of the movement guidelines), and 3 (meeting all 3 movement guidelines).

Physical Health Outcomes
Physical health outcomes included objectively measured BMI, waist circumference, WHR, PBF, SBP, DBP, and physical fitness. Participants were informed to not participate in any vigorous PA 12 hours before the assessment. The assessments were conducted at indoor multi-function sport gymnasiums, with ambient temperature kept constant during the measurements for all participants.

Body weight and body height were measured using a portable stadiometer (GMCS-SGJ3; to the closest 0.05 kg) and a calibrated medical digital scale (GMCS-RCS3), which were further used to calculate BMI (kg/m²) [48]. Waist and hip circumference were measured using specific tape measures (GMCS-WD3; to the closest 0.1 cm). WHR was calculated as waist circumference (cm) divided by hip circumference (cm). PBF was measured using a portable bioelectrical impedance device (GMCS-TZL3). Participants were measured after either an overnight or 2-hour fast and were asked to remove their footwear and socks before stepping on to the measurement instrument. The whole assessment followed a standard procedure (eg, placing the feet on 4 pads, keeping the arms straight down, and not touching the inner thighs) guided by qualified assessors. SBP and DBP were measured after participants sat for 15 minutes, using digital instruments (GMCS-XY3).

Physical fitness was measured according to the standard protocol of the National Physical Fitness Surveillance of China [49,50]. The entire physical fitness assessment included 7 tests in this study: (1) vital capacity test using a spirometer (GMCS-FHL), (2) handgrip strength test using a mechanical dynamometer (GMCS-WCS3), (3) chair sit-and-reach test, (4) 30-second chair stand test, (5) 2-minute step test, (6) 1-leg standing with eyes closed balance test, and (7) choice reaction time test using a traditional test plate (GMCS-FYS). Each test was conducted twice, and the best performance of the 2 trials was recorded for analysis. The total physical fitness score was the sum of the weighted score of each test, ranging from 10 to 100, with a higher score indicating a greater physical fitness [49,50]. Prior to testing, all participants were fully familiarized with the measurement procedures.

Mental Health Outcomes
Depression was measured using the Chinese version of the Patient Health Questionnaire-9 (PHQ-9) [51,52]. Following the instruction question “how often were you bothered by the following problems over the past two weeks...”, participants were asked to give answers to 9 situations (eg, “little interest or pleasure in doing things”) on a 4-point Likert scale ranging from 0 (“not at all”) to 3 (“nearly every day”) (Cronbach α=.88). The total score of the 9 items was calculated (range 0-27), with
a higher score indicating a more severe level of depressive symptoms.

Loneliness was measured using the Chinese version of the 10-item Emotional and Social Loneliness Scale (ESLS-10) [53,54]. Participants were asked to answer how often the 10 designated feelings occurred over the past year (eg, “I feel as if nobody really understands me”). Responses were indicated on a 5-point Likert scale ranging from 1 (“not at all”) to 5 (“very often”) (Cronbach α=.85). The total score of the 10 items was calculated (range 10-50), with a higher score reflecting a higher level of loneliness.

Covariates
Covariates were chosen in accordance with prior research [30,31,37] and included age, gender, place of residence (urban/rural), educational attainment, marital status, chronic diseases (eg, hypertension, cardiovascular diseases, stroke, osteoporosis, cancer, and type 2 diabetes), current smoking and alcohol consumption behaviors, and the economic status of municipalities (as determined by provincial gross domestic product [GDP] statistics) [55].

Statistical Analysis
Data analyses were performed using SPSS 28.0 (IBM Corp). We excluded 248 cases owing to missing demographic details (73 cases lacking age and gender information), movement behaviors (73 cases), and physical and mental health outcomes (248 cases without data on BMI, PBF, physical fitness, and 2 mental health indicators) and 143 cases owing to invalid or abnormal values in movement behaviors (122 cases) and health-related outcomes (76 cases; eg, BMI and PBF), particularly those cases with skewness and kurtosis absolute values beyond ±1.5 and z-scores exceeding the ±3 SD threshold [56]. Thus, data from 4562 participants were retained for the final analysis. Based on a retrospective power estimate, the final sample size of 4562 was adequate to detect an effect size (Cohen $f^2$) of 0.01, with an $\alpha$ of .05 and a statistical power (1-β) of 0.8, in the regression model [35,41]. Odds ratios (ORs) of 1.68, 3.47, and 6.71 were considered to indicate a small, medium, and large effect size, respectively [57]. A statistical significance level of $P<.05$ (2-tailed) with 95% CI not covering 0 was used for all analyses.

Results
Sample Characteristics
Of 4953 participants, 4562 (retention rate of 92.1%) were included in the final data analysis (Figure 1). In addition, 69.2% (3157/4562) of participants were aged 65 years or older, and the mean age of the total sample was 67.68 (SD 5.03) years. Moreover, 55.8% (2544/4562) were female and 53.0% (2417/4562) were living in urban areas. Participants with an education level of secondary school accounted for the largest proportion (2115/4562, 46.4%), while only 12.2% (555/4562) of participants had an education level of college or above. Furthermore, 86.9% (3964/4562) of participants were married, and 46.8% (2134/4562) reported a history of chronic diseases. Details of the study sample are presented in Table 1.

Prevalence of Adherence to 24-Hour Movement Guidelines

The rates of adhering to 0, 1, and 2 movement guidelines were 24.7% (1126/4562), 50.5% (2303/4562), and 23.0% (1050/4562), respectively. The proportion of participants meeting individual movement guidelines was 32.1% (1466/4562) for MVPA, 3.4% (155/4562) for SB, and 66.4% (3031/4562) for sleep. Prevalence rates of meeting a combination of 2 movement behaviors ranged from 1.8% (83/4562) to 23.3% (1063/4562), while only 1.8% (83/4562) of participants met all 3 movement guidelines (Figure 2).

Figure 2. Adherence to 24-hour movement guidelines among the study participants. The value within each circle is added to the percentage of participants meeting each individual guideline (ie, 32.1% for MVPA, 3.4% for SB, and 66.4% for sleep). The overall nonoverlapped area of each circle refers to the percentage of participants meeting 1 of the 3 guidelines (ie, 7.3%+0.1%+43.1%=50.5%). The overall overlapped area of 2 circles refers to the percentage of participants meeting 2 movement guidelines (ie, 21.5%+1.5%+0%=23.0%). The overlapped area of 3 circles refers to the percentage of participants meeting all 3 movement guidelines (ie, 1.8%). The outside area of the circle refers to the percentage of participants meeting none (0) of the guidelines (ie, 24.7%). MVPA: moderate-to-vigorous physical activity; SB: sedentary behavior.

Correlates of Adherence to 24-Hour Movement Guidelines

Table 2 presents the correlates of meeting 24-hour movement guidelines in the study sample. Participants who were older and who were female had a comparatively poorer adherence to either individual movement guidelines or the combinations of 2 or 3 behaviors (all P<.001). The municipality economic status was positively associated with meeting all 3 movement guidelines. Participants living in urban areas were more likely to adhere to MVPA and sleep guidelines (all P<.001). A higher education level and no chronic diseases were associated with a higher adherence to MVPA, sleep, and MVPA+SB guidelines, while marital status was not associated with guideline adherence.
Table 2. Correlates of adherence to 24-hour movement guidelines in the study sample (N=4562).

Associations of Adherence to 24-Hour Movement Guidelines With Physical and Mental Health Outcomes

The associations between adherence to movement guidelines (individual and combination) and health-related outcomes are outlined in Tables 3 and 4. Adhering to either MVPA or sleep guidelines was associated with favorable physical and mental health outcomes (all $P<.001$), except 2 blood pressure indicators ($P=.08-.57$). Similar results were observed for adherence to SB guidelines, except a significant correlation with SBP ($P=.02$).

Adhering to both MVPA and SB guidelines was associated with greater health-related outcomes (all $P<.01$), except DBP ($P=.88$). Adhering to MVPA+sleep or SB+sleep guidelines was associated with better performance regarding physical health (all $P<.05$), except 2 blood pressure indicators ($P=.09-.78$). Adhering to MVPA+sleep guidelines was associated with lower levels of both depressive symptoms and loneliness (both $P<.001$), while adhering to SB+sleep guidelines was not significantly associated with loneliness ($P=.18$).

Relative to not meeting any movement guidelines, adherence to 1, 2, or 3 movement guidelines was associated with lower values of BMI, waist circumference, WHR, and PBF, alongside higher levels of physical fitness among participants (all $P<.001$). However, this association did not extend to blood pressure (both SBP and DBP; $P=.17-.89$). For mental health outcomes, adherence to 1, 2, or 3 movement guidelines was significantly and inversely associated with both depressive symptoms and loneliness (all $P<.001$) compared with not meeting any guidelines (Table 4). Dose-response associations were identified between the number of adhered guidelines and health-related outcomes (all $P<.01$), except blood pressure ($P=.18-.64$).

Discussion

Principal Findings

This study provides timely evidence on the prevalence and correlates of adherence to 24-hour movement guidelines as well as its associations with physical and mental health outcomes among older adults. The results showed that only 1.8% (83/4562) of participants met all 3 movement guidelines, while 32.1% (1466/4562), 3.4% (155/4562), and 66.4% (3031/4562) met individual behavioral guidelines for MVPA, SB, and sleep, respectively (aim 1). Participants who were older, were female, and lived in municipalities with a lower economic status were less likely to comply with all 3 movement guidelines, while those who lived in urban areas, had higher education levels, and had no chronic diseases showed a higher adherence to specific individual movement guidelines or combinations of movement guidelines (aim 2). With regard to aim 3, adherence to either individual movement guidelines or combinations of movement guidelines was associated with a higher level of physical fitness and lower levels of BMI, waist circumference, WHR, PBF, and loneliness.
depressive symptoms, and loneliness. This did not extend to the relationship between adherence to SB+sleep guidelines and loneliness. Furthermore, adherence to movement guidelines did not correlate with 2 blood pressure indicators, except when adhering to SB or MVPA+SB guidelines.

Regarding guideline adherence (aim 1), the percentage of Chinese older adults meeting all 3 movement guidelines was lower than that of other age groups as reported in previous national surveys (eg, Chinese children and adolescents: 2.1%; Chinese caregivers of preschoolers: 15.1%; Canadian adults: 7.1%; and Thailand adults: 21.3%) [36,38,41,42]. This is consistent with previous studies, which indicated a poorer adherence to 24-hour movement guidelines among older adults compared with other age groups [30,37,38]. Age-related decreases in PA and sleep and increases in sedentary time have been demonstrated in previous studies [61,62]. This is not surprising as older adults generally experience physical and cognitive hypofunction with age, coupled with worries of life transition, diseases, and death [63], which, to some extent, may weaken the antecedents of behavioral initiation (eg, perceived capability and motivation), eventually leading to unhealthy patterns of movement behaviors (eg, physical inactivity, prolonged SB, and insufficient sleep) [64]. In addition to this explanation, the time frame of data collection should be considered. The data in our study were gathered during the COVID-19 period, and at that time, local preventive measures were still being undertaken (eg, mandatory quarantine, physical distancing, and emergent closure of some public areas). This might have contributed to the low adherence rate of meeting 24-hour movement guidelines among Chinese older adults [65,66]. Overall, the above findings underline the long-term requirement of effective behavioral promotion strategies and policy making. In addition, as there is a lack of evidence on the adherence of older adults to 24-hour movement guidelines, we could not make a comparison with previous studies using the same age group, which implies that more surveillance studies on this topic are warranted.

Regarding the correlates of movement guideline adherence among Chinese older adults (aim 2), we found that participants who were female and who were older were less likely to comply with movement guidelines, which is in accordance with the findings of previous studies involving children and adults [35-38]. Interestingly, we also found a lower adherence to all 3 movement guidelines among participants who lived in municipalities ranking <9th in terms of GDP. This might reflect the fact that compared with those who lived in cities with a lower economic status and lower modernization, Chinese older adults who lived in cities with a higher GDP had a healthy lifestyle. For other covariates, some were only associated with specific guideline adherence (eg, a higher adherence to MVPA and sleep was found among participants living in urban areas, yet residence was not associated with SB guideline adherence), where mixed results were also demonstrated in previous studies with children and adults [30,35,42,67]. Overall, the above findings imply that future health promotion programs and policy making should take age, gender, and municipality economic status differences into account. For example, more effective strategies for motivating female individuals and older age groups are needed (eg, designing programs based on participants’ preferences, tailoring the intervention content based on preidentified psychosocial determinants targeting these samples, and introducing a more supportive policy for these economically disadvantaged municipalities). In addition, more research on examining the role of other demographic factors is warranted.

Regarding the association between movement guideline adherence and health-related outcomes among Chinese older adults (aim 3), we found that adherence to movement guidelines, individually or in combination, was associated with greater physical health indicators, including BMI, PBF, waist circumference, WHR, and physical fitness. These findings are consistent with previous findings from children and adult populations [37-42], suggesting the broader applicability of these guidelines. Notably, our research showed that only adherence to SB or MVPA+SB guidelines was associated with a lower systolic pressure, contrasting with the lack of an association between adherence to other guidelines and blood pressure indicators. The limited evidence on the relationship between 24-hour movement guideline adherence and the health of older adults constrains a comprehensive comparison with existing studies. Notably, current research on movement behaviors and their relationships with blood pressure indicators (eg, using a compositional data analysis) has presented mixed findings among older adults [27,68,69]. This discrepancy may be attributed to different types of PAs (eg, muscle strength training and aerobic exercise) and dietary factors (eg, sodium intake) [70,71]. In relation to blood pressure among older adults, the quality of PA (eg, specific modality) and dietary patterns may serve as more sensitive and significant correlates than the quantity of PA (eg, minutes per week). Moreover, age-related physiological changes may reduce the sensitivity of blood pressure to movement behaviors [72], and the prevalent use of antihypertensive medications within the elderly population could also obscure the potential benefits of adhering to movement guidelines (eg, achieving the recommended levels of MVPA) [73]. Nevertheless, these assumptions were not explored in our study, highlighting the need for systematic investigations in future research.

For mental health outcomes, we found that adherence to movement guidelines was associated with lower levels of depressive symptoms and loneliness, except adherence to SB+sleep guidelines, which showed no significant relationship with loneliness. Engaging in a variety of physical activities, especially peer-based or group-oriented ones, significantly benefits the emotional and social well-being of elderly people [74]. The influence of SB and sleep duration on loneliness among older adults has not been convincingly demonstrated by prior research [27,75,76]. It is important to recognize that not all sedentary activities exert the same effect on mental well-being. Engaging in socially interactive sedentary activities (eg, internet-based social activities and playing chess with friends) may actually contribute to reducing depressive symptoms and feelings of loneliness [76,77]. The findings of our study support the connection between adherence to movement guidelines and mental health outcomes among older adults. However, evaluating activity solely by its duration does not provide a comprehensive understanding of its effect on
mental health. Future research is needed to investigate the specific mechanisms by which movement behaviors contribute to the improvement of mental health, thereby informing the development of more effective health promotion initiatives.

Finally, the results of the sensitivity analyses corroborate the robustness of our data analyses, with certain exceptions noted in the associations between adherence to SB guidelines and loneliness; adherence to sleep guidelines and BMI, waist circumference, and PBF; adherence to MVPA+SB guidelines and WHR; and adherence to MVPA+sleep guidelines and loneliness. These exceptions suggest that the weight status and the severity of depressive symptoms might affect the solidity of our findings, warranting further investigations in future studies. Additionally, our e-value analyses consistently yielded values exceeding 1, affirming the resilience of our findings against the influence of unmeasured confounders and therefore strengthening the stability of our results. These findings validate the integrity of the associations identified in our study. It is worth noting that our observations also reveal that lower adherence to movement guidelines corresponds with reduced e-values, suggesting a comparatively increased susceptibility to unobserved confounders. This discrepancy indicates the importance of cautious interpretation and necessitates further exploration of potential unmeasured confounders, such as social and environmental factors, to enhance our comprehension of the intricate relationship between adherence to 24-hour movement guidelines and health-related outcomes.

**Limitations**

Several limitations should be noted. First, although our study applied stratified random sampling with a large sample size, the study findings to some extent could only reflect the behavioral profiles of Chinese older adults living in the central region of China, and the generalizability to other regions (eg, the north and south of China) and different cultural contexts should be further examined. Second, the causal relationship between movement behaviors and health outcomes could not be well supported by the cross-sectional design. A further examination using longitudinal and experimental designs is warranted. Moreover, all the movement behaviors were evaluated by self-reported items. Although these kinds of measures have been well validated and have been shown to have advantages in several aspects (eg, could reach wider participants and be more feasible in a large sample surveillance), they might lead to measurement biases (eg, recall bias and social disabilities). Objective measures for movement behaviors are warranted in future research. In addition, for the correlates of movement guideline adherence, our findings could only explain a small percentage of the variance. Further examination of the potential correlates (eg, psychosocial and environmental factors) should be performed in future studies.

**Conclusions**

This study found that only 1.8% of Chinese older adults adhered to 24-hour movement guidelines. Older age, female sex, and lower municipality economic levels were associated with poor adherence to movement guidelines among Chinese older adults. Importantly, adherence to either individual or combined movement guidelines was associated with better physical and mental health outcomes. These findings suggest the potential benefits of promoting a holistic lifestyle encompassing adequate MVPA, reduced SB, and sufficient sleep for improving the physical and mental well-being of elderly populations.

**Acknowledgments**

This research was funded by the Humanities and Social Science Fund of the Ministry of Education of China (23YJCZH121) and the Humanities and Social Sciences Revitalization Grant of Shenzhen University (WKZX0312). The funding organization had no role in the study design, study implementation, manuscript preparation, or publication decision. This work is the responsibility of the authors.

**Authors' Contributions**

WL and YD contributed to design and methodology. YW, QH, BS, LZ, and NS contributed to investigation and data management. WL and YW contributed to data screening and analysis. WL wrote the first draft. WL, RER, NS, LZ, and YD revised the manuscript. RER and JSB performed language editing. All authors read and approved the final manuscript.

Abstract

Background: The biological characteristics of mosquito vectors vary, impacting their response to control measures. Thus, having up-to-date information on vector bionomics is essential to maintain the effectiveness of existing control strategies and tools, particularly as India aims for malaria elimination by 2030.

Objective: This study aims to assess the proportions of vector species resting indoors and outdoors, determine their preference for host biting/feeding, identify transmission sites, and evaluate the susceptibility of vectors to insecticides used in public health programs.

Methods: Mosquito collections were conducted in 13 districts across 8 Indian states from 2017 to 2020 using various methods to estimate their densities. Following morphological identification in the field, sibling species of Anopheles mosquitoes were identified molecularly using polymerase chain reaction (PCR)–specific alleles. Plasmodium falciparum and Plasmodium vivax infections in the vectors were detected using enzyme-linked immunosorbent assay (ELISA) and PCR assays. In addition, we assessed the insecticide susceptibility status of primary malaria vectors following the World Health Organization (WHO) protocol.

Results: Anopheles culicifacies, a primary malaria vector, was collected (with a man-hour density ranging from 3.1 to 15.9) from all states of India except those in the northeastern region. Anopheles fluviatilis, another primary vector, was collected from the states of Madhya Pradesh, Maharashtra, Karnataka, and Odisha. In Haryana and Karnataka, An. culicifacies sibling species A predominated, whereas species C and E were predominant in Madhya Pradesh and Maharashtra. An. culicifacies displayed mainly endophilic behavior across all states, except in Madhya Pradesh, where the proportion of semigravid and gravid mosquitoes was nearly half of that of unfed mosquitoes. The human blood index of An. culicifacies ranged from 0.001 to 0.220 across all study sites. The sporozoite rate of An. culicifacies ranged from 0.06 to 4.24, except in Madhya Pradesh, where none of the vector mosquitoes were found to be infected with the Plasmodium parasite. In the study area, An. culicifacies exhibited resistance to DDT (dichlorodiphenyltrichloroethane; with <39% mortality). Moreover, it showed resistance to malathion (with mortality rates ranging from 49% to 78%) in all districts except Angul in Odisha and Palwal in Haryana. In addition, resistance to deltamethrin was observed in districts of Maharashtra, Gujarat, Haryana, and Karnataka.
Conclusions: Our study offers vital insights into the prevalence, resting behavior, and sibling species composition of malaria vectors in India. It is evident from our findings that resistance development in An. culicifacies, the primary vector, to synthetic pyrethroids is on the rise in the country. Furthermore, the results of our study suggest a potential change in the resting behavior of An. culicifacies in Madhya Pradesh, although further studies are required to confirm this shift definitively. These findings are essential for the development of effective vector control strategies in India, aligning with the goal of malaria elimination by 2030.

Introduction

Malaria continues to stand as a significant contributor to both morbidity and mortality within the realm of vector-borne diseases. As outlined in the World Malaria Report of 2021, there were 241 million reported cases and 627,000 deaths attributed to malaria, with the majority occurring in African nations (accounting for 95% of the total cases) [1]. The World Health Organization South-East Asia Region (WHO-SEARO) contributed approximately 2% to the global malaria burden. Over the past 2 decades, malaria incidence in this region has seen a notable decline, dropping from 23 million cases in 2000 (18 cases per 1000) to approximately 5 million cases in 2020 (3 cases per 1000). India has shown remarkable progress within the WHO-SEARO zone, achieving substantial reductions from approximately 20 million malaria cases in 2000 to around 4.1 million cases in 2020. However, despite this improvement, India still represented 83% of malaria cases and 82% of malaria fatalities in the South-East Asian region [1]. Data from the national program in 2020 further indicated that approximately 82% of malaria cases reported in India were concentrated in 6 states: Odisha, Chhattisgarh, Uttar Pradesh, Jharkhand, Maharashtra, and West Bengal [2].

The significant reduction in the malaria burden across India can be largely attributed to the expansion of control interventions. These include prompt diagnosis facilitated by the widespread availability of rapid diagnostics and microscopy, treatment using artemisinin-based combination therapy, and crucially, the effective implementation of vector control measures such as indoor residual spraying (IRS) and distribution of long-lasting insecticidal nets (LLINs). In India, 6 primary malaria vectors have been identified, namely, Anopheles culicifacies, Anopheles fluviatilis, Anopheles minimus, Anopheles stephensi, Anopheles baimaii, and Anopheles sundicus. The secondary vectors are Anopheles annularis, Anopheles philippinensis, Anopheles nivipes, and Anopheles varuna [3]. According to national guidelines, the distribution of LLINs aims for 80% coverage, with an average of 1 LLIN per 1.8 people, particularly targeting all subcenters reporting an annual parasite incidence of greater than 1. IRS, by contrast, is directed toward epidemic-prone areas and malaria-affected communities with limited access to health care services [4]. Vector control interventions have played a pivotal role and have been the primary contributors to the reduction in malaria transmission.

In the pursuit of malaria elimination, the effectiveness of vector control interventions hinges greatly on understanding the diverse biological characteristics of vectors [5]. These include physiological and behavioral traits that directly impact malaria transmission. Therefore, to maintain the efficacy of vector control measures, it is imperative to prioritize the entomological aspects of prevalent malaria vectors. This entails staying abreast of recent data on their bionomics and assessing the efficacy of chemical interventions. Such insights are crucial for evaluating the effectiveness of current vector control tools and for making informed decisions regarding the most suitable control strategies to be deployed in the field.

India’s diverse topographies, climatic conditions, and ecosystems give rise to varying levels of malaria endemcity across the country [6]. In addition to the presence of multiple vectors, India faces the challenge of vector incursion and migration. An. culicifacies, a primary malaria vector in India, has expanded its range into the northeastern states, where it has established itself as a malaria vector in this previously unaffected territory [7]. Likewise, An. stephensi, an urban malaria vector in India, has spread its presence into regions such as Sri Lanka, Djibouti, Ethiopia, and Sudan in Africa [8]. The emergence of these vectors in new areas highlights the critical need for continuous entomological surveillance to monitor and effectively address these evolving challenges. The migration of various malaria vectors across neighboring areas, ecological transitions, and colonization of new habitats through evolutionary adaptation to eco-climatic changes have been documented in numerous instances in India [9]. An entomological surveillance study [10] was conducted to monitor the Aedes invasion in the Guilan Province of Iran, which boasts several ports of entry. Although no specimens of Aedes aegypti or Aedes albopictus were collected, the importance of such regular surveillance was acknowledged [10]. Similarly, in India, the Indian Council of Medical Research’s (ICMR) Vector Control Research Centre is conducting a study to explore the relationship between human and mosquito mobility and its implications for the control of mosquito-borne infections. In this regard, this study aims to unravel the intricate phenomenon of dispersion and movement of short- and long-distance cargo, as well as human transportation, along with the surrounding travel infrastructure such as ports, stations, and markets. Recently, there has been an increasing demand for comprehensive nationwide vector surveillance studies [11]. The ICMR, headquartered in New Delhi, serves as the nodal research organization under the Ministry of Health and Family Welfare, tasked with conducting biomedical research across the country. The ICMR, through its permanent institutes located in several malaria-endemic states, has conducted extensive entomological research over the past several decades. It has made significant contributions to the understanding and dissemination of the science of vector biology
in the country, particularly in the context of malaria elimination goals [12]. The current multicenter study was conceptualized and formulated by the ICMR. In consultation with experts, common objectives were formulated, and a standardized methodology for studying vector bionomics was developed. The study was conducted by 4 research institutes of the ICMR and their respective field stations situated across different regions of the country from 2017 to 2020. The objectives of the study were to assess (1) the proportions of vector species resting indoors and outdoors over time; (2) host biting/feeding preferences, biting rhythms, and peak biting activity of vector species across different seasons; (3) the sites of transmission; and (4) the susceptibility status of vectors to various insecticides.

**Methods**

**Study Sites**

The study was conducted by 4 institutes of the ICMR: the National Institute of Malaria Research in Delhi, along with its field units in Bengaluru and Nadiad; the National Institute of Research in Tribal Health in Jabalpur, Madhya Pradesh; the Regional Medical Research Centre in Bhubaneswar, Odisha; and the Regional Medical Research Centre in Dibrugarh, Assam. A total of 13 districts from 8 Indian states, each characterized by distinct ecotypes, vector distributions, insecticide susceptibility statuses, among others, were included in the study. In each district, we identified 1 or more blocks (subdistrict level) with varying epidemiological situations. Within each block, we selected 2-3 villages, each representing a characteristic ecotype such as forest, foothill, riverine, or plains. The study encompassed all 4 prevailing seasons: premonsoon, monsoon, postmonsoon, and winter. Figure 1 illustrates the criteria, number of states, districts, blocks/community health centers (CHCs), and villages selected for the study. Figure 2 depicts the locations of the participating institutes and the districts covered by each institute.

**Figure 1.** Criteria for study site selection. GJ: Gujarat; HR: Haryana; KR: Karnataka; MG: Meghalaya; MH: Maharashtra; MP: Madhya Pradesh; NIMR: National Institute of Malaria Research; NIRTH: National Institute for Research on Tribal Health; OR: Odisha; RMRC: Regional Medical Research Center; TR: Tripura.
Ethical Approval

After community sensitization, verbal approval was sought from the chiefs and elders of the communities for mosquito collection in the selected villages. In addition, written consent was obtained from individuals who participated as human baits. Given that the study protocol entailed human landing collections, which could potentially result in mosquito bites on the human baits, efforts were made to collect mosquitoes immediately upon landing on the host, before engorgement, to prevent actual biting. The human baits received prophylaxis as part of the malaria prevention measures. Ethical approval for the study was obtained from the ethics committee of each respective participating institute.

Institutional Ethical Committee approval was obtained vide letter no. ECR/NIMR/EC/2017/142 dated 21 June 2017 by National Institute of Malaria Research.

Entomological Surveys

Overview

The various methods used for the collection of adult anopheline mosquitoes from the study sites are described in the following sections.

Indoor Resting Collections

Anopheles mosquitoes resting indoors were captured manually using a mouth aspirator and a flashlight. In each village, 4 human dwellings and 4 cattle sheds were searched for mosquitoes in the morning from 6 AM to 8 AM hours, allocating 15 minutes for each structure [13]. The standard morpho-taxonomic keys were used to identify the mosquito species collected from the field [14]. The density of each vector species, expressed as per man-hour density (MHD), was calculated from the number of female mosquitoes, as per the formula provided in the “Data Analysis” section.

Light Trap Collections (Center for Disease Control Light Trap)

Adult vector density was also monitored using light traps. These traps were suspended inside human dwellings near eaves, sleeping hosts, and doors for mosquito collection from 6 PM to 6 AM. Outdoor collections were conducted by hanging traps both near the houses and in open areas away from the houses. The collected mosquitoes were placed in cartons lined with wet towels at the bottom and kept outside during transportation to maintain a temperature of 26-28°C and a relative humidity of 70%-80%. Vector density, defined as the number of female mosquitoes collected per trap night indoors or outdoors, was calculated from the light trap collections.

Pyrethrum Spray Collection

Another method used in the study for collecting adult mosquitoes that were resting indoors was pyrethrum spray collection. Most, if not all, of the Anopheles mosquitoes resting indoors were collected using this method during the morning hours (8 AM to 10 AM). In this method, the entire floor of the room (human dwelling) was covered with a white cotton sheet. Using a flit sprayer, the complete room was sprayed with 0.1%-0.2% pyrethrum spray, causing all mosquitoes resting inside the room to be knocked down onto the sheet. The collected mosquitoes were then transferred into petri dishes lined with wet cotton or filter paper and transported to the laboratory. This method provided the total number of mosquitoes and species resting per house or structure.
Mosquito Landing Collections on Human Baits

A whole-night collection of mosquitoes landing on human bait was conducted from dusk to dawn (6 PM to 6 AM). Landing collections were made hourly, continuously for 12 hours. Mosquitoes were collected from the exposed legs of the human bait. Efforts were made to collect mosquitoes immediately upon landing on the host, before engorgement, to prevent actual biting. Mosquitoes collected from each hour were placed in separately labeled paper cups covered with a mosquito net. These collections were used for estimating the man-biting/landing density and determining the entomological inoculation rate of vector species.

Laboratory Processing

Mosquito Species Identification

Mosquitoes collected through various methods were morphologically identified to different Anopheles species using the taxonomic keys provided by Nagpal and Sharma [14].

Sibling Species Identification

The mosquito specimens preserved in isopropanol underwent molecular identification to distinguish sibling species of An. culicifacies and An. fluviatilis, following the methods outlined by Goswami et al [15] and Singh et al [16], respectively.

Blood Meal Preferences

Blood from the stomachs of fully-fed mosquitoes obtained from the field was collected onto Whatman No. 1 filter paper to identify the source of the blood meal against human and bovine antisera. The human blood index (HBI) of An. culicifacies was determined using the gel diffusion technique [17].

Vector Incrimination

Mosquitoes collected via various methods were examined for vector infection with human malaria parasites. The heads and thoraces of the mosquitoes were dissected and stored in isopropanol at –20°C until use. Both polymerase chain reaction (PCR) and enzyme-linked immunosorbent assay (ELISA) were used as the primary methods for detecting sporozoites in mosquitoes, and both methods were applied in our study. Vector incrimination was conducted using the ELISA-based method to detect species-specific circumsporozoite antigen of Plasmodium falciparum, Plasmodium vivax 210, and P. vivax 247, following the protocol outlined by Wirtz et al [18,19]. In addition, diagnostic PCR was used for the detection of malaria parasites. In our study, a total of 4067 An. culicifacies mosquitoes were tested by PCR, and 4164 An. culicifacies mosquitoes were tested by ELISA. In our study, specific antibodies against circumsporozoite protein were used in ELISA, enabling the identification of Plasmodium parasite species as well as the subtyping of P. vivax sporozoites. Furthermore, PCR was conducted using the nested PCR protocol outlined by Snounou et al [20].

Insecticide Susceptibility Tests

Vector susceptibility to the insecticides used in the national control program was assessed once during the peak abundance of vector species, adhering to the guidelines set by the WHO [21]. Field-collected, preferably from unsprayed villages or houses, mixed-age vector mosquitoes were exposed to WHO papers impregnated with insecticides at diagnostic concentrations (DDT [dichlorodiphenyltrichloroethane] 4%, malathion 5%, and WHO-recommended discriminating concentrations of various synthetic pyrethroids) using WHO test kits. For each test, 100 mosquitoes were exposed in 4 or 5 replicates, with 20-25 mosquitoes per replicate for the treatment group and 50 mosquitoes in 2 replicates, with 25 mosquitoes per replicate, for the control group. The tests were conducted in a room free from insecticide contamination and maintained at a temperature of 26-28°C and a relative humidity of 70%-80% both during exposure and the subsequent 24-hour holding period. Following the 24-hour holding period, the percent mortality was calculated based on the total number of alive and dead mosquitoes in the replicates. If the control mortality fell within the range of 5%-20%, the Abbott formula was applied to correct the treatment mortality. According to the criteria outlined by the WHO, mortality rates of 98% or higher were categorized as “susceptible,” mortality rates below 90% were classified as “resistant,” and mortality rates between 91% and 97% were labeled as “possible resistance.”

Data Analysis

All data generated during the study were inputted into a computer using Microsoft Excel, and the following parameters were analyzed:

- MHD, calculated as the number of mosquitoes collected by 1 person in 1 hour. It is determined by considering the total number of mosquitoes (n) collected, the time spent (t), and the number of persons involved in the collection (p). The formula for MHD is MHD = n × 60/t × p.
- The HBI, calculated based on the proportion of fed Anopheles mosquitoes found to contain human blood.
- The sporozoite rate, calculated based on the proportion of female Anopheles mosquitoes carrying sporozoites in their salivary glands.
- The human landing density, defined as the ratio of the total mosquitoes captured landing on a human bait for a given period to the total person-nights used for the same period.
- The entomological inoculation rate, calculated from human landing/biting catches as the product of the human landing density and the sporozoite rate of mosquitoes.

Results

Anopheles Species Collection Methods and Results: Insights from Resting, Pyrethrum Spray, Light Traps, and Human Landing Surveys

The results of Anopheles species collected through various methods including resting, pyrethrum spray, light traps, and human landing at different sites are described below and summarized in Table 1.
Table 1. Malaria vector density by various collection methods in districts of India.

*aMan-hour density is defined as the number of mosquitoes collected by 1 person in 1 hour.

bNot done.
Density and Proportion of Indoor Resting Anopheline Vectors

**Madhya Pradesh (Sidhi District)**

An. culicifacies and An. fluviatilis vectors were prevalent, with an MHD of 9.47 (62%) and 0.47 (4%), respectively (Table 1). In addition, 13 other Anopheles species were collected, including An. annularis, a recognized secondary vector. The majority of An. culicifacies (92.3%) and An. fluviatilis (81%) were collected from cattle sheds. July and August recorded the highest density of anopheline mosquitoes, including the 2 vector species, whereas May and June had the lowest (Figure 3).

**Figure 3.** Monthly density of Anopheles culicifacies collected from selected districts of India. MHD: man-hour density.

**Gujarat (Kheda and Panchmahal Districts)**

Three vector species, namely, An. culicifacies, An. stephensi, and An. fluviatilis, were collected. An. culicifacies predominated in Kheda and Panchmahal, with an MHD of 3.15 and 4.0, respectively. The MHD of An. stephensi and An. fluviatilis was less than 0.2. Further, 3 other Anopheles species, namely, An. subpictus, An. vagus, and An. annularis, were collected. The density of An. culicifacies was higher in cattle sheds in Panchmahal compared with that in Kheda. However, overall, anopheline density was higher in human dwellings in Kheda than in Panchmahal. Two peaks of An. culicifacies densities were observed in Gujarat, specifically in February-April and July-August.

**Karnataka (Kalaburagi District)**

In this area, An. culicifacies, An. stephensi, and An. fluviatilis were the 3 recorded vector species, while other Anopheles species, including An. annularis, An. vagus, Anopheles nigerrimus, An. tessellatus, and An. barbirostris, were also prevalent. The MHD of An. culicifacies was higher in cattle sheds than in human dwellings. An. subpictus and An. culicifacies accounted for over 95% of all anophelines, and both were perennial species, with the highest density observed in August.

**Haryana (Nuh and Palwal Districts)**

An. culicifacies and An. stephensi were primarily collected from cattle sheds. The density of these vector species was generally low but increased considerably during the postmonsoon period and the onset of winter, with an MHD ranging between 8 and 21. Among other anophelines, An. subpictus was found in high densities, followed by An. annularis and Anopheles pulcherrimus. The monthly MHDs of An. culicifacies and An. stephensi exhibited high variations across different seasons. Two peaks of densities of An. culicifacies were observed in March-April and September-October. An. stephensi showed the first peak from January to April and a more prominent peak from September to December. The peak densities of An. culicifacies were in March (48.5) and October (29.5).

**Tripura (Dhalai and South Tripura Districts) and Meghalaya (West Garo Hills and South Garo Hills Districts)**

An. minimus and An. baimaii, the primary vectors in the states, were collected in the study districts of Tripura and Meghalaya. An. minimus was found in 9 out of the 16 selected villages, but their densities were low, especially in the state of Meghalaya. In addition to the primary vectors, An. annularis, An. vagus, An. varuna, and Anopheles jeyporiensis were among the other Anopheles species collected. In Tripura, the density of Anopheles species was higher in August, whereas in Meghalaya, it peaked in September.
**Odisha (Angul and Kalahandi Districts)**

The proportion of *An. culicifacies* and *An. fluviatilis* was higher in Kalahandi than in Angul, with an increased density of *An. culicifacies* observed in both districts. Throughout the study period, 15 and 18 different *Anopheles* species were collected in Kalahandi and Angul, respectively. The density of *An. fluviatilis* was significantly higher during winter than during the rainy and summer seasons in both districts. By contrast, the densities of *An. culicifacies* were considerably higher during the rainy season than during the postmonsoon and winter seasons.

**Anopheline Density From Spray Sheet Collections**

The districts of Palwal and Nuh in Haryana exhibited the highest density of *An. culicifacies*, with 36.0 and 10.9 mosquitoes captured per room, respectively. In the remaining districts (Sidhi, Kheda, Panchmahal, Gadchiroli, and Kalaburagi), the per-room density of *An. culicifacies* ranged from 1.9 to 3.9. Similarly, collections from Palwal (45.0) and Nuh (20.4) districts showed high densities of *An. stephensi*, while in Kheda (0.02) and Panchmahal (0.06) districts in Gujarat, its density was low. *An. fluviatilis* was collected from Sidhi (Madhya Pradesh) and Kalaburagi (Karnataka) districts with a per-room density of 0.33 and 0.06, respectively.

**Anopheline Density From Light Trap Catches**

The density of vectors recorded from light trap collections, that is, the number per trap night, both indoors and outdoors, is provided in Table 1. The density of *An. culicifacies* indoors and outdoors ranged from 0.4 to 3.9 mosquitoes per trap night, except in Gadchiroli, where the density was negligible. *An. stephensi* was only collected from light traps set outdoors in Palwal (8.5 mosquitoes per trap night) and Nuh (2.9 mosquitoes per trap night) districts. *An. fluviatilis* was collected from both indoor and outdoor traps in Kalaburagi, Kalahandi, and Angul, and only from indoor traps in Sidhi. In all these districts, the density of *An. fluviatilis* was below 3.8, with the exception of Kalaburagi, where it was 18.6 from indoor trap collections.

**Abdominal Condition of Vector Species in Different Collections**

**Madhya Pradesh (Sidhi District)**

In Kusumu CHC, the proportion of semigravid plus gravid *An. culicifacies* in indoor human dwelling collections (hand catch and pyrethrum spray collections) was 32.8%, while in Sumaria CHC, it was 31.16%. In both CHCs, the proportion of unfed plus fully fed mosquitoes was 65.75% and 69.07%, respectively.

**Gujarat (Kheda and Panchmahal Districts)**

In Panchmahal, the proportion of unfed plus fully fed mosquitoes was higher in March, May, and June, whereas in all the remaining months, the proportion of semigravid plus gravid mosquitoes was higher, ranging from 51% to 100%. Similarly, in Kheda district, the proportion of the semigravid plus gravid category was similar to Panchmahal, except in January, October, and December. With a few monthly variations, the data suggest a predominantly endophilic behavior of *An. culicifacies* in the 2 districts.

**Karnataka (Kalaburagi District)**

In Kalaburagi district in Karnataka, the proportion of semigravid plus gravid mosquitoes in indoor human dwelling collections in all 3 villages, Laxmipurwadi (60.4%), Shankerpurwadi (81.9%), and Muglegaon (65%), was higher than unfed plus fully fed mosquitoes, suggesting that *An. culicifacies* continues to exhibit endophilic behavior. Similarly, the proportion of semigravid plus gravid *An. fluviatilis* was significantly higher than unfed plus fully fed mosquitoes in Lashmipurwadi village, also indicating its endophilic behavior. From the collection of other villages, no conclusion can be drawn as only a few specimens of *An. fluviatilis* were collected from Muglegaon village, and in Shankerpurwadi, the collection was nil.

**Maharashtra (Gadchiroli District)**

In Gadchiroli, the proportion of semigravid plus gravid *An. culicifacies* in human dwellings (from resting and pyrethrum spray collections) was 57.6% in Ahiri CHC and 46.1% in Dhanora CHC, indicating its endophilic behavior in the district with little difference between the 2 CHCs.

**Blood Meal Preferences**

The HBI of *An. culicifacies* recorded in different study sites is shown in Figure 4. In Madhya Pradesh (Sidhi district), the HBI of *An. culicifacies* was 0.03 and of *An. fluviatilis* was 0.09. In Gujarat (Kheda and Panchmahal districts), the HBI of *An. culicifacies* in the canal-irrigated area of Kheda district was 0.02, whereas in the riverine area, none contained human blood. In Panchmahal district, the HBI was 0.016 in the canal-irrigated area and 0.01 in the riverine area. In Karnataka (Kalaburagi district), the HBI of *An. culicifacies* and *An. fluviatilis* was 0.22 and 0.06, respectively. In Maharashtra (Gadchiroli district), the HBI of *An. culicifacies* was 0.10 in the Gadchiroli district of Maharashtra. In Haryana (Nuh and Palwal districts), the HBI of *An. culicifacies* was low, 0.09 in Nuh and 0.07 in Palwal. Similarly, the HBI of *An. stephensi* was also low in the 2 districts, 0.01 and 0.004, respectively. In Tripura (Dhalai and South Tripura districts) and Meghalaya (West Garo Hills and South Garo Hills districts), the blood meal analysis revealed a higher HBI of 2 vector species: *An. minimus* (0.76-0.78) and *An. baimei* (0.85), indicating their higher anthropophagic behavior in northeast India. The HBI of *An. jeyporiensis* was also found to be higher (0.66-0.75) in the same region. In Odisha (Angul and Kalahandi districts), the HBI of *An. fluviatilis* was higher in both districts, indicating that the species was primarily anthropophagic. The HBI observed in Kalahandi was 0.52, and in Angul, it was 0.32. By contrast, *An. culicifacies* was found to be primarily a zoophagic mosquito, as the observed HBI was 0.086 and 0.062, respectively, in the 2 districts.
Sibling Species Composition
The proportion of An. culicifacies sibling species B, C, and E was 23%, 44.4%, and 33%, respectively, in the Sidhi district of Madhya Pradesh (Figure 5). In the Kheda district of Gujarat, sibling species A/D was 12%, and B/C/E was 82%, whereas in the Panchmahal district of the same state, the corresponding proportion was 8% and 91%, indicating the predominance of sibling species B/C/E over A/D in both districts. In the Kalaburagi district of Karnataka, An. culicifacies mostly comprised species A (57.2%) and species B (42.8%). The proportion of 3 sibling species S, T, and U of An. fluviatilis was found to be 4.6%, 94.2%, and 1.2%, respectively, in this state. A total of 1050 specimens of An. culicifacies were analyzed in Maharashtra (Gadchiroli district) for the sibling species composition, where sibling species C was predominant (43.9%), followed by species E (25%). In Haryana (Nuh and Palwal districts), An. culicifacies species A, which is an efficient vector, predominantly constituted 99.4% in Nuh and 99.4% in Palwal.

Vector Infection
Madhya Pradesh (Sidhi District)
A total of 1038 An. culicifacies and 27 An. fluviatilis specimens were screened for sporozoite positivity using PCR assay, and none were found positive (Figure 6).
Gujarat (Kheda and Panchmahal Districts)
In Kheda district, 916 An. culicifacies specimens were analyzed, and 12 were detected with malaria parasites (7 P. falciparum positive and 5. P. vivax positive), with a sporozoite positivity rate of 1.31%. In Panchmahal district, 4 An. culicifacies (3 P. falciparum positive and 1 P. vivax) specimens were found positive (n=900) with a sporozoite positivity rate of 0.44%.

Karnataka (Kalaburagi District)
In total, 1305 An. culicifacies and 691 An. fluviatilis specimens were screened, and the sporozoite rate was 0.08% and 0.14%, respectively.

Maharashtra (Gadchiroli District)
Out of 3029 An. culicifacies tested, only 2 were positive, showing a sporozoite positivity rate of 0.06%.

Haryana (Nuh and Palwal Districts)
In Nuh, 831 An. culicifacies specimens were analyzed for Plasmodium infection, and 18 were positive, with a sporozoite positivity rate of 2.16%. There was higher positivity for P. falciparum (n=11) than for P. vivax (n=7). By contrast, in Palwal district, 9 An. culicifacies specimens were detected positive (7 Pf positive and 2 Pv) out of 212 screened, and the sporozoite positivity rate was 4.24%.

Tripura (Dhalai and South Tripura Districts) and Meghalaya (West Garo Hills and South Garo Hills Districts)
None of the primary (An. minimus and An. baimaii) or secondary vectors (An. nivipes, An. philippinensis, and An. annularis) were found infected with malaria parasites.

Odisha (Angul and Kalahandi Districts)
The sporozoite rate of An. fluviatilis was 0.22% in Kalahandi. The sporozoite rate of An. culicifacies was 2.6% and 0.66% in Kalahandi and Angul districts, respectively.

Entomological Inoculation Rate
The entomological inoculation rate of An. culicifacies in the Kheda and Panchmahal districts of Gujarat was 3.09 and 0.47, respectively, followed by 0.25 in the Kalaburagi district of Karnataka. The entomological inoculation rate could not be calculated for other sites.

Vector Susceptibility to Insecticides
Overview
Susceptibility testing was conducted on An. culicifacies, An. stephensi, An. fluviatilis, An. minimus, and An. baimaii collected from various study sites against DDT, malathion, and synthetic pyrethroids, including deltamethrin, cyfluthrin, and alphacypermethrin, approved by the National Malaria Control Program. The susceptibility/resistance status is visually represented in Figures 7 and 8.
Figure 7. Insecticide susceptibility status of Anopheles culicifacies in India (≥98%-100% mortality: susceptible; 90-97% mortality: possible resistance; and <90% mortality: resistant). DDT: dichlorodiphenyltrichloroethane.
**Figure 8.** Insecticide susceptibility status of *Anopheles stephensi*, *Anopheles fluviatilis*, *Anopheles minimus*, and *Anopheles baimaii* in India (≥98-100% mortality: susceptible; 90-97% mortality: possible resistance; and <90% mortality: resistant).

**DDT (4%)**

*An. culicifacies* was tested against DDT in all districts except the Kheda and Panchmahal districts of Gujarat state, and this species exhibited resistance to DDT in all the tested districts (<39% mortality; Figure 7). *An. baimaii* and *An. minimus* were found to be susceptible to DDT in the study districts of Meghalaya and Tripura. *An. stephensi* displayed resistance to DDT in both the districts of Haryana, while *An. fluviatilis* showed possible resistance to DDT in the 2 districts of Odisha (Figure 7).

**Malathion (5%)**

*An. culicifacies* exhibited resistance to malathion (49%-78% mortality) in all districts except Angul in Odisha, where it was susceptible. *An. baimaii* was found to be susceptible to malathion in all study districts of the northeast except Dhalai, where the test could not be performed. *An. stephensi* demonstrated resistance to malathion in both districts of Haryana, whereas *An. fluviatilis* was susceptible to malathion in the 2 districts of Odisha (Figure 7).

**Deltamethrin (0.05%)**

*An. culicifacies* displayed resistance to the synthetic pyrethroid deltamethrin in Maharashtra, Gujarat, Haryana, and Karnataka study sites, but showed susceptibility in Sidhi (Madhya Pradesh) and Angul (Odisha) districts. Moreover, it exhibited possible resistance (92.5% mortality) in the Kalahandi district of Odisha. *An. stephensi* demonstrated resistance to deltamethrin in both districts of Haryana, whereas *An. fluviatilis* was found to be susceptible to this insecticide in the 2 districts of Odisha (Figure 8).

**Cyfluthrin (0.15%)**

Susceptibility tests against cyfluthrin, another synthetic pyrethroid, were conducted in Odisha and Maharashtra only. *An. culicifacies* exhibited resistance to cyfluthrin in the Gadchiroli district of Maharashtra and the Kalahandi district of Odisha, while “possible resistance” was observed in the Angul district of Odisha. *An. fluviatilis*, by contrast, was susceptible to cyfluthrin in both districts of Odisha.

**Alpha-cypermethrin (0.25%)**

Susceptibility to alpha-cypermethrin, another synthetic pyrethroid, was tested only for *An. culicifacies*. The mortality rate of *An. culicifacies* against this synthetic pyrethroid was 95%-96.7% in Panchmahal, Palwal, and Sidhi districts, indicating a possible resistance. However, in Gadchiroli (with 88.1% mortality) and Kalaburagi (with 16% mortality) districts, it exhibited resistance.
Discussion

Principal Findings

This study was conducted in 13 districts spanning 8 different states of India, encompassing various eco-epidemiological zones, including tribal, hilly, plain, and forested regions across the country. Notably, this is the first nationwide study covering nearly all parts of India, including the east, west, north, south, central, and northeast regions. Updated knowledge of bionomics is essential to bolster vector control activities and assess the effectiveness of such measures [22]. Therefore, the data generated in this study are crucial and highly pertinent to the country’s malaria elimination objective. Regular surveillance of malaria vectors is vital to identify any alterations in their distribution, behavior, and susceptibility to insecticides, which are essential for achieving the malaria elimination target. The findings from this study could contribute significantly to addressing these challenges.

Mosquito collections confirmed the presence of *An. culicifacies* in all study districts except those in Assam and Tripura states. The density of *An. culicifacies* obtained indoors through hand catch and pyrethrum spray sheet collection suggested that this species could be endophilic in most districts. However, the proportions of gravid and semigravid mosquitoes were lower (31%-33%) in Madhya Pradesh, indicating that *An. culicifacies* may not be entirely endophilic, and some proportions might also be resting outdoors. This could potentially indicate a shift in the resting behavior of *An. culicifacies* in Madhya Pradesh, although larger studies are necessary to confirm this possible change definitively. The alteration in resting behavior might be attributed to the use of LLINs inside houses. Similar changes in resting behavior have been reported for *An. fluviatilis* in Odisha, where it was predominantly found in mixed dwellings with a high anthropogenic nature [23]. Likewise, in Kenya and Tanzania, a shift in the resting behavior of *Anopheles gambiae* s.s. and *Anopheles funestus* was noted from endophily to exophily following the introduction of LLINs [24]. In the case of *An. stephensi*, the indoor resting density was higher than outdoors, suggesting a possible endophilic behavior as well.

*An. culicifacies*, a significant malaria vector in India, comprises a complex of 5 sibling species. It is estimated that up to about 70% of malaria transmission in India is facilitated by *An. culicifacies* [3]. Thus, the implementation of effective insecticide-based vector control interventions is crucial for malaria elimination efforts. *An. culicifacies* sibling species exhibit distinct distributions, with varying proportions of each species across different regions of the country [3], a pattern observed in this study as well. Understanding the distribution and proportions of *An. culicifacies* sibling species is crucial, as species A, C, D, and E are vectors, whereas species B is considered a poor or nonvector [25-28]. Moreover, these species vary in their susceptibility to different insecticides [28-30]. The study results indicated that species A predominated in Nuh, Palwal, and Kalaburagi districts, whereas species C was predominant in Sidhi and Gadchiroli districts. Species B was found in very low densities in Haryana, while in Gujarat and Karnataka states, its density was higher. This study offers a comprehensive overview of the contemporary distribution of sibling species in various eco-epidemiological settings across the country. Previously, the distribution pattern showed the ubiquitous presence of species B wherever *An. culicifacies* was encountered. Species A predominated in the northern part of the country, whereas species C was predominant in the western and eastern regions. In addition, species D was found in sympatric association with species A and B in the northwestern region [31].

Resistance to DDT in *An. culicifacies* was detected in all study sites, indicating widespread resistance throughout the country. Moreover, this species has developed resistance to malathion and deltamethrin in most study districts. Deltamethrin resistance in *An. culicifacies* was previously reported in the Gadchiroli district of Maharashtra [32,33], Kalahandi, and 4 other districts in Odisha [34]. Furthermore, in Nuh, Haryana, possible resistance to deltamethrin was observed [35]. A multidistrict study conducted in 2009 on the susceptibility of *An. culicifacies* to DDT, malathion, and deltamethrin in multiple districts of Madhya Pradesh reported its resistance to deltamethrin in Mandla and Dindori districts. Possible resistance was observed in Balaghat, Betul, Chhindwara, Jhabua, Sidhi, and Shadol districts, while the species remained susceptible in Guna district [36]. The national vector control program in India primarily depends on insecticide-based IRS and LLINs. Consequently, the development of resistance in malaria vectors to synthetic pyrethroids is of significant concern because of their widespread use in IRS and LLINs.

In the 1950s, DDT was used for IRS to control vectors. However, as a result of selection pressure, *An. culicifacies* was found to be resistant to this insecticide in 1959 [37]. Subsequently, malathion was introduced for vector control in 1969. However, resistance to malathion was reported in Gujarat as early as 1973 [38]. Further reports of resistance to malathion emerged from other states such as Andhra Pradesh, Odisha, Madhya Pradesh, Chhattisgarh, and Jharkhand [39]. In 1996, synthetic pyrethroids were introduced for IRS in India owing to their safety, excito-repellent, and knockdown properties. Just 6 years after their initial use, the first report of deltamethrin resistance in *An. culicifacies* emerged in Gujarat in 2002 [40]. Subsequently, triple resistance (to DDT, malathion, and deltamethrin) in *An. culicifacies* was reported from 31 districts in India [41]. The findings of this study align with these earlier reports.

*An. stephensi*, another malaria vector, was found to be resistant to deltamethrin, DDT, and malathion in the Nuh and Palwal districts of Haryana. Currently, IRS is not used as a vector control strategy for *An. stephensi* in India, except in Rajasthan, where it has been identified as the primary vector of malaria [41]. However, this species has been reported to be double resistant, specifically to DDT and malathion in 7 districts, and to malathion and deltamethrin in 1 district [41]. In our study, possibly for the first time in the country, triple resistance (to DDT, malathion, and deltamethrin) in *An. stephensi* was reported.

*An. fluviatilis* demonstrated susceptibility to malathion and synthetic pyrethroids, but exhibited possible resistance to DDT.
in the Kalahandi and Angul districts of Odisha. This vector species remained susceptible to deltamethrin and malathion in most parts of the country, except in Gadchiroli (Maharashtra), where possible resistance was reported [33]. In the Mayurbhanj district of Odisha, possible resistance to malathion was reported in *An. fluviatilis*. It was found to be susceptible to DDT in Odisha but resistant in Jharkhand and Chhattisgarh [41,42]. In this study, *An. minimus* and *An. baimaii*, the 2 primary malaria vectors in the northeast, were found to be susceptible to DDT and malathion. Another study by Raghavendra et al [41] reported that these 2 vector species were susceptible to DDT, malathion, and deltamethrin. However, in the eastern state of Odisha, there was only 1 report of resistance in *An. minimus* to DDT.

The WHO has proposed 3 main strategies for insecticide resistance management in malaria vectors: rotation, mosaics, and mixtures [43]. The primary objective of insecticide resistance management is to prevent the emergence of resistance in susceptible populations, delay the evolution of insecticide resistance, or reverse it to a level that allows for the effective use of insecticides for vector control [44]. Information regarding insecticide resistance among malaria vectors and the underlying mechanisms of resistance in various ecological settings is essential for formulating rational strategies for insecticide use and resistance management [45]. Therefore, further research studies on the frequency and intensity of insecticide resistance, as well as its underlying mechanisms among malaria vectors, are crucial to suggest an appropriate resistance management strategy. Using synergist piperonyl butoxide–based LLINs effectively reduced populations of insecticide-resistant (synthetic pyrethroid) vectors [46]. The ICMR-Vector Control Research Center assessed the efficacy of a piperonyl butoxide-αphacypermethrin–incorporated LLIN in experimental huts in Odisha and found it to be superior to the reference net in terms of mosquito mortality in the huts and cone bioassays [47]. Another potential method for managing insecticide-resistance populations could involve the use of attractive toxic sugar baits in combination with LLINs, although insecticide-resistant populations could involve the use of attractive toxic sugar baits in combination with LLINs, although this approach is still under development and evaluation [48-50]. These proposed measures hold significant epidemiological importance for India.

We screened over 8000 anopheline mosquitoes for *Plasmodium* parasite infection, but only 2 species, *An. culicifacies* and *An. fluviatilis*, tested positive. An earlier study conducted in Nuh in 2015-2016 reported a sporozoite positivity rate of 0.26% [35], which is lower than the rate reported in this study (2.1%). The observed variability in the sporozoite rate could be attributed to differences in sample size, usage of LLINs, and malaria endemicity of the study sites. Moreover, the high positivity rate of *An. culicifacies* in Nuh and Palwal districts might be due to the predominant proportion of sibling species A (>99%) in the area. This sibling species is recognized as an established malaria vector in the malaria-endemic regions of India [35]. In a previous study conducted in 8 southern districts of Odisha, sporozoite-positive *An. culicifacies* was reported only from Kandhamal district (with a 1.5% infectivity rate), and none of the mosquito pools tested positive in the rest of the districts, including Kalahandi [51]. Regarding *An. stephensi*, none were found positive for *Plasmodium* infection in Nuh and Palwal districts. This observation might be due to the abundance of *An. stephensi* mysorensis form, which, being primarily zoophagic in nature, is not considered a competent vector [3]. An observed HBI of 0-0.01 in this study confirms the zoophilic behavior of *An. stephensi* mysorensis in the area.

**Limitations**

This study conducted nationwide surveillance of malaria vectors, successfully collecting all primary vectors of malaria in India except *An. sundaicus*, which is the only vector in Andaman and Nicobar Islands, India. This represents a major limitation of our study. Another limitation is the unavailability of data on density bioassays for determining the level of insecticide resistance among the main malaria vectors. The results of intensity assays could inform decisions on whether to continue existing insecticide vector control measures or to change insecticides. The third limitation of the study was the lack of information on mosquito larval breeding habitats. This information could provide a more comprehensive understanding of the anopheline breeding habitats present in the selected study sites. The final limitation of the study was the lack of data on the parity status of vector mosquitoes, which is a robust indicator of mosquito age.

**Conclusions**

This study provides a comprehensive overview of essential aspects of vector bionomics, including seasonal prevalence, resting and biting behavior, insecticide resistance status, composition of sibling species, and malaria transmission potential. It clearly indicates a growing development of resistance in *An. culicifacies* against synthetic pyrethroids in the country. These findings underscore the importance of continuous monitoring of insecticide resistance for effective planning, implementation, and evaluation of malaria vector control strategies. Furthermore, because sibling species can vary in the rate of development of insecticide resistance, monitoring should be conducted at the sibling species level rather than at the sensu lato level. The observed shift from endophilic to exophilic behavior in parts of India among *An. culicifacies* highlights the necessity for continuous monitoring of such behavioral changes in vector species, especially in light of the extensive use of LLINs in the country. The localized and focal nature of malaria transmission is influenced by variations in the biological characteristics of vector species, cultural aspects of human populations, and environmental factors within a region. Therefore, further research on vector behavior is crucial to corroborate specific findings that have implications for malaria transmission and to strengthen control measures.

Abstract

Background: The worldwide incidence of preterm births is increasing, and the risks of adverse outcomes for preterm infants significantly increase with shorter gestation, resulting in a substantial socioeconomic burden. Limited epidemiological studies have been conducted in China regarding the incidence and spatiotemporal trends of preterm births. Seasonal variations in risk indicate the presence of possible modifiable factors. Gender influences the risk of preterm birth.

Objective: This study aims to assess the incidence rates of preterm birth, very preterm birth, and extremely preterm birth; elucidate their spatiotemporal distribution; and investigate the risk factors associated with preterm birth.

Methods: We obtained data from the Guangdong Provincial Maternal and Child Health Information System, spanning from January 1, 2014, to December 31, 2021, pertaining to neonates with gestational ages ranging from 24 weeks to 42 weeks. The primary outcome measures assessed variations in the rates of different preterm birth subtypes over the course of the study, such as by year, region, and season. Furthermore, we examined the relationship between preterm birth incidence and per capita gross domestic product (GDP), simultaneously analyzing the contributing risk factors.

Results: The analysis incorporated data from 13,256,743 live births. We identified 754,268 preterm infants and 12,502,475 full-term infants. The incidences of preterm birth, very preterm birth, and extremely preterm birth were 5.69 per 100 births, 4.46 per 1000 births, and 4.83 per 10,000 births, respectively. The overall incidence of preterm birth increased from 5.12% in 2014 to 6.38% in 2021. The incidence of extremely preterm birth increased from 4.10 per 10,000 births in 2014 to 8.09 per 10,000 births in 2021. There was a positive correlation between the incidence of preterm infants and GDP per capita. In more developed economic regions, the incidence of preterm births was higher. Furthermore, adjusted odds ratios revealed that advanced maternal age, multiple pregnancies, and male infants were associated with an increased risk of preterm birth, whereas childbirth in the autumn season was associated with a protective effect against preterm birth.

Conclusions: The incidence of preterm birth in southern China exhibited an upward trend, closely linked to enhancements in the care capabilities for high-risk pregnant women and critically ill newborns. With the recent relaxation of China's 3-child policy, coupled with a temporary surge in advanced maternal age and multiple pregnancies, the risk of preterm birth has risen. Consequently, there is a pressing need to augment public health investments aimed at mitigating the risk factors associated with preterm birth, thereby alleviating the socioeconomic burden it imposes.
Neonatal diseases constitute the primary cause of mortality in children younger than 5 years, comprising approximately 37.7% of such deaths [1]. Globally, preterm birth (PTB) stands as the most significant risk factor for neonatal morbidity and mortality [2,3], contributing to around 18% of all fatalities in children younger than 5 years and as much as 35% of all fatalities among neonates (aged <28 days) [4]. The United Nations Sustainable Development Goal (SDG) 3.2 for 2030 aims to eliminate preventable child mortality worldwide, targeting a reduction of neonatal mortality to below 12 per 1000 live births and under-5 mortality to below 25 per 1000 live births. Data indicate that, although the global under-5 mortality rate declined by almost one-half, decreasing from 71.2 per 1000 to 37.1 per 1000 between 2000 and 2019, the neonatal mortality rate exhibited a slower reduction, dropping from 28.0 per 1000 to 17.9 per 1000. Notably, 32% of countries are projected to fall short of attaining any of the SDG 3.2 targets by 2030 [1]. Hence, directing attention to health care systems in regions experiencing a high prevalence of PTBs, augmenting investments in public health and medical interventions to mitigate PTB, and enhancing perinatal and neonatal care in focal areas may contribute to diminishing child mortality, progressively aligning with the 2030 SDGs.

The World Health Organization (WHO) defines PTB as the delivery of newborns before 37 completed weeks of gestation. Over the past 2 decades, there has been a global increase in the incidence of PTB, resulting in a global PTB rate of 11% [5]. In 2022, data from the US National Vital Statistics indicated that the rate of PTB for singletons was 10.38% [6]. Twins constitute 20% of all preterm deliveries, with 60% and 10.7% of twins delivered before 37 and 32 weeks of gestation, respectively [7]. Twin pregnancies are associated with a higher risk of PTB than singleton pregnancies. A meta-analysis conducted in China revealed that the pooled rate of preterm delivery in hospital-based studies was 7.2% (95% CI 6.9%-7.6%), whereas the population-based rates were 5.3% for eastern, 4.6% for central, and 3.8% for western regions [8]. Six countries—India, China, Nigeria, Pakistan, Indonesia, and the United States—collectively contribute to 45.9% (approximately 7.4 million) of the total global PTBs, and it is projected that China will have a PTB rate of around 6.9% [2]. In a study conducted in the United States concerning mortality, in-hospital morbidity, and a 2-year follow-up of extremely preterm infants, 78.3% survived until discharge. Among newborns delivered at gestational ages below 27 weeks, rehospitalization and neurodevelopmental disorders were more prevalent at 2 years of age [9]. This underscores that PTB constitutes a significant health care challenge and a substantial socioeconomic burden [4].

Our study specifically investigated the spatiotemporal aspects and risk factors associated with PTB in 21 cities in southern China from 2014 to 2021. This research aimed to guide the development of public health and health care policies that address regional health equity and balanced development.
Ethical Considerations

This study received approval from the Ethics Committee of Guangdong Women and Children Hospital (approval number: 202201332). The study relied on routine registration data and did not involve patients’ participation in questionnaires, outcome assessments, and other research methods. Additionally, privacy information such as personal identity and contact details have been concealed. The requirement for informed consent was waived by the hospital’s ethics review committee.

Statistical Analysis

Maternal and neonatal characteristics are presented as a mean (SD) for continuous variables and number (%) for categorical variables. Independent samples Satterthwaite t tests were conducted to examine differences in the means of continuous variables. Prevalences of total PTBs (<37 completed weeks of gestation, per 100 births), VPTBs (<32 completed weeks of gestation, per 1000 births), and EPTBs (<28 completed weeks of gestation, per 10,000 births) according to the year, area of residence, region of Guangdong, season of delivery, maternal age, neonatal gender, and number of fetuses were calculated using a binomial distribution exact method. Chi-square tests were used to compare prevalences and obtain the P value.

Crude or adjusted associations between PTB and season of delivery, maternal age, neonatal gender, and number of fetuses were examined separately using a logistic regression model. The univariable model included PTB as the dependent variable and included only season of delivery, maternal age, neonatal gender, and number of fetuses as separate independent variables. The multivariable model included PTB as the dependent variable and adjusted for season of delivery, maternal age, neonatal gender, and number of fetuses.

Analyses were done using SAS 9.4 (SAS Institute) and R version 4.2.1 (R Core Team) for the figures. A 2-sided P<.05 was considered statistically significant.

Results

We conducted an analysis of 13,501,312 infants delivered between January 1, 2014, and December 31, 2021, in 21 cities in southern China and spanning gestational ages from 24 weeks to 45 weeks (Multimedia Appendix 1). Exclusions from the data analysis were for the following reasons: 17,794 cases (0.13%) involved non-Chinese pregnant women, 148,351 cases (1.10%) had non-Chinese fathers, 9812 cases (0.07%) were not live births, 56 cases (<0.01%) had an unspecified gender, 6017 cases (0.04%) had a maternal age outside the range of 15 years to 60 years or a missing maternal age, 56,047 (<0.41%) had a paternal age beyond the range of 15 years to 60 years or a missing paternal age, 333 cases (<0.01%) had a birth weight outside the range of 350 g to 6000 g, and 7159 cases (0.05%) had a gestational age outside the range of 16 weeks to 45 weeks. The data set included a total of 13,256,743 live births (Multimedia Appendix 2).

Table 1 provides an overview of the characteristics of the live-born infants included in the analysis. The conception rate varied significantly by season, with winter showing a relatively higher proportion, at approximately 32.68% (4,332,432/13,256,743), while autumn had a higher rate of childbirth, at 27.96% (3,706,674/13,256,743). Over the period spanning from 2014 to 2021, there were 754,268 preterm infants and 12,502,475 full-term infants. Among the PTBs, 419,314 (55.59%) occurred among Aboriginal inhabitants, and a significantly larger proportion occurred in urban areas (89.86%) compared with rural areas. Notably, within the PRD region, there were 472,468 PTBs, constituting a substantially higher percentage (472,468/754,268, 62.64%) than in the eastern, western, and northern regions of Guangdong.
Table 1. Comparison of maternal and neonatal characteristics between preterm births (<37 completed weeks of gestation; n=754,268) and term births (≥37 completed weeks of gestation; n=12,502,475) in southern China, 2014-2021 (N=13,256,743).

Additionally, Table 1 presents data on the average maternal age, which was 28.12 (SD 5.07) years, with an 11.36% (1,505,566/13,256,743) rate of advanced maternal age (≥35 years old), and the average paternal age, which was 30.49 (SD 5.62) years, with a 21.49% (2,848,679/13,256,743) rate of advanced paternal age (≥35 years old). In their first birth, 373,655 women delivered a preterm baby. Among PTB, 79.52% (599,814/754,268) were singleton pregnancies. The average gestational age of infants was 38.76 (SD 1.53) weeks, with an average birth weight of 3153.76 (SD 448.06) g. In contrast, preterm infants had an average gestational age of 34.66 (SD 1.92) weeks and an average birth weight of 2381.40 (SD 519.20) g.

Figure 1 illustrates the temporal trend in the 3 distinct categories of preterm infants from 2014 to 2021. PTB, VPTB, and EPTB increased year on year. PTB increased from 5.12 (per 100 births) in 2014 to 6.38 (per 100 births) in 2021, VPTB rose from 3.93 (per 1000 births) in 2014 to 4.46 (per 1000 births) in 2021, and EPTB surged from 4.10 (per 10,000 births) in 2014 to 8.09 (per 10,000 births) in 2021. Notably, a marked reduction in the incidence of preterm infants was evident at the start of the subsequent year, with the rates of PTB and VPTB experiencing a sharp increase in 2016 followed by a decline in 2017.

Figure 2 and Multimedia Appendix 3 spatially delineate the 3 distinct categories of preterm infants. Generally, PTB rates across all types are higher in the PRD region, with Guangzhou, as the provincial capital, having the highest prevalence. It is noteworthy that, in the case of EPTB, the cities with higher quantities of PTBs are not predominantly concentrated in the PRD region. Additionally, there are 1 to 2 cities in eastern, western, and northern Guangdong with high EPTB rates.
Figure 2. In southern China, 2014-2021: (A) spatial distributions of the prevalence of preterm births (<37 completed weeks of gestation, per 100 births); (B) spatial distributions of the prevalence of very preterm births (<32 completed weeks of gestation, per 1000 births); (C) spatial distributions of the prevalence of extremely preterm births (<28 completed weeks of gestation, per 10,000 births).

Figure 3 provides a detailed description of the incidence and temporal trends of preterm infants in 21 cities within southern China. Irrespective of the type of PTB, the rate was lower in eastern Guangdong than in the other regions. For both VPTB and EPTB, the rates in Guangzhou and Shenzhen were notably high, with the incidence of EPTB in Shenzhen continuously increasing relative to Guangzhou since 2015.

Figure 3. Across 21 cities in southern China, 2014-2021: heat maps of the yearly prevalences of (A) preterm births (<37 completed weeks of gestation, per 100 births); (B) very preterm births (<32 completed weeks of gestation, per 1000 births); (C) extremely preterm births (<28 completed weeks of gestation, per 10,000 births).

Table 2 provides a comparative analysis of the incidences of various types of preterm infants. Over the period of 2014 to 2021, the incidence rates for PTB, VPTB, and EPTB were 5.69 (per 100 births), 4.46 (per 1000 births), and 4.83 (per 10,000 births), respectively. All 3 types of preterm infants occurred more frequently in urban areas than in rural regions. It is noteworthy that the 3 types of preterm infants have the lowest birth rates in the autumn season. Additionally, advanced maternal age ($\geq 35$ years) and multiple pregnancies posed a higher risk for PTB, regardless of PTB, VPTB, or EPTB. Furthermore, PTB is significantly more common in boys than in girls.
### Table 2. Prevalence of total preterm births (<37 completed weeks of gestation, per 100 births), very preterm births (<32 completed weeks of gestation, per 1000 births), and extremely preterm births (<28 completed weeks of gestation, per 10,000 births) in southern China, 2014-2021.

Includes September, October, and November.

Includes December, January, and February.

Figure 4 illustrates the association between the incidence of the 3 distinct types of preterm infants and per capita gross domestic product (GDP). As the economy developed, there was an increase in the incidences of PTB, VPTB, and EPTB. Notably, the positive correlation between VPTB and GDP per capita was the most pronounced (r=0.64).

Figure 4. Across 21 cities in southern China, 2014-2021: correlations between per capita gross domestic product (GDP) and (A) preterm births (PTB; <37 completed weeks of gestation, per 100 births); (B) very preterm births (VPTB; <32 completed weeks of gestation, per 1000 births); (C) extremely preterm births (EPTB; <28 completed weeks of gestation, per 10,000 births).

Table 3 examines the risk factors associated with the 3 categories of preterm infants. The adjusted odds ratios (ORs) revealed that advanced maternal age (adjusted OR 1.59, 95% CI 1.58-1.60), multiple pregnancies (adjusted OR 40.52, 95% CI 37.63-43.64), and male infants (adjusted OR 1.24, 95% CI 1.23-1.25) were risk factors for PTB. In contrast, giving birth in the autumn season was found to be a protective factor against PTB.
enhancing the equity of maternal and child health services and disparities in health care but also points toward directions for by a more developed economy. Discussion

Principal Findings

As medical technology continues to advance, the Chinese 4-level maternal and child health service network and 2-way referral systems have played significant roles in the gradual increase of the survival rate among PTBs. In this study, we analyzed and reviewed the epidemiological trends and risk factors associated with preterm infants in 21 cities in southern China over the past 8 years, using the largest, most recent, and most comprehensive data set available for southern China. These cities, which are densely populated with a significant migrant population, offer a representative sample for assessing premature birth incidence in China. Additionally, our research presents a comprehensive classification of premature infants. The findings indicated a higher rate of PTB in the PRD region, which is characterized by a more developed economy. This not only highlights regional disparities in health care but also points toward directions for enhancing the equity of maternal and child health services and proposing prepregnancy health care guidance. These efforts aim to promote a healthy development model for women and children in the new era in China.

In general, the PTB rate shows a positive correlation with GDP levels, a relationship deeply intertwined with the specific conditions and the maternal and child health system in China. Roughly 15 million preterm infants, representing an adverse pregnancy outcome, are born globally each year. It is worth noting that the rate is as low as 5% even among healthy pregnant women at low risk during pregnancy [13]. Hence, the vast majority of PTBs are linked to multiple pregnancies, pregnancy complications, placental abnormalities, and other contributing factors [14]. Our results support that advanced maternal age and multiple pregnancies are risk factors for the incidence of PTB. Using the maternal and child health service network and referral system in China, the majority of high-risk pregnant women are referred to tertiary hospitals. This results in a scenario in which a significant proportion of preterm infants are born in urban or economically developed regions. Additionally, it is evident that the population of permanent
residents in urban areas or more economically developed areas is substantially higher than in less economically developed areas, contributing to the elevated PTB rates in these regions. An investigation spanning from 1990 to 2019 that focused on the global, regional, and national incidences of and mortality associated with neonatal PTB revealed a noteworthy positive correlation between the prevalence of neonatal PTB and the sociodemographic index in 2019, as well as the universal health coverage index in 2019. This correlation was particularly pronounced in high-income countries, such as Greece, Bahrain, Japan, the United Kingdom, and the United States, which corroborates our findings [15].

In October 2015, the Chinese government initiated the universal 2-child policy, which officially took effect in July 2016. The alteration in fertility policy had the potential to result in shifts in the sociodemographic characteristics of pregnant women, including a transient increase in advanced maternal age (≥35 years) [16]. Consequently, the rates of PTBs in 2016 and 2017 notably increased compared with previous years, particularly in the case of EPTB. Despite intensified public health and medical intervention efforts aimed at reducing PTB, the rate has increased in the majority of countries. For instance, PTB rates in the United States increased from 9.98% in 2010 to 10.09% in 2020 [17], while the rate of EPTB decreased from 0.71% to 0.64%. Since 1990, worldwide neonatal mortality has decreased by 37%, and the reduction in the incidence of EPTB has played a role in further lowering neonatal mortality rates [18]. According to survey data from the National Maternal and Child Health Center in China, the incidence of preterm infants in China increased from 5.9% in 2012 to 6.4% in 2018, with an overall rate of approximately 6.1% [16]. The PTB rate in South China also exhibited an upward trend, with the rate of EPTB significantly lower than that in the United States.

The province housing 21 cities in southern China ranks as China’s most densely populated region, boasting a preterm rate significantly below the global average. This achievement can be attributed to the establishment of a robust maternal and child health system and the successful implementation of the national health care reform plan. Nonetheless, there exists a glaring issue of regional health care inequality, exemplified by the concentration of PTBs in the PRD region. Apart from the PRD region, 1 to 2 prominent cities in other regions also had high PTB rates. This suggests that the standard of care for newborns facing severe complication is consistently improving in these leading cities, while health care in other cities remains underdeveloped. Hence, regional management, augmented investment in public health initiatives within these leading cities, and the gradual establishment of a core medical hub centered around these cities represent an appropriate strategy. Ultimately, this approach aims to catalyze the advancement of health care services in the surrounding cities, aims to alleviate the health care burden on provincial capital cities and the PRD areas, and holds significant implications for the promotion of child health in China.

In our study, we observed that season had a notable impact on PTB. Our observation revealed that, although the number of births was higher during autumn than in other seasons, the incidence of PTBs was at its lowest during that time of the year. Simultaneously, our analysis of risk factors suggested that giving birth in autumn (September to November) was associated with a protective effect against PTB. In general, there were 2 peaks in the incidence of PTBs during summer (June 1 to August 31) and winter (December 1 to February 30). These findings align with a Norwegian survey that explored the seasonal impact on PTBs by analyzing data from 2,321,652 birth registrations. When analyzing the underlying reasons for this pattern, it is possible that an increase in unplanned pregnancies during longer summer and winter holidays is a contributing factor. Moreover, individuals with unplanned pregnancies may be less likely to engage in preconception preparation [19].

Specifically, the incidence of PTBs exhibited substantial annual fluctuations, with a notable decrease near the onset of the subsequent year. This phenomenon may be attributed to the subtropical monsoon climate characteristic of southern China, which implies that December has relatively mild temperatures, and such variations in temperature may influence the occurrence of PTBs. Liang et al [20] conducted an analysis of the impact of the 2008 cold spell on PTBs in 2 cities in South China. Regarding the total number of vaginal PTBs, their study revealed that there was a 22.44% increase in Dongguan and a 21.25% increase in Shenzhen during the 2008 cold spell, thereby supporting the influence of a cold spell on PTB. Additionally, a global analysis encompassing 14 lower- to middle-income countries investigated the connection between extreme heat and the occurrence of PTB and stillbirth. The results indicated that higher maximum temperatures and a narrower diurnal temperature range experienced during the last week before birth were associated with an increased risk of PTB and stillbirth [21]. This finding reinforces our findings.

Furthermore, data from 13 studies conducted in the United States and Europe revealed that 54.6% of PTBs were male infants, with a risk ratio of 1.14 (95% CI 1.11-1.17) for PTBs of male infants compared with female infants, aligning with our findings [22]. If the risk ratio for PTB between genders remains consistent within each region and is applied to sex-specific live birth data to estimate sex-specific PTB prevalence, it can offer guidance for future public health investments.

In this study, we investigated the prevalence and risk factors associated with preterm infants in southern China, approaching the analysis both from a spatiotemporal perspective and using a substantial data set. Our findings suggest that, despite a year-on-year increase in the incidence of PTBs, it remains below the global average, which bodes well for the advancement of public health initiatives in China. However, this study has certain limitations. Although the sample size was large, we lacked information on maternal pregnancy complications and general health status, preventing a more in-depth analysis of risk factors and the elimination of potential confounding variables. Additionally, the causal mechanism behind the seasonal influence on PTBs, potentially associated with temperature variations, remains unexplored. In the future, further investigations involving extensive sampling and questionnaire surveys are essential to delve deeply into the impact of climatic factors on PTBs, ultimately contributing to the development of theories for prepregnancy health care.
Conclusions
The incidence of PTB in South China exhibited an upward trend, closely linked to enhancements in the care capabilities for high-risk pregnant women and critically ill newborns. With the recent relaxation of China’s 3-child policy, coupled with a temporary surge in advanced maternal age and multiple pregnancies, the risk of PTB has risen. Consequently, there is a pressing need to augment public health investments aimed at mitigating the risk factors associated with PTB, thereby alleviating the socioeconomic burden it imposes.

Data Availability
All data generated or analyzed during this study are included in this published article and its supplementary information.

Authors' Contributions
XL obtained funding for the study. HM, HH, and XL conceptualized and designed the study. XL, CN, and JR provided administrative, technical, or material support and supervised the study. All authors contributed to the acquisition, analysis, or interpretation of the data. HM, HH, and XL had full access to all the data in the study and take responsibility for the integrity of the data and the accuracy of the data analysis. HH and HM performed the statistical analysis and drafted the manuscript, and all authors critically revised the manuscript for important intellectual content.

Abstract

Background: Chronic kidney disease (CKD) is a significant complication in patients with sickle cell disease (SCD), leading to increased mortality.

Objective: This study aims to investigate the burden of CKD in Medicaid-enrolled adults with SCD in California, examine differences in disease burden between male and female individuals, and assess mortality rates and access to specialized care.

Methods: This retrospective cohort study used the California Sickle Cell Data Collection program to identify and monitor individuals with SCD. Medicaid claims, vital records, emergency department, and hospitalization data from 2011 to 2020 were analyzed. CKD prevalence was assessed based on ICD (International Classification of Diseases) codes, and mortality rates were calculated. Access to specialist care was examined through outpatient encounter rates with hematologists and nephrologists.

Results: Among the 2345 adults with SCD, 24.4% (n=572) met the case definition for CKD. The SCD-CKD group was older at the beginning of this study (average age 44, SD 14 vs 34, SD 12.6 years) than the group without CKD. CKD prevalence increased with age, revealing significant disparities by sex. While the youngest (18-29 years) and oldest (>65 years) groups showed similar CKD prevalences between sexes (female: 12/111, 10.8% and male: 12/101, 11.9%; female: 74/147, 50.3% and male: 34/66, 51.5%, respectively), male individuals in the aged 30-59 years bracket exhibited significantly higher rates than female individuals (30-39 years: 49/294, 16.7%, \(P=0.01\); 40-49 years: 52/182, 28.6%, \(P=0.02\); and 50-59 years: 76/157, 48.4%, \(P<0.001\)). During this study, of the 2345 adults, 435 (18.5%) deaths occurred, predominantly within the SCD-CKD cohort (226/435, 39.5%). The median age at death was 53 (IQR 61-44) years for the SCD-CKD group compared to 43 (IQR 33-56) years for the SCD group, with male individuals in the SCD-CKD group showing significantly higher mortality rates (111/242, 45.9%; \(P=0.009\)) than female individuals (115/330, 34.9%). Access to specialist care was notably limited: approximately half (281/572, 49.1%) of the SCD-CKD cohort had no hematologist visits, and 61.9% (354/572) did not see a nephrologist during this study’s period.

Conclusions: This study provides robust estimates of CKD prevalence and mortality among Medicaid-enrolled adults with SCD in California. The findings highlight the need for improved access to specialized care for this population and increased awareness of the high mortality risk and progression associated with CKD.

Introduction
Chronic kidney disease (CKD) presents a significant complication in sickle cell disease (SCD), marked by its high prevalence and a notable increase in mortality. Nearly 70% of adults with SCD develop albuminuria [1], and roughly 20% progress to overt CKD, characterized by a glomerular filtration rate (GFR) of less than 60 ml/min/1.73 m² [2]. Each year, over 100 patients with SCD advance to end-stage renal disease (ESRD) [3]. The mortality risk in patients with SCD-related ESRD is 3-fold higher compared to those without CKD [4], particularly with proteinuria. Key predictors of mortality in SCD are a reduced GFR and rapidly deteriorating kidney function [5-7], contributing to 16% to 18% of overall mortality in SCD [8]. Increasing age is a risk factor for CKD [9], and male individuals are more likely to have a faster and more rapid kidney function decline [10]. As life expectancy in patients with SCD increases [11], the burden of SCD-associated CKD is expected to rise.

While the impact of CKD on SCD outcomes is well recognized, contemporary data on its prevalence and burden, especially in the aging population with SCD, are limited. This is particularly true for patients outside of specialized sickle cell clinics. Most current prevalence estimates are derived from pediatric sickle cell centers [2] or older patient cohorts [12]. However, the situation for adults with SCD is starkly different. Comprehensive care for adults is notably lacking [13], and most do not have access to specialized hematological care [14]. Thus, patients who are followed at established sickle cell centers may not represent the entire population of patients with SCD, and CKD in the population with SCD may be underrecognized. Furthermore, the majority of patients with SCD, often reliant on Medicaid, face significant barriers to accessing specialized care [15]. Access to timely and early nephrology care can impact the treatment of CKD and subsequent complications. Thus, more robust and contemporary population-wide approaches may help us in improving our understanding of the burden and prevalence of CKD in adults with SCD.

To address the current limitations in the field, our study aims to investigate the burden of CKD among Medicaid-enrolled adults with SCD in California using the Sickle Cell Data Collection (SCDC) program’s large administrative database over a 10-year time frame (2011-2020). The SCDC program offers a comprehensive view as a state-based, population-wide public health surveillance system for SCD [16]. Our report estimates the prevalence of CKD in the population with SCD by age groups, providing insights into mortality rates and access to specialized care, both hematology and nephrology, for adults with and those without CKD.

Methods
Study Design
This is a retrospective cohort study of Medicaid-enrolled people with SCD in California. All study data were obtained from the California SCDC program. The SCDC program leverages a variety of data sources to identify and longitudinally monitor individuals with SCD within the state. These data sources include newborn screening, nonfederal hospital discharge records, emergency room visits, ambulatory surgery encounters, vital records death files, Medicaid claims, and enrollment data, as well as clinical case reports from SCD care centers within the state. The data are linked and deduplicated across various sources and multiple years. Detailed information about the SCDC program and case definitions have been previously published [16-19].

Ethical Considerations
The SCDC program and this study were reviewed and approved by the California Committee for the Protection of Human Subjects (protocol 15-10-2249) and the Public Health Institute Institutional Review Board (protocol I16-001). California SCDC received a waiver of consent.

Data Sources
Data sources used in this analysis include Medicaid claims, hospital discharge data, and vital records data from 2011 to 2020. The source data included all outpatient provider claims, inpatient hospital, emergency department encounters, and all-cause mortality.

Study Population
Individuals aged 18 years and older, who met the case definition for SCD, were enrolled in Medicaid in 2011, and who maintained their Medicaid coverage for at least 75% (75/100) of their time in this study were included. For example, if someone’s enrollment spanned 6 years, they were required to be enrolled for at least 4.5 years cumulatively, regardless of whether the enrollment was continuous.

Study Measures
The demographic characteristics of individuals are reported by the total study population. Age was calculated on the first date of this study, January 1, 2011. SCD subtype was recorded from State Newborn Screening records or clinical case reports from SCD centers. Subtypes were categorized as hemoglobin (Hb)–SS or Hb-Sβ0 thalassemia (sickle cell anemia), Hb-Sβ+ thalassemia, Hb-SC, other compound homozygous forms of SCD, or unknown if laboratory confirmation was not available within the SCDC database. An individual was considered dual eligible, meaning they were enrolled in both Medicare and Medicaid, if any Medicaid claims data indicated dual eligibility. For the prevalence estimation, age is calculated at the last date of this study, December 31, 2020, or date of death, whichever came first.
first. Disposition codes within the emergency department and hospitalization data as well as linked vital death records were used to identify all-cause deaths occurring during this study’s period. The proportion of deaths was calculated as the number of people with CKD who died, regardless of cause, by age group divided by the total number of people who developed CKD by age group, calculated at age on the last date of this study, December 31, 2020, or date of death, whichever came first.

We ascertained individuals’ CKD status (none versus any, the latter encompassing stages 1 through 5, unspecified stage, and ESRD), stage of CKD is based on ICD-9-CM (International Classification of Diseases, Ninth Revision, Clinical Modification) and ICD-10-CM (International Classification of Diseases, Tenth Revision, Clinical Modification) diagnosis codes. Individuals met the case definition for CKD if, within 5 years, they had 3 or more outpatient or emergency department encounters with CKD-coded diagnoses (ICD-9-CM: 585, 5851-5856, or 5859; ICD-10-CM: N18, N181-N185, or N188-N189) recorded in any diagnostic position, or at least 1 hospitalization with such codes in any position [20]. We identified a cohort of 572 individuals who by the end of this study’s period met the case definition for CKD. Subsequently, we will reference this subset as the SCD-CKD cohort. The remaining that did not meet the case definition will be referred to as the SCD cohort.

Hematologist and nephrologist encounters were identified using the National Provider Identifier of the rendering provider, as listed in the Medicaid claims records [21]. Providers with any health care provider taxonomy code listed as hematologist (207RH0000X, 207RH0003X, or 2080P0207X) were categorized as a hematologist; nephrologists were categorized as such if they had any health care provider taxonomy code listed as a nephrologist (207RN0300X). To calculate an individual’s total number of encounters with a hematologist (both groups) or nephrologist (CKD only), Medicaid claims were deduplicated by stipulating that an individual could only be recorded as having 1 encounter with a specific provider per day. The outpatient encounter rate was calculated by dividing the total number of unique encounters by the total person-years attributed to each group. To calculate the proportion of individuals who had no visits with a nephrologist or hematologist, the entire study duration was examined, and those with no encounters with either specialist were identified.

Statistical Analysis
Categorical variables were summarized using frequencies and percentages and compared for statistical significance using chi-square tests. Continuous variables were summarized by means and rates, and the Wilcoxon-Mann-Whitney U test was used to test for differences between SCD-CKD and the SCD groups. All analyses were performed using SAS (version 9.4; SAS Institute Inc).

\(^a\)Met case definition by the end of this study period.

\(^b\)SCD: sickle cell disease.

\(^c\)CKD: chronic kidney disease.

\(^d\)Age at the start of this study from January 1, 2011.

\(^e\)SCA: sickle cell anemia.

\(^f\)Hb: hemoglobin.

\(^g\)Thal: thalassemia.

At the start of this study’s period, the SCD-CKD group (n=572) were older in age, with nearly half (n=284, 49.7%) being in the aged 40-59 years categories (n=148, 25.8%, 40-49 years; n=136, 23.8%, 50-59 years). The mean age at the start of this study for the SCD-CKD cohort was 44 (SD 14) years. In contrast, the SCD cohort (n=1773) had an average age of 34 (SD 12.6) years, with 45.7% (n=811) of them between the ages of 18 and 29 years. In both the SCD-CKD and SCD groups, female individuals were more predominant at 57.7% (330/572) and 65.7% (1165/1773) respectively. Among the people with a known genotype across both groups, sickle cell anemia was more prevalent than Hb-S\(^g\)\(^{-}\) thalassemia or Hb-SC. However, nearly 79.7% (1869/2345) had unknown genotypes. More than half (333/572, 58.2%) of the SCD-CKD cohort were considered dual eligible for Medicaid and Medicare.

### CKD Prevalence by Age Group and Sex

The prevalence of CKD by age group and sex, as presented in Figure 1, shows a notable pattern of increasing prevalence with advancing age, alongside a distinct variation between female and male individuals. In the youngest age group (18-29 years) and oldest age groups (>65 years), the prevalence is similar between female and male individuals, at 10.8% (12/111) female and 11.9% (12/101) male and 50.3% (74/147) female and 51.5% (34/66) male, respectively. Male individuals have a significantly higher CKD prevalence in the 30 (\(P=0.01\)), 40 (\(P=0.02\)), and 50 (\(P<0.001\)) years age groups. The highest prevalence is observed in the age group of 65 years and older, with 50.3% (74/147) in female individuals and 51.5% (34/66) in male individuals, resulting in a combined prevalence of 50.7% (108/213). These estimates are from the end of this study’s period.
Of the 2345 adults, there were 435 (18.5%) deaths that occurred during this study’s period, with the majority of deaths occurring in the SCD-CKD cohort (226/572, 39.5% of the SCD-CKD group). The median age at death was 53 (IQR 61-44) years for the SCD-CKD cohort and 43 (IQR 33-56) years for the SCD cohort. When compared to the SCD cohort, the SCD-CKD cohort had higher death rates for all age groups (Table 2). The lowest total number of deaths was identified in the youngest age group with SCD-CKD (>18-29 years); however, we identified a 63% mortality rate among individuals with SCD-CKD in this youngest age group. The remaining age groups also had high rates of mortality that ranged from 34% (33/96; 30-39 years) to 45% (73/163) among the 50-59 years age group (Figure 2). Male individuals with SCD-CKD had a significantly higher rate of mortality (45.9%;111/242, \(P=.009\)) compared to female individuals (34.9%, 115/330) with SCD-CKD; this trend, although not statistically significant, persisted across most age groups (Table 2).

Access to Care

Figure 3 and Table 3 show the rate of outpatient encounters with a hematologist or a nephrologist per person-year and the proportion of people with SCD-CKD who had zero visits with either specialist. Among those with SCD-CKD, visit rates with a hematologist were approximately 2 visits per person-year; however, almost half (281/572, 49.1%) of people had no encounters with a hematologist over the entire study period. Access to nephrology care was also limited; in the group with SCD-CKD, individuals had only approximately 1 visit to a nephrologist per person-year, and 61.9% (354/572) of people did not have any encounters with nephrologists throughout the entire study period.

Figure 3. Proportion of individuals with sickle cell disease, with and without chronic kidney disease, who had 0 hematologist encounters for over 10 years, 2011-2020. CKD: chronic kidney disease; SCD: sickle cell disease.

Discussion

Principal Findings

Our study estimates the prevalence and mortality associated with CKD in Californian adults with SCD using a large administrative database. Similar to other single and multi-institutional cohorts, we found a high prevalence of CKD (572/2345, 24.4%) among adults with SCD. Prevalence of CKD increased with age, with significant differences between male and female individuals. Mortality rates were higher in the SCD-CKD cohort. Access to specialized care was limited, with a significant proportion of individuals having no encounters with hematologists or nephrologists.

Prevalence of CKD by Age Group and Sex

We identified 2345 adults (aged >18 years) during 10 years within the SCDC cohort. Of these, 572 fulfilled case definitions for CKD, with an estimated CKD prevalence of 24.4% (572/2345). Prior studies show a high prevalence of CKD in the population with SCD, and our study confirms these findings. Further, 1 observational study tracked 427 patients over 4 years, finding a baseline CKD prevalence of 21.4% in sickle cell anemia and 17.2% in Hb-S\(^B\) thalassemia and Hb-SC SCD [2].

Studies from countries such as Nigeria and Ghana report even higher prevalence rates, around 38% and 39%, respectively [22,23]. Another study, a 25-year cohort study [24], identified the prevalence of renal failure at 4.2% in patients with sickle cell anemia (median age of onset was 23.1, range 13-57 years) and 2.4% in patients with Hb-SC SCD (median age of onset was 49.9, range 29-65 years). On additional follow-up, the prevalence increased to 12% [24]. The prevalence of CKD, calculated using the age at the end of this study or age at death, demonstrated an expected increase with advancing age. Our study continues to highlight the high prevalence of SCD-CKD in patients aged 18-29 years. By age >50 years, around 50% of patients will have developed SCD-CKD. Interestingly, our cohort predominantly comprised female individuals (1495/2345, 63.75%); this overrepresentation may be attributed to higher Medicaid coverage in female individuals, especially during their reproductive years [25]. Despite this female predominance, male individuals appear to have a higher prevalence of CKD compared to female individuals for each age category: a higher percentage of male individuals in our study had CKD (242/850, 28.5% vs 330/1495, 22.1%), deviating from the general population’s CKD distribution where female individuals slightly outnumber male individuals [26]. This finding further confirms
sex differences in the prevalence of SCD-CKD at a population level [27]. This may be explained by the fact that male individuals with SCD have a higher rate of decline in GFR when compared to female individuals [28,29], leading to a greater burden of CKD.

While male individuals appear to have a higher prevalence of CKD for each age category, CKD prevalences for male and female individuals are the same in the aged 60-64 years group. This phenomenon may be partially explained by higher mortality rates for male individuals in the SCD-CKD cohort, and hence the comparable CKD rates in the oldest age groups may be because more male individuals with SCD-CKD are dying at a younger age. Taken together, these findings further emphasize the importance of the early CKD screening and intervention in SCD, especially in younger and male populations.

**CKD and Mortality**

During this study’s period, 435 deaths occurred, translating to an overall mortality rate of 18.6% (435/2345). Notably, the mortality rate in the SCD-CKD cohort was high at 39.5% (226/572). Male individuals in the SCD-CKD cohort exhibited a higher death rate (45.9%, 111/242) compared to female individuals (34.9%, 115/330), deviating from previous studies that did not find a sex difference in mortality among patients with CKD and with SCD [1]. Notably, 50.9% (115/226) of the deaths in the SCD-CKD cohort occurred in individuals with ESRD, reinforcing the association of kidney disease with heightened mortality risk in SCD. The high mortality rate seen in our study is notably higher than the 18% found in the study by Platt et al [8]. In total, 1 key difference is the level of health care access between the 2 populations; the study by Platt et al [8] followed patients enrolled and regularly seen at established SCD centers, whereas nearly half or more of the patients included in this analysis never had an encounter with a hematologist (281/572, 49.1%) or nephrologist (354/572, 61.9%). In addition, the definition for renal failure was different in Platt et al [8], where they defined renal failure as a 20% increase in baseline creatinine concentration and a creatinine clearance rate below 100 mL/min [8], while we used ICD (International Classification of Diseases) codes to identify individuals with CKD. In our study, the median age at death was 10 years higher in the SCD-CKD cohort compared to the non-CKD SCD cohort, which was an unexpected finding given that CKD is a known risk factor for mortality in SCD [7]. This could be attributed to the older age distribution of the SCD-CKD cohort. This suggests that CKD may be more prevalent in the aging population with SCD, potentially characterizing it as a complication of the aging population with SCD and perhaps can be considered a disease of the “survivors.”

The significantly higher mortality rate in the SCD-CKD group, especially in younger age groups, is another important finding. The stark contrast in mortality rates between male and female individuals with SCD-CKD in the youngest age group indicates a need for focused research on gender-specific factors contributing to these outcomes. This elevated mortality risk associated with CKD in patients with SCD underscores the importance of the early detection and management of kidney disease.

**Access to Care**

Severe lack of access to specialty services remains a critical issue for adults with SCD [14]. Notably, while the SCD-CKD group had more hematologist visits than the SCD group, nearly half had no specialist visits over the 10 years, highlighting a critical gap in specialty care access for adults with SCD. This lack of access is even more considerable given that 67.2% (152/226) of individuals with SCD and CKD who died had not consulted a hematologist, compared to 37.3% (129/346) among survivors. Furthermore, only 38.1% (n=218) of those with CKD had consulted a nephrologist, and likely only in the advanced stages of their disease. This is not a surprising observation, since it is likely that patients who had more access to care also had more access to preventative care, early detection of CKD, and likely disease-modifying strategies. Despite ESRD qualifying for Medicare, only 58.2% (333/572) were dual eligible, indicating that Medicaid coverage alone may not provide sufficient access to nephrology care [3]. This issue is not unique to the population with SCD and reflects broader systemic disparities in health care access, particularly for younger, predominantly Black and Hispanic individuals on Medicaid [3]. These findings emphasize the need for improved access to specialized care to better manage CKD and potentially reduce mortality in the population with SCD.

**Limitations**

While there are several strengths to our study approach as outlined above, there are also several limitations. The major limitation of our study is that it is a retrospective administrative data-based study. The use of ICD codes to capture CKD diagnoses has been validated previously [20], however, we are likely underestimating the burden of CKD for multiple reasons. We did not include ICD codes for proteinuria since we felt this would be less reliable when relying on administrative data alone for data collection. While we included all stages of CKD, we likely underestimated CKD 1 and 2 where the GFR is >60 mL/min because not all of these may have been recognized or coded correctly. In assessing the limitations of our methodology for calculating the prevalence, it is important to consider the following aspects. First, individuals were categorized as either having CKD or not based on meeting the case definition at any point within a 10-year timeframe. This approach simplifies the classification process but may overlook cases of CKD who did not use health care or were not identified or documented with the relevant codes during the specified period. Additionally, because we used ICD codes within a set period of time, we could only identify when the first ICD CKD code appeared and not when a person was first diagnosed with CKD. Lastly, only Medicaid recipients were included in our study and about a third of patients with SCD may have commercial insurance or Medicare only and may not have been included in our analysis. In our assessment of care access, we focused exclusively on visits to hematologists, without distinguishing providers with specific training in SCD. Previous research indicates that adult patients with SCD in California face significant access barriers, and including primary care providers with SCD expertise—defined as having 20 or more patients with SCD—did not substantially improve access [14]. In addition, we could not ascertain whether individuals who disenrolled
from Medi-Cal then enrolled in other health plans or became uninsured. While our data does not enable us to confirm whether individuals accessed specialty care during periods they were not enrolled in Medicaid, the literature suggests that accessing specialist services without insurance is highly unlikely [30]. Since this was an administrative database-based study, we had limited access to detailed clinical information, and could not adjust for covariates or perform robust statistical analysis, hence our results are presented descriptively.

**Conclusions**

We used administrative data to estimate the prevalence of CKD in SCD among California state Medicaid recipients. Our prevalence estimates for CKD are higher than what has been reported previously. Those with SCD and concurrent CKD experienced significantly higher mortality rates compared to individuals with SCD who did not meet the case definition for CKD. In California, individuals with SCD face substantial barriers to accessing specialty care. Our findings highlight the critical need for this data to guide state health care stakeholders and government policy makers in addressing these access issues. As the SCDC program expands to include additional states, similar studies may inform our understanding of the true burden of CKD in the population with SCD, including its effects on mortality, morbidity, health care use, and quality of life.

Syndromic Surveillance Tracks COVID-19 Cases in University and County Settings: Retrospective Observational Study

Lily Minh Wass¹, BS; Derek O'Keeffe Hoare², MS; Georgia Elena Smits², MS; Marwan Osman¹,³, MPH, PhD; Ning Zhang⁴, MPH; William Klepack⁵, MD; Lara Parrilla¹, MPH; Jefferson M Busche⁶, MS; Marin E Clarkberg⁶, PhD; Sumanta Basu², PhD; Casey L Cazer¹,⁷, DVM, PhD

Abstract

Background: Syndromic surveillance represents a potentially inexpensive supplement to test-based COVID-19 surveillance. By strengthening surveillance of COVID-19–like illness (CLI), targeted and rapid interventions can be facilitated that prevent COVID-19 outbreaks without primary reliance on testing.

Objective: This study aims to assess the temporal relationship between confirmed SARS-CoV-2 infections and self-reported and health care provider–reported CLI in university and county settings, respectively.

Methods: We collected aggregated COVID-19 testing and symptom reporting surveillance data from Cornell University (2020 - 2021) and Tompkins County Health Department (2020 - 2022). We used negative binomial and linear regression models to correlate confirmed COVID-19 case counts and positive test rates with CLI rate time series, lagged COVID-19 cases or rates, and day of the week as independent variables. Optimal lag periods were identified using Granger causality and likelihood ratio tests.

Results: In modeling undergraduate student cases, the CLI rate ($P=.003$) and rate of exposure to CLI ($P<.001$) were significantly correlated with the COVID-19 test positivity rate with no lag in the linear models. At the county level, the health care provider–reported CLI rate was significantly correlated with SARS-CoV-2 test positivity with a 3-day lag in both the linear ($P<.001$) and negative binomial model ($P=.005$).

Conclusions: The real-time correlation between syndromic surveillance and COVID-19 cases on a university campus suggests symptom reporting is a viable alternative or supplement to COVID-19 surveillance testing. At the county level, syndromic surveillance is also a leading indicator of COVID-19 cases, enabling quick action to reduce transmission. Further research should investigate COVID-19 risk using syndromic surveillance in other settings, such as low-resource settings like low- and middle-income countries.

Introduction

SARS-CoV-2 continues to be one of the most significant causes of morbidity and mortality, with over 697,000,000 total COVID-19 cases and 6,900,000 deaths recorded worldwide as of November 1, 2023 [1]. Although rates of COVID-19 infection, hospitalizations, and mortality have significantly declined due to global vaccination efforts [2], the emergence of the highly mutated Omicron variant and following subvariants continue to fuel spikes in COVID-19 cases [3]. National public health programs have primarily relied on diagnostic testing to gauge COVID-19 case trends. While useful for tracking the incidence of COVID-19 cases, large-scale polymerase chain reaction–based surveillance testing programs
have high supply and labor costs. Coupled with the shift to at-home testing—a practice that mainly grew in the first Omicron wave beginning in December 2021—which is largely unreported [4], this has led to a substantial decline in reported daily tests in the United States. Shifting the responsibility of case reporting from health care facilities to patients has led to the underestimation of true COVID-19 trends and has challenged public health measures such as isolation and quarantine of individuals who are infected, as well as the measurement of negative effects or financial costs of COVID-19. Furthermore, May 11, 2023, marked the expiration of the US federal COVID-19 Public Health Emergency declaration, along with authorizations to collect certain public health data [5]. This triggered a pivot from COVID-19 case-based surveillance to COVID-19–associated hospital admissions as the leading indicator of COVID-19 trends, with many national COVID-19–reporting platforms like the Centers for Disease Control and Prevention (CDC) removing case-based metrics from their websites. Looking at hospitalization data as an indication of the current state of COVID-19, over 16,000 hospitalizations were reported in the week of October 15, 2023 [6].

As endemic COVID-19 seems to be the likely future of the pandemic [7], sustainable disease monitoring systems are warranted. Syndromic surveillance, or the detection and recording of symptoms before a diagnosis is confirmed, could serve as a less resource-intensive method to monitor trends in COVID-19–like illness (CLI) for public health departments and health care facilities. The National Syndromic Surveillance Project of the CDC defines CLI as “fever and cough or shortness of breath or difficulty breathing with or without the presence of a coronavirus diagnosis code. Visits meeting the CLI definition that also have mention of flu or influenza are excluded” [8].

Syndromic surveillance has already been used in a few ways throughout the pandemic. The National Syndromic Surveillance Project pivoted to reporting on CLI using local, academic, and private partnerships [9], while county health departments like Seattle and King County of Washington State have reported CLI trends from hospitalizations and emergency department (ED) visits [10]. COVID Control, a Johns Hopkins University study, piloted a symptom reporting app in 1019 counties and identified loss of taste or smell to be a leading predictor of SARS-CoV-2 rates, appearing 5 days before confirmatory diagnostic tests [11]. Limitations of these prior syndromic surveillance studies include reliance on ED data [10], which may exclude patients with COVID-19 who are asymptomatic or have mild symptoms. Although COVID-19 hospitalizations are ongoing, they have significantly declined since the onset of the pandemic and subsequent Omicron spikes, and are largely composed of populations older than 70 years [6], making surveillance that relies exclusively on ED admissions and hospitalizations biased. Additionally, the COVID Control study selected participants experiencing CLI, which does not indicate how rates of symptoms relative to the total community or population track true SARS-CoV-2 positivity rates [11]. To date, there is still limited information on how CLI surveillance can be used to accurately monitor community transmission, including asymptomatic and mild infections.

Cornell University and Tompkins County Health Department (TCHD) each developed a CLI surveillance system and a robust tracking system for confirmed COVID-19 cases. In the university setting, surveillance testing and daily symptom reporting were enforced among all individuals on campus, resulting in a daily record of testing, symptom reporting, and exposure data. In contrast, the county recorded CLI data from patients who voluntarily sought out practitioner-based care, and they had a robust free COVID-19 testing program. In this paper, we assess whether levels of reported COVID-19 symptoms are correlated with test positivity levels during the Delta and B.1 variant predominant period in a county and university setting. We identify the optimal temporal lag between changes in symptom reporting and increases in COVID-19 cases, and which symptom or health screening questions had the strongest association with test positivity rates. We provide recommendations that can be used by institutions of higher education and local county health departments to improve SARS-CoV-2 surveillance in the endemic phase of the pandemic.

Methods

Study Design and Population

During the 2020-2021 academic year, Cornell University students (n=12,988 undergraduates, n=6549 graduate and professional students), faculty (n=1332), and staff (n=6739) participated in a robust COVID-19 testing program and daily syndromic surveillance, called the Daily Check. Undergraduate and professional students were tested twice a week, and graduate students, faculty, and staff were tested weekly for SARS-CoV-2 via anterior nares swab and polymerase chain reaction [12], as described elsewhere [13,14]. Supplemental SARS-CoV-2 testing occurred at the request of individuals and when increased case counts were noted in specific subpopulations. For the Daily Check, all on-campus students were asked to report daily whether they had COVID-19–like symptoms or had potential exposures to a confirmed SARS-CoV-2 case or a person with CLI. Each day, students who answered “yes” to any of these questions were labeled with a “red” status until cleared by Cornell Health with either a SARS-CoV-2 test or follow-up questions. A flowchart with the labeling logic is provided in Multimedia Appendix 1. Cornell University’s Office of Institutional Research and Planning provided aggregated data on the daily number of students, faculty, and staff who were flagged as “red,” experiencing CLI themselves, had been exposed to a confirmed COVID-19 case, had been exposed to someone experiencing CLI, and tested positive for SARS-CoV-2. The daily total number of SARS-CoV-2 tests conducted at Cornell and Daily Checks was also provided [15]. For this study, we analyzed data collected between August 17, 2020 (the first day of data collection for both the syndromic surveillance and testing programs) and February 3, 2021 (the last date before questions on the Daily Check survey changed substantially) from undergraduate students. Days with fewer
than 100 SARS-CoV-2 tests conducted in the undergraduate population were excluded from the analysis.

Starting in June 2020, local health practitioners in Tompkins County were encouraged by the health department to record how many patients they saw each day and, of those patients, how many presented with CLI. TCHD defines CLI as “cough and/or shortness of breath OR at least two of the following: fever; chills; repeated shaking with chills; myalgias; headache; sore throat; new loss of sense of taste or smell.” Practices were excluded from this study if they reported fewer than 50 times between June 2020 and March 2022. A pediatric practice was excluded because the prevalence of CLI varies greatly in children relative to adults, and children also experience differing clinical presentations of COVID-19 [16,17]. Data from the remaining practices were aggregated by the date of data collection. CLI data reported on weekends were excluded because most practices were not open on the weekends. This resulted in a data set of total patient encounters, CLI encounters, and the number of practitioners who contributed to reporting each day.

Free SARS-CoV-2 testing has been available to Tompkins County residents since March 2020. A record of new positive results, cumulative total positive results, and cumulative total tests were kept between March 14, 2020, and December 20, 2022, and is publicly available on TCHD’s website [18]. As Cornell University is within Tompkins County, surveillance and diagnostic testing data from the university were included in the data set provided by Tompkins County. Starting December 1, 2020, the number of daily laboratory tests was also reported. Our analysis focused on the period from December 1, 2020 (after the number of tests was available to calculate the proportion of positive SARS-CoV-2 tests) to March 11, 2022, the last week of surveillance before the BA 2.2.12.1 variant (Omicron subvariant) exceeded more than 50% of new cases in New York State [19]. The predominant variants within our study were Delta and BA.1 [19], which minimizes possible variation due to increased transmissibility or different predominant symptoms caused by BA.2. Dates when fewer than 300 SARS-CoV-2 tests were conducted were excluded.

Ethical Considerations

This study was determined to not meet the definition of human subject research by the Cornell University Institutional Review Board because the data were deidentified and aggregated. The original data were collected as part of public health surveillance activities by the TCHD and Cornell University, and therefore did not meet the definition of human subject research.

Data Analysis

Within both the Cornell and TCHD data sets, the rate of SARS-CoV-2 positivity was calculated by dividing the count of new daily positive test results by the number of daily tests conducted within the undergraduate or county setting. For Cornell undergraduates, rates of CLI, exposure to CLI, and exposure to COVID-19 were calculated as the sum of each Daily Check variable over the total number of Daily Checks completed that day. The CLI rate in Tompkins County was the sum of patients experiencing CLI divided by the total number of patients seen that day. The rate of county CLI encounters on weekends was imputed as the average of Friday and Monday rates. The county CLI rate on US holidays was imputed in the same manner, by averaging rates from the two nearest dates before and after the holiday. In addition, a variable for the day of the week was encoded based on the date of data collection for both data sets.

All variables defined for the statistical analysis are detailed in Supplemental Tables 1 and 2 in Multimedia Appendix 1. For the initial descriptive analysis, the moving 7-day averages of the CLI and SARS-CoV-2 positivity rate time series were plotted. The moving average was symmetrical; the values of each variable from ±3 days and at present were summed and divided by 7.

The autocorrelation of SARS-CoV-2 positivity rates and the cross-correlation between the CLI and SARS-CoV-2 positivity time series were plotted at up to 10-day lags to identify the optimal lag period between independent variables and the outcome of SARS-CoV-2 positivity. The Granger causality test assesses whether previous values of variable x are useful for forecasting current values of variable y [20]. The grangertest function of the lmtest R package compares an autoregressive model of y that only uses previous values of y as independent variables with a model that includes previous values of x and y as independent variables [21]. We used the Granger causality test to determine if the addition of CLI rates (x) forecasted SARS-CoV-2 positivity rates (y) better than autocorrelation of y alone. The temporal lag of the CLI rate to be included in subsequent models was selected based on which previous days of x had the smallest P values in the Granger causality test.

Based on the findings of the autocorrelation and cross-correlation plots, two types of models were built to assess the association between CLI rates at present and from the prior 1-6 days, and the current SARS-CoV-2 positivity measure. The linear model used the SARS-CoV-2 positivity rate as the outcome. Independent variables included CLI rates at present (day 0) and from the prior 1-6 days, day of the week, and the SARS-CoV-2 positivity rate from the prior 1-6 days. In the university setting, two linear models were constructed with independent variables including either the rate of CLI or rate of exposure to CLI from up to 6 days prior. Significant variables were identified if their associated P value was less than .05.

\[
\text{SARS-CoV-2rate (day i)} = \text{CLIrate (day i)} + \text{SARS-CoV-2rate (day i− weekday)}
\]

where i=0, ..., I, and I is the selected maximum number of days prior.

Next, the county data was tested for overdispersion, and a negative binomial model was fitted to the data. In the negative binomial model, counts of daily SARS-CoV-2 positive tests were the outcome. CLI rates (day 0 through 6 days prior), day of the week, and counts of SARS-CoV-2 infection from the prior 1-6 days were independent variables. The CLI variable was transformed to a (0, 100) scale for the model estimates to be interpreted as percentage changes in the outcome variable of SARS-CoV-2 counts. To account for variation in the number of positive tests caused by the daily number of tests conducted.
administered, an offset of the log of daily tests conducted was included in the model.

$$\log (\text{SARS}_\text{CoV}_2 \text{ count}) = \phi_0 + \sum_{i=1}^{7} \phi_i \log (\text{CLI rate})_{i+1} + \sum_{i=1}^{16} \phi_i \log (\text{SARS}_\text{CoV}_2 \text{ count})_{i+\text{weekday} + \log (\text{daily tests})}$$

where \(i=0, \ldots, I\), and \(I\) is the selected maximum number of days prior.

The significance of independent variables was assessed by comparing the \(P\) value associated with each input with an \(\alpha\) of 0.05. As the negative binomial model applies a log transformation to both independent and outcome variables, the incident rate ratio estimates of the model were exponentiated to undo the log transformation.

Models within the same class were compared using the likelihood ratio test to determine whether the addition of CLI information and the day of the week yielded a significantly better fit than a model based on previous measurements of SARS-CoV-2 positivity alone.

Data were analyzed using R version 4.1.0 (R Foundation for Statistical Computing) in the RStudio environment [22].

## Results

### Analysis of CLI and Cases in University Setting

We collected 124 days of Daily Check and surveillance testing data between August 17, 2020, and February 3, 2021, from Cornell University. The symmetrical 7-day moving average of SARS-CoV-2 positivity rates and the rate of “red” flagged students are plotted in Figure 1.
The SARS-CoV-2 test positivity rate ranged between 0 and 0.021 with an average of 0.002. The maximum number of SARS-CoV-2 positive cases on a single day was 20. On average, 1893 tests were conducted daily. The CLI rate ranged from 0 to 0.005 with a maximum of 58 students reporting CLI in one day. The rate of exposure to CLI ranged from 0 to 0.006, with a daily maximum of 69 students reporting exposure to CLI. Finally, the rate of exposure to a confirmed COVID-19 case ranged from 0 to 0.008 with a maximum count of 87 exposures reported in one day.

The rate of SARS-CoV-2 test positivity from 1 to 4 days prior and 7 days prior was significantly autocorrelated with the SARS-CoV-2 test positivity rate at present (Supplemental Figure 1 in Multimedia Appendix 1). We observed significant cross-correlation coefficients between the present-day SARS-CoV-2 positivity rate and lagged rates of students experiencing COVID-19 symptoms, contact with someone experiencing COVID-19 symptoms, and contact with a confirmed COVID-19 case (Supplemental Figure 2 in Multimedia Appendix 1).

The results of Granger causality test, comparing autoregression of the rate of positive tests with and without previous daily rates of CLI or exposure among undergraduates, are shown in Figure 2. The rate of COVID-19 symptoms from up to 6 days prior was found to improve forecasting of the test positivity rate relative to prior values of the positivity rate alone ($P<.001$).
Similarly, including the rate of newly exposed students to CLI from up to 6 days prior significantly improved the forecasting of test positivity ($P=.02$). However, the addition of data regarding exposure to a confirmed COVID-19 case from up to 6 days prior did not significantly improve forecasting relative to an autoregression of the test positivity variable alone ($P=.51$). The results of the regressions used in the Granger test can be seen in Supplemental Tables 3-5 in Multimedia Appendix 1.

Based on the linear models, a 1 percentage point (pp) increase in the rate of undergraduates experiencing CLI was significantly associated with a 1.36 (95% CI 0.46-2.26) pp increase in the rate of SARS-CoV-2 test positivity on the same day ($P=.003$). A 1 pp increase in the rate of students reporting new contacts with people experiencing CLI was significantly associated with a 1.66 (95% CI 0.83-2.50) pp increase in the SARS-CoV-2 positivity rate on the same day as well ($P<.001$; Table 1). The full model outputs can be found in Supplemental Tables 6 and 7 in Multimedia Appendix 1.

The rate of CLI and exposure to CLI had the largest statistically significant model coefficients in their models, even compared to previous rates of SARS-CoV-2 positivity (Supplemental Tables 6 and 7 in Multimedia Appendix 1). Using the likelihood ratio test, models were found to be significantly different from the nested model that removed the time series of CLI or exposure to CLI ($P<.001$). The likelihood ratio test also showed that the addition of the day of the week did not significantly improve the rate of the CLI model ($P=.15$) but did significantly improve the exposure to the CLI model ($P=.02$) and was therefore included as an independent variable for both models.
Figure 2. Granger causality test $P$ values for models including the proportion of undergraduate students with new COVID-19 symptoms (blue), students newly in contact with people who have COVID-19 symptoms (red), and students newly in contact with a confirmed COVID-19 case (yellow) from up to 6 days prior as independent variables, with the SARS-CoV-2 positivity rate as the outcome variable, relative to the autoregressive model of the positivity rate alone. Values below the green dotted line are significant ($\alpha=.05$). pos: positive test results.
Table. Optimal lag time between previous rates of surveillance indicators (x) and current SARS-CoV-2 positivity (y), and regression coefficient for the optimal lag. A lag time of 1 indicates COVID-19–like illness (CLI) data are taken from 1 day prior to the COVID-19 testing data, a lag of 2 is from 2 days prior, and so on.

\(^a\)Optimal lag time is selected based on the largest model coefficient for linear models and largest incidence rate ratio for negative binomial models that is significant at \(\alpha=0.05\).

\(^b\)Granger causality assesses correlation of previous days of CLI with current measures of positivity; therefore day 0 is not included.

Analysis of CLI and Cases in the County Setting

In the Tompkins County setting, 403 days of CLI and SARS-CoV-2 testing data between December 1, 2020, and March 11, 2022, were included after data cleaning. The 7-day moving averages of the CLI rate and SARS-CoV-2 positivity rate are plotted in Figure 3.

The SARS-CoV-2 positivity rate ranged from 0.00 to 0.64, with the maximum value observed around the peak of the first Omicron (BA.1.1) wave [23] on December 19, 2021. The average positivity rate was 0.02. The minimum daily SARS-CoV-2 positivity count was 0, while the maximum was 523 cases. On average, 3235 SARS-CoV-2 tests were conducted daily. The CLI encounter (CLI encounters per total patient encounters) rate ranged from 0 to 0.71; the most patients with CLI seen on a single day was 60 with an average of 15 patients with CLI seen daily.

There was substantial autocorrelation of SARS-CoV-2 positivity rates; 1- through 5-day lags of the SARS-CoV-2 positivity rate had autocorrelation coefficients greater than 0.20, after which values declined (Supplemental Figure 3 in Multimedia Appendix 1). The cross-correlation plots revealed nonzero correlation coefficients between CLI rates up to 10 days prior and current rates of SARS-CoV-2 positivity (Supplemental Figure 4 in Multimedia Appendix 1). However, the highest correlation coefficients were observed in the 4-day lag (\(\beta=0.295\)) and 6-day lag (\(\beta=0.346\)) of the CLI rate. This result was confirmed by Granger causality, which revealed that including CLI rates from 3 to 6 days prior yielded the smallest P values (Figure 4). For CLI rates from 1 week prior (lags 1-6), minimum Granger causality P values were observed at a lag of 4 and 6 days (\(P<.001\); Supplemental Table 8 in Multimedia Appendix 1). Based on these results, rates of CLI from 1 to 6 days prior were selected to be included in subsequent models. Previous rates of SARS-CoV-2 positivity from up to 6 days were included based on the significant autocorrelation observed (Supplemental Figure 3 in Multimedia Appendix 1). Significant autocorrelation and Granger causality of rates from 7 days prior and at present were observed, but 7-day lagged variables were not included to account for the variation that the day of the week may cause in surveillance testing and CLI reporting capabilities. Instead, the weekday variable was included to account for possible variation due to the day of the week that data was collected.
Figure 3. Seven-day symmetrical mean of the CLI encounter rate, shown by the solid line, and SARS-CoV-2 positivity rate, shown by the dotted line, from December 1, 2020, to March 11, 2022, in Tompkins County. CLI: COVID-19–like illness.
Figure 4. Granger causality test $P$ values for a model using the COVID-19–like illness rate from 1 to 6 days prior as independent variables, with present-day SARS-CoV-2 positivity rates as the outcome variable. All values are significant at $\alpha=.05$; however, $P$ values decline sharply upon including lags from up to 3 or more days prior. Values below the dashed green line are significant at $\alpha=.05$.

In the linear regression model (Supplemental Table 9 in Multimedia Appendix 1), a 1 pp increase in the rate of CLI 3 days prior was significantly associated with a 0.20 (95% CI 0.10-0.30) pp increase in the current SARS-CoV-2 positivity rate ($P<.001$). Similarly, a 1 pp increase in the rate of CLI 4 and 6 days prior was significantly associated with a 0.15 (95% CI 0.04-0.26) pp and 0.19 (95% CI 0.08-0.30) pp increase in current SARS-CoV-2 positivity rates ($P=.01$ and $P<.001$), respectively. The rate of CLI from up to 3 days prior had the largest regression coefficient across all linear model independent variables (Supplemental Table 8 in Multimedia Appendix 1).

In the negative binomial model (Supplemental Table 10 in Multimedia Appendix 1), a 1 pp increase in the rate of CLI encounters at a 3-day lag was significantly associated with a 4% (95% CI 1.01-1.07) increase in the number of SARS-CoV-2 positive tests at present ($P=.005$). The rate of CLI from up to 3 days prior had the highest incidence rate ratio across all numeric independent variables, including previous counts of SARS-CoV-2 positive results (Supplemental Table 10 in Multimedia Appendix 1).

Both full models were found to be significantly different from the nested model, which excluded all CLI independent variables, using the likelihood ratio test (linear model: $P<.001$; negative
binomial model: \( P = .02 \). In addition, the likelihood ratio test also found that the inclusion of the day of the week variable significantly improves the model (linear model: \( P < .001 \); negative binomial model: \( P < .001 \)). Therefore, this variable was included in the final model output (Supplemental Tables 9 and 10 in Multimedia Appendix 1).

**Discussion**

**Overview**

Tompkins County and the Cornell University community presented a unique opportunity to investigate the utility of CLI syndromic surveillance as an indicator of COVID-19 cases due to required testing and CLI reporting at Cornell University, in addition to widespread free testing and robust reporting of CLI by health practitioners encouraged by TCHD. We looked for congruence in rates of CLI and SARS-CoV-2 positivity to understand whether CLI trends were temporally correlated with measures of SARS-CoV-2–positive tests.

**Principal Findings**

Significant autocorrelation of the SARS-CoV-2 positivity variable was observed in the university and county setting, suggesting current test positivity is influenced by levels of test positivity from earlier in the week. Cross-correlation analysis also revealed CLI to lead and lag SARS-CoV-2 rates in both settings, indicating that the two measures can offer valuable insights into each other. This reflects the expected nature of infectious disease transmission in a population without complete immunity, in which exponential growth of infections can lead to more exposures, symptoms, and positive SARS-CoV-2 tests. Given our interest in the potential use of CLI to monitor SARS-CoV-2 positivity, we demonstrate that the addition of CLI and CLI exposure data can improve efforts to assess SARS-CoV-2 positivity in low-resource settings (ie, when large-scale testing is not possible). However, the rate of exposure to confirmed COVID-19 cases was not significantly associated with the SARS-CoV-2 test positivity rate and may not be a useful measure of COVID-19 risk in universities. A possible explanation for COVID-19 exposure not being a significant variable in our analysis is that confirmed exposure to a COVID-19 case is dependent on testing capacity to deliver a quick test result. In the university’s syndromic surveillance, students could have already been flagged as “red” based on reporting exposure to CLI before a positive test result has confirmed the case. Depending on testing capacity and availability, possible exposure to COVID-19 could be a stronger variable than confirmed exposure to COVID-19 for tracking SARS-CoV-2 in real time.

In the university setting, linear models demonstrated that reporting of CLI and exposure to CLI among students track changes in the SARS-CoV-2 positivity rate in real time. Within Tompkins County, both the linear and negative binomial model indicated that the strongest variable associated with present-day SARS-CoV-2 positivity is the rate of CLI from up to 3 days prior. This discrepancy in the lag time of the CLI indicator could reflect the difference in adherence to the two programs. The university surveillance program was strictly enforced for the entire on-campus population and may have been able to identify changes in SARS-CoV-2 cases immediately. By comparison, the testing and CLI reporting of Tompkins County was voluntary. This may have caused lags between when symptoms appeared and diagnosis by a positive test result due to delays in testing based on appointment availability, patients’ work schedules, access to transportation, and other conflicting factors. Cornell University demonstrates how mandatory symptom and exposure reporting could track SARS-CoV-2 positivity in real time. However, with mandatory surveillance programs being unrealistic to implement, Tompkins County illustrates how the utilization of existing infrastructure like local practitioners is also able to effectively measure CLI, which is associated with cases. Practitioners were asked to count CLI cases each day, a process that could be applied to larger practitioner and hospital networks. We demonstrated that CLI rates from practitioner-based surveillance track SARS-CoV-2 positivity rates with a small lag. Trends such as spikes in COVID-19 identified from syndromic surveillance programs could then be validated by brief surveillance testing or distribution of at-home tests.

**Limitations**

The study findings should be carefully interpreted within the context of the study population. Cornell University is located in a small county in upstate New York, with a population of 105,162 in 2021 [24]. Tompkins County is somewhat isolated geographically, so these results may not generalize to denser urban areas or more rural areas. While influenza rates substantially decreased during the 2020–2021 flu season [25], some presentations of CLI in the study population are inevitably due to flu and other respiratory illnesses. This may explain a spike in university cases of CLI during November and December 2021 that was not accompanied by an increase in SARS-CoV-2 positivity, as flu rates did increase in New York State during this period [26]. On the other hand, given that both flu seasons included in our study period were less severe than usual, it is possible that the associations we observed may not be as strong when other common respiratory illnesses are in wider circulation. In addition, participating practitioners of our study voluntarily partook in syndromic surveillance without reimbursement. To apply this model of surveillance on a larger scale, financial incentives should be considered to ensure robust reporting—a cost that would need to be considered before implementation. Finally, as this was an observational study, we can only infer relationships and not their underlying cause.

**Significance**

Our findings are contextualized by the shift away from robust SARS-CoV-2 testing and reporting in the United States. At-home tests are now commonly used and typically are not included in COVID-19 case count reporting [4]. Federal funding for SARS-CoV-2 testing is diminishing [27], and COVID-19 response teams of health departments are being scaled back. On May 11, 2023, the US federal government ended the COVID-19 Public Health Emergency declaration [5]. As a result, the CDC and other reporting platforms no longer publish SARS-CoV-2 testing and reporting in the United States.

Our findings are contextualized by the shift away from robust SARS-CoV-2 testing and reporting in the United States. At-home tests are now commonly used and typically are not included in COVID-19 case count reporting [4]. Federal funding for SARS-CoV-2 testing is diminishing [27], and COVID-19 response teams of health departments are being scaled back. On May 11, 2023, the US federal government ended the COVID-19 Public Health Emergency declaration [5]. As a result, the CDC and other reporting platforms no longer publish SARS-CoV-2 testing and reporting in the United States.
Low-resource alternatives like syndromic surveillance could help to fill this gap in our knowledge of SARS-CoV-2 local transmission and build on the currently favored methods of hospital-based surveillance. Alternatives to resource-intensive testing are especially important for detecting outbreaks in low-resource settings where diagnostic testing infrastructure is poor [28,29]. This includes low- and middle-income countries as well as impoverished communities in the United States.

Conclusions

Finally, we emphasize that the estimates of our regressions, both linear and negative binomial, should not necessarily be interpreted as definite predicted changes in the rate of SARS-CoV-2. Our goal was not to build a predictive model but to instead investigate associations between the outcome, current levels of SARS-CoV-2 cases and test positivity, and recent measures of CLI. We focused on the statistically significant lagged CLI rate variables that demonstrate changes in CLI rates can lead SARS-CoV-2 rates by a few days, as confirmed by both the negative binomial and linear models in the county setting. The university setting models the advantage of an enforced daily health questionnaire whose measures of CLI and exposure to CLI appear to track on-campus SARS-CoV-2 positivity in real time. The strongest takeaway from our results is that the two variables, CLI and SARS-CoV-2 positivity, are correlated, and CLI should be further explored as a low-resource way to monitor the risk of SARS-CoV-2 in the absence of robust testing. Our results support the push to integrate CLI symptom reporting into the routine services of health practitioners as a potentially easy and cost-effective approach to monitoring SARS-CoV-2 transmission. This forms a foundation for future research that should further characterize the relationship between COVID-19 symptoms and SARS-CoV-2 positivity rates.

Acknowledgments

This project was supported by the David and Lucile Packard Foundation (#2021-72608). MO was supported by the Cornell University Office of the Provost. We would like to thank all of the health care practices in Tompkins County who contributed to the COVID-19–like illness syndromic surveillance program.

Data Availability

Researchers who wish to request access to the Cornell University data may contact Cornell's Office of the Vice President for Research and Innovation (vp_research@cornell.edu), which oversees research access to Cornell COVID-19 surveillance data. Data from the Tompkins County COVID-19–like illness syndromic surveillance program can be requested from Tompkins County Whole Health.

Abstract

Background: The proliferation of digital disease-detection systems has led to an increase in earlier warning signals, which subsequently have resulted in swifter responses to emerging threats. Such highly sensitive systems can also produce weak signals needing additional information for action. The delays in the response to a genuine health threat are often due to the time it takes to verify a health event. It was the delay in outbreak verification that was the main impetus for creating EpiCore.

Objective: This paper describes the potential of crowdsourcing information through EpiCore, a network of voluntary human, animal, and environmental health professionals supporting the verification of early warning signals of potential outbreaks and informing risk assessments by monitoring ongoing threats.

Methods: This paper uses summary statistics to assess whether EpiCore is meeting its goal to accelerate the time to verification of identified potential health events for epidemic and pandemic intelligence purposes from around the world. Data from the EpiCore platform from January 2018 to December 2022 were analyzed to capture request for information response rates and verification rates. Illustrated use cases are provided to describe how EpiCore members provide information to facilitate the verification of early warning signals of potential outbreaks and for the monitoring and risk assessment of ongoing threats through EpiCore and its utilities.

Results: Since its launch in 2016, EpiCore network membership grew to over 3300 individuals during the first 2 years, consisting of professionals in human, animal, and environmental health, spanning 161 countries. The overall EpiCore response rate to requests for information increased by year between 2018 and 2022 from 65.4% to 68.8% with an initial response typically received within 24 hours (in 2022, 94% of responded requests received a first contribution within 24 h). Five illustrated use cases highlight the various uses of EpiCore.

Conclusions: As the global demand for data to facilitate disease prevention and control continues to grow, it will be crucial for traditional and nontraditional methods of disease surveillance to work together to ensure health threats are captured earlier. EpiCore is an innovative approach that can support health authorities in decision-making when used complementarily with official early detection and verification systems. EpiCore can shorten the time to verification by confirming early detection signals, informing risk-assessment activities, and monitoring ongoing events.

Introduction

Background

World Health Organization (WHO) leadership has recently suggested the need for collaborative surveillance within and beyond the health sector for more robust event detection, risk assessment, and response monitoring [1-3]. Furthermore, the recent quadripartite partnership among the Food and Agriculture Organization of the United Nations, the World Organization for Animal Health, the UN Environment Programme, and the WHO has noted the need for intelligence systems to use an integrated “One Health” approach to reduce the risk of ongoing and emerging threats [2].

Although early warning “signals” from such systems are leading to earlier detection and swifter responses to emerging threats, the proliferation of these systems can also generate a large volume of data that must be processed before contributing toward the early warning or risk assessment of ongoing threats [3]. This large volume of data may also result in false alarms that might propagate rumors and quickly overwhelm the surveillance infrastructure [2,4]. This risk of false alarms underscores the crucial role of human input for data curation and signal verification.

Delays in the effective response to a genuine health threat are often the result of the time to verification of a health event—determining if an unofficial reported threat is real so an appropriate response can ensue. An analysis by Chan et al [5] based on WHO-verified outbreaks reported in Disease Outbreak News noted median time from “outbreak start” to “outbreak discovery” dropped from 29.5 days (95% CI 13-59 days) to 13.5 days (95% CI 3.5-44.5 days) during that time. More recently, the time to detection has been reduced due in part to the advancement of digital epidemiology, but the task of timely verification remains a challenge [5,6]. WHO has presented data on additional delays in verifying that outbreaks are indeed real events, noting up to a 1-week delay [7]. It was the extra several days for outbreak verification that was the main impetus for creating EpiCore, a virtual multi-sectoral community of human, animal, and environmental health professionals that supports the rapid verification of potential health threats. EpiCore aims to contribute to the reduction in time to verify human, animal, or environmental health events to obtain event details within 24 hours of initiating a request for information (RFI) within a digital secure information system. The objective of this paper is to describe the potential of the crowdsourcing of information from qualified professionals through EpiCore to facilitate the verification of early warning signals of potential outbreaks and support the monitoring and risk assessment of ongoing threats.

About EpiCore

Conceptualized in 2012 by Ending Pandemics as an initial partnership between the TEPHINET (Training Programs in Epidemiology and Public Health Interventions Network) [8,9], Program for Monitoring Emerging Diseases (ProMED)–mail [10], and HealthMap of Boston Children’s Hospital, EpiCore became operational in 2016 [11]. EpiCore does not aim to replace any official verification system and is meant to be a complementary verification tool. An epidemic intelligence expert in the role of the focal point oversees the system’s operations. This individual is responsible for ensuring the system is accessible and running 24/7, providing support and training to the users of the system and ensuring privacy protocols are being followed. The focal point also oversees communications between the various users as well as the distribution of a quarterly newsletter.

Several epidemic intelligence and disease prevention and control organizations use EpiCore to confirm signals detected from primarily digital sources. These groups are referred to as “requesters” in the system. Requesters have included members from ProMED, GeoSentinel, HealthMap, the Hungarian National Association of Radio Distress-Signaling and Info-communication that operates the Emergency and Disaster Information Services, and Médecins Sans Frontières (MSF) Operational Centre Barcelona [10,12-15]. Requesters send out RFIs, a specific question sent through EpiCore about known or potential “events” to EpiCore responders (see below) for verification.

The virtual community of health professionals in EpiCore are referred to as “responders” in the system. To become an EpiCore responder, a health professional applies and must have at least two of the following qualifications: (1) a degree in public health (eg, MS, MPH, and PhD) or a related field (eg, MD, DVM, and RN); (2) health profession certification or licensure (eg, livestock officer and food inspector); (3) at least 3 years of experience in human or animal health or environmental health; (4) affiliation with a medical center, ministries or departments of health, or other health-related organizations (eg, nongovernmental organizations and private sector); and (5) successful completion of a field epidemiology training program. In the first 5 years after it became operational in 2016, EpiCore membership grew to over 3300 individuals with members spanning 161 countries. Over one-third of members identify themselves as experts spanning multiple sectors (n=1134, 34.3%). Most members (n=2807, 84.9%) list themselves as human health experts; 926 (28%) listed themselves as animal health experts, and 962 (29.1%) as environmental health experts. Responders join the network and contribute as individuals (ie, they do not represent any organization and their contributions can be provided anonymously if so desired). As an incentive to increase participation, responders have access to select resources related to infectious disease prevention and control, including web-based courses and publications.

When evidence of a health event is detected, local information is requested from EpiCore responders to rapidly provide details on the event (Figure 1). Responders near (in the district, country, or region) where events are reported are selected, in essence, providing the “eyes and ears” on the ground. The radius around the event where responders are selected depends on the density of the responders in the location of the potential event. In areas with fewer responders, the radius is increased by requesters to the country or regional level to include more responders. Through EpiCore’s secure digital platform, responders with knowledge of the event can easily and quickly provide details and expert opinions to inform event verification or ongoing event monitoring. Information provided by responders can only be seen by requesters. Other EpiCore responders are unable to
see individual responses to ensure the privacy and anonymity of the responders. However, all EpiCore requesters can view the RFIs from other requesters as well as the responses to those requests. This ensures that information silos between requesters and their organizations are minimized.

**Figure 1.** Illustration of key steps in the EpiCore verification process. RFI: request for information.

An RFI is considered verified if an EpiCore requester deems sufficient reliable additional details have been collected from the responders to confirm a reported event is true, or enough details have been collected to confirm the reported event or early warning signal is a false alarm. RFIs are considered verified if the report is confirmed to be valid or a false alarm. EpiCore requesters give the highest priority to reliable sources of information, including official statements and complementary reports or documents obtained at the locality of the reported event. Requesters create an RFI summary of verified health events, which constitutes a synopsis of the information received via the platform as well as other information publicly available that contributes to the understanding of the situation. These RFI summaries are made available on EpiCore’s public dashboard as well as via the requesters’ own dissemination channels, so anyone can have access to details on events verified by EpiCore [11,16]. Requesters are urged to close RFIs as soon as helpful information is available to ensure timely dissemination of the information to the public. If no information is received from responders, RFIs are automatically closed after 7 days.

In addition to disseminating information via the public dashboard, EpiCore is also contributing information to the Epidemic Intelligence from Open Sources platform and supports the goal of the WHO Hub for Pandemic and Epidemic Intelligence to combine information from traditional surveillance, event-based surveillance, participatory or community surveillance, and on-the-ground investigations with contextual information to generate an assessment of public health risk [17]. EpiCore is also facilitating organizations to improve their information-dissemination activities. For example, ProMED noted an increased number of responses to their RFIs about health events on the EpiCore platform compared to requests sent through their network [10,11].

**Methods**

**Study Design**

Data on the EpiCore platform from January 2018 to December 2022 were analyzed to evaluate key descriptive statistics, as well as to identify use cases illustrative of the various utilities of the system. All RFIs created over the 5 years were analyzed to calculate the annual mean and median time to reply to an RFI. Annual RFI response rates and verification rates were also calculated. RFIs that received a response, regardless of whether the information was considered useful or not, were categorized as “RFIs with a response.” The response rate was calculated as the number of RFIs with a response as a percentage of the total number of RFIs to indicate members’ engagement on the platform. All RFIs that requesters deem to have sufficient and useful information through responder contributions with additional information to confirm an event or to debunk misinformation or disinformation were categorized as “verified.” The verification rate was calculated as the number of RFIs that the requesters have classified as verified as a percentage of the total number of RFIs with a response. This rate informs the proportion of RFIs obtaining information from EpiCore members that were deemed useful in the verification of a reported event.

**Ethical Considerations**

This study does not constitute human subject research as it is a descriptive analysis of a system. The data collected were limited to the time of information flow and summarization of information about health events to describe EpiCore. The data set has no personal identifiers. This rationale is consistent with the Harvard University policies on human subjects research [18].
Results
EpiCore Platform and Statistics
During the observed period, 622 RFIs were sent out globally. Of these RFIs, 485 (78%) were related to health events regarding human exposure, 121 (19.4%) to health events regarding animal exposure, 12 (1.9%) to health events with human and animal exposure, and 4 (0.6%) to environmental health events. A total of 398 RFIs received a response during the observed period. The mean and median response times are indicated in Table 1.

*RFI: request for information.*

Figure 2 illustrates the locations of the RFIs with a response, demonstrating the geographic distribution of the RFIs over the 5 years. A majority of the RFIs with a response received responses within 24 hours (n=334, 84%). Furthermore, 247 (62.1%) RFIs of those that received a response (n=398) were deemed to have sufficient and useful information through responder contributions to verify the reported event and were summarized on the public dashboard. The annual verification rate has increased each year from 2018 to 2022 ranging from 50.7% to 84.8% (Table 2). The response rate increased from 65.4% in 2018 to 68.8% in 2022.

Figure 2. Map of frequency of EpiCore RFIs by location of potential event between 2018 and 2022. RFIs represented in this map are generated by EpiCore requesters for additional input for verification by EpiCore responders. The map is not a representation of all potential health events during the observed period, but is limited to the subset of events identified by the requesters on EpiCore. RFI: request for information.
EpiCore plays a crucial role in reducing the time to verification by confirming early detection signals, informing risk assessment activities, and monitoring ongoing events. Gathering timely information is pertinent both during the early days of a potential outbreak and for continued situational awareness. EpiCore provides access to a network of health experts who can share information about a specific event in response to an RFI. Information provided by members of this trusted network is valuable, including knowing how a disease is spreading within a country, if an outbreak has crossed borders, the epidemiological characteristics, severity and transmissibility, and laboratory results. The following case studies highlight the various uses of EpiCore.

Case Study 1: Ruling Out False Alarms

Unnecessary alarms can result in wasted valuable resources in responding to essentially a nonevent. EpiCore members provide information to help rule out false alarms that may circulate through various media outlets, especially during the early days of a potential infectious disease outbreak. For example, EpiCore members provided timely information during an uptick in rash illness observed in November 2021 among fishermen in Senegal as reported in the local media. EpiCore responders provided information within 24 hours of the RFI being sent to those within the geographical area of the reported “event.” Their responses clarified that the health conditions were likely caused by environmental factors and not an infectious disease [19].

Case Study 2: Real Time Details on an Evolving Event

In another situation in October 2020, local media in South Sudan reported 3 sudden deaths in Western Bahr el Ghazal State in patients presenting with hemorrhagic symptoms, raising fears of Ebola. Responders confirmed the occurrence of the event and shared additional specifics that also quoted national health authorities. They noted that the 3 reported cases were buried before the arrival of the rapid response team and samples could not be taken for further laboratory investigation. It was also shared, however, that 3 more cases presenting with similar symptoms were still alive in the same area and tested negative for Ebola and other hemorrhagic fever viruses. The RFI was summarized, documenting the lack of laboratory results for the first cases and reporting that additional cases tested negative for hemorrhagic fever viruses, hence quelling the fears of Ebola [20].

Case Study 3: Tracking an Unknown Pathogen

In an event that garnered the world’s attention, local media reported on December 31, 2019, that health authorities in Wuhan (Hubei, China) were investigating an unexplained cluster of severe respiratory disease that had sickened at least 27 people within a short period. A viral pathogen was suspected, raising rumors of severe acute respiratory syndrome on several media outlets. It was also suggested that some cases were linked to a seafood market in Wuhan city. The same cluster of an unknown illness was noted in a web-based report by Hong Kong’s Centre for Health Protection (December 31, 2019). EpiCore responders in proximity to Wuhan (n=36) were sent an RFI to provide any additional details to document the reported event and provide information on the level of local spread. Initial responses were provided within 7 hours, confirming the event’s occurrence. Figure 3 illustrates the timeline of key responses received for this RFI. Among the received responses, 1 responder reported that the seafood market in Wuhan also sold wild animals, noting that the risks of zoonotic disease were significant. On January 2, 2020, responders mentioned that local authorities suspected that the responsible pathogen was likely a known coronavirus able to cross species (spillover). In the following days, the network noted that around 60 pneumonia cases had been identified at Jinyintan Hospital in Wuhan. The network also provided preliminary information on at least 15 laboratory-diagnosed cases with a new strain of coronavirus (influenza, avian influenza, adenovirus, SARS-CoV-1, and MERS [Middle East Respiratory Syndrome] were ruled out). On January 10, members shared information about the first occurrence of cases in a different city (Jingmen, the same province as Wuhan). In addition, information was shared about the first cases with no known or substantiated exposure to the Wuhan market. Responders also noted a particular concern about the proximity of this outbreak to the Chinese New Year with the vast exodus of people from Wuhan to rural areas to come in the following weeks. The RFI was summarized for the public dashboard and further shared on EpiCore’s first quarterly newsletter in 2020 [21,22].

аRFI: request for information.
Case Study 4: Supporting Decision-Making

In August 2018, MSF Operational Center in Spain [23] received a report about several human deaths and an illness from an unknown disease in Douna, Mali. All cases experienced an extreme burning or heating feeling in the legs with edema often followed by “blackening” of the skin. MSF issued an RFI on EpiCore to obtain details to help with their risk assessment. Responders confirmed the occurrence of this event, which had been observed for several months. They also shared the investigation report from local health authorities that indicated that the cases had likely had acute severe malnutrition (scurvy and beriberi) due to a significant food shortage in the affected communities. MSF used the information provided by the responders for risk assessment purposes [24].

Case Study 5: New and Evolving Presentation of Disease

EpiCore has also proven pertinent for monitoring diseases involving multiple countries. In May 2021 for example, the incidence of a rare fungal infection, mucormycosis, was observed to be increasing across India in patients with COVID-19; EpiCore responders from countries with historically reported mucormycosis were asked to provide their professional opinion and share clinical details observed in their own countries. Several responders from around the world provided details on the incidence of COVID-19–associated mucormycosis (CAM) and shared their clinical perspective on the increased incidence in certain parts of the world. Some responders in India noted that this was likely a result of a misuse of steroids during the treatment of such patients. This theory was also supported by responders from other countries. In Pakistan, several cases of mucormycosis and other fungal infections in patients with COVID-19 were attributed to the combination of viral infection, use of steroids, uncontrolled diabetes, and a long stay in the intensive care unit. In Australia, mucormycosis increases were not documented; however, several cases of another fungal infection were reported in patients with COVID-19. In the United Kingdom, sporadic CAM cases had been reported in patients with COVID-19. EpiCore member reports revealed the incidence of CAM was increasing in geographies across the globe and not limited to the occurrence in India as initially noted by the media [25,26].

Discussion

Principal Results

EpiCore provides an innovative mechanism to increase the specificity of signals of events detected across the globe through epidemic intelligence activities from several sources. Over half of all RFIs received a response, and of those, virtually all received responses within 24 hours. Response rates and verification rates increased year by year during the observed period.

Limitations

Although EpiCore has representation in 161 countries, several areas of the globe are without any responders or have suboptimal numbers. The limitation of responder coverage consequently reduces the number of responses an RFI may receive. To circumvent this situation, RFIs are sent to responders in neighboring geographies when none are in the geography related to the RFI or it has very low numbers of EpiCore members. Currently, RFI generation is limited by the number of requesters, their availability at the time, and their subjective assessment of ongoing multiple global threats. Increasing the number of
requestors can help alleviate some of these challenges. Additionally, because most EpiCore responders have human expertise, we recognize that this may hinder the speed with which RFIs about animal and environmental health events are verified. Concerted efforts will continue to recruit responders with animal and environmental health expertise to ensure EpiCore can provide timely and useful responses to RFIs across all One Health sectors. The timely dissemination of information provided via the RFI summary on the public dashboard is a priority for EpiCore. However, the tradeoff between the speed at which the RFI summary is published on the dashboard and the quantity and specificity of information received from responders by leaving the RFI open longer is recognized. To counter this issue, verified RFIs that are made available on the public dashboard can be updated on an ongoing basis with additional information rather than delaying the summary until all details have been received.

Looking Ahead

EpiCore continues to foster a collaborative approach to support the verification of potential early warning signals and provide information relevant for risk assessment purposes to the growing number of organizations focused on the use of data for epidemic and pandemic intelligence in the future. The ability of all requestors on the EpiCore platform to view all requests and responses regardless of who sends the requests is one way to reduce the duplication of efforts and siloes of information that are common among groups engaged in epidemic and pandemic intelligence.

EpiCore aims to achieve an average time of response to an RFI of less than 24 hours in all regions of the world. Increasing the number of members and their geographic distribution will further enable this goal. Recruitment efforts will continue in the coming years with a particular focus on regions of the world with the fewest EpiCore members. Mechanisms to motivate responder engagement will be considered, including nonfinancial incentives such as increased training opportunities and access to curated web-based trainings and scientific publications. EpiCore will continue to share quarterly digital newsletters to document and disseminate the value of member contributions and provide updates on recently verified events. Additionally, EpiCore will expand its incorporation into human, animal, and environmental training curricula to ensure the next generation of those on the front lines are better positioned to expedite global pandemic and epidemic intelligence.

Certain functionalities within EpiCore may benefit from the application of generative AI tools. The use of machine learning capabilities will be explored and tested against human-curated RFIs to ensure validity and accuracy. Digital disease-detection platforms using machine learning models to identify and aggregate reports of health events through informal sources (eg, social media) [27], can also be leveraged to identify health events for which an RFI should be sent.

Conclusion

The global demand for data to improve disease prediction, prevention, and control continues to grow. A recent paper authored by the WHO underlines that being better prepared for future pandemics and epidemics will require increased collaboration among stakeholders and investment in collective abilities to detect and understand public health risks [3]. The use of EpiCore by multiple sectors can contribute toward furthering a multi-sectoral approach to epidemics and pandemics (ie, One Health Intelligence). With members spanning human, animal, and environmental health, EpiCore can help the expeditious verification of any health event. EpiCore will continue to provide information for the verification of health events to complement traditional systems and will evolve as needed to better address the global need for situational awareness and risk assessment.

Acknowledgments

We would like to recognize the efforts of all of our requestors and responders without whom EpiCore would not be possible. We also recognize the efforts and early partnership with ProMED, HealthMap, and TEPHINET in the early development of EpiCore. We thank Carrie McNeil, Jay Atanda, and Elizabeth Aaron for reviewing a draft of this paper. All work by the authors was supported by the Ending Pandemics, a project of the Tides Center. No generative AI was used for the writing of this paper or analysis of the data.

Abstract

Background: Recognition of the importance of valid, real-time knowledge of infectious disease risk has renewed scrutiny into private providers’ intentions, motives, and obstacles to comply with an Integrated Disease Surveillance Response (IDSR) framework. Appreciation of how private providers’ attitudes shape their tuberculosis (TB) notification behaviors can yield lessons for the surveillance of emerging pathogens, antibiotic stewardship, and other crucial public health functions. Reciprocal trust among actors and institutions is an understudied part of the “software” of surveillance.

Objective: We aimed to assess the self-reported knowledge, motivation, barriers, and TB case notification behavior of private health care providers to public health authorities in Lagos, Nigeria. We measured the concordance between self-reported notification, TB cases found in facility records, and actual notifications received.

Methods: A representative, stratified sample of 278 private health care workers was surveyed on TB notification attitudes, behavior, and perceptions of public health authorities using validated scales. Record reviews were conducted to identify the TB treatment provided and facility case counts were abstracted from the records. Self-reports were triangulated against actual notification behavior for 2016. The complex health system framework was used to identify potential predictors of notification behavior.

Results: Noncompliance with the legal obligations to notify infectious diseases was not attributable to a lack of knowledge. Private providers who were uncomfortable notifying TB cases via the IDSR system scored lower on the perceived benevolence subscale of trust. Health care workers who affirmed “always” notifying via IDSR monthly reported higher median trust in the state’s public disease control capacity. Although self-reported notification behavior was predicted by age, gender, and positive interaction with public health bodies, the self-report numbers did not tally with actual TB notifications.

Conclusions: Providers perceived both risks and benefits to recording and reporting TB cases. To improve private providers’ public health behaviors, policy makers need to transcend instrumental and transactional approaches to surveillance to include building trust in public health, simplifying the task, and enhancing the link to improved health. Renewed attention to the “software” of health systems (eg, norms, values, and relationships) is vital to address pandemic threats. Surveys with private providers may overestimate their actual participation in public health surveillance.
Introduction
Nigeria experienced five major infectious disease outbreaks during 2017, representing an unprecedented crisis for the public health system that laid bare many of the intersectoral collaboration gaps that hamper an effective public health response [1]. The existence of parallel reporting systems, authorities, and periods, along with variable case definitions challenge even the most well-intentioned and highly motivated health care workers to comply [2,3]. The globally networked, economically and culturally dynamic hub of Lagos, Nigeria, has long been identified as a place where timely information on emerging pathogens, pharmacovigilance, and infectious disease surveillance is crucial to the country’s public health [4].

Tuberculosis (TB) notification and cohort analysis are illustrative of the classical surveillance practice of a stigmatized condition worldwide and a bellwether of a country’s capacity for public health surveillance. Although TB service provision and reporting by the private sector is long recognized as an essential component of an effective TB program, it is still poorly theorized [5,6]. Many efforts to engage the private sector have been directive or transactional, driven by an incomplete or simplistic understanding of how private providers think [7]. The COVID-19 and mPox pandemics have heightened attention to the issues of trust and mistrust in public health authorities, whereas their centrality in TB surveillance has yet to be quantified [8,9].

Efforts to incentivize the private sector to render quality TB care and contribute to TB notification have intensified in recent years [10-13]. Many models are designed around logical inferences, but often without compelling evidence of efficacy to distinguish them [14]. Many public-private mix (PPM) models are transactional and/or directive, with a focus on resource transfer and regulatory oversight [7]. Although advocacy, additional professional society engagement, subsidized drugs, coordinating bodies, the introduction of advanced TB diagnostics, financial incentives, stricter penalties, and supervision interventions have been shown to improve notification initially, the gains are often modest and challenging to sustain [12]. Local stakeholders thus requested a study to generate insights into how to best set priorities among the diverse solutions and how best to distribute scarce drugs, diagnostics, staffing, and supervision resources.

We posited that the act of notifying a TB case is predicated on a set of expectations about systems, risks, rewards, penalties, and costs [15]. Surveillance assumes that specific types of patient information are available to be recorded (eg, test results and treatment outcomes) and that certain data formats (eg, registers and electronic platforms) exist that are accessible and intelligible. Notification obligations assume a certain knowledge of the legal and technical process of recording and reporting. Crucially, such an integrated approach assumes a set of values and willingness to contribute to surveillance as a public service [2]. For the desired public health participation to occur, potential contributors to systems may need to perceive the benefits as outweighing the risks [15-17]. As shown in Figure 1, we grouped the hypothesized influences on infectious disease reporting behavior into four categories: structural context, hardware, tangible software, and intangible software. This framework highlights how an enabling environment includes both mechanical and instrumental elements (ie, the “hardware”) and more relational or perspectival elements (ie, the “software”) [7,18].
Insights into the underlying reasons for facility noncompliance with surveillance requirements are needed if systems are to be reengineered in ways that make it worthwhile for providers to participate in TB notification. Indeed, early warning systems and antibiotic stewardship efforts are equally reliant upon the voluntary contribution of time-sensitive facility data. Mutual perceptions of competence, benevolence, and integrity form a crucial part of a surveillance system’s “software,” yet rarely receive as much focus as the “hardware” [7,18-20].

To improve private providers’ willingness to contribute to surveillance systems in Lagos, State Ministry of Health (SMOH) stakeholders sought assistance to answer the following policy questions: Given multiple systems for TB notification, how do private providers decide where and when to contribute their data to different surveillance systems? What are “unengaged” private providers’ concerns about notification? Is noncompliance with notification specific to TB or are they broadly noncompliant with infectious disease notification obligations? How does trust in the SMOH affect willingness to engage in public health surveillance?

The Nigerian Integrated Disease Surveillance and Response (IDSR) system is among one of the most dynamic and well-characterized surveillance systems in Africa [21]. Efforts to build and maintain rigorous surveillance systems to tackle emerging threats with pandemic potential have included policy, training, legislation, and validation exercises [3,22-28]. Over time, the system has evolved from a narrow Disease Surveillance and Notification Office (DSNO) to the comprehensive World Health Organization (WHO)–recommended IDSR of today.

The formal engagement of the Nigerian private sector in the PPM program for nationally recognized TB management commenced in 1993 [29]. PPM in Nigeria has been standardized, protocolized, and cautiously implemented by the national TB program [29,30]. Training and equipping health facilities with drugs and reagents were the most common forms of PPM engagement in Nigeria initially. Guidelines were updated approximately every 10 years. The use of incentives, performance-based finance, peer-led, and digital models have been employed and results have varied. Investments to increase private-provider collaboration in TB control in Lagos have been intense and involved multimethod approaches [12,30-34].

**Methods**

**Study Design**

We undertook a cross-sectional survey of the persons in charge of private health facilities without an ongoing relationship to the TB program, because these sites are considered to be those most likely to treat TB without reporting it. This assessment was part of a TB inventory study conducted to estimate the magnitude of underreporting [35,36]. Private facilities previously trained and equipped by the TB program were studied separately.
Study Setting
Lagos State is in Southwest Nigeria, the commercial heart of Nigeria and home to the country’s most dynamic private sector. Although Lagos is the smallest state in Nigeria in terms of land mass, the population estimates range from 13 to 21.5 million. The population density exceeds 5000 individuals/km², roughly 25 times the national average population density of 226 individuals/km². More than 65% of Lagos’ population lives below the poverty line. Lagos has 2.5 private health facilities per 10,000 people, making it one of the more complex health systems of any megacity [37]. The health facilities open, operate, and then cease operations or move locations dynamically [37]. Faith-based and private not-for-profit health facilities represent a smaller proportion (1.7%) of the Lagosian health sector than in other Nigerian states [38].

Sampling
Probability proportional to size sampling was conducted among private health facilities with no documented engagement with the TB program. Private facilities provided with TB registers and trained by the national TB program were recruited for a parallel study with distinct aims. Full details on health facility sampling, pilot testing, data collection, data management, and quality assurance have been described previously [35].

Recruitment
Potential participants were contacted by telephone for recruitment appointments. Written information and letters from the TB program and ethical review board were shared to establish the factual basis of the visit.

One interview was conducted at each of the participating facilities. Inclusion criteria for survey respondents were two-fold: (1) health care workers with influence over the completion of TB case notification and (2) able to provide individual informed consent (e.g., over 18 years of age). Semistructured interviews were administered on site using paper questionnaires by trained interviewers (see Multimedia Appendix 1).

At “unengaged” private facilities, the following 10 issues were explored: (1) awareness of the mandatory reporting of TB in Nigeria; (2) perceived trustworthiness, competence, and beneficence of the SMOH; (3) attitude toward specific aspects of TB notification processes; (4) attitude toward specific PPM engagement incentives (clinical training, drugs, reagents); (5) self-reported participation in the State TB & Leprosy Control Program (STBLCP) and/or the IDSR, also known as the DSNO; (6) self-reported challenges with disease reporting via IDSR (closed-ended); (7) self-reported reasons for nonreporting diseases (closed-ended); (8) self-reported participation in either reporting system (STBLCP or IDSR); (9) self-reported reasons for nonreporting diseases (closed-ended); (10) willingness to engage (and prior TB engagement experiences) with the STBLCP.

Study Measures
The scale for Citizen Trust in Government Organizations (CTGO), a validated 11-item scale of public perceptions toward government institutions, was adapted to capture Nigerian private practitioners’ trust in public health and disease surveillance systems [39]. The CTGO scale measures three dimensions: (1) perceived competence of public health authorities, indicating the extent to which a provider perceives a (government) organization to be capable, effective, skillful, and professional (4 items); (2) perceived benevolence, indicating the extent to which a private provider perceives a (government) organization to care about the welfare of the public and to be motivated to act in the public interest (3 items); and (3) perceived integrity, indicating the extent to which a provider perceives a (government) organization to be sincere, tell the truth, and fulfill its promises (4 items). Pilot testing of the questionnaire occurred in 5 facilities. Cronbach α and the intraclass correlation coefficient of the scale were used to gauge validity and internal consistency. Survey items with poor construct validity during pretesting were deleted. Survey items were reduced from a total of 76 to 53 and worded via piloting to improve validity and acceptability.

SPSS (IBM) version 25 and the R psych package were used for statistical analyses. The magnitude and variance of the responses were examined to identify central tendencies and outliers were considered for further exploration. Data were summarized as percentages, means, and medians, and Student t tests were used to compare mean scores. For statistical tests, P < .05 was considered statistically significant. A regression model was developed to predict the binary outcome of infectious disease case notification using IDSR.

Ethical Considerations
The study protocol was reviewed and approved by the Health Research and Ethics Committee of the Lagos State University Teaching Hospital (registration number 04/04/2008). Participation was voluntary and providers could consent to zero, partial, or full patient data access. Noncompliance with notification obligations was kept confidential and is described in ways to preclude deductive disclosure. After the data sets were linked, all personal and geographic identifiers were removed. A small monetary incentive (US $5) was offered for participation.

Results
Sample Characteristics
There were 278 representatives surveyed from private facilities that did not report TB. They ranged in age from 21 to 81 years, with a mean age of 46 (SD 0.8) years and an average of 18.2 (SD 0.8) years of clinical practice. Among the 278 respondents, 62.9% (n=175) were men and 36.3% (n=101) were women. Among the private facilities represented, 40.6% were at the primary level, 53.6% at the secondary level, and 4.7% unclassified; 94.6% (n=263) of the facilities were for-profit and 5% (n=14) were faith-based (see Table 1). Among the total 294 representatives contacted, 278 (84.2%) consented to participate. The recruited sample of health care workers was in line with the intended sample in terms of the total sample size, local government area distribution, and facility level [35].

Knowledge of Obligations and Self-Reported Infectious Disease Reporting Behavior

As shown in Table 2, over three-quarters of the respondents were aware of the obligation to notify TB cases. A minority (13.5%) reported having been notified a disease recently (within weeks of the survey), 58.2% had last reported a disease within months of the survey, and 28.4% last reported it within years of the survey. Among those surveyed, nearly one-quarter reported on-site capacity to diagnose TB (Table 2).

<sup>a</sup>TB: tuberculosis.

<sup>b</sup>LGA: local government area.

<sup>c</sup>IDSR: Integrated Disease Surveillance Response.

<sup>d</sup>DSNO: Disease Surveillance and Notification Office.

The vast majority (90.6%) of respondents reported being hypothetically comfortable with notifying TB patients to the local government. In contrast to high levels of comfort with notification as a norm, only about half (51.2%) reported ever...
having notified a TB case. Of those who self-reported ever having notified a TB case, roughly half (49.0%) reported doing so via the IDSR (DSNO) system, while 49.7% reported doing so via the TB program and 1.3% could not recall which system they used. Among the 33 health facilities with records of treating 156 TB cases, none had been notified [36]. Self-reported participation in disease notification and disease surveillance varied and did not often align with the findings of independent verification of notification by the facility [36].

As shown in Figure 2, a majority of unnotified TB cases (31/33) were discovered in the records of health facilities of respondents who self-reported comfort with notification. TB cases were also found in the records of health facilities where respondents stated that they lacked the capacity to treat TB (8/23).

Self-reported notification behavior differed according to sociodemographic characteristics. Older health care workers with more experience were more likely to self-report comfort with notification of TB cases, having previously notified of a case, and participation in monthly disease surveillance. Women reported less comfort with notification than men (87.2% vs 92.4%) and were significantly less likely to report “always” contributing to monthly surveillance (41.5% vs 52.7%) (Table 3).

aTB: tuberculosis.

Perceived Competence, Benevolence, and Integrity of Public Health Authorities

The adapted trust items had a Cronbach α of 0.91, suggesting good internal consistency. However, the scale showed ceiling effects and a bimodal distribution, necessitating reciprocal transformation (see Figure S1 in Multimedia Appendix 2). Initially, the gender difference in trust was not explained by age or years of experience (see Figure S2 in Multimedia Appendix 2). After transformation, the distribution of the trust scores...
varied by gender and self-reported notification behavior; men tended to report more trust and more monthly IDSR notification behavior than women (Figure S3 in Multimedia Appendix 2).

Neither the trust scale nor the subscales (competence, benevolence, and integrity) were normally distributed according to the Kolmogorov-Smirnov test. The Nigerian public health authority trust scale had a 3-factor structure with loading of four competence items, three benevolence items, and four integrity items (see Figure S4 in Multimedia Appendix 2). Scores on the trust scale ranged from 11 to 55, with higher values implying greater trust. The median value was 44 (IQR 39-48) (Table 4).

A minority of health care workers expressed doubts about the trustworthiness of the SMOH to conduct disease surveillance (Figure 3). Private providers who were not comfortable notifying TB scored the SMOH lower on the benevolence subscale of trust. Health care workers who affirmed always notifying via IDSR monthly reported higher median trust in the state’s public disease control capacity and had higher median scores on all three subscales compared to those of health care workers who indicated never reporting (Table 4).

The minority of private providers who reported being uncomfortable reporting TB cases to the state were also less likely to report that the SMOH was benevolent, acting in their interests (Table 4). Private providers who reported that they did not participate in the IDSR monthly reporting system were slightly less likely to report that the SMOH was competent and effective in providing health services (91% vs 98%; P=.03) and were less likely to view the SMOH as a capable regulatory agency (81% vs 95%; P=.02). Nonparticipants in disease surveillance reported lower median scores of SMOH competence, benevolence, and integrity than those who reported “always” submitting monthly reports. There were no significant differences in attitudes among those who reported ever notifying a TB case and those who did not (Figure 3).

Among those who were not comfortable notifying TB as mandated (n=156), the reasons for discomfort with disease notification included practical, logical, strategic, and economic concerns. The most common reason (58/156, 28.9%) given for noncompliance was lack of access to the surveillance “hardware” (eg, notification forms and registers). Approximately one-quarter of TB providers were doubtful that the low volume of TB patients they treated in their facility merited mastery of the TB notification forms and procedures. In addition, approximately 16% of the respondents incorrectly believed that notification to the TB program was unnecessary if they participated in the IDSR system (Table 5).

bIDSR: Integrated Disease Surveillance Response.

Discussion

Principal Findings

Private providers who did not notify TB cases via the disease surveillance system were younger and more likely to doubt the competence and effectiveness of public health authorities. Younger health care workers and women perceived fewer incentives to notify and indicated many obstacles to compliance. The summary of our hypothesis testing results is provided in Table S1 of Multimedia Appendix 2.

In contrast to the conclusion of a 2018 rapid assessment of TB surveillance in Nigeria, our findings show that over three-quarters (77.6%) of the “unengaged” providers fully understood that TB notification is required by law. More than half (51%) had notified TB in the past [40]. However, some private providers seemed confused by the seemingly duplicative notification mandates of the IDSR and the STBLCP.

A plurality of Lagos providers remained skeptical of the value of notification to the SMOH. Providers had low levels of trust in the state’s disease control and surveillance efforts. Our study demonstrates that lower trust scores correlate with lower participation. Such a perceived lack of effectiveness and
regulatory competence of Nigerian state public health authorities is not without precedent. Oleribe et al [16,17] also found that clinicians throughout Nigeria reported limited faith in the governmental commitment to public health and health care workers. Uchenna et al [3] identified a “bad attitude” as a barrier to completion of IDSR in Enugu state. Lafond et al [26] showed that providers often lack confidence that notification would make a positive difference. Our study extends this body of work by showing that the “software” of public health in Nigeria (ie, the values, norms, relationships, power, and mutually defined aims) are associated with mission-critical behaviors of key actors.

The development of trust needs reciprocal strengthening. Nigerian TB program stakeholders also express ambivalence regarding the competence, integrity, and motives of the private for-profit sector in TB care [29,41]. Distrust in the ethics and altruism of private providers is similarly well documented [42]. In India, Nair et al [43] found that lack of trust on the part of health authorities was a barrier to public-private TB collaboration. Some policy makers assume that private practitioners only respond to financial incentives; however, the evidence for this hypothesis is often overstated [41,44-46]. While providers who participated in this study reported a willingness to notify in exchange for free or subsidized drugs, diagnostic commodities, and patient materials, they also expressed support for nonmonetary incentives. Peer norming and social network recognition can be powerful forces in the health professions [44,45]. A majority (57.9%) of Lagos private providers stated that they would contribute to TB notification if they received professional recognition of their contributions from their medical peers and they were certain their peers were also engaged. Implementation research on these lower-cost peer-norming means to improve behavior is needed.

This study sought to understand attitudes toward participation in infectious disease surveillance using TB notification as an illustration. A unique feature of the study is the holistic measurement of complex governance trust constructs such as public health competence, benevolence, and integrity using validated scales.

Private provider “noncompliance” with public health obligations is a complex, multicausal behavioral phenomenon. Providers are influenced by peer norms around recording and reporting but also harbored doubts about the purpose and value of participation in public health surveillance. In contrast to earlier studies, Nigerian private providers did not lack knowledge of the notification obligation, nor did transactional “engagement” prompt full compliance. Although 17% of the respondents stated that electronic systems would be favored, 1 in 10 private providers had concerns about safeguarding patient confidentiality, which may impact their willingness to partner in WhatsApp groups, notification apps, and electronic registers.

In India, Thomas et al [47] found that patients’ confidentiality concerns (24%) and fear of offending patients (11%) were barriers to notification. El Emam et al [15] also found that private providers worry that disclosure of case counts could have adverse legal, ethical, financial, and regulatory consequences.

Effective engagement of private sector providers in Lagos and elsewhere will require mutual trust building, compromise, and respect. Achieving this will involve trade-offs, especially early on. Greater attention to end-user acceptability and the design of surveillance systems is paramount. While women were more likely to state that they were uncomfortable with disease reporting, none of the 156 TB cases found in the 33 facilities had been notified, highlighting the limits of PPM surveys as a method to understand notification behavior. Going forward, ethnographic research and inventory studies are needed to explore the gap between the rhetoric of self-reported notification behavior and actual notification behaviors.

As private providers’ motivations and TB capacity-building needs varied widely, offering a menu of incentives and enablers to this heterogeneous group would be a strategic approach to gain broad compliance. Some of the strategies that are being trialed to engage private sites include continuing medical education credits, vouchers for subsidized rapid molecular testing, and computerized chest-x-ray imaging, among others. Although these traditional PPM incentives (eg, training; free informational, educational, and communication materials; medical commodities; and free diagnostic tests) make sense for private providers with substantial TB caseloads, for small practitioners who will only ever treat limited TB patient volumes, sustainable options might include simpler, less-onerous, anonymous notification systems [2].

Simultaneous PPM initiatives funded by the Global Fund, United States Agency for International Development, Directorate-General for International Cooperation of the Netherlands, and the Centers for Disease Control and Prevention were implemented in Lagos during 2017-2020 [2,12,34,41,48]. Simplified private-sector TB surveillance systems have been introduced, including an Android app (STARRTB) and peer-to-peer WhatsApp notifications [13]. Efforts to improve the interoperability and integration of the IDSR and STBLCP TB notification systems have also been implemented by the WHO [2,13,49]. Although no interventions have yet addressed the issues of perceived regulatory effectiveness of public health agencies explicitly, efforts to streamline and simplify reporting burdens for private providers could contribute to increases in the perceived beneficence of public health agencies.

Nationally, the proportion of TB notifications by private providers increased from 11% in 2015 to 22% in 2021, but the addition of multiple reporting modalities raises the possibility of double counting and complicates attribution [2,12,13,41,48]. In the National Strategic Plan of the TB program, an additional US $35 million was foreseen for improving reporting in 2022. Continued appraisal of the return on investment of these diverse strategies is warranted.

One of the critical hurdles in gaining private-sector cooperation in antibiotic stewardship, surveillance, pandemic response, and other vital public health efforts is building the reputation of state public health institutions as credible, competent, and committed stewards of data. Training and deploying of apps are necessary, but likely insufficient to substantially and sustainably increase notification in the long term [13]. A possible strategy to build trust in the SMOH should be part of
any approach to boost stakeholders’ motivation to comply with notification obligations. Timely provision of valid scientific information and appreciation of the complementary strengths of private providers can help ministries of health earn the respect of private providers. Few contributors to the IDSР in Nigeria receive regular feedback or are aware of how the data are used [50]. Going forward, this “software” of surveillance needs as much attention as the equipment and human resources required to perform it.

Sensitivity on the part of TB policy makers will be required to craft a minimalist TB surveillance system that is easy to use and appropriately concise to be acceptable to reluctant providers. Private providers are numerous, but their individual TB caseloads tend to be small; therefore, it is unsurprising that they may not wish to invest time in mastery of the complex TB registers common in infectious disease surveillance. This is particularly true when providers are unsure how their TB data are to be used or whether public health gains accrue to their communities via participation in these systems. A plurality of private providers (49%) stated that they are willing to contribute to a TB notification system if the data submitted were anonymous. As unique IDs are instituted via electronic recording and reporting, the necessity of the collection of patient names should be revisited. Ways to satisfy providers’ anonymity preferences for case notification should be explored [15].

An infectious disease surveillance system acceptable to private providers would collect fewer variables, report less frequently, and integrate the task with the existing IDSР obligations. TB stakeholders at the national and international levels would need to be willing to accept less granular information from the private sector in exchange for higher adherence, fidelity, and completeness. Surveillance systems based on semitrusted partners that protect privileged and proprietary information are possible [15].

Limitations
Given the sensitivity of the topics in the study, the methods have certain caveats and design choices that need to be taken into consideration when interpreting the findings. Scales to detect social desirability were not included. A bimodal distribution with ceiling effects was observed; use of a structured survey did not allow us to probe all underlying rationales for noncompliance and the model did not explain all variances. Survey refusals were more common among facilities that treated TB but did not notify it (22% vs 4%), suggesting that the findings may underrepresent the full diversity of rationales for noncompliance. Sampling quotients overestimated TB treatment provision in the unengaged private sector, meaning that the majority (88%) of those interviewed were not faced with decisions about whether or not to notify TB cases and thus their responses may reflect historical or hypothetical choices. However, a strength of the study design is that it measured both providers’ self-reported reporting behavior and their actual reporting behavior so that socially desirable response bias is revealed in the juxtaposition as a finding.

This exploratory study endeavored to adapt and test a scale of public health authority trust as a possible contributor to understanding infectious disease surveillance behavior. While the trust scale proved robust, trust alone was insufficient to explain the variability in notification behavior. Mistrust in public authorities proved difficult to disentangle from mistrust of surveys. Additional methodological innovation may be required to overcome the influences of social desirability and acquiescence. The greater mistrust reported by those with more seniority may be confounded by the greater candor afforded by stature.

Conclusion
New forms of public-private collaboration in surveillance are needed that align with the varied interests of private providers, reflecting their varied caseloads and capacity for recording and reporting. While spurring desired provider behavior may seem a matter of assembling an enticing package of carrots and sticks, achieving this is demonstrably difficult without addressing the underlying governance and trust considerations that blunt private providers’ willingness. Moreover, our study suggests that it may be more effective to adapt the TB notification system to make it more responsive to end-user needs than to modify providers’ attitudes and behavior. The lessons learned are relevant for the design of other surveillance systems, including postmarketing pharmacovigilance of new health technologies, patient safety reporting, antibiotic stewardship, and early warning systems for emerging pathogens.

Abstract

Background: Smell disorders are commonly reported with COVID-19 infection. The smell-related issues associated with COVID-19 may be prolonged, even after the respiratory symptoms are resolved. These smell dysfunctions can range from anosmia (complete loss of smell) or hyposmia (reduced sense of smell) to parosmia (smells perceived differently) or phantosmia (smells perceived without an odor source being present). Similar to the difficulty that people experience when talking about their smell experiences, patients find it difficult to express or label the symptoms they experience, thereby complicating diagnosis. The complexity of these symptoms can be an additional burden for patients and health care providers and thus needs further investigation.

Objective: This study aims to explore the smell disorder concerns of patients and to provide an overview for each specific smell disorder by using the longitudinal survey conducted in 2020 by the Global Consortium for Chemosensory Research, an international research group that has been created ad hoc for studying chemosensory dysfunctions. We aimed to extend the existing knowledge on smell disorders related to COVID-19 by analyzing a large data set of self-reported descriptive comments by using methods from natural language processing.
Methods: We included self-reported data on the description of changes in smell provided by 1560 participants at 2 timepoints (second survey completed between 23 and 291 days). Text data from participants who still had smell disorders at the second timepoint (long-haulers) were compared with the text data of those who did not (non–long-haulers). Specifically, 3 aims were pursued in this study. The first aim was to classify smell disorders based on the participants’ self-reports. The second aim was to classify the sentiment of each self-report by using a machine learning approach, and the third aim was to find particular food and nonfood keywords that were more salient among long-haulers than those among non–long-haulers.

Results: We found that parosmia (odds ratio [OR] 1.78, 95% CI 1.35-2.37; \( P < .001 \)) as well as hyposmia (OR 1.74, 95% CI 1.34-2.26; \( P < .001 \)) were more frequently reported in long-haulers than in non–long-haulers. Furthermore, a significant relationship was found between long-hauler status and sentiment of self-report (\( P < .001 \)). Finally, we found specific keywords that were more typical for long-haulers than those for non–long-haulers, for example, fire, gas, wine, and vinegar.

Conclusions: Our work shows consistent findings with those of previous studies, which indicate that self-reports, which can easily be extracted online, may offer valuable information to health care and understanding of smell disorders. At the same time, our study on self-reports provides new insights for future studies investigating smell disorders.

Introduction

Chemosensory dysfunctions are among the distinguishing symptoms of COVID-19 [1-3]. Although many infected patients recover within weeks, a large percentage of patients experience long-term olfactory dysfunction even after recovery from the acute phase [4,5]. These individuals are known as smell long-haulers. Since smell impairment is often hard to notice and even harder to describe by patients (eg, patients commonly confuse smell disorders with taste disorders), information that can clarify the process of smell impairment or recovery can be useful to describe, understand, and track the phenomenon [6]. It is also unclear how distorted chemosensory perception relates to well-being or changes in behavior such as those related to food intake or avoidance.

Smell disturbances, categorized as quantitative (alterations in odor intensity) or qualitative (changes in perceived odor quality) [7,8], are common among COVID-19 long-haulers [1,9]. Symptoms can range from increased perceived intensity (hyperosmia) to faint perception of odors (hyposmia) or even complete loss of olfactory perception (anosmia). Qualitative changes may occur when the quality of the perceived odor is altered [7,8], which occurs, for instance, in case of parosmia (ie, distorted smell perception typically leading to perceived smells as bad odors, eg, the smell of food in good condition is perceived as garbage) or phantosmia (ie, perceiving smells without an olfactory stimulus, eg, smoke when there is no fire). Although these distortions are prevalent, individuals often lack technical terminology awareness, leading to challenges in accurate self-reporting and potential impacts on emotional well-being. Confusion may, for example, arise from terms such as “flavor” and “taste” [10], where individuals may report that they do not taste anything while only their smell is affected and not their taste. Similarly, different types of smell changes may cause confusion, as the quantity (complete or partial loss of smell) and quality of the changes indicate different impairments. Moreover, people are often inaccurate in reporting their olfactory performances, which may affect their emotional well-being and their awareness of olfactory dysfunction [11]. Properly classifying symptoms is crucial for clinical and research purposes, emphasizing the need for open-ended survey formats to capture nuanced experiences [12]. The difficulties in symptom description make it hard to capture a person’s particular olfactory experience in close-ended survey questions [9,13,14]. In our study, we employed open-ended surveys to collect comments [2], providing valuable insights like “smell is back to normal,” “my sense of smell fluctuates and is not as good as before,” or “the smell of coffee and onions has changed.”

The strong connection between smell and emotional-cognitive states involves neural pathways connecting the amygdala, thalamus, orbitofrontal cortex, and hippocampus [15-18]. Olfactory dysfunctions, often preceding neurodegenerative disorders, are evident in conditions such as Alzheimer disease, Parkinson disease, autism, and depression [16,19,20]. The detrimental effect of chemosensory dysfunction on emotional well-being is well-recognized [21-23] but is not fully understood with respect to olfaction in long-haulers. Patients have reported altered mental status as well as frustrations with COVID-19–related olfactory dysfunction [24]. Furthermore, olfactory dysfunction predicts the development of depression in adults [20]. Therefore, a negatively affected well-being or emotional tone when describing their symptoms would be expected in patients with COVID-19 and olfactory dysfunctions such as anosmia or parosmia, particularly in long-haulers.

In this study, we analyzed open-ended questions that were included in surveys conducted by the Global Consortium for Chemosensory Research (GCCR) [2,3]. As an initial validation of the informative value of the comments, a comparison was made between symptoms coded from open-ended comments and from the multiple-choice answers alone, administered during COVID-19 (survey 1) and after recovery (survey 2). This sets the stage to address the following 3 questions: (1) What are the frequencies of parosmia, phantosmia, and other olfactory dysfunctions (ie, hyposmia and anosmia) as reported in open-ended comments? (2) What is the well-being or emotional tone of people experiencing these symptoms as reported in...
open-ended comments? (3) What specific food-related experiences are related to these symptoms? Open-ended questions allow participants to voice their concerns that may not be covered by the other type of questions and are closer to how patients may report these symptoms to their general practitioner or health care worker [25]. The questions addressed smell loss while participants experienced COVID-19 (survey 1) and during a follow-up survey (survey 2). Analyzing these comments and their content contributes to better understanding, in a more ecologically valid way, of how long hauling might affect emotional well-being as it relates to olfactory experiences and the frequency and severity of symptoms compared with analyzing close-ended survey questions alone. On the basis of previously reported information, the following hypotheses have been formulated in this study.

1. Hypothesis aim 1: Recovery from smell loss is often accompanied by parosmia and phantosmia and is considered a sign of olfactory mucosa regeneration [1]. Considering that some smell-related symptoms may remain in COVID-19 long-haulers, we predict that long-haulers will have a greater occurrence of parosmia and phantosmia in addition to other potential chemosensory dysfunctions compared with non–long-haulers based on their own description of their olfactory symptom progression in survey 2.

2. Hypothesis aim 2: Using a machine learning aspect–based sentiment analysis, we predict that long-haulers will report significantly more emotional and psychological distress compared to non–long-haulers.

3. Hypothesis aim 3: We hypothesize that long-haulers reporting parosmia and phantosmia will exhibit avoidance behavior, resulting in omission of certain food and nonfood items. This will be apparent from a qualitative semantic analysis of the comments in survey 2.

**Methods**

**Study Design**
To investigate the study hypotheses, we used data previously available to the GCCR [2,3] that analyzed closed-ended responses. More specifically, we used data acquired by means of open-ended questions included in those surveys, not analyzed before in those studies. The data collection has been designed and planned following the structure of a prospective cohort study with cross-sectional characteristics, in which participants experiencing smell disorders completed a survey at timepoint 1 (survey 1) and were invited to complete a follow-up survey again at timepoint 2 (survey 2). Participants who had recovered at timepoint 2 were classified as non–long-haulers, whereas participants still experiencing smell disorders at timepoint 2 were classified as long-haulers. The differences between these 2 groups were analyzed and described.

**Study Participants**
The initial survey (survey 1) was completed between April and September 2020 by 12,313 participants [2,3], of which 3386 participants also completed the follow-up survey (survey 2) at timepoint 2 (between September 2020 and February 2021). Participants self-selected to participate in survey 1. They were invited via email to participate in survey 2 if they previously agreed to be recontacted; provided an email address; completed survey 1 in English, Spanish, Italian, Dutch, or French; and reported a change in smell, taste, and flavor (via a symptom checkbox) in survey 1. Participants completed the second survey between 23 and 291 (median 200) days after the first survey. From this, data from 1560 participants were included in this study. The participants were classified as either non–long-haulers (n=673) or long-haulers (n=887) based on their self-reported smell ability at survey 2 relative to survey 1 (Table 1). We refer the reader to [1] for a detailed overview of the data collection. Dutch, French, Italian, and Spanish comments were translated to English for our analyses. Translations were conducted by native speakers.

**Ethics Approval**
This preregistered cross-sectional web-based study was approved by the Office of Research Protections of the Pennsylvania State University in the United States (STUDY00014904). This study was approved as an exempt study. The protocol complies with the revised Declaration of Helsinki and is compliant with privacy laws in the United States and European Union. Data reported here were collected from the GCCR core questionnaire. All participants provided an
online consent to participate in the survey prior to proceeding with answering the survey questions. Only those participants who previously agreed to be recontacted and provided their emails were approached to complete the second survey. The study data were deidentified at the Pennsylvania State University before these were provided to other researchers for analysis. All participants volunteered to participate in this study, and no compensation was provided.

Procedure

**Aim 1: Occurrence of Smell Disorders in Long-Haulers**

Our first aim was to determine the incidence of anosmia, hyposmia, phantosmia, and parosmia in long-haulers versus that in non–long-haulers by analyzing the free-text comments. At variance with [1], these complaints were categorized and counted based on descriptive comments and not on the participants’ self-reports by means of closed questions. The self-report question in [1] asking for changes in smell was meant to capture quantitative changes and was not always sensitive to capture individual experiences. The question that prompted the free-text comment was “Please describe any current changes in smell. Type ‘none’ if this is not applicable.”

The data were first processed by means of a concept-driven quantitative content analysis, as described by [26]. Comments recorded at both timepoints (n=2543) were coded manually by 8 different coders for the presence of anosmia, hyposmia, parosmia, phantosmia; whether the person indicated that they had recovered, not at all, partially or fully; and for mentioning food and nonfood odorous items according to a predetermined coding scheme (see coding scheme in Multimedia Appendix 1). Cases that did not meet any of the symptoms were excluded from further analyses. The responses that contained “none” entries (n=469) were also excluded from further analyses.

As an additional validation measure, the overlap between coded symptom prevalence of the free-text comments was compared to the self-reported prevalence on the multiple-choice question that was used in [1] (Multimedia Appendices 2-4). In these multiple-choice questions, participants were asked to rate whether they had noticed anosmia, hyposmia, parosmia, or phantosmia by asking the following questions, respectively: “I cannot smell at all/smells smell less strong than they did before my impairment” (anosmia/hyposmia), “smells smell different than they did before my impairment (the quality of smell has changed)” (parosmia), and “I can smell things that aren’t there (eg, I smell burning when nothing is on fire)” (phantosmia). Since multiple-choice questions for anosmia and hyposmia were not provided separately, we could only validate parosmia, phantosmia, as well as anosmia and hyposmia together.

**Aim 2: Emotional Distress in Long-Haulers**

For this aim, we trained a sentiment classification algorithm with LCF-ATEPC (local context focus–aspect term extraction and polarity classification) from PyABSA [27] (version 1.16.15; Heng Yang) on a data set of restaurant reviews available in PyABSA (Restaurant16) and then used the trained algorithm to first extract the so-called aspects, that is, keywords in each comment. Each aspect in each comment was classified as being negative, neutral, or positive (numerically coded as 1, 2, and 3, respectively). Comments such as “mustard smells really pungent, and I can’t be around it” or “I smell things a little less well” were classified as negative, while comments such as “I am back to normal in smelling” or “smell has come back completely after recovering” were classified as positive. To validate the results of the first model, we trained a second model with the same parameters on a data set of laptop reviews also available in PyABSA (Laptop14) and used that model to classify the comments and conduct the same analyses.

**Aim 3: Salience of Food and Nonfood Items in Long-Haulers**

Once the incidence and impact of smell disorders were established, we determined whether specific foods, drinks, or other objects were associated with long hauling, with the goal to examine whether specific items were more salient in long-haulers than in non–long-haulers. We first extracted all food and nonfood items from the comments that had been coded for aim 1. Qualitative relationships between items were visualized using word clouds. To quantify the use of specific words across groups, we then conducted a relative frequency analysis on the extracted food and nonfood words from comments.

Statistical Analyses

**Aim 1: Occurrence of Smell Disorders in Long-Haulers**

We used logistic regressions to approach aim 1 (glm function with a binomial error structure of the stats package in R) and assessed whether the 2 categories of participants (long-haulers vs non–long-haulers) differed in terms of the reported disorders that they respectively experienced. The dependent variables were each of the 4 smell disorders studied, namely, parosmia, phantosmia, hyposmia, or anosmia (0 for absence, 1 otherwise). Our explanatory variable was “smell-long-hauler status” (long-hauler vs non–long-haulers). We included age and gender of the participants and whether the comments were translated in English (0 for untranslated comments vs 1 for translated comments) as control variables as well as their interactions with the explanatory variable. We included all the main effects and interaction terms in the initial model, which were then simplified by removing the nonsignificant interaction terms to achieve the minimal adequate model. We centered “age” in all the models in order to make the effects more easily interpretable. Statistical analyses were performed using R software (version 4.1.3; R Foundation for Statistical Computing).

**Aim 2: Emotional Distress in Long-Haulers**

A chi-square test was conducted to examine the relationship between sentiment classifications and long-hauler status of the aspect-based sentiment classification algorithm. A mixed-effects logistic regression model was used to examine the relationship among sentiment, long-hauler status, and olfactory dysfunction type. All analyses were conducted with Python (version 3.8.8; Python Software Foundation) and the packages Scipy (version 1.9.3; Community library project) and Statsmodels (version 0.13.5; Jonathan Taylor).
Aim 3: Salience of Food and Nonfood Items in Long-Haulers

This aim was approached initially by creating word clouds and subsequently conducting a relative frequency analysis. For the word clouds, the extracted words describing food and nonfood objects were converted to lower case unigrams, bigrams, and trigrams by using the R package RWeka (version 0.4.44; Kurt Hornik) and TM (version 0.7.8; Ingo Feinerer). The R package wordcloud2 (version 0.2.1; Dawei Lang) and RColorBrewer (version 1.1.3; Erich Neuwirth) were used to create word clouds, where the frequency of an n-gram determines the size within the cloud. For the relative frequency analysis, we preprocessed and aggregated each group’s comments into a corpus based on the long-hauler status. Preprocessing steps included splitting the plain text comments into tokens. Tokens were lowercased, and numerals and punctuations were removed. Commonly used stop words were removed, and the text was lemmatized using Wordnet [28]. We then computed the frequency lists for each corpus in the comparison based on our preprocessed comments. The log-likelihood statistic was calculated for each word in the 2 frequency lists by constructing a contingency table based on word frequencies within and across corpora as per the method in [29]. Given that log-likelihood is a statistical significance measure, it does not compute the size of the difference between corpora; rather, it provides the words we have the most evidence for. Thus, to determine the influence of each word in each of the corpora, the relative frequency [30] method was used. By comparing the normalized frequencies for each word, this method returns a value (−1, 1). In our case, 1 indicates that the word is overused in the long-hauler corpus, and −1 in the non–long-hauler corpus. Using these metrics, we determined the food and nonfood words in the corpora by manually coding words from each category with log-likelihood values greater than 3.84 (a significance threshold of $P<.05$ or lower) and selected for further analysis.

Results

Aim 1: Occurrence of Smell Disorders in Long-Haulers

The logistic regression examining the association between anosmia and long-hauler status could not be performed, as the number of participants reporting anosmia was too small in both long-haulers (17/750) and non–long–haulers (0/338; see Table 2; Multimedia Appendix 5). For the other smell disorders, the minimal adequate models that were run to obtain the results reported below were obtained by removing the nonsignificant interaction terms between smell long-hauler status and the 3 control variables (age, gender, and translation) in all models (.06<$P<.98). The logistic regressions revealed a significant effect of the smell long-hauler status (long-hauler vs non–long-haulers) in terms of reported disorders (Multimedia Appendix 6). Long-hauler participants were significantly more likely to report symptoms interpreted as parosmia ($β=.58$, SE .14; $z=4.06$; odds ratio [OR] 1.78, 95% CI 1.35-2.37; $P<.001$; Multimedia Appendix 7) and hyposmia ($β=.55$, SE .13; $z=4.16$; OR 1.74, 95% CI 1.34-2.26; $P<.001$; Multimedia Appendix 8) compared to non–long-haulers. However, long-hauler status did not affect the likelihood to report symptoms associated with phantosmia ($β=.09$, SE .19; $z=0.49$; OR 1.10, 95% CI 0.76-1.62; $P=.63$; Multimedia Appendix 9). To obtain in-depth information on the relationship between smell disorders and the control variables (eg, sex, age), please consult Multimedia Appendices 6-9.

Table 2. Sample size of reported olfactory dysfunctions by smell long-hauling status and gender as coded from self-reports in the Global Consortium for Chemosensory Research survey on COVID-19 that was administered globally between September 2020 and February 2021.

Aim 2: Emotional Distress in Long-Haulers

The classifier that was trained on restaurant reviews was unable to classify the sentiment of 854 out of 1560 comments, and 838 out of 1560 could not be classified by the model trained on laptop reviews. These comments were removed from further analyses. There was a relationship between the classified sentiment and long-hauler status based on the model that was...
trained on restaurant reviews ($\chi^2 = 15.1; P < .001$; Table 3) and laptop reviews ($\chi^2 = 30.3; P < .001$).

In addition to comparing the sentiments of long-haulers and non–long-haulers, an additional analysis examined the effect of specific olfactory dysfunction on the comment’s sentiment. We therefore split the data set based on each smell disorder (Table 4; Multimedia Appendix 10) and compared how the sentiment changed when a smell disorder was reported versus when it was not reported. It is important to note that the split of the data was not exclusive, that is, participants who, for example, did not report parosmia, could still have reported hyposmia, phantosmia, or anosmia.

Within the comments of long-haulers, there was an effect of parosmia ($\beta = -1.13$, SE .35; OR 0.32, 95% CI 0.16-0.62; $P = .001$) and hyposmia ($\beta = -.76$, SE .33; OR 0.47, 95% CI 0.24-0.90; $P = .02$). No significant effects were found for phantosmia ($\beta = -.53$, SE .50; OR 0.62, 95% CI 0.36-1.06; $P = .08$), hyposmia ($\beta = .16$, SE .20; OR 1.17, 95% CI 0.80-1.72; $P = .43$), or anosmia ($\beta = .27$, SE .62; OR 1.31, 95% CI 0.37-4.39; $P = .66$). For the non–long-hauler comments (Multimedia Appendix 13), a significant effect was found for parosmia ($\beta = -.71$, SE .30; OR 0.49, 95% CI 0.27-0.89; $P = .02$) and hyposmia ($\beta = -.55$, SE .28; OR 0.58, 95% CI 0.33-1.00; $P = .05$) but not phantosmia ($\beta = .01$, SE .51; OR 1.01, 95% CI 0.37-2.81; $P = .99$).

As a validation of these results, the same analyses were conducted for the model that was trained on laptop reviews (Multimedia Appendix 12). The sentiment classification of long-hauler comments showed no significant effects for parosmia ($\beta = -.22$, SE .19; OR 0.80, 95% CI 0.56-1.15; $P = .24$), phantosmia ($\beta = -.47$, SE .28; OR 0.62, 95% CI 0.36-1.06; $P = .08$), hyposmia ($\beta = 1.17$, SE .20; OR 1.17, 95% CI 0.80-1.72; $P = .43$), or anosmia ($\beta = .27$, SE .62; OR 1.31, 95% CI 0.37-4.39; $P = .66$). For the non–long-hauler comments (Multimedia Appendix 13), a significant effect was found for parosmia ($\beta = -.71$, SE .30; OR 0.49, 95% CI 0.27-0.89; $P = .02$) and hyposmia ($\beta = -.55$, SE .28; OR 0.58, 95% CI 0.33-1.00; $P = .05$) but not phantosmia ($\beta = .01$, SE .51; OR 1.01, 95% CI 0.37-2.81; $P = .99$).

Aim 3: Salience of Food and Nonfood items in Long-Haulers

Word clouds were generated to visually explore differences in food and nonfood items mentioned differently in the comments of long-haulers and non–long-haulers (Multimedia Appendices 14 and 15). Superficially, the word clouds appeared similar for both groups. Non–long-haulers appeared to mention cheese, urine, and sweat somewhat more often than long-haulers. Both groups most often mentioned coffee, onion, and food, and for the nonfood items, they mentioned perfume and smoke.

The relative frequency analysis, reported in Table 6, revealed that lemon was mentioned more often by long-haulers, whereas wine, cheese, vinegar, and mustard were mentioned more often by non–long-haulers. For the nonfood items, long-haulers more often mentioned weird (presumably for weird smells), fire, gas, and eucalyptus among other smelling objects. This is in line with the finding that long-haulers more often report parosmia and thus report more of these foul-smelling objects in their comments, whereas non–long-haulers might report the objects that they can smell and taste again in their comments (eg, wine, cheese).
Table 6. Results of a relative frequency analysis showing a list of words that were reported significantly ($P<.05$) more often by long-haulers or non–long-haulers. These words were extracted from smell-related self-reports in a web-based survey on COVID-19 that was administered globally between September 2020 and February 2021.

$^a$A larger occurrence value indicates that words were reported more frequently by long-haulers, and a lower (negative) value indicates a higher frequency for non–long-haulers.

Discussion

Principal Findings

First, our study shows that there is a strong relationship between long-hauler status and the incidence of both quantitative and qualitative smell changes, as apparent from our analysis of the open-ended comments. In addition, our analysis shows that there is a strong relationship between the smell disorder status as extracted from open-ended comments compared to those extracted from multiple-choice questions. Second, the sentiment analysis revealed that long-haulers are more negative in tone, underscoring the socioemotional impact of smell disorders on the individual. Third, we found that specific smell objects were mentioned in the free-text comments, differentiated by long-haulers and non–long-haulers, and specific smell dysfunction symptoms. We will elucidate these results more in the remainder of this discussion.

Our data show that, according to our first hypothesis, long-haulers reported a significantly higher occurrence of olfactory dysfunctions, in particular, parosmia ($P<.001$) and hyposmia ($P<.001$), than non–long-haulers did. This agrees with previous research that shows that olfactory dysfunctions, especially parosmia, appear to be part of long COVID [1]. This marks the need for accurately defining the sensory experience by introducing a clinical routine testing that may highlight the recovery pathway, even if partial, as well as to give feedback to patients on their clinical course. It also points toward a need for better sensory education among the population that often has no means of describing their perception accurately. Moreover, it is relevant that clinicians become aware of the relative inaccuracy of patients when reporting their chemosensory symptoms. Olfactory unawareness has been reported several times [31], in particular, in older and at-risk populations. However, even if reported to health care professionals, olfactory dysfunctions are seldom objectively tested [32]. Reduced or simplified tests may be of value [33,34]; yet, the clinical practice largely relies on self-reporting. In the case of patients with COVID-19, guided classification of odors revealed a perceptual landscape different from controls [35].

Our second aim was to link emotional distress to long-hauler status by using a machine learning model, thereby eliminating human bias. The sentiment classifier revealed a more negative tone in long-haulers’ comments, as has also been shown by other studies [36-38]. Clustering by symptoms indicated that parosmia or hyposmia was associated with more negative words for both long-haulers and non–long-haulers. This raises the question why this was not the case for phantosmia. The reason might be that parosmia and its stronger relationship with food...
intake results in, for example, loss of appetite [37,39] and therefore stronger emotional impact. However, ambiguity exists in the interpretation of these results as is also mentioned by [40], who argue that there is much room for improvement of machine learning models in the domain of health. The tendency of these results is interesting nonetheless, and follow-up analyses coupled to the analysis of food intake habits [41] that more specifically delves into the quality of life could shed a clearer light on the matter.

A semantic analysis of the objects mentioned within the comments suggested that the most frequently mentioned objects were similar for long-haulers and non–long-haulers concerning nonfood items (eg, perfume, smoke), while for food items, the 2 most frequent words were the same but switched between long-haulers and non–long-haulers. The word “onion” was used most frequently by non–long-haulers and “coffee” by long-haulers. Concerning differentially reported food words, “lemon” was mostly reported by long-haulers and “red wine” by non–long-haulers. When looking at the specific olfactory dysfunction, the largest problem seemed to arise in the nonfood words mentioned by participants with phantosmia. They seemed to often mention words such as “smoke” and “burning.” Objects reported by both groups may represent the most salient odor objects. Long-haulers may no longer smell these, while non–long-haulers may perceive them as the first smells they regain. However, aim 3 words were only analyzed on their occurrence and thus did not provide a means to examine whether their occurrence elicited positive or negative feelings. Exploring whether certain foods were avoided or approached during smell dysfunction and investigating compounds triggering parosmia could provide valuable indicators, such as pyrazines for coffee, disulfides for onion, thiols for garlic, and methoxypyrazines for wine [42].

The mentioning of words that describe a burning sensation in participants with phantosmia is consistent with those mentioned in previous findings [43]. It provides confirmation of these findings in a large sample and offers an overview of other words and sensations that may be associated with phantosmia, which may be helpful for clinicians. Although multiple hypotheses have been proposed on the causes of phantosmia, it may very well be that phantasmic sensations have varying causes [44]. Our data consist of a wide range of self-reports of these phantasmic sensations and are therefore suitable for a follow-up analysis on specific contexts that evoke a phantasmic sensation to further the understanding of phantasmic experiences and the mechanisms that underlie them. This also highlights the value of internet in medical research, which allows for a collection of large data sets on patients’ self-reports that may add to the understanding of olfactory dysfunctions.

The difficulty people face in discussing smells and olfactory experiences is a well-known phenomenon [11]. In this study, we analyzed open-ended comments to gain insight into the experiences of individuals experiencing olfactory dysfunctions that are not entirely understood or correctly named by patients experiencing these. First, we found a discrepancy between the information in the open-ended comments and the close-ended multiple-choice question that asks for olfactory dysfunction. This suggests that the comments contain valuable information that differs between groups and symptoms, highlighting the importance of this approach. This study emphasizes the importance of considering open-ended comments to gain a more holistic understanding of participants’ experiences and perceptions. The approach presented here, that is, manually coding short open-ended responses for different symptoms, may be used in combination with machine learning classification paradigms, to better understand patients’ concerns voiced in web-based settings such as in web-based survey research, online patient council groups, or by using brief digital notes from general practitioners as input. This additional source of information could lead to better identification of different diagnoses, and along the line, better understanding of the different types of smell disorders.

Finally, few people mentioned that months after developing COVID-19–induced smell dysfunction, their smell did improve, even to a level of functioning that was better than before the onset of COVID-19. We identified 13 cases of hyperosmia. It is currently unknown in what percentage this phenomenon occurs and what the mechanisms underlying this phenomenon are, and hyperosmia has been seldom reported after COVID-19 [45,46]. Speculatively, an increase in the awareness of smells after having lost one’s sense of smell for a brief period could potentially drive attentional experience with odors—in an “you don’t know what you’ve got until you lose it” way [47]. In the future, large-scale prevalence studies on smell disorders could investigate the percentage of people who report an improved sense of smell after recovering from a smell dysfunction.

We considered the validity of our analyses of open-ended responses, as opposed to the analyses of close-ended questions in [1]. Concurrent with their results, we found that long-haulers were more likely to experience parosmia and hyposmia, but in contrast to their findings for phantosmia, we did not find that long-haulers were more likely to experience phantosmia. This may result from the lack of overlap between our coding and participants’ self-reports. Generally, coders underestimated the prevalence of smell disorders. This effect was the highest for phantosmia, and may, therefore, have led to the discrepancy between [1] and our study. Possible explanations for the high underestimation of prevalence by coders are that participants did not report their whole experience in the comments or that participants overestimated their experiences in the multiple-choice questions. This is a downside to our approach, but overall, the overlap between the coded and self-reported smell disorders seemed to be in a good range and should therefore allow for a useful interpretation of the results that our natural language processing measures yielded.

Limitations in Our Study

Our study has several limitations. There was a selection bias in the participant group. As in [1], we are aware that there might be a self-selection bias in completing these surveys, as participants experiencing severe symptoms may be more motivated to also complete the second survey. At the same time, participants who felt that they had severe smell disorders may select additional answer options on the multiple-choice questions and clarify their symptoms in the open-comment field. Thus, this selection bias, as compared with [1], could go either way.

https://publichealth.jmir.org/2024/1/e47064
This provides an opportunity to compare both ways of asking about symptoms from participants, which we included in aim 1. Notwithstanding, we interpret the results with caution and phrase future suggestions and implications cautiously.

**Conclusion**

The use of web-based surveys proved of value during COVID-19 since it allowed the rapid collection of data for monitoring infection-related chemosensory deficits. In addition to multiple-choice answers, a thorough description of symptoms could be extracted from open-ended answers. The surveys in this study made it possible to describe the qualitative changes in the chemosensory functions and explore their frequency. The distress of long-haulers could be investigated using a nonhuman unbiased algorithm for sentiment classification. Lastly, it was possible to highlight the different use of words related to food and nonfood items, possibly relating to the different perceptual experiences. In conclusion, we proved the validity of our approach, based on the analysis of open-ended questions to better understand the perceptual world of patients, described using their own words. Our analysis provides a new perspective on olfactory disturbances following COVID-19 that cannot be captured through closed-ended questions. On a more general level, this data science perspective can advance web-based survey-based patient research studies.

**Data Availability**

The data sets and scripts generated and analyzed during this study are available in the Open Science Framework repository “Giving a voice to adults with COVID-19: An analysis of the open-ended comments from COVID-19 smell long-haulers and non-long-haulers on the Global Consortium for Chemosensory Research survey” [48].

**Authors' Contributions**

IC, SB, KWC, PRD, MCF, TH, SK, NSM, CM, VDCS, and AD conceptualized this study. IC, SB, MCF, NSM, AT, and VP-L curated the data for this study. IC, KWC, PRD, TH, NSM, AT, and VDCS performed the formal analysis in this study. CM acquired the funds. IC, SB, KWC, NSM, and AT devised the methodology. IC, SB, and SK administered the project. IC, SB, KWC, PRD, MCF, TH, NSM, CM, DP, AT, VDCS, AD, and VP-L provided the resources. IC, KWC, NSM, and AT designed the software. IC, SB, NSM, and AT supervised this study. IC, KWC, MCF, NSM, and AT visualized this study. IC, PRD, NSM, and AT contributed to the writing of the original draft. IC, SB, KWC, PRD, MCF, TH, SK, NSM, CM, DP, AT, VDCS, and AD reviewed and edited this paper.

Modeling the Regional Distribution of International Travelers in Spain to Estimate Imported Cases of Dengue and Malaria: Statistical Inference and Validation Study

Abstract

Background: Understanding the patterns of disease importation through international travel is paramount for effective public health interventions and global disease surveillance. While global airline network data have been used to assist in outbreak prevention and effective preparedness, accurately estimating how these imported cases disseminate locally in receiving countries remains a challenge.

Objective: This study aimed to describe and understand the regional distribution of imported cases of dengue and malaria upon arrival in Spain via air travel.

Methods: We have proposed a method to describe the regional distribution of imported cases of dengue and malaria based on the computation of the “travelers’ index” from readily available socioeconomic data. We combined indicators representing the main drivers for international travel, including tourism, economy, and visits to friends and relatives, to measure the relative appeal of each region in the importing country for travelers. We validated the resulting estimates by comparing them with the reported cases of malaria and dengue in Spain from 2015 to 2019. We also assessed which motivation provided more accurate estimates for imported cases of both diseases.

Results: The estimates provided by the best fitted model showed high correlation with notified cases of malaria (0.94) and dengue (0.87), with economic motivation being the most relevant for imported cases of malaria and visits to friends and relatives being the most relevant for imported cases of dengue.

Conclusions: Factual descriptions of the local movement of international travelers may substantially enhance the design of cost-effective prevention policies and control strategies, and essentially contribute to decision-support systems. Our approach contributes in this direction by providing a reliable estimate of the number of imported cases of nonendemic diseases, which could be generalized to other applications. Realistic risk assessments will be obtained by combining this regional predictor with the observed local distribution of vectors.

KEYWORDS
epidemiology; imported infections; modeling; surveillance system; vector-borne diseases
Introduction

Throughout history, human mobility has been a key determinant for the spread of infectious diseases. From the 14th century bubonic plague pandemic to the 1918 Spanish flu as well as the more recent Ebola epidemic and COVID-19 pandemic, the way individuals travel across the globe has shaped the evolution and geographical dynamics of infectious diseases [1-3].

International mobility flows are especially relevant for the spread of vector-borne diseases (VBDs), which often receive less attention in routine epidemiological surveillance plans in countries where they are not endemic. In recent years, global warming and intensified urbanization processes have favored the establishment of previously foreign species around the globe, such as Aedes, Anopheles, and Culex mosquitoes [4-7]. These are vectors for malaria, dengue, yellow fever, West Nile virus, Zika, and chikungunya, and thus, they pose a significant public health risk that needs adequate preparedness [8-10]. Air travel plays a central role in the diffusion of most of these diseases, allowing their spread through imported cases at nonendemic locations [11-13] with vector presence, and it must be incorporated in decision-support systems to achieve operational preparedness and risk prediction [14-16]. Reliable descriptions and predictions of migration flows have been proven to be valuable tools for the design of more effective public health policies [17-20]. However, new developments are always needed as complex dynamics are expected to arise from the multi-step life cycle of VBDs [21-23].

A wide range of approaches have been used to model risks of imported cases of dengue [24-27] and malaria [28-30] from endemic to nonendemic regions. Several studies [31-33] have incorporated data on the global airline network to assist outbreak prevention and public health preparedness. However, accurate estimations of how such imported cases disseminate locally after arrival in the receiving countries are harder to devise. While fine-grained data on local mobility are available from cellular networks [34-36], it is not clear how the specific behavior of travelers can be differentiated from the local population dynamics. Moreover, travel-related data are usually obtained through coarse-grained spatial statistics, thus involving large territories. A reason for this is the inherent complexity and range of scales involved in human flows. While it is possible to record information at designated locations (e.g., airports), it is much more difficult to reliably collect detailed movement data of target groups over larger geographical regions. In these cases, insights on the nature of human traveling behaviors and motivations that uncover hidden patterns in these processes are crucial as they may be used to sidestep the need for excessively detailed and thus unreachable data [37-39].

We aimed to provide accurate descriptions of how infected travelers may distribute in a territory, which could be valuable input for local authorities in the design of cost-effective VBD prevention and control strategies. For this, we approximated the local distribution of travelers arriving at a specific country (or any other territory) in terms of readily available indicators, rather than considering travel information that is usually not quantified at a local scale. These statistics gauge the appeal of each region to foreign travelers, quantifying the number of imported cases each region may receive. We calibrated our model with the number of imported cases of dengue and malaria at each province in Spain from 2015 to 2018 and then performed validation by comparing our model’s estimates for the number of imported cases in 2019 with official data.

Methods

Travelers’ Distribution

We first developed a theoretical framework to estimate how travelers distribute throughout the territory after their arrival in the country. See Figure 1 for a schematic description of this approach.
Figure 1. Summary of the rationale behind our approach. Infected travelers arrive at the importing country from $L$ exporting countries across the world by means of air travel. For each country $k$, the prevalence of the disease in the country ($p_k$) and the number of travelers arriving from it to the importing country ($a_k$) are combined to obtain an estimate of the number of imported cases ($p_k a_k$). These spread across $R$ regions or spatial units of the importing country following a distribution that can be estimated by means of the “travelers’ index.” The index is computed from local statistics concerning economic and touristic activity and the number of foreign residents at each region. The travelers’ index $v_{ki}$ measures the proportion of imported cases from country $k$ moving to local region $i$ upon arrival at the importing country. The total number of cases expected to arrive at the region ($c_i$) is then obtained as the sum of the estimated number of imported cases over all exporting countries: $c_i = \sum p_k a_k v_{ki}$. AENA: Aeropuertos Españoles y Navegación Aérea (Spanish Airports and Aerial Navigation); GHDx: Global Health Data Exchange; INE: Instituto Nacional de Estadística (Spanish National Statistics Institute).

Input Data

We used the following yearly statistics from 2015 to 2019 to compute the relative appeal of each province in Spain to international travelers, which are publicly available and curated by the Spanish National Statistics Institute [40]:

- **Tourist indicators:** For both hotels and tourist apartments, we used the variables total capacity, number of national travelers, number of foreign travelers, number of overnight stays by national travelers, and number of overnight stays by foreign travelers.

- **Economic indicators:** We considered each province’s population, gross domestic product (GDP), GDP per capita, number of private limited companies (Sociedades Limitadas), and number of public limited companies (Sociedades Anónimas).

- **Indicators for visits to friends and relatives:** For each country and province, we used the number of foreign residents by nationality, number of foreign residents by birthplace, and number of national residents by birthplace (other than Spain).

The following 3 additional data inputs were used in our approach:

- **Arrival data:** We computed the yearly number of travelers arriving in Spain from 2015 to 2019 at each of the 100 airports with the largest flows of incoming travelers and aggregated publicly available monthly data provided by the public entity in charge of the Spanish Airports and Aerial Navigation (Aeropuertos Españoles y Navegación Aérea, AENA) [41].

- **Disease data:** We used yearly prevalence estimates for malaria and dengue from 2015 to 2019 provided by Global Health Data Exchange (GHDx) [42]. Data on malaria were supplied by the Malaria Atlas Project [43].

- **Cases in Spain:** The number of imported cases of malaria and dengue (including any type of infection by the dengue virus) is reported by each province to the Spanish National Surveillance System (Red Nacional de Vigilancia Epidemiológica, RENAVE). These data were used.

Travelers’ Index

We have described the rationale used to combine the above statistics in an informed indicator to estimate the propensity of international travelers to move to a specific region. We considered a country that receives travelers from other countries of the world (these are denoted as importing and exporting countries, respectively). We assumed that the importing country is divided into regions, which may represent geographical regions or administrative units, for instance.

Motivations for international travel are usually classified into 3 major categories: tourism, business, and visits to friends and relatives [44,45]. Based on this principle, we computed the relative importance of each region in the importing country in
terms of each of these drivers as follows: \( t_i \) measures the relative importance of region \( i \) in terms of tourism, \( e_i \) measures the relative importance of region \( i \) in terms of economy, and \( r_{ik} \) measures the relative importance of region \( i \) in terms of visits to friends and relatives for travelers arriving from country \( k \).

The last indicator depends on the exporting country \( k \). For instance, when computing the travelers’ index with \( k=\text{Brazil} \), only the number of Brazilian residents is considered in the computation. The 3 indicators were computed from several available statistics concerning the regions of the country (see the Input Data subsection) as the relative contribution of each region to the country’s total. For instance, when using GDP to measure economic status, the relative importance of region \( i \) in terms of economy would be as follows:

\[ t_i = \frac{\text{GDP of region } i}{\text{total GDP of the importing country}} \tag{1} \]

We then computed the travelers’ index for each region \( i \) of the importing country and any exporting country \( k \) as the average of the 3 indicators as follows:

\[ v_{ik} = \frac{1}{3} \left( t_i + e_i + r_{ik} \right) \tag{2} \]

It follows from equations 1 and 2 that for each exporting country \( k \), the sum of the travelers’ index of the country over all the regions \( i \) of the importing country is as follows:

\[ \sum_{i} v_{ik} \]

Therefore, given an exporting country \( k \), the travelers’ index \( v_{ik} \) may be understood as an estimate of the portion of travelers \( a_k \) arriving from this country to each province \( i \). Hence, we can estimate the total number of travelers arriving at a given region \( i \) as follows:

\[ \sum_{k} a_k p_k v_{ik} \]

where the sum runs over all exporting countries \( k \), and \( a_k \) is the total number of travelers arriving from any such country \( k \). Accordingly, we estimated the number of imported cases of a disease at each province \( i \) as the sum of the imported cases from each of the exporting countries \( k \) as follows:

\[ \sum_{k} a_k p_k v_{ik} \]

where \( p_k \) denotes the prevalence of the disease in the exporting country \( k \). Plainly speaking, we estimated the total number of cases arriving from country \( k \) as the product of the total number of travelers arriving from the country and the prevalence of the disease in the country. We then estimated how these cases disseminate across regions by means of the travelers’ index, which assigns to travelers a relative importance or preference for each of the regions. Adding these local distributions over all the exporting countries resulted in the total number of expected cases at each of the regions in the importing country. See Figure 1 for a visual representation of this reasoning.

**Model Calibration and Validation**

In order to test the validity of our approach, we followed the pipeline depicted in Figure 2. The steps involved in this process were (1) input variables, (2) model fitting, (3) model selection, and (4) model validation and assessment.

**Input Variables**

We considered data from Spain (importing country) and its 52 provinces (regions over which the imported cases disseminate). We computed the relative importance of \( t_i, e_i, \) and \( r_{ik} \) using each of the statistics listed in the Input Data subsection for each of the 3 drivers (ie, tourism, economy, and visits to friends and family).

**Model Fitting**

We used equation 2 to construct the travelers’ index (1 for each possible combination of the indicators). We combined these with arrivals and prevalence data to obtain estimates for the expected number of cases at each province for 2015-2018 (equation 4), resulting from simple averages of the indicators \( t_i, e_i, \) and \( r_{ik} \). We also considered a generalized version of the travelers’ index by replacing the average in equation 2 with a weighted average as follows:

\[ t_i = \text{GDP of region } i / \text{total GDP of the importing country} \tag{1} \]

**Model Selection**

To identify which travelers’ index best approximates the number of imported cases per province, we computed the correlation

\[ 0 \leq a_j \leq 1 \text{ and } a_1 + a_2 + a_3 = 1. \]
between the estimates provided by each of our models (1 for each combination of indicators) and the actually reported cases of malaria and dengue at each province for the years 2015 to 2018. The model reporting the highest value for this correlation was selected as the best model. We followed the same procedure for the case of the weighted averages, and a different estimate was obtained for each choice of the indicator and weight $a_j$.

**Model Validation and Assessment**

As a final test for accuracy, we computed the correlation between the best model’s estimates for 2019 (data not used during the fitting and selection process) and the officially reported cases for this year, both for the simple and weighted averages. In case this correlation was high, we considered the model as validated and proceeded to the next step.

We assessed 3 features of the resulting model. First, we fit a linear model explaining the estimated number of imported cases at each province in 2019 in terms of the officially reported cases. The coefficient of the linear model may be understood as the number of cases predicted by the model per officially reported case, thus informing of the overestimation or underestimation of the model’s prediction of actually reported cases. This refers only to the raw number of cases as the accuracy of the distribution is captured by the validated correlation. Second, we ranked the contribution of each of the statistics considered in the model by computing the average correlation with 2019 official data of those estimates obtained from models including each particular variable. We also computed the average loss of accuracy associated with each variable as the difference in the average correlation of those models including and not including each statistic. This allowed us to identify which statistics among the choices made for each indicator $t_i, e_i$, and $r_{ij}$ provided more reliable predictors of the disease. Third, we followed an analogous procedure for the assessment of the weighted averages and computed the average correlation of those models built from each choice of the indicator and weight $a_j$. Those indicators scoring higher for larger values of the corresponding weight were expected to inform about the motivations of the travelers carrying each disease among business, tourism, and visits to friends and relatives.

**Human Mobility Model**

Finally, we tested the validity of our results against a well-established model for human mobility [46,47], assuming that the movement of travelers does not follow motivations different from those of resident populations. For this, we assumed that, on arrival to their destination airport in Spain, a proportion $q$ of imported cases stay at that destination and the rest move to a different province following a well-known, generic, and random human mobility pattern [47,48]. The probability of these travelers moving to each province in Spain is assumed to follow a decaying power law with exponent $\gamma$ on the distance $d$ between the origin and destination province centroids ($p(d) = d^{-\gamma}$).

We then grouped the total number of expected cases at each province as the sum of those arriving at the province according to their final flight destination and those arriving from any other province by means of other transport modes reflected in a geographically bounded power law distribution. This model was then fitted to the data on the officially reported cases of dengue and malaria from 2015 to 2018 for values of $q$ between 0 and 1 (proportion of travelers who leave their destination province upon arrival) and values of $\gamma$ between 1 and 5 (exponent of the power law, with lower values favoring longer-ranged movement and higher values favoring shorter-ranged movement).

We followed an analogous philosophy for the model building and assessment process as in the travelers’ index model. The parameters leading to the highest correlation with the reported cases for the period of 2015 to 2018 were used to compute an estimate for 2019, and the correlation between this estimate and the 2019 official record was then computed to allow for comparison with the travelers’ index model. A linear model between the human mobility model’s estimate and the official 2019 record was also fitted to assess the underestimation or overestimation of the model.

**Ethical Considerations**

Our study used publicly available aggregated secondary data with no characteristics that allowed for individual identification. There are no relevant data protection and privacy issues to report.

**Results**

**Input Data**

A preliminary analysis showed that among all statistics used, those concerning the same drivers were usually highly co-dependent, with some exceptions (eg, GDP per capita; see Figures S1 and S2 in Multimedia Appendix 1 [40]). The relative importance appearing in the computation of the travelers’ index (equation 2) showed little variation over the years (see Figure S3 in Multimedia Appendix 1). This temporal stability has been observed before in the distribution of international [37] and national [49] human mobility flows across destinations, which have been obtained from expressions analogous to equation 1.

The 100 airports with the highest number of incoming travelers were located in 49 countries and accounted for 99.75% of the total incoming travelers to Spain from 2015 to 2019. Out of these countries, 10 were removed from our study as neither malaria nor dengue was present during the time span under study (according to prevalence data from GHDx), resulting in 39 exporting countries. Table 1 shows the number of incoming travelers from each of these countries and the average prevalences of dengue and malaria from 2015 to 2019 as provided by GHDx.

aCountries with no malaria or dengue prevalence have been removed from the list.
bTotal incoming travelers and average malaria and dengue prevalences (total cases per 100,000 inhabitants) from 2015 to 2019 for the 39 exporting countries.
Estimates and Model Assessment

High correlation values were found for both malaria (0.94) and dengue (0.86) between the best model’s estimates for 2019 and the notified cases. The models that provided the most accurate estimates included public limited companies, foreign travelers at hotels, and foreign residents by birthplace in the computation of the travelers’ index. The same variables led to the best estimates for both malaria and dengue. While considering weighted averages in the construction of the travelers’ index did not improve the accuracy of the models, different motivations were obtained for travelers carrying each of the diseases: economy seemed to best capture the appeal of each region for imported cases of malaria (relative weight of 0.7, with GDP being the most accurate indicator) and visits to friends and relatives seemed to be the main motivation for travelers with dengue (relative weight of 0.9, assigned to the number of foreign residents in the province by birthplace). Different proportions of overestimation were found for each disease (99% for malaria and 86.5% for dengue). A summary of the relevant features of the models provided by the fitting and selection process is presented in Table 2.

aFor the models including weighted averages, the weight $a_i$ of each indicator is included in parenthesis. If the weight of a given indicator is 0, no contribution to the estimate is provided by the corresponding indicator.

bEach row shows the statistics that provide the best estimate of imported cases of each disease, the correlation with the actually reported data in 2019, and the approximation for the proportion of overestimation as obtained from the linear models.

cGDP: gross domestic product.

Figure 3 shows the fit of the weighted models and their estimates for 2019, together with the officially reported number of cases of each disease (malaria and dengue) at each province in Spain. Upon visual inspection, 2 provinces seemed to have a high influence on the fit of the models. These corresponded to Madrid and Barcelona, which hosted a much larger number of reported cases of both diseases. We excluded these provinces from the input data set and repeated the analysis (Table S1 and Figure S4 in Multimedia Appendix 1). While a decrease in correlation was found overall (approximately 0.12 over all models), the resulting estimates still showed high agreement with the official report for 2019 (above 0.74 correlation with 2019 data; see Figure 3, and Table S1 and Figure S4 in Multimedia Appendix 1).
Figure 3. Summary of the best linear models for 2019 imported cases of malaria (top row) and dengue (bottom row). The left column shows the predictions of the models (in red), together with the number of reported cases (in blue) for 2019 at each province in Spain. The right column shows the fit between the estimates of the models and the official records (inset figures correspond to the fit after removing Madrid and Barcelona from the data set).

We performed a residual analysis to check for normality and autocorrelation of the residuals of the models. The malaria model showed close-to-normal residuals with no autocorrelation (statistically significant $W=0.67$ and $DW=2.03$ in the Shapiro-Wilk and Durbin-Watson tests, respectively). For the dengue model, a relevant deviation was caused by the estimate for Barcelona (Figure 3). Exclusion of this outlier resulted in normally distributed and not autocorrelated residuals (statistically significant $W=0.94$ and $DW=1.87$). See Table S3 in Multimedia Appendix 1 for complete details on the residual analysis.

Variable Performance

The models constructed using simple averages provided a unanimous choice of indicators associated with tourism, economy, and visits to friends and relatives. On the contrary, the best weighted models included different economic indicators. GDP provided the best estimate for imported malaria cases, while no influence of the economic indicator was considered in the best dengue model. In addition, different drivers were the most important ones for each disease, as shown by the much higher relative weight for economic motivations in malaria cases and for visits to friends and relatives in dengue cases (Table 2).

When ranking the contribution of each of the variables to the accuracy of the models, similar results were found for both diseases, with some minor variations across variables (Table 3). Several statistics concerning tourism ranked the highest in this classification, although several others ranked in a low position, indicating that appropriate choices of indicators may be important and may need careful examination. All economic indicators provided an improvement (or absence of a decrease) in correlation, except for GDP per capita, which resulted in less accurate estimates (average decrease of approximately 0.08 in correlation with 2019 data). Indicators corresponding to visits to friends and relatives had mild average effects on the outputs of the models (the largest variation in correlation with 2019 data was $-0.02$).

<sup>a</sup>The average correlation of the estimates of the models including each variable in their fit with the officially reported 2019 data.

<sup>b</sup>The average difference in correlation between models including each variable in their fit and models not including each of the variables (variables ranked by the average correlation for predictions).

<sup>c</sup>GDP: gross domestic product.

A similar procedure was followed for the weighted models. The average correlation between the models including each variable and the 2019 official data was computed in this case with stratification by the weight assigned to the variable (Figure 4). In addition to the ranking of variables (similar to data in Table 3), this provided a measure of the variability of each variable’s contribution to the accuracy of the model in terms of the weight assigned to it. Smaller overall variations in model accuracy were identified for variables measuring visits to friends and relatives, for instance, while much larger variability was recorded for some tourist indicators. This shows the higher potential loss in accuracy that would result from including these variables in the models than including other variables.
**Figure 4.** Summary of each input variable’s performance on the estimates for malaria (A) and dengue (B). Each square in the figure is colored according to the average correlation between the official 2019 reports and the estimates provided by the weighted models including each of the variables, with the associated weight ranging from 0 (no contribution from the variable is assumed in the model) to 1 (the model only includes that variable). The variables are ranked from top to bottom according to the overall average correlation with 2019 data of the estimates of the models including each variable. GDP: gross domestic product; SA: Sociedades Anónimas; SL: Sociedades Limitadas.

### Comparison With a Generic Mobility Model

For both dengue and malaria, the human mobility models ranked higher in terms of correlation with 2019 data for higher values of the assumed proportion of travelers who do not move from their destination province upon arrival ($q$; see Figures S5 and S6 in Multimedia Appendix 1). Models also favored the choice of smaller values of the exponent of the power law distribution (highest average correlation with 2019 data for $\gamma=1$), indicating that longer movements may take place if a displacement occurs after arrival. Much higher variability in the correlation with...
Discussion

We computed estimates for the number of imported cases of malaria and dengue at each province in Spain based on simple methodological assumptions. Our approach makes use of readily available data and provides approximations of the actually declared number of cases of the disease. This advance may contribute to the adequate modeling and monitoring of VBDs, which might be relevant for effective outbreak prevention strategies. More efficient resource allocation strategies for both vector control and disease prevention can be designed if reliable predictions of the geographical locations of imported cases are available. By circumventing the need for detailed large-scale data on human mobility or traveler behavior, this methodology is accessible and suitable to be used in countries lacking more exhaustive data infrastructure, for instance [39,50]. The reasoning presented here could also be generalized to other choices of territories.

The high correlation found between our estimates and real data support the validity of our approach based on a priori theoretical conceptualization. This agreement in trend suggests that our estimates are reliable enough for the elaboration of scale-less risk indicators, for instance. On the other hand, our estimates of the raw number of imported cases were simplistic (product of yearly prevalence and total number of travelers), which resulted in substantial overestimation of the number of imported cases. For the case of malaria, this is coherent with the epidemiology of the disease, being more severe unless treatment is available and having a higher incidence in economically deprived populations [51]. These factors may prevent individuals with malaria from engaging in international displacements. For dengue, however, the identified overestimation (8 predicted cases per notified case) lies relatively close to previously obtained estimates of the underreporting of cases in other contexts [52]. This suggests that our approach could also provide a valid method for assessing the sensibility of epidemiological systems. In any case, our focus was on assessing the validity of the travelers’ index as a method to improve risk analysis, rather than developing a predictive model for imported cases of the diseases.

The proposed computation of the key indicators involved in our model (the travelers’ index \(v_B\)) has the advantage of being partially robust considering errors in declaration or incomplete data collection. Indeed, as these only involve the relative importance of each region in the country, correction factors are unnecessary in our approach, and incomplete data will yield equally valid estimates as long as the underreporting can be assumed to be comparable for all regions. Moreover, the little variation in time shown by these quantities (see Figure S3 in Multimedia Appendix 1) could allow for reliable estimates even when only past statistics are available.

A key finding in this direction is that while the impact of each particular indicator in the quality of the estimate was similar for both diseases, the relevant drivers for case importation were different (economic motivations for malaria cases and visits to friends and relatives for dengue cases). This may be due to the different nature of the motivation for international travel across countries in the world. Most malaria cases were imported from African countries, while travelers carrying dengue usually arrived from America or Asia (see Table S1 in Multimedia Appendix 1). Travelers arriving from these continents are expected to follow different motivations for international displacement. Actually, malaria cases imported to Spain in the pre-pandemic era were mainly due to visits to friends and relatives or migration in almost 75% of cases, corresponding to travelers following economic motivations [53]. On the other hand, dengue cases were imported mainly by tourist travelers or visits to friends and relatives [54].

Further evidence of the appropriateness of our approach was provided by a comparison with the human mobility model. While the validity of this model has been established in many contexts and is widely acknowledged [47], it provided much

less accurate estimates and was highly sensitive to data retrieval from provinces with a larger number of disease cases. This demonstrates the need to consider specific designs that take into account travelers’ behaviors and differentiate them from general resident population dynamics.

Future developments of our approach should cover the following improvements:

- Coupling with postimportation dynamics: Our framework could be integrated into more complicated models incorporating transmission dynamics that involve the life cycle of the disease within the vector and the host [55-58]. Well-developed approaches, such as compartmental models, could benefit from more precise estimates on the expected location of arrival of imported cases of diseases.

- Refining the gross estimate of imported cases: As mentioned above, we computed simple estimates for the total number of cases arriving to the importing country (product of yearly prevalence and total number of travelers). We focused on how these cases distribute over the regions of the importing country. Consideration of more elaborate estimates of these quantities or the local distribution of the disease in the exporting countries would probably yield more precise final estimates.

- Extending the scope of the model to other diseases: A particular feature of the treated examples is that virtually all incoming streams of travelers into Spain from regions where malaria and dengue are endemic, which may result in transmission, may be assumed to be associated with air travel. This may not be the case for other diseases and countries, for which detailed data on the total traveler flow or further development of the proposed methodology could be necessary. Similarly, other importation phenomena that may depend on human behavior or allocation of resources could be analyzed under our assumptions, such as passive mobility of vectors by human means of transportation [59] or migratory flows [60,61].

It should be noted that our model was focused on countries with high dengue and malaria prevalences, and hence, they were likely to export these diseases to Spain. However, this concept could be generalized to other types of risk-related importation scenarios like the transport of new vectors or exotic species (invasion biology), which is another crucial process in the spread of VBDs.

Several factors may be limiting the extent of our results. First, both malaria and dengue are diseases known to be subject to high underreporting [51,52]. Second, we validated our models with annual data, as data on the number of monthly reported cases were too noisy. In any case, model predictions could be generated at a higher temporal resolution by incorporating monthly numbers of arriving travelers in the country, for instance. Third, our model was designed to address the motivations of international travelers; however, a significant number of imported cases may correspond to national travelers returning to the country or individuals from other nonendemic regions, especially for dengue. It would be desirable to devise an accurate method to differentiate between these 2 types of travelers and incorporate both motivations in the model. Finally, geographical borders are not always the best spatial human structure [62], and therefore, the availability of data with a finer geographical resolution could result in significant improvements in our estimates. We also note that our model has been validated with data obtained prior to the COVID-19 pandemic, and differences may arise in the postpandemic era. Therefore, further validation with future data is desirable.

We have shown the validity of the travelers’ index as a method to estimate the distribution of imported cases of malaria and dengue from endemic regions. This is an appropriate way to improve disease risk prediction on the basis of human mobility patterns. Our methodology adds value to available socioeconomic information relevant to public health. Nonetheless, human mobility is just 1 component of VBD risk models. The other key components that need to be added are vector (mosquito) distribution and suitability. Our work will be combined with multi-sourced presence/absence and suitability vector data in Spain, including both authoritative and citizen science data collections [63], and integrated into the Spanish National Surveillance System for VBDs. Pairing the risk of importation of cases and the risk of local transmission through the presence of vectors will provide a more comprehensive evaluation of the threats posed by VBDs to public health.

Acknowledgments

The project leading to the present results has received funding from “la Caixa” Foundation (ID 100010434) under agreement HR-18-0036.

Data Availability

Indicators for tourism, economy, and visits to friends and relatives are available from the Spanish National Institute for Statistics [40]. Arrival data are available from the Spanish Aviation and Airports Office [41]. Disease prevalence data for exporting countries are available from Global Health Data Exchange [42]. Reported cases of dengue and malaria in Spain are collected by the National Surveillance System and managed by the Spanish National Center for Epidemiology, and the data are available upon reasonable request (contact email: vigilancia.cne@isciii.es).

Abstract

Background: In this study, we built upon our initial research published in 2020 by incorporating an additional 2 years of data for Europe. We assessed whether COVID-19 had shifted from the pandemic to endemic phase in the region when the World Health Organization (WHO) declared the end of the public health emergency of international concern on May 5, 2023.

Objective: We first aimed to measure whether there was an expansion or contraction in the pandemic in Europe at the time of the WHO declaration. Second, we used dynamic and genomic surveillance methods to describe the history of the pandemic in the region and situate the window of the WHO declaration within the broader history. Third, we provided the historical context for the course of the pandemic in Europe in terms of policy and disease burden at the country and region levels.

Methods: In addition to the updates of traditional surveillance data and dynamic panel estimates from the original study, this study used data on sequenced SARS-CoV-2 variants from the Global Initiative on Sharing All Influenza Data to identify the appearance and duration of variants of concern. We used Nextclade nomenclature to collect clade designations from sequences and Pangolin nomenclature for lineage designations of SARS-CoV-2. Finally, we conducted a 1-tailed t test for whether regional weekly speed was greater than an outbreak threshold of 10. We ran the test iteratively with 6 months of data across the sample period.

Results: Speed for the region had remained below the outbreak threshold for 4 months by the time of the WHO declaration. Acceleration and jerk were also low and stable. While the 1-day and 7-day persistence coefficients remained statistically significant, the coefficients were moderate in magnitude (0.404 and 0.547, respectively; P<.001 for both). The shift parameters for the 2 weeks around the WHO declaration were small and insignificant, suggesting little change in the clustering effect of cases on
future cases at the time. From December 2021 onward, Omicron was the predominant variant of concern in sequenced viral samples. The rolling test of speed equal to 10 became insignificant for the first time in April 2023.

**Conclusions:** While COVID-19 continues to circulate in Europe, the rate of transmission remained below the threshold of an outbreak for 4 months ahead of the WHO declaration. The region had previously been in a nearly continuous state of outbreak. The more recent trend suggested that COVID-19 was endemic in the region and no longer reached the threshold of the pandemic definition. However, several countries remained in a state of outbreak, and the conclusion that COVID-19 was no longer a pandemic in Europe at the time is unclear.

**Introduction**

**Background**

COVID-19, the disease caused by the virus SARS-CoV-2, was first detected in Wuhan, China, in the fall of 2019 [1-5]. The first European [6] case of COVID-19 was reported in France on January 24, 2020, with additional cases reported in Germany and Finland soon afterward [7,8]. Our research team conducted an analysis of the pandemic in Europe 1 year into the pandemic [9]; this study provides 2 additional years of updated surveillance and analysis for the region.

We adopt the World Bank’s definition of Europe, which is based on economic development and geographical proximity, encompassing Albania, Andorra, Austria, Belarus, Belgium, Bosnia and Herzegovina, Bulgaria, Croatia, the Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Greenland, Hungary, Iceland, Ireland, the Isle of Man, Italy, Latvia, Liechtenstein, Lithuania, Luxembourg, Moldova, Monaco, Montenegro, the Netherlands, Norway, Poland, Portugal, Romania, San Marino, Serbia, Slovakia, Slovenia, Spain, Sweden, Switzerland, Ukraine, the United Kingdom, and the Vatican City [6].

The World Health Organization (WHO) and Director-General Tedros Ghebreyesus declared the end of COVID-19 as a public health emergency of international concern on May 5, 2023 [10-12], based on the recommendation of the COVID-19 Emergency Committee [12]. To that end, we compared how the pandemic was progressing before and after the declaration.

**Empirical Definition of Pandemic Versus Epidemic Versus Outbreak Versus Endemic**

Epidemiological terms, such as pandemic, epidemic, outbreak, and endemic, are used to describe the occurrence and spread of diseases [13,14]. The distinctions between these terms lie in their scope, geographic extent, and severity. An epidemic refers to a sudden increase in the number of disease cases in a specific population or region. If the epidemic spreads across several countries or continents, it becomes a pandemic. An outbreak, on the other hand, describes a sudden increase in a concentrated setting, usually involving a more limited geographic area than an epidemic. Endemic refers to the constant presence of a disease in a particular geographic region or population, with no sudden increases in case volume [15,16].

**Traditional Surveillance Versus Enhanced Surveillance**

Public health surveillance is the “ongoing, systematic collection, analysis, and interpretation of health-related data essential to planning and evaluation of public health practice” [17]. Surveillance not only explains the burden of death and disease due to a virus but also generates research questions and guides researchers on topics that require further investigation [18-32]. Surveillance allows us to compare the burden of disease between geographical regions and to understand which regions are most impacted. The impact can be measured through rates of how many people contract a disease and how many die, as well as the affiliated costs.

However, traditional surveillance carries several limitations that this study had addressed. Traditional surveillance provides a snapshot of what has already happened [18-32], meaning surveillance is static and only considers the past. In the middle of a burgeoning pandemic, policy makers and public health practitioners also need to understand what is about to happen. Is an outbreak increasing? Will growth switch from linear to exponential? Are more people dying from that particular condition in one place than another? To inform health policy and practice, knowledge of what is about to happen is often more valuable than knowledge of what did happen. To that end, we have developed enhanced surveillance metrics that reflect the dynamics of a pandemic and inform imminent growth, most importantly, where along the epidemiological outbreak curve a particular region is situated. We have also included dynamic metrics about the speed of the pandemic at the national, regional, and global levels and measured how the acceleration of speed this week compared to last week, as well as how novel infections last week would predict new cases this week. We can think of the latter measure as the echoing forward of cases. These metrics were tested and validated in prior research [9,33-43].

The novel metrics add acceleration, jerk, and 1-day and 7-day persistence to the traditional measure of speed. The rate of new COVID-19 cases per 100,000 population is the “speed” of the pandemic. Acceleration is the difference in speed from one unit to the next. We define the rolling test of speed equal to 10 as becoming insignificant for the first time in April 2023.
of time to the next. A positive (negative) acceleration means cases are rising (falling), and an acceleration of 0 indicates an inflection point or stable speed. From physics nomenclature, “jerk” is the change in acceleration from one time interval to the next. A positive jerk may indicate explosive growth in a disease. Finally, 1-day and 7-day persistence measures capture the impact of the 1-day and 7-day lag of speed on current speed. These measures derive from an Arellano-Bond dynamic panel data model, and they capture the echo-forward effect of COVID-19 cases on future cases either 1 or 7 days later [44].

This research team used these metrics to effectively analyze the role of economic reopening on COVID-19 transmissions [42]. These metrics also provided the status of the pandemic in global regions, including Europe [9]. Finally, they helped quickly identify the emergence of the Omicron variant, and they were used in policy briefs throughout the pandemic [45].

For the purpose of this study, standard surveillance metrics explain what has already happened in Europe, while enhanced surveillance metrics speak to what is about to happen or where along an epidemiological curve a country may sit. We used both types of metrics to analyze the possible end to the pandemic.

Objectives

This study has 3 objectives. First, we aimed to measure whether there was an expansion or contraction in the pandemic in Europe when WHO declared the end of the COVID-19 pandemic as a public health emergency of international concern on May 5, 2023. At both the region and country levels, we used advanced surveillance and analytical techniques to describe the status of the pandemic in a 2-week window around the WHO declaration. From a public health perspective, we need to know whether the rate of new COVID-19 cases was increasing, decreasing, or stable from week to week and whether any changes in the transmission rate indicated an acceleration or deceleration of the pandemic. Statistical insignificance is significant; it can signal the epidemiological “end” to the pandemic if the rate of new cases is 0 (or very low) and stable, meaning the number of new cases is neither accelerating nor decelerating.

Second, we used dynamic and genomic surveillance methods to describe the history of the pandemic in the region and situate the time window around the WHO declaration within the broader history. We included the ratio of COVID-19 deaths to the number of transmissions as a proxy for the mortality risk from infection at the population level. We also included a historical record of genomic surveillance from sequenced viral specimens to identify the appearance and spread of variants of concern in the region.

Third, we aimed to provide historical context for the course of the pandemic in Europe. We addressed several questions. How did countries respond to the pandemic? How did the region fare in terms of disease burden? Furthermore, what social, economic, and political factors shaped the course of COVID-19 in the region? This context can provide important lessons for disease prevention and mitigation in future pandemics.

Methods

Overview

This study conducted trend analyses with longitudinal COVID-19 data from Our World in Data [46]. This study provides updates of traditional surveillance data and dynamic panel estimates from the original study by Post et al [9,41,42,47,48]. For the region of Europe, the data comprised an unbalanced panel of 44 countries and territories, running from August 14, 2020, to May 12, 2023. Because a number of countries around the world switched from daily to weekly reports at various points in 2023, we used a cubic spline to interpolate daily new cases and deaths if any country had 4 consecutive periods of nonzero new cases interspersed by 6 days of 0 new cases.

To identify the appearance and duration of variants of concern, we also used data on sequenced SARS-CoV-2 variants from the Global Initiative on Sharing All Influenza Data (GISAID), which is an effective and trusted web-based resource for sharing genetic, clinical, and epidemiological COVID-19 data [49-52]. We used Nextclade nomenclature [53] to collect clade designations from sequences and Pangolin nomenclature for lineage designations of SARS-CoV-2 [54,55]. Metadata for the study period, which add geographic location to the clade designations, were collected on June 22, 2023. To avoid low-frequency or potentially erroneous samples, the data set was further filtered to exclude months with <100 available samples, variant groups with <5 samples in a month, and variant groups representing <0.5% of the total samples in a month. The final data set consisted of 184,386 total samples available on GISAID [49-52].

We analyzed the potential “statistical end” to the pandemic with a 1-tailed t-test for whether the mean of speed was equal to or greater than the outbreak threshold of 10. We ran the test on a rolling 6-month window over weekly speed for the region, and we plotted the P values from the test over time. All statistical analyses were conducted in R (version 4.2.1; R Foundation for Statistical Computing) with the plm package (version 2.6-2) [47,56].

Ethical Considerations

This study does not constitute research with human participants (as defined by 45CFR46.102) because all data are publicly available and contain no identifiable private information. The institutional review board’s review was therefore unsolicited.

While the 1-day and 7-day lag coefficients were positive and statistically significant (P<.001 for both), they were moderate in magnitude (0.404 and 0.547, respectively). For example, the 7-day coefficient suggests a cluster effect in which 1 case on a given day predicts 0.547 cases 1 week later. The shift parameters for the weeks of April 28, 2023, and May 5, 2023, were small and statistically insignificant (P=.42 and P=.48, respectively), however, suggesting the cluster effect of cases remained stable around the window of the WHO declaration.

The dynamic panel estimates have several advantages over the basic reproductive number, R₀, which estimates the average number of people a contagious person will infect [57]. Foremost, R₀ depends on many variables, such as social distancing, vaccination rates, demographics, and the transmissibility of a pathogen. Because the SARS-CoV-2 virus has mutated over time, so has its R₀, but rapidly updated estimates for R₀ are difficult to obtain. Vaccination campaigns and public health mitigation efforts have also evolved and thereby shaped R₀. The dynamic panel estimates are based on a recent, 120-day window, so they can quickly adjust to new circumstances. The Arellano-Bond model is also robust to time-invariant, unobservable factors (in the application, stable differences between countries); corrects for autocorrelation; and allows for statistical tests of various model parameters [42].

The Wald and Sargan tests can assess the validity of the dynamic panel model. The Wald hypothesis test checks whether the independent variables have explanatory power for the dependent variable. From Table 1, the Wald test was highly significant (P<.001), rejecting the null hypothesis of no explanatory power. The Sargan test checks the validity of the overidentifying restrictions of the model. A rejection of the null would be evidence against the validity, but the test failed to reject the null with P>.99.

**Statis Surveillance Metrics**

Static surveillance metrics for the weeks of April 28 and May 5, 2023, are provided in Tables 2 and 3.
Table 2. Static COVID-19 surveillance metrics for European countries for the week of April 28, 2023.

</table>
Most countries had a transmission rate considered low by the US Centers for Disease Control and Prevention [9,33-43,58]. Specifically, a “low” transmission is considered to be no more than 10 cases per 100,000 people per week. “Moderate” transmission is 10 to 50 cases per 100,000 people per week. “Substantial” transmission is 50 to 100 cases [58,59]. However, a number of countries were in a state of outbreak. In particular, Greece had a speed of 119 new cases per 100,000 population in the week of April 28, and San Marino had a speed of 45. Greece was therefore in a “substantial” outbreak, while San Marino was in a “moderate” outbreak. Austria, Croatia, Malta, Romania, Spain, Switzerland, and Ukraine were also in “moderate” outbreaks.

By the following week, only Greece, Romania, San Marino, Spain, and Ukraine remained in an outbreak. While speed dropped notably for San Marino, speed alarmingly increased for Greece and Spain. We noted that speed in island nations often vacillates between high and low rates of transmission.

Overall, the status of the pandemic around the WHO declaration in Europe is consistent with an “end” to the pandemic, but the distinction is muddied by continued outbreaks in several countries. The outbreaks in Greece and San Marino comprise a small portion of the overall European population, and speed is more variable in island nations. On the basis of the definition of a pandemic or an outbreak in several countries, the data suggest a shift from pandemic to endemic COVID-19, but the continued outbreaks in 3 other countries do caution that the conclusion may be premature.

Comparing Tables 2 and 3 demonstrates a drop in transmission rates before and after the WHO declared an end to COVID-19 as a public health emergency. Overall, the United Kingdom, Italy, and Germany had the most cases of COVID-19 transmissions and deaths, but these ranks are largely a function of population size. Thus, a better measure of COVID-19 fatality risk is the number of COVID-19 cases and deaths per 100,000 people. Moreover, death is often a better proxy for the state of an outbreak than transmissions because deaths are less likely to be undercounted [60]. Undercounting may be due to poor public health infrastructure, home antigen testing, or a dearth of polymerase chain reaction testing or other resources. When we control for the risk of death given the number of COVID-19 transmissions, we find that Eastern European countries, such as Bosnia and Herzegovina, Moldova, and Poland, had the highest conditional death rates. For example, Bosnia and Herzegovina had the highest conditional death rate of 0.04 deaths per confirmed case. These disparities could be driven by differences in public health infrastructure, demographics, and the influx of refugees from the Russian invasion of Ukraine.

Enhanced Dynamic Surveillance Metrics
Tables 4 and 5 contain enhanced dynamic surveillance metrics for the weeks before and after May 5.

We note that the figures in Tables 4 and 5 are not calculated as day-over-day averages across the week, as they are in Tables 2 and 3. Thus, the magnitudes of speed differ slightly across the tables. Again, by the week of May 5, speed was low for every country except Greece, Romania, San Marino, Spain, and Ukraine. The 7-day persistence effect on speed was also relatively high for these countries but low for others. Acceleration was almost uniformly negative, with the exception of Greece and Spain, which saw their outbreaks grow somewhat from the first week to the second. Across the board, jerk tended to be very small in magnitude, suggesting little change in acceleration rates.

Table 6 compares the 7-day persistence effect on speed for the top 5 countries around the 2 weeks of the WHO declaration. These ranks largely reflect the speed in the countries with outbreaks in the prior tables.
Table 4. Novel surveillance metrics for European countries for the week of April 28, 2023.

These metrics suggest that the pandemic may have ended in the region. Still, speed and persistence measures were moderate to high for several countries in outbreaks, and the region had not exited the pandemic with as much clarity as had several other global regions, such as South Asia or sub-Saharan Africa.

Figure 1 plots regional speed, acceleration, jerk, and 7-day persistence metrics from August 14, 2020, to May 12, 2023.

Figure 1. Novel surveillance metrics (speed, acceleration, jerk, and 7-day persistence) for COVID-19 transmissions in Europe from August 2020 to May 2023.

The region did see a slight bump in cases around the end of February 2023. Still, the bump did not cause the region to cross the outbreak threshold.

Europe saw one especially pronounced outbreak over the course of the pandemic. The outbreak caused speed to reach a peak of 246 novel COVID-19 cases per 100,000 population in the last week of January 2022. Figure 2 plots variant groups as a proportion of all viral specimens collected and sequenced in the region (and made available through GISAID) each month. The outbreak occurred just after the arrival of the Omicron variant. Europe, like much of the rest of the world, saw a surge in cases amid the heightened transmissibility of Omicron [45]. Earlier outbreaks were driven by the ancestral, Alpha, and Delta variants.
Another potential indication of the end of the pandemic is the continued dominance of the Omicron variant. Subclades of Omicron continue to circulate 4.5 months after WHO declared the end of the COVID-19 emergency [61]. Viral sequences have almost exclusively returned as Omicron and its subvariants ever since its arrival.

Figure 3 plots $P$ values from a series of 1-tailed $t$ tests of whether speed for the region was equal to or greater than the threshold outbreak of 10. These tests were conducted over a rolling 6-month window of weekly regional speed. The dashed gray line denotes the least restrictive conventional significance level threshold of $\alpha=0.10$. The test strongly rejected the null in favor of the alternative until the very end of April 2023. While this more recent lack of statistical significance is consistent with the end of the pandemic in the region, its relative recency around the WHO declaration suggests prematurity in the conclusion that COVID-19 had transitioned from the pandemic to endemic phase in Europe.

**Figure 2.** Variants of concern (VOCs) as a proportion of all sequenced SARS-CoV-2 specimens from April 2020 to May 2023 in Europe.

**Figure 3.** $P$ values from $t$ tests of weekly COVID-19 transmissions per 100,000 people equal to 10 over a rolling, 6-month window in Europe.
Figure 4 provides a timeline of the onset of COVID-19 in Europe as well as vaccination programs and major events that likely shaped the course of disease control, such as the Next Generation European Union (NGEU) economic recovery package and the Russian invasion of Ukraine. Millions of refugees fled Ukraine, accelerating the spread of disease in the region. Mass human migration is affiliated with increased disease transmission [62].

Figure 4. Timeline of the COVID-19 pandemic in Europe. EU: European Union; VOC: variants of concern; WHO: World Health Organization.
Discussion

**Principal Findings**

Multiple metrics suggest the pandemic had largely subsided in Europe by the time of the WHO declaration. Regional speed acceleration and jerk were both low and stable. The 1-day and 7-day persistence coefficients did remain statistically significant ($P<.001$ for both), but the coefficients were moderate in magnitude, and the shift parameters for the weeks around the WHO declaration were insignificant. This statistical insignificance implies no change in the clustering effect of cases on future cases at the time. The rolling $t$ test of speed equal to 10 became insignificant for the first time in the month ahead of the declaration. Finally, Omicron had been the predominant variant of concern in sequenced viral samples for approximately 6 months.

Still, among the 44 countries in Europe, 5 had surpassed the outbreak threshold at the time of the WHO declaration. While the region as a whole did not breach the outbreak threshold, 5 countries were classified as having epidemic status, with 4 being categorized as having mild epidemics. Our analysis of transmission rates, outbreak testing, and statistical findings suggests that the pandemic is likely concluding in Europe. Nevertheless, exercising caution, we refrain from definitively declaring the end of the pandemic at the time of the WHO declaration.

**History of Policy and Disease Burden**

For a brief history of policy and disease burden, differences in health outcomes across countries remained relatively minor despite heterogeneity in European COVID-19 mitigation efforts in terms of school closures, business restrictions, quarantines, social distancing, and mask mandates [63]. For instance, Denmark implemented the most stringent measures, while Sweden pursued a comparatively relaxed approach [63,64]. The environment and climate factors also factored into differential transmission and death rates [64,65]. Notably, widespread vaccination efforts proved effective in reducing the severity of COVID-19 cases and lowering mortality rates [66].

Age structure and environmental risk factors such as pollution affected the COVID-19 pandemic at its onset [67]. Italy reported their first cases in March 2020 [68-70]. Hospitals and cities lacked preparedness, with the initial wave claiming 35,000 lives [68]. Similar challenges were observed in France, which struggled despite having robust health care resources [7,68,71-74]. Around 6 months into the pandemic, France had one of the highest prevalence rates of the virus in Europe, with >2 million cumulative confirmed cases at the time [73]. Despite benefiting from a universal health insurance system, centralized presidential regime with a strong public administration, and a relatively high number of health care professionals and hospital beds compared to other European countries, France was still underprepared for the pandemic’s onset, with the health care system soon overwhelmed by cases and fatalities [73,75]. During the peak months in 2020, Spain, Belgium, and Ireland had the highest incidence and mortality rates [76]. European health care systems improved as vaccines became available [77]. Despite difficulties, Europe’s health care system benefited from risk recognition, treatment availability, and increased vaccine access [78-81]. Throughout the pandemic, new variants and fluctuating social protection measures have led to additional waves of infection [82,83]. Since this time, case rates have fallen despite mild rebound periods, with the COVID-19 social and financial recovery in Europe benefiting from rapidly decreased social restrictions and unprecedented monetary investments [84].

**Policies Implemented to Control and Mitigate the Transmission of COVID-19**

When the WHO declared COVID-19 a pandemic [85], Europe was the epicenter [86]. The European Union (EU) responded by closing external borders [7,87], but public reactions to social restrictions were volatile, leading to protests [88,89]. Despite this, Europe adapted to new regulations and accelerated its digital transformation [90,91].

The pandemic caused a 4% economic decline in Europe in 2020, with wide variation between countries [92]. To aid response, the EU allocated funds, including €140 million (US $159.6 million) in emergency funding [93]. Member states received continuous support through programs such as European instrument for temporary Support to mitigate Unemployment Risks in an Emergency [94,95]. In addition, in July 2020, the European Council, the European Commission’s sibling executive arm in the EU, agreed to an unprecedented €750 billion (US $855 billion) recovery package titled NGEU to be disseminated to member states through the end of 2023 [96]. NGEU, the largest stimulus package in European history, included special investments in future health care preparedness and modernization [97].

The EU’s Health Security Committee held its first meeting regarding COVID-19 on January 17, 2020, with the first mobilization of COVID-19 research funds taking place on January 31, 2020 [94]. Early efforts were made in conjunction with member states to secure medical equipment and protective gear for health care workers and ensure the free movement of critical workers to and around the EU [94]. Lockdowns and travel restrictions put in place by mid-March 2020, which is approximately when Italy’s total death toll overtook China during the first wave of the pandemic, affected >250 million Europeans [98]. As the pandemic intensified in the spring and summer of 2020, the European Commission partnered with Global Citizen and the European Investment Bank to develop tests, treatments, and vaccines with >€10 billion (US $11.4 billion) in new funds [94]. The most stringent virus mitigation orders in the United Kingdom came from Prime Minister Boris Johnson and the House of Commons in late March 2020, which granted the prime minister emergency powers to enforce widespread lockdowns and travel restrictions [99].

**Vaccination Campaigns**

Europe’s vaccination strategy featured early collective bargaining, resulting in 2.8 billion vaccine doses secured for member states through an advance purchase agreement in June 2020 [93]. The United Kingdom administered its first vaccine dose on December 8, 2020 [100], and by August 2021, the EU had fully vaccinated 70% of its adult population, exporting >1
billion vaccine doses to low- and middle-income countries by October 2021 [94]. However, some Eastern European countries, such as Hungary, Poland, Romania, and Bulgaria, lagged behind with <65% of their populations fully vaccinated by February 2022 [101].

In total, 4 vaccines received emergency use authorization and were widely used in Europe throughout the pandemic: BioNTech or Pfizer, Moderna, Oxford or AstraZeneca, and Johnson & Johnson [102-104]. Vaccine development, approval, and rollout occurred in rapid fashion due to collective efforts by regulatory agencies, private pharmaceutical companies, public universities, and public health agencies [102].

Humanitarian Crises
During the Omicron surge in early 2022, Russia’s attack on Ukraine displaced two-thirds of Ukrainians, leading to surges in Omicron and other infectious diseases, including tuberculosis. This conflict hindered COVID-19 vaccine distribution and access to essential medical services, such as HIV treatment [105-107]. Ukrainians faced obstacles in migrating without vaccination proof, as only 36% were vaccinated when the war began [108-113].

Europe absorbed many refugees during the COVID-19 pandemic, including those fleeing political unrest and violence in the Middle East and Eastern Europe [114,115]. In addition to overcrowded and unsafe living conditions and limited access to financial or medical support, many migrants were unable to access timely COVID-19 vaccination [114,115]. Some countries, like Spain, prioritized migrant vaccination, while Portugal granted temporary residence to ensure equal access [115].

Limitations
The COVID-19 data had become less frequently reported around the world by the time the WHO declared an end to the pandemic public health emergency [116]. In addition, more people began to use at-home tests as the pandemic evolved [117], and the Russian invasion of Ukraine damaged public health infrastructure, which may have reduced the accuracy of reported cases in the region. Because the enhanced surveillance metrics of speed, acceleration, jerk, and 7-day persistence are based on rates, not total counts, statistical bias caused by countries dropping in or out of the sample is mitigated, but to the extent that a nonincluded country is unrepresentative of the region in disease burden; the omission of a country or territory can still influence historical data comparisons. Viral specimen tests for variants of concern in GISAID are also dependent on testing and sequencing capacity, which varied by country across the region.

Conclusions
While there is significant evidence indicating that the pandemic in Europe has transitioned to an endemic phase, the persistent risk of new COVID-19 variants underscores the need for vigilance, robust vaccination campaigns, and international cooperation to effectively curb the spread of coronavirus in the region [40]. As the data on transmissions become less frequent [117] and as pandemic fatigue grows [118], the challenge of vigilance also evolves. The public health lessons from European policy and disease burden can inform not only the continued challenge but also responses to inevitable future pandemics.

Abstract

Background: The decline in global child mortality is an important public health achievement, yet child mortality remains disproportionately high in many low-income countries like Guinea-Bissau. The persisting high mortality rates necessitate targeted research to identify vulnerable subgroups of children and formulate effective interventions.

Objective: This study aimed to discover subgroups of children at an elevated risk of mortality in the urban setting of Bissau, Guinea-Bissau, West Africa. By identifying these groups, we intend to provide a foundation for developing targeted health interventions and inform public health policy.

Methods: We used data from the health and demographic surveillance site, Bandim Health Project, covering 2003 to 2019. We identified baseline variables recorded before children reached the age of 6 weeks. The focus was on determining factors consistently linked with increased mortality up to the age of 3 years. Our multifaceted methodological approach incorporated spatial analysis for visualizing geographical variations in mortality risk, causally adjusted regression analysis to single out specific risk factors, and machine learning techniques for identifying clusters of multifactorial risk factors. To ensure robustness and validity, we
divided the data set temporally, assessing the persistence of identified subgroups over different periods. The reassessment of mortality risk used the targeted maximum likelihood estimation (TMLE) method to achieve more robust causal modeling.

**Results:** We analyzed data from 21,005 children. The mortality risk (6 weeks to 3 years of age) was 5.2% (95% CI 4.8%-5.6%) for children born between 2003 and 2011, and 2.9% (95% CI 2.5%-3.3%) for children born between 2012 and 2016. Our findings revealed 3 distinct high-risk subgroups with notably higher mortality rates, children residing in a specific urban area (adjusted mortality risk difference of 3.4%, 95% CI 0.3%-6.5%), children born to mothers with no prenatal consultations (adjusted mortality risk difference of 5.8%, 95% CI 2.6%-8.9%), and children from polygamous families born during the dry season (adjusted mortality risk difference of 1.7%, 95% CI 0.4%-2.9%). These subgroups, though small, showed a consistent pattern of higher mortality risk over time. Common social and economic factors were linked to a larger share of the total child deaths.

**Conclusions:** The study’s results underscore the need for targeted interventions to address the specific risks faced by these identified high-risk subgroups. These interventions should be designed to work to complement broader public health strategies, creating a comprehensive approach to reducing child mortality. We suggest future research that focuses on developing, testing, and comparing targeted intervention strategies unraveling the proposed hypotheses found in this study. The ultimate aim is to optimize health outcomes for all children in high-mortality settings, leveraging a strategic mix of targeted and general health interventions to address the varied needs of different child subgroups.

**KEYWORDS**
child mortality; causal discovery; Guinea-Bissau; inductive-deductive; machine learning; targeted preventive and risk-mitigating interventions

**Introduction**

Child mortality in Guinea-Bissau has decreased significantly over the past 40 years but is still unacceptably high (1 in 13 children dying before the age of 5 years in 2021 [1]). Thus, there is a constant need to design relevant interventions to reduce mortality [2,3]. In particular, identifying subgroups of children at high risk of dying may inform targeted preventive or risk-mitigating interventions to supplement population-wide approaches [4,5].

To identify actionable points for interventions to prevent or mitigate risk, we want to document the fuller causal structure. This spans distal causes such as social and economic conditions, legal rights, and welfare policies to immediate causes such as congenital malformations or infectious agents [6]. However, obtaining high-quality data on these factors can be challenging, particularly in low-income countries. One potential data source is Health and Demographic Surveillance Systems (HDSS), which collect individual-level data on demographics and health for a portion of the population [7].

In this exploratory study, we used HDSS data from urban Bissau, the capital of Guinea-Bissau, to identify subgroups of children at high risk of dying before 3 years of age. We analyzed data from 2003 to 2019, where the birth years from 2003 to 2011 were used to identify risk factors and high-risk groups, which we then tested in the birth years from 2012 to 2016. This allowed us to focus on factors consistently associated with high mortality over time. To do this, we used 3 different types of analyses, that are, spatial analysis to map child mortality in specific areas, regression analysis to identify single risk factors associated with high mortality, and a machine learning model to identify multifactorial risk groups. By integrating these approaches, we aimed to discover subgroups of children with high mortality without being limited to prior hypotheses [8]. Such discoveries are necessary for developing new hypotheses and identifying interventions to reduce child mortality.

**Methods**

**Study Population and Follow-Up**

The study population included children living in Bissau, the capital city of Guinea-Bissau. All the children were part of the HDSS Bandim Health Project [9] and were seen by data collectors within the first 6 weeks of life. Children under 3 years of age are routinely visited every 3-4 months to collect vital and health information. Many recorded child deaths in this population are due to infectious diseases such as respiratory infections, malaria, and diarrhea [10,11].

Follow-up for this study began at 6 weeks of age to ensure that a sufficient proportion of children had their baseline information recorded. Children, who died before 6 weeks of age or did not have complete baseline information, were excluded from the study (30,441/51,446, see flowchart in Figure S1 in Multimedia Appendix 1). To account for the potential selection bias caused by migrating children, inverse probability of censoring weights (IPCW) was used in all analyses and presented results (Multimedia Appendix 2) [12].

**Baseline Information**

To identify relevant factors for child mortality, available baseline information was divided into environmental, household, and individual and birth domains. Figure 1 depicts the assumed causal structure [12] or the data-generating process linking these domains. Operational definitions of the variables and a visualization of their pairwise associations can be found in Table S1 and Figure S2 in Multimedia Appendix 1, respectively.
Analyses

A temporal split of the data, rather than a random split, was used in this study. This allowed us to determine whether identified subgroups consistently had a higher mortality risk across different time periods and thus, may be relevant subgroups for future intervention. The sample size allowed us to divide the data into 2 cohorts. The temporal validation cohort also allowed us to test the robustness of our findings, as there have been various changes over time that may have affected child mortality, such as a significant decline in respiratory infections [11,13].

To describe the temporal trends in child mortality, the Kaplan-Meier estimator was used to calculate overall risks and risks split by age, accounting for censoring during follow-up. All subsequent analyses excluded censored children and used IPCW to adjust for selection bias.

We conducted the following 3 analyses to investigate the association between the baseline information collected before 6 weeks of age and mortality during the entire follow-up period (from 6 weeks to 3 years). All association measures were reported as mortality risk difference (MRD), with 0 indicating no difference between the compared subgroups. The MRD was expressed as a percentage (ie, the difference in deaths per 100 children). All estimates in the results section are adjusted mortality risk differences (aMRD).

Spatial Analysis

We examined whether certain residential areas had a higher mortality risk than others by mapping the children’s households at baseline and moving a sliding window (250 m × 250 m) 10 m at a time to visualize the mortality risk across the study area. Estimates were only presented when at least 100 children were included within the sliding window to avoid small cell sizes. The estimates were adjusted for the linear effect of birth year, as child mortality has approximately decreased linearly by birth year (Figure S3 in Multimedia Appendix 1).

Single Risk Factors

We used generalized linear regressions to investigate the associations between single factors and a higher risk of child mortality. Adjustments were made according to the assumed causal structure (depicted in Figure 1) by blocking the common causes in higher-order domains using the backdoor criterion [12].

Multifactorial Risk Groups

We applied the Causes of Outcome Learning approach [14,15] to identify vulnerable subgroups with a combination of baseline information that was associated with a higher risk of child mortality. This causal inference-inspired machine learning approach has been optimized to prevent causal biases such as confounding by calendar time and collider bias, which could occur in other supervised clustering approaches. Details of the implementation of the Causes of Outcome Learning approach can be found in Multimedia Appendix 3. Since this approach is optimized for interactions in subpopulations, it is expected to find other patterns than the first-order linear regression which averages across the entire population.

Summarization and Causal Modeling

To summarize the findings from the 3 analyses, key statistics such as prevalence, crude risks, and identification of synergistic associations [16] (where the risk from simultaneous exposure to multiple factors is greater than the sum of the individual risks) were calculated. Adjusted risk differences were determined using causal modeling (targeted maximum likelihood estimation [TMLE] [17]) for the defined subgroups compared to all other children. The probability of the estimates from the hypothesis-generating and temporal validation cohorts being similar was also calculated. In addition, a combined estimate for both cohorts was obtained to estimate the population attributable fraction (PAF) [18], which represents the fraction of all mortality that would be prevented if the causal exposure of interest was removed. The analyses were conducted using R (version 4.2; R Core Team), and some sentences were revised using ChatGPT (OpenAI) to improve clarity.

Ethical Considerations

The study does not include biologically, physically invasive, or potentially dangerous procedures. The HDSS collection of data is at the request of the Ministry of Health, Guinea-Bissau.
**Results**

**Overview**

A total of 51,446 children were registered between 2003 and 2019, with 30,441 being excluded from our analysis due to registration after 6 weeks of age, lack of follow-up information, death by 6 weeks of age, missing baseline information, or emigration during follow-up (see flowchart in Figure S1 in Multimedia Appendix 1). The study sample included 21,005 children, which was weighted to an analytical sample of 27,998 children using IPCW to account for nonrandom emigration. The hypothesis-generating and temporal validation cohorts were based on weighted samples of 19,311 and 8687 children, respectively. The weights were not extreme (Multimedia Appendix 2). The mortality risk during the follow-up period (from 6 weeks to 3 years of age) was 5.2% (95% CI 4.8%-5.6%) in the hypothesis-generating cohort and 2.9% (95% CI 2.5%-3.3%) in the temporal validation cohort.

**Spatial Analysis**

We explored the results from the spatial analysis of the hypothesis-generating cohort, which gave rise to defining 4 areas; A, B, C, and D where the child mortality rate was considerably high. We marked these areas with circles on top of the spatial results in Figure 2. By comparing children living in the residential areas marked by circles A, B, C, and D (constituting between 1% [n=253] and 3% [n=533] of children) to those living outside these areas (Figure 2), the aMRD was 4.5% (95% CI –0.6% to 9.6%), 1.9% (95% CI –1.2% to 5.0%), 3.3% (95% CI –0.3% to 6.9%), and 4.0% (95% CI 0.1%-8.0%), respectively. When the 4 suggested high-risk residential areas were assessed in the temporal validation cohort, only area D still tended to exhibit higher mortality though the estimate was associated with more uncertainty (aMRD of 2.0%, 95% CI –2.8% to 6.7%) (Table 1 and Figure S4 in Multimedia Appendix 1). The combined estimate for both cohorts for area D was an aMRD of 3.4% (95% CI 0.3%-6.5%). If causal, the excess risk translates to a PAF of 1.1% of all deaths.

**Figure 2.** Spatial analysis mortality risk among the hypothesis-generating cohort adjusting for a linear effect of calendar time. Mortality risk (deaths per 100 children) in 250 m x 250 m squares by a resolution of 10 m for the birth years 2003-2011. Results are only shown if at least 100 children were under observation. A, B, C, and D indicate areas with a high child mortality risk. E is an uninhabited area, which is flooded during the rainy season.

**g**These findings were considered consistent across the cohorts by the authors.

**h**Adjustment for calendar time and environmental factors.

**i**HDSS: Health and Demographic Surveillance Systems.

**j**Adjustment for calendar time and environmental and household factors.
**Single Risk Factors**

In the hypothesis-generating cohort, children of mothers with less education than 7 years compared to those with 7 years or more of education were common (n=11,739, 60.8%) and had an aMRD of 1.6% (95% CI 0.9%-2.4%; Table 2). Crowding (ie, having multiple children in the household under 3 years of age) was common (n=16,054, 83%) and associated with an aMRD of 1.6% (95% CI 0.6%-2.6%) compared to being the sole child (Table 2). Having functioning electricity, a television, and a toilet inside the house indicates higher wealth, which was associated with lower child mortality. Across both cohorts with very similar estimates, both less maternal schooling and more crowding were associated with an aMRD of approximately 1.5% (Table 1, the column “aMRD visualizations” shows virtually the same estimates). If causal 19.4% of all deaths could be attributed to low-maternal education and 30.0% to crowding.

The most pronounced environmental factor was living within 50 m of a major road, associated with an aMRD of 2.1% (95% CI 0.6%-3.6%) compared with children living further away.

Children of mothers lost to follow-up were at a marked increased mortality risk. Still, they constituted a very small number of children in the temporal validation cohort (additional explanation in Table S1 in Multimedia Appendix 1).

Being a twin was consistently associated with higher mortality, with an aMRD of 4.3% (95% CI 1.0%-7.7%) and 3.0% (95% CI –0.5% to 6.5%) in the hypothesis-generating and temporal validation cohorts, respectively (Table 1).

No prenatal consultation was recorded for 4% (n=834) of the children in the hypothesis-generating cohort and was associated with an aMRD of 6.4% (95% CI 2.5%-10.2%; Table 1). In the temporal validation data set, this was associated with an aMRD of 2.8% (95% CI –0.9% to 6.6%).
Table 2. The association between single risk factors and child mortality below 3 years of age. Hypothesis-generating cohort (Bandim Health Project Health and Demographic Surveillance Systems data from the birth years from 2003 to 2011).

*a* For the environmental category, adjusted risk differences are adjusted for a calendar effect, risk differences in the household category are additionally adjusted for the environmental variables, and risk differences in the information related to the delivery category are further adjusted for the household variables.

*b* The prevalence differs from 10% to 90% because the cutoff is based on data from both cohorts (2003-2016).

*c* Reference group.

*d* N/A: not applicable, since the effect of sex and birth season is not expected to be confounded and thus does not need adjustment.

**Multifactorial Risk Groups**

In the hypothesis-generating cohort, twins born in the rainy season had higher mortality risk compared with those born in the dry season (aMRD of 7.0%, 95% CI 2.0%-11.9%; Figure 3, group 4, and Table 1), but this association was not found in the temporal validation data (aMRD 1.3%, 95% CI –3.0% to 5.6%; Table 1). Children of polygamous families born in the dry season had an aMRD of 1.8% (95% CI 0.2%-3.3%) compared to all other children (Figure 3, group 5, and Table 1). This subgroup constituted 9% (n=1770) of the children in the hypothesis-generating cohort, and the finding was consistent in the temporal validation cohort (an aMRD of 1.7%, 95% CI –0.4% to 3.9%, covering 8% [n=720] of all children; Table 1, see the column with aMRD visualization for consistency). If these associations are causal, 3.3% of all deaths could be attributed to this combination. A supplementary analysis of both cohorts (birth years 2003-2016) was conducted to understand the phenomenon better. The results suggested that (1) the finding was not artificially introduced by the IPCW approach; (2) the increased risk was highest in the first half-year of follow-up (6 weeks to 7 months of age) but continued throughout the entire follow-up period (up to 3 years of age); (3) the association varied across birth years without any trend; (4) the association was strongest among the Manjaco and Mancanha ethnic groups; (5) the association was most pronounced in the eastern part of the HDSS area; and (6) the association was not confounded by crowding, but was driven by the strata of children living in a household with other children under 3 years of age (Multimedia Appendix 4).
Figure 3. Multifactorial risk groups results from the Causes of Outcome Learning approach. (A) The prevalence and mean risk by the identified subgroups based on the Causes of Outcome Learning approach. Group 8 had a higher mortality risk than could be shown in the plot. (B) The mean risk contributions by each subgroup are visualized, where the color white indicates no risk contribution and dark red indicates the highest risk contribution. We identify 4 subgroups with a prevalence above 0.5% (n=97): (1) twins born in the rainy season (group 4); (2) children of polygamous families born in the dry (group 5); (3) no consultations, boys, and other ethnicity (group 6); (4) mothers not under Health and Demographic Surveillance Systems surveillance, Fula, or Mandinga ethnicity, born in the dry season (group 7). For more details, see Multimedia Appendix 3. BCG: Bacillus Calmette-Guérin vaccination.
Discussion

Principal Findings
In this study, we aimed to discover subgroups of children with high mortality in urban Guinea-Bissau. We used complementary analyses and split the data into a hypothesis-generating cohort and a temporal validation cohort. Of children with high mortality who may be targeted for interventions, we identified (1) a residential area (area D), (2) children of mothers who did not attend prenatal consultations, and (3) children born in polygamous families during the dry season had excess mortality risk throughout the study period. Of population-wide findings, maternal education and household crowding were important factors.

Limitations
Excluding children without complete information (Figure S1 in Multimedia Appendix 1), and conditioning on children being alive at 6 weeks of age [19] may have limited the generalizability of our findings. The HDSS is a valuable source of information but is focused on specific key health indicators as data collection in Guinea-Bissau is resource-demanding. Thus, we lacked information about other relevant baseline characteristics such as vector-borne diseases, health care and systems, weather, pollution, water and sanitation, community relations (social capital), and household and macroeconomic conditions. We did not include factors that varied during follow-up, such as season, vaccinations, vitamins, and other health campaigns. This may be important as child mortality is considerably higher in the rainy season [19,20]. Live and nonlive vaccines have been shown to affect child mortality more generally than their effects on the targeted diseases explained [21].

We acknowledge that data gathered from the real world may have some natural limitations in terms of completeness and accuracy, which could potentially affect the reliability of the identified risk factors. Efforts to account for missing or incomplete data were made where feasible. Furthermore, as this study concentrates on urban Guinea-Bissau, its findings may not readily apply to different socioeconomic and cultural contexts. Further research in varied settings is necessary to validate and understand the transferability of these factors.

To acknowledge the challenges in establishing causality, we integrated multiple methods and used an inductive-deductive research methodology (ie, take the learnings from the hypothesis-generating cohort to be tested in the temporal validation cohort) [22]. This approach guided us to propose future research directions to validate and understand the mechanisms driving the observed phenomena. While total effects can be diluted in the Causes of Outcome Learning approach, particularly when including individual and birth-related factors in the model (Figure 3), our methodology is strengthened by using a causal structure (Table 1) for adjustments and the TMLE approach. This enhances the validity of our findings and contributes toward a more robust inference of causality by better adjustment and more robust model specification [17]. It could be explored if other novel machine learning methods could supplement the findings [23].

Interpretation
The temporal split allowed us to investigate consistency across 2 time periods. While a lack of consistency can be due to chance, it may also reflect changes in the causal structure over time. We found that children of mothers not under HDSS surveillance were strongly associated with child mortality in the hypothesis-generating cohort. However, in the temporal validation cohort, close to no children had mothers who were not under HDSS surveillance. Changes in data collection methods might explain this discrepancy; after 2013, mothers of children in new families were registered by the same data collector as the child, whereas before 2013, the mother’s registration was handled by a separate team. The increased risk among twins born in the rainy season in the hypothesis-generating cohort may have occurred by chance. Still, it could also indicate better health care for high-risk children in the validation cohort.

Local Environmental Factors
Previous spatial studies have shown large differences in disparities within and between countries [24,25], and temporal persistence at local levels [26]. The population movement in Bissau may have made it more difficult to identify high-risk residential areas. Area D contains a busy market called Caracol which is known for traditional medicine and care. High population density and possibly high infectious load, may offer 1 explanation for the high risk in residential area D. The proportion of mothers with less than 7 years of schooling was similar in area D as outside of it (Figure S5 in Multimedia Appendix 1).

To further understand and address the high mortality rate in this residential area, several future studies could be conducted, such as (1) qualitative study following families in this area may add insight and create new hypotheses; (2) network analysis to reveal contact patterns and exposed jobs most relevant in this area; and (3) spatial analysis of distance to specific proximate places (eg, places for traditional medicine and care), infrastructures (eg, wells), or potentially hazardous areas (eg, waste collection areas).

Lack of Prenatal Consultations
Prenatal consultations are designed to prevent early child mortality and may directly affect maternal behavior. The association between lack of a prenatal consultation and mortality is reflected in other studies [27], but we cannot exclude that some of the association was confounded by social and economic factors, as well as health care-seeking behavior. This may be especially important as we are considering postneonatal mortality. Various mechanisms may contribute to postneonatal mortality, such as out-of-pocket fees associated with increased child mortality in sub-Saharan Africa [28]. In Guinea-Bissau, the expansion of free antenatal care was, however, not associated with reduced perinatal mortality [29], and thus some of the observed associations of prenatal consultations may reflect confounding.

To further understand and address the lack of prenatal consultations and its impact on child mortality, a number of future studies could be conducted, such as (1) studies examining...
various characteristics of mothers not participating in prenatal consultation and their outcomes to understand further how this subgroup is associated with mortality and morbidity, (2) assess the effectiveness of interventions such as active home visits with prenatal consultations in reducing child mortality, and (3) explore if health care decisions during prenatal consultations can be assisted by artificial intelligence–based assessment systems [30].

**Family Type and Birth Season**

Connecting children of polygamous families born in the dry season, an HDSS-based study from the Gambia identified that children born in the harvest season (January–June, approximately equivalent to the dry season in Guinea-Bissau which is December–May) were at increased postneonatal mortality risk [31] and a study from Ghana found that children from polygamous families had higher child mortality than those of monogamous families [32]. We could not identify other studies assessing the combination of family type and birth season. Within our study, we further observed that the finding was not indicated to be confounded by crowding, though residual confounding may persist. However, we found that the pattern was only present for children living in households with other children under 3 years of age. Some mothers travel to rural villages to harvest cashew nuts in the late dry season and return in the rainy season. One explanation may lie in the divided attention between labor in the cashew plantations and care for other children (potentially in a different environment). With reduced or limited breastfeeding during the cashew harvest, children may lose maternal antibodies and thus become more susceptible to infections. How these mechanisms interact with family structure is still to be understood.

To further understand and address the association between birth season and family type on child mortality, several future studies could be conducted, such as (1) investigation into accidents as causes of death may reveal if the combination of shared child attendance and busy months in relation to the harvest increases the risk of domestic accidents, (2) interviews with these families may give insight into the observed phenomenon, and (3) triangulating the findings with other health-related behaviors such as vaccination uptake may help uncover mechanisms.

**Resource Prioritization**

As repeatedly described in the literature, social and economic factors affecting a wide part of the population strongly predict mortality [33]. In our data, social and economic factors may account for 20%-30% of all deaths in children aged 6 weeks to 3 years. In contrast, the 3 subgroups of children with high mortality identified in our study may represent a smaller fraction of the overall mortality burden (less than 5%), but they are characterized by significantly higher absolute mortality risks. This distinction raises important questions about the feasibility and potential impact of targeted interventions for these subgroups as compared to more widespread, universal public health strategies. While recognizing the challenges in reaching these smaller subgroups, targeted interventions could be crucial in addressing their disproportionately high mortality risks. Therefore, it is imperative to consider both cost-effectiveness and equity in designing these interventions, ensuring they complement broader public health measures to provide comprehensive and effective child health care.

**Demonstration of a Novel Approach for Targeted Public Health Research**

This study not only provides insights into child mortality in urban Guinea-Bissau but also demonstrates the practical application of the Causes of Outcome Learning approach [14] on real-world data. Our findings illustrate how this approach effectively deciphers complex patterns and suggests potential synergistic causes in public health data, revealing phenomena that would be overlooked by traditional analytical methods. Future research should focus on identifying when the Causes of Outcome Learning approach is most effective and on refining the methodology to improve its accuracy and adaptability for a variety of public health research questions and study designs.

**Conclusions**

Reaching the Sustainable Development Goal of reducing under-5 child mortality to below 1 in 25 children by 2030 will require a range of interventions. By using several different and complementary approaches, we were able to identify subgroups of children at a high mortality risk that would not be evident otherwise. These high-risk children live in a specific area near a marked area known for traditional medicine and care, have mothers who did not attend prenatal consultations, and were born in the dry season and in polygamous families. We have suggested several future studies that may help explore these hypotheses. Potential targeted interventions should be evaluated in comparison with the impact of population-wide structural interventions both from cost-effectivity aspects and equity aspects and tested under proper evaluation schemes [34] to reduce child mortality.

**Acknowledgments**

The study would not have been possible without the dedicated work of the many data collectors, supervisors, and mothers of children under surveillance who were willing to provide answers to the questions. AR was supported by an International Postdoctoral Grant (9034-00006B) from the Independent Research Fund Denmark. HA was supported by Novo Nordisk Foundation Challenge Programme (NNF17OC0027812) and by National Institutes of Health (UL1TR004419 and P30ES023515). SWM was supported by a DFF-International Postdoctoral Grant (0164-00023B) from the Independent Research Fund Denmark. ABF was supported by an Ascending investigator grant from Lundbeck Foundation (R313-2019-635) and a Sapere Aude grant from Independent Research Fund Denmark (9060-00018B). Many funders supported the data collection at Bandim Health Project over the years (full list available [35]).
Authors' Contributions
The study was based on secondary analyses of data collected at the Bandim Health Project under the supervision of SWM, IBS, PA, and ABF. All authors contributed to the study concept and design. AR, SN, and ABF extracted and verified the data. AR is responsible for all the data analyses. AR, PD, WS, NHR, and CTE contributed to the implementation of the Causes of Outcome Learning approach. All authors contributed to the interpretation of the results. AR, SN, and ABF contributed to drafting the study. All authors critically revised the study for important intellectual content.

Abstract

Background: We have previously demonstrated that opioid prescribing increased by 127% between 1998 and 2016. New policies aimed at tackling this increasing trend have been recommended by public health bodies, and there is some evidence that progress is being made.

Objective: We sought to extend our previous work and develop a data-driven approach to identify general practices and clinical commissioning groups (CCGs) whose prescribing data suggest that interventions to reduce the prescribing of opioids may have been successfully implemented.

Methods: We analyzed 5 years of prescribing data (December 2014 to November 2019) for 3 opioid prescribing measures—total opioid prescribing as oral morphine equivalent per 1000 registered population, the number of high-dose opioids prescribed per 1000 registered population, and the number of high-dose opioids as a percentage of total opioids prescribed. Using a data-driven approach, we applied a modified version of our change detection Python library to identify reductions in these measures over time, which may be consistent with the successful implementation of an intervention to reduce opioid prescribing. This analysis was carried out for general practices and CCGs, and organizations were ranked according to the change in prescribing rate.

Results: We identified a reduction in total opioid prescribing in 94 (49.2%) out of 191 CCGs, with a median reduction of 15.1 (IQR 11.8-18.7; range 9.0-32.8) in total oral morphine equivalence per 1000 patients. We present data for the 3 CCGs and practices demonstrating the biggest reduction in opioid prescribing for each of the 3 opioid prescribing measures. We observed a 40% proportional drop (8.9% absolute reduction) in the regular prescribing of high-dose opioids (measured as a percentage of regular opioids) in the highest-ranked CCG (North Tyneside); a 99% drop in this same measure was found in several practices (44%-95% absolute reduction). Decile plots demonstrate that CCGs exhibiting large reductions in opioid prescribing do so via slow and gradual reductions over a long period of time (typically over a period of 2 years); in contrast, practices exhibiting large reductions do so rapidly over a much shorter period of time.

Conclusions: By applying 1 of our existing analysis tools to a national data set, we were able to identify rapid and maintained changes in opioid prescribing within practices and CCGs and rank organizations by the magnitude of reduction. Highly ranked organizations are candidates for further qualitative research into intervention design and implementation.

(JMIR Public Health Surveill 2024;10:e51323) doi:10.2196/51323)
Introduction

The prescription of opioids is common and appropriate in the management of acute pain, but their efficacy with regards to chronic pain is not supported by empirical evidence [1], and there is a global problem with opioid overuse [2]. Long-term use of opioids has been shown to be associated with the accumulating risk of dependence and overdose [3]. The continually rising rates of opioid prescription, particularly in England and Wales [4-6], prompted the publication of new guidance in 2010 [7] advocating for a cautious approach in the long-term prescribing of opioids [8], and opioids have been a specific priority for governmental advisory groups [9]. In 2019, Public Health England (PHE) published the *Prescribed Medicines Review*, which aimed to “identify the scale, distribution and causes of prescription drug dependence, and what might be done to address it” [10]. This review included data from the National Health Service Business Services Authority (NHSBSA) primary care prescription data set, which suggested that some progress had been made in reducing opioid prescribing, with a small but consistent fall in rates between 2015 and 2018. However, there was also evidence that opioid prescribing remains a persistent public health problem in England, with higher rates of prescription in areas of higher deprivation and evidence that long-term prescribing was associated with opioid overdose and dependence. The first recommendation of this report was “increasing the availability and use of data on the prescribing of medicines that can cause dependence or withdrawal to support greater transparency and accountability and help ensure practice is consistent and in line with guidance” [10].

Our group produces OpenPrescribing [11], which allows open access to the same NHSBSA primary care prescription data set used in the PHE review. It is a free and widely used tool with 20,000 unique users per month, where anyone can explore the prescriptions dispensed at any practice in England and monitor prescribing patterns down to the level of individual brands, formulations, and doses.

In OpenPrescribing, we perform automated analyses to generate monthly reports covering 80 measures of prescribing safety, effectiveness, and cost. Our analyses included all general practices (GPs) and their regional organizations, which were known as clinical commissioning groups (CCGs) at the time of this study. Several measures have been developed to capture trends and variations in opioid prescribing [12]. This window into national opioid prescribing data presents an opportunity to identify changes—both increases and decreases—in prescribing that could inform National Health Service (NHS) decision-making and policy.

It is our experience that the best practice is typically defined by organizations identifying themselves as having improved, following the implementation and internal assessment of interventions. We are seeking to pursue an alternative, data-driven, and unbiased approach that instead exploits the national prescribing data set to identify prescribing patterns that may be representative of best practice (i.e., where we can identify a significant reduction in opioid prescribing).

We set out to apply our change detection algorithm [13] to identify patterns indicative of maintained and significant reduction that may help identify best practices with regard to opioid prescribing policy.

Methods

Study Design

We conducted a retrospective database study using GP primary care electronic health record data from all GPs in England.

Data Source

We extracted data from the OpenPrescribing database. This imports openly accessible prescribing data from the large monthly files published by the NHSBSA, which contain data on cost and items prescribed for each month, for every typical GP and CCG in England since mid-2010 [14]. We extracted data up to November 2019. We note that CCGs were replaced by integrated care boards as of July 1, 2022. We have retained results by CCGs as this was an active administrative unit of the NHS in England during the study period. The monthly prescribing data sets contain 1 row for each different medication and dose, in each prescribing organization in NHS primary care in England, describing the number of items (i.e., prescriptions issued) and the total cost. These data are sourced from community pharmacy claims data and, therefore, contain all items that were dispensed. We extracted all available data for typical GPs, excluding other organizations such as prisons and hospitals, according to the NHS Digital data set of practice characteristics [15]. The numbers of patients registered at each practice were obtained from NHS Digital [15].

Study Measures

A total of 3 measures were used in this study to capture various aspects of opioid prescribing. The first (“total oral morphine equivalence per 1000 patients”) expresses the oral morphine equivalence (OME) of all opioid prescriptions per 1000 patients [16]. The second and third look to capture information about regularly prescribed opioids—those used on a regular basis to control pain rather than preparations used for breakthrough pain or opioid injections. Of the regularly prescribed opioids, high-dose opioids were defined as those with ≥120 mg OME per day [8]. The “high dose opioids as percentage regular opioids” measure captures the number of prescriptions of these high-dose, regularly prescribed opioids as a percentage of all long-acting opioids [17]; the “high dose opioid items per 1000 patients” measure captures the same number of high-dose, long-acting opioids but expresses this per 1000 patients [18]. For all measures, higher values represent higher rates of opioid prescription.
In England, an individual will be registered at 1 GP or practice; and each practice belonged, at the time of analysis, to a regional CCG that can influence their prescribing. These organizations and their membership can change over time (e.g., a practice may be reassigned to a different CCG, a CCG may be renamed or replaced, or a practice may close). In our results, we report results for any practice or CCG that existed during the study period, acknowledging that some of these no longer exist. CCGs have now also been replaced with subintegrated care board locations, but some still retain their previous CCG code.

Practices may act independently to change prescribing or participate in an action coordinated by their CCG. We, therefore, conducted analysis at both organizational levels. Monthly values for each measure were calculated for every practice and CCG between December 2014 and November 2019 (this study period was chosen so as to assess prescribing rates over a reasonable period of time, without being affected by the COVID-19 pandemic). The monthly data were summarized as deciles and presented as decile charts across all practices or CCGs each month.

**Statistical Methods**

For this study, we used our innovative change detection Python library (available via the Python Package Index) [19], which is an automated method of detecting change in time-series data. This algorithm was originally developed to determine how clinicians vary in their response to new guidance on existing or new interventions. By measuring the timing and magnitude of change in the relevant organizations, it is able to identify both steep, sudden changes and more gradual, smooth transitions over multiple months. The full methods are described elsewhere [13] and the code is available for anyone to use as a single command with our open Python library [19].

Data for each of the 3 measures were analyzed for all 191 CCGs and 7458 practices. The time series for each organization was analyzed using our change detection algorithm (using the default parameters) to identify the location and magnitude of significant reductions in the measure (substantial increases were filtered out as they are not relevant to the research question). These results were then filtered to remove (1) a total of 678 closed or dormant practices and (2) a further 237 practices with a list size of less than 2000 (this latter group was excluded to avoid analyses of time series with a high level of noise due to low prescribing volume); this process left 6543 practices to be subject to further analysis. We filtered out practices where more than half of the monthly denominator values were 0 (either no registered population or no total opioid prescribing as per measure definitions) across the study period. Among the organizations where our code detected a substantial reduction, for each measure, we selected those whose starting level immediately before the reduction was in the top 20% of all practices (top 150) or CCGs (top 38); this was to remove any organizations with consistently low prescribing from our results. For each measure, we then ranked practices and CCGs by the total measured change (the percentage reduction between the predrop value and the end-drop value) to identify which organizations exhibited the most substantial reductions.

The decile plots provided show an individual organization’s prescribing rates across the period (thick red line), in the context of all peer organizations (summarized using deciles, as blue lines).

**Software and Reproducibility**

Data management and analysis were carried out using Python (version 3.8; Python Software Foundation) and Google BigQuery. Our change detection library [19] is a Python wrapper for the GETS R package [20]. All our methods and underlying code are openly available on GitHub [21]. The full results, summary statistics of changes detected, and top 10 CCGs and practices can be seen in the notebooks folder, in the files ccg-opioids-change-detection-analysis.ipynb and practice-opioids-change-detection-analysis.ipynb. All organizations that existed in the study period (including those that have since closed or been replaced) are included in these reports.

**Ethical Considerations**

This study uses open, publicly available, and anonymized data. This analysis did not need a review from an institutional review board because it used previously collected, fully anonymized data [22]. Informed consent and compensation were similarly not required and would not be possible.

**Results**

**Overview**

We identified substantial reductions in at least 49% of all CCGs (94/191, 49.2%) and practices (4100/7460, 55%) for all measures; summary statistics for these reductions are provided in Table 1. Note that these data describe all substantial reductions detected, that is, before filtering for a top 20% (top 38 CCGs or top 150 practices) starting value. For both CCGs and practices, reductions are on average greater for both high-dose opioid prescribing measures as compared to those observed for the total OME measure, although the IQR values demonstrate that there is also more variability in the high-dose opioid prescribing measures. Reductions appear more modest among CCGs than practices (with lower medians and lower maximum values), but these reductions may be more consistent (with lower variability and greater minimum values observed in CCGs as compared to practices). There is at least 1 practice in each measure where the reduction is almost 99% to 100% and at least 1 practice where the reduction detected is very close to 0.

\textsuperscript{a}Count indicates the number of organizations (clinical commissioning groups or practices) in which a reduction was identified. Median, IQR, and range summarize the size of the reductions identified in those organizations (expressed as % reduction from the predrop value to the end-drop value).

\textsuperscript{b}OME: oral morphine equivalence.

**Changes for CCGS**

Table 2 illustrates the CCGs that exhibited the biggest reduction in each of the 3 OpenPrescribing measures over the study period, detailing the proportion of change and the month in which the change started. Note that these CCGs meet the criteria for identification, that is, their prescribing rate immediately before the reduction was in the top 38 (20%) CCGs.

The total OME measure shows a gradual reduction over time in all 3 CCGs, with the algorithm identifying a reduction of up to 31%. The results for the 2 regular high-dose opioid measures also exhibit a gradual reduction over time but capture greater reductions in regular high-dose opioid prescription, with 40% and 39% reductions identified as a proportion of all regular opioids and per 1000 patients respectively.

Changes for Practices

Table 3 illustrates the practices that exhibited the biggest change in each of the 3 OpenPrescribing measures over the study period, detailing the proportion of change and the month in which the change started. Note that these practices meet the criteria for identification as described in the “Statistical Methods” section, that is, their prescribing rate immediately before the reduction was in the top 150 (20%) practices.

The practice time series (Table 3) are noticeably different from those of the CCGs (Table 2), the magnitude of the measured changes is larger, and the slope of the time series is much steeper for practices. In the case of the regular high-dose opioids as a percentage of all opioids, all 3 practices are seen to completely eliminate all regular high-dose opioids for several months; similarly, very low values are observed for the top 3 practices with regards to reductions in high-dose opioid items per 1000 patients.

Discussion

Main Findings

We have identified significant reductions in 3 measures of opioid prescribing using a data-driven approach in over 7000 practices across 191 CCGs in England (Table 1). These organizations have then been ranked by the magnitude of reduction to identify where the largest reductions have been realized. The top-ranked CCGs exhibit a slow and gradual reduction in opioid use (Tables 1 and 2); by contrast, the top-ranked practices exhibit rapid and sudden reductions over a few months (Tables 1 and 3). Opioid prescribing and treatment of pain more broadly can be complex, but our findings illustrate that some CCGs and practices appear to have significantly reduced their prescribing of opioids over the study period, more so than many of their peers.

Findings in Context

The PHE review identified evidence of tentative progress in reducing opioid prescribing between 2015 or 2016 and 2017 or 2018 [10]. Our analysis includes and extends this time period and finds evidence that some organizations may be driving this tentative progress more than others (eg, the CCGs reported in Table 2).

We do have evidence that 1 of the organizations that has emerged as a potential candidate by our methodology is a genuine example of improved performance. Between 2017 and 2019, Great Yarmouth and Waveney designed and implemented an extensive program of opioid reduction interventions, including target trajectories for improvement; incentive schemes for clinicians; dialogue with practice pharmacists, patient groups, and relevant clinical groups (eg, prescribing leads and pain management teams); new patient information materials; collecting case studies for discussion; and associated press and social media to raise awareness. While this CCG still exhibits high levels of opioid prescribing, rates have reduced significantly, with the organization being recognized for this progress nationally [23]. Our methodology ranked Great Yarmouth and Waveney as first (reduction of 39% [absolute reduction 2.0] starting in August 2017) for high-dose opioid prescribing per 1000 patients and second (reduction of 33%...
implement this best practice can systematically identify organizations that may have already implemented effective interventions. However, it is critical that policy makers undertake further investigations for reasons outlined in the limitations. This tool offers an opportunity to reduce the resources needed to identify best practices. Similarly, local medicines optimization teams may wish to use data and tools like this to identify peers across the country who have already delivered successful interventions to inform local initiatives. Further quantitative research is also possible from the data set, for example, drilling down by opioid type and monitoring the impact of any local or national interventions or policies.

Strengths and Limitations

The national prescribing data used for this analysis, being collected for reimbursement purposes, are highly complete and accurate. We have taken into account most (6543/7458, 87.7%) typical primary care practices in England, thereby minimizing the risk of biased sampling. Executing this analysis in an existing, open platform such as OpenPrescribing ensures accountability and transparency—both identified as priorities in the PHE report [10]; by default, all code in this study, from data curation to completed output, is shared openly on GitHub and the Python Package Index. Furthermore, there exists a robust and tested framework with which relevant new measures can be introduced or existing measures can be amended as required in order to respond to any evolving change in tackling opioid dependency and abuse. Our use of OME conversion permits the reporting of trends for opioid medicines overall while accounting for variation in strength.

We also note some limitations. First, the prescribing data set does not include secondary care prescriptions as this was unavailable at the time of the study [32], and as such, the opioid measures implemented here may underestimate the extent of opioid prescribing nationally, although financial data would indicate that the vast majority of analgesics (British National Formulary (BNF) section 4.7, which includes the BNF subsection 4.7.2 opioid analgesics) are prescribed in primary care [33]. Second, we acknowledge that practice-level time-series data, in particular, could be significantly impacted by local circumstances, including low patient numbers, a change in patient population, a change to prescription frequency (eg, from weekly to monthly scripts), or a shift in responsibility of opioid prescribing (eg, from primary to secondary care) and, therefore, that an apparent reduction in any opioid measure may not be due to a successful intervention. For example, practice G (Table 3) rapidly increased their high-dose opioid items per 1000 patients in 2016 followed by a similar rapid reduction 2 years later; this could be due to a change to daily prescribing as can be clinically justified for some patients. While we acknowledge these limitations, it is important to note that the intention of this methodology was always to rank or prioritize organizations for further investigation, rather than definitively ascribe reductions in opioid prescribing to successful interventions.

Conclusions

We have demonstrated that data-driven approaches to detect substantial changes in time-series data have potential value in the context of opioid prescribing. We have been able to rank organizations with regards to the extent of opioid prescribing reduction; organizations occupying the top of that list show large drops that warrant further qualitative investigation and could be indicative of success in tackling an important public health concern.

Should this further qualitative research reveal that reductions have been driven by well-designed and well-implemented interventions, methods of best practice will have been identified using an unbiased, evidence-based approach. The organizations found to be implementing this best practice may have valuable insights, approaches, and policies to share regarding how positive change can be achieved elsewhere. It also demonstrates, particularly in the most robust and gradual change observed among CCGs, that positive change is possible and, therefore, that continued and wider success in reducing opioid prescribing is dependent, at least in part, on closing the implementation gap.
Acknowledgments
We are grateful to wider National Health Service (NHS) colleagues for discussions that have informed our work on this topic. This project is funded by the National Institute for Health Research (NIHR) under its Research for Patient Benefit (RIPPB) Programme (PB-PG-0418-20036). The views expressed are those of the authors and not necessarily those of the NIHR or the Department of Health and Social Care. Funders had no role in the study design, collection, analysis, and interpretation of data; in the writing of the report; and in the decision to submit the paper for publication.

Data Availability
The data sets generated and analyzed during this study are available in the “opioids-change-detection-notebook” repository [21]. All our methods and code can also be found in this repository [21]. The underlying data are available via the National Health Service Business Services Authority (NHSSBA) [14].

Abstract

Background: Adverse events associated with vaccination have been evaluated by epidemiological studies and more recently have gained additional attention with the emergency use authorization of several COVID-19 vaccines. As part of its responsibility to conduct postmarket surveillance, the US Food and Drug Administration continues to monitor several adverse events of special interest (AESIs) to ensure vaccine safety, including for COVID-19.

Objective: This study is part of the Biologics Effectiveness and Safety Initiative, which aims to improve the Food and Drug Administration’s postmarket surveillance capabilities while minimizing public burden. This study aimed to enhance active surveillance efforts through a rules-based, computable phenotype algorithm to identify 5 AESIs being monitored by the Center for Disease Control and Prevention for COVID-19 or other vaccines: anaphylaxis, Guillain-Barré syndrome, myocarditis/pericarditis, thrombosis with thrombocytopenia syndrome, and febrile seizure. This study examined whether these phenotypes have sufficiently high positive predictive value (PPV) to ensure that the cases selected for surveillance are reasonably likely to be a postbiologic adverse event. This allows patient privacy, and security concerns for the data sharing of patients who had nonadverse events can be properly accounted for when evaluating the cost-benefit aspect of our approach.

Methods: AESI phenotype algorithms were developed to apply to electronic health record data at health provider organizations across the country by querying for standard and interoperable codes. The codes queried in the rules represent symptoms, diagnoses, or treatments of the AESI sourced from published case definitions and input from clinicians. To validate the performance of the algorithms, we applied them to electronic health record data from a US academic health system and provided a sample of cases for clinicians to evaluate. Performance was assessed using PPV.

Results: With a PPV of 93.3%, our anaphylaxis algorithm performed the best. The PPVs for our febrile seizure, myocarditis/pericarditis, thrombocytopenia syndrome, and Guillain-Barré syndrome algorithms were 89%, 83.5%, 70.2%, and 47.2%, respectively.

Conclusions: Given our algorithm design and performance, our results support continued research into using interoperable algorithms for widespread AESI postmarket detection.

Introduction

Background

The US Food and Drug Administration (FDA) Center for Biologics Evaluation and Research (CBER) is responsible for ensuring the safety, purity, potency, and effectiveness of biological products. This includes vaccines; allergens; blood and blood products; and cell, tissue, and gene therapies for the prevention, diagnosis, and treatment of human diseases, conditions, or injuries [1]. The FDA’s history of safety surveillance for vaccines includes the creation and monitoring of the Vaccine Adverse Event Reporting System (VAERS). VAERS, jointly administered by the FDA and the Centers for Disease Control and Prevention (CDC), accepts spontaneous reports of suspected vaccine adverse events (AEs) after administration of any vaccine licensed in the United States.

VAERS has been successfully used as an early warning system to identify rare AEs; however, it has limitations. VAERS is a passive surveillance system that relies on individuals, patients, and clinical staff to send in reports, as opposed to automatically collecting them based on clinical data. This can lead to undercounting AEs. In addition, a causal relationship cannot be established using information from VAERS reports alone [2]. Because of VAERS’s limitations, more robust data systems are needed to enhance AE detection. These systems would be especially important for detecting the most severe AEs that require medical attention so that the FDA and CDC can offer guidance for these potentially life-threatening events and ensure that product labeling reflects known risks.

To address this gap, CBER established the Biologics Effectiveness and Safety Initiative (BEST) Initiative in 2017 to build data assets, analytics, and infrastructure for an active, large-scale, efficient postmarket surveillance system that can evaluate the safety and effectiveness of biologic products and develop innovative methods [3]. The BEST system is a collection of real-world data (RWD) sources: data related to patient health status and the delivery of health care that are routinely collected from several sources, such as electronic health record (EHR) or claims data [4]. EHR databases, specifically, are a rich source of information. They include data such as clinical notes, which can help address the limitations of VAERS. They also include entire populations of patients to identify whether cases are underreported. In addition, they may include patients’ entire clinical history, which can help establish a causal relationship for an AE. BEST has reached agreements with a limited number of foundational data partners. Access to these data partnerships does not fully address the possible undercounting of AEs of special interest (AESIs). However, these partnerships allow accelerated development and testing of AESI detection algorithms.

BEST is currently researching a system of distributed computable phenotype algorithms that could be applied at scale to many or all EHR systems across the United States to semiautomatically detect and report potential AESIs from RWD. Such a system could increase the speed and scope of AE surveillance beyond what is currently available to public health agencies through data partner agreements. To be candidate phenotypes for distributed surveillance use, the phenotypes need to identify probable AEs and avoid false detections. This reflects the need to balance the correct detection of AESIs with the protection of privacy and the reduction of burden on health provider systems. For the wider population of health providers to consider deploying such detection algorithms, these phenotype algorithms need to have reasonably high performance (measured by positive predictive value [PPV]) to ensure that the cases identified as AEs are likely to be verifiable cases with the outcome of interest. Toward this goal, the computable phenotypes in this study focus on existing EHR data reflecting a detected AE, which are reportable events for public health purposes. The algorithmic identification of undetected AEs or AEs that were not coded properly is beyond the scope of this study. Such research must include data from patients who had no AEs to fully evaluate the performance of a computable phenotype algorithm. Although scientifically desirable in the long term, the inclusion of non-AE cases falls outside of initial goals for a distributed surveillance system, which is assessing performance (measured by PPV) of the phenotypes for wide-scale surveillance purposes. The goal of distributing the phenotypes also poses limitations on designing the algorithms. Specifically, the components and complexity of the underlying algorithms need to take into account the current EHR standards and technology because they must be deployable and executable across EHR databases without imposing large overhead on health provider systems. If the phenotypes have sufficient PPV and are sufficiently easy to implement at health provider sites, the FDA could share the phenotypes to detect AESIs following vaccination in EHRs across the country, which could then be reported to the FDA for further review. The ability to detect AESIs using RWD could create an active surveillance system that enhances overall vaccine safety and helps make recommendations to minimize risks for postvaccination AESIs. The implementation of algorithmic detection and automated reporting of AESIs found in RWD has been shown to increase the odds of submitting a VAERS report by >30 times the preimplementation rate [5].

Objective

Although there is a history of studies around postvaccination AESIs, including those for influenza [6-8] and COVID-19 vaccines [9-13], there has been an increased interest in the analysis of vaccine safety and surveillance since the emergency use authorization (EUA) of 3 COVID-19 vaccines in the United States (Pfizer-BioNTech, Moderna, and Novavax) and their subsequent boosters (eg, bivalent boosters). The FDA hopes to contribute to this research through the development and performance validation of phenotypes for 5 postvaccination AESIs to identify potential vaccine safety events within EHR databases for this study. The 5 AESIs chosen include
myocarditis/pericarditis, anaphylaxis, Guillain-Barré syndrome (GBS), intracranial or intra-abdominal thrombosis with thrombocytopenia syndrome (TTS), and febrile seizure. These AESIs were chosen because they are documented priorities of the CDC’s vaccine surveillance [14] for COVID-19 vaccine safety. In addition, several of these AESIs (anaphylaxis, GBS, and febrile seizure) are found following exposure to other vaccines, such as influenza; shingles; pneumococcal conjugate; and measles, mumps, and rubella. This study describes the methods to develop and validate these 5 computable phenotype algorithms on an EHR database and the validation results. It is part of the FDA’s efforts to improve postmarket surveillance and is valuable for public awareness, safety, and transparency.

Methods

Ethical Considerations

Ethical approval was not required for the study involving humans in accordance with the local legislation and institutional requirements. This study was part of the Sentinel activities conducted by the FDA as part of its postmarket surveillance duties. The Office of Human Research Protection (OHRP) in Health and Human Services (HHS) determined that the studies done under the Sentinel programs are not subject to regulation (45 CFR part 46) administered by OHRP. Written informed consent to participate in this study was not required from the participants or the participants’ legal guardians or next of kin in accordance with the national legislation and the institutional requirements.

Computable Phenotype Development

Overview

In total, 5 AESIs were selected to develop computable phenotypes for our validation study. The study’s main focus was detecting COVID-19 vaccine–related AESIs; therefore, we selected AESIs that the CDC specifically identified for monitoring after COVID-19 vaccination [14] or AESIs that have been reported for some subpopulations [15]. Given the uncertainty about the future use of COVID-19 seasonal boosters, the FDA also wanted to ensure that the AESIs selected had broad applicability to the safety surveillance of other widely used vaccines such as influenza; shingles; pneumococcal conjugate; diphtheria-tetanus-pertussis; and measles, mumps, and rubella. Three of our 5 selections met those criteria given in the CDC’s documented monitoring of anaphylaxis [16], GBS [17], and febrile seizures [18] for at least one of the vaccines listed.

The phenotype algorithms were designed to be relatively simple and interoperable so that any new health care organization’s IT department could translate and run them on their EHR database. They were built to query only structured data for interoperable, standard codes, such as Logical Observation Identifiers Names and Codes, Systematized Nomenclature of Medicine Clinical Terms, and RxNorm, so that the algorithm can be generalized or translated across different EHR systems. Historically, this has been a challenge for developing algorithms, since EHR databases often contain their own local code systems specific to the EHR vendor. For example, for this effort, we worked with the study partner to map Cerner Multum medication and observation codes to standard RxNorm and Logical Observation Identifiers Names and Codes, respectively.

Recent regulation now requires each EHR database to have an application programming interface (API) endpoint that translates any EHR data and many of the EHR’s proprietary codes to the United States Core Data for Interoperability (USCDI) implementation of the Fast Healthcare Interoperable Resources (FHIR) specification [19]. This specification requires the use of interoperable, published code lists [20] (Table 1). These code systems cover almost all clinical events for the detection of AEs, such as medical diagnoses, medication prescriptions, laboratory tests or vital signs taken, and procedures performed. These APIs currently focus on supporting use cases where a single patient’s data are queried as opposed to aggregate searches across patients; therefore, we were unable to use them to identify the cohort that our phenotype would select. We were, however, able to use the FHIR API endpoints to pull data for each patient in our validation samples so that the participating clinicians could have data with the standard, interoperable code sets for their review.

</table>
diagnosis care settings values were grouped into inpatient, outpatient, or emergency care setting types. Care setting was used to filter out diagnosis codes made during encounters with care settings unlikely to have the specific AESI diagnosis in the phenotype. The included care settings are defined by case definition and clinician input.

**Clean Window**

Next, a clean window (ie, a period before the coded diagnosis identified in step 1) is checked to ensure that the target diagnosis is the first known diagnosis of its type. This prevents the inclusion of historical or ongoing conditions. For all algorithms in this paper, the clean window is defined by all historical patient data in our data set. To make sure that all patient cases had at least a 1-year clean window, we pulled an additional historical year of data from our data partner before the study period. Cases where there were multiple occurrences of an AESI diagnosis suggested possible evidence of a chronic condition unrelated to vaccine exposure and thus were excluded.

**Condition Window**

Finally, the algorithm searches for sufficient supportive evidence within a condition window. The condition window is defined around the AESI diagnosis date and includes the entire medical encounter period when the condition was diagnosed, as well as 2 days before and 10 days after a condition is diagnosed. Clinical subject matter experts defined condition windows as the timeframe around a diagnosis that supportive evidence would likely present itself in the medical record.

**Supporting Evidence**

Within the condition window period, the algorithm may filter cases based on supporting evidence of an AESI. This filter looks for either laboratory test results found in observations, AESI treatment procedures, AESI treatment medications, or procedure or a combination of the 3 supporting evidence with a code that matches a code on to the phenotypes’ concepts code lists. These code lists in the lists aim to include all medical codes that could represent a particular concept, such as administration of epinephrine for an anaphylactic reaction. This AESI supporting evidence filter was applied to all phenotypes except for our febrile seizure AESI phenotype because a review of existing research [32] showed febrile seizure algorithms, in general, had the highest PPV among the selected AESIs. The concepts to build code lists for the supporting evidence were identified using various types of clinical data. Following this, we prioritized improving specificity in the other AESI phenotypes by including filters requiring additional supporting evidence [32-35] and our clinician’s input.

**Vaccine Exposure**

In real-world operation, the algorithm would also include a vaccine exposure and risk window or a period surrounding vaccination in which diagnoses are searched. For the study’s purposes of having sufficient volume and statistical power to estimate operating characteristics of the algorithm, these exposure rules were not included.

**Additional Details**

Ideally, to assess whether these algorithms generalize to other sites, we would have a multisite validation study. Because of the high cost of data agreements, however, we only had data available for a single EHR site. To avoid overfitting and ungeneralizable results, we designed our algorithm development methods to only use our EHR data as a validation set and not use any of it to train, develop, or fine-tune the algorithm. While this does not remove the need for additional external validation, it reduces the likelihood of finding ungeneralizable results. To identify what medical concepts the algorithm should use as evidence, clinicians identified observations, medications, conditions, and procedure concepts from the AESI’s case definition, their relevant clinical experience, or other research from their literature review. A brief description of the AESI and the reference of the case definition used is captured in Table 1, and additional information on the case definition is saved in Table S2 in Multimedia Appendix 1 [21-23,25-27].

An analyst completed a text search for a list of terms for these identified concepts, a list of which is captured in Table S2 in Multimedia Appendix 1, to build the code lists of relevant codes from selected interoperable coding libraries (Textbox 1) [21-23,25-27]. This was accomplished by searching the open-sourced OHDSI Observational Medical Outcomes Partnership concepts table and ATLAS tool (OHDSI community) [36], which is a collection of thousands of interoperable codes and their definitions and descriptions. The table was searched for any definition or description that matched the identified concept for the interoperable code systems that we listed in Textbox 1 and then was reviewed by a clinician for their suitability for the algorithm.

**Textbox 1.** Codes used for each type of clinical data.

### Clinical data and interoperable code lists used

- **Diagnosis**: International Classification of Diseases, Tenth Revision, Clinical Modification, Systematized Nomenclature of Medicine Clinical Terms
- **Medication or immunization**: National Drug Code, RxNorm
- **Procedures**: Current Procedural Terminology, International Classification of Diseases, 10th Revision Procedure Coding System
- **Observations**: Logical Observation Identifiers Names and Codes

The immunization and the diagnosis International Classification of Diseases, 10th Revision, clinical modification (ICD-10) and Systematized Nomenclature of Medicine Clinical Terms code lists have been published on the Value Set Authority Center [37], and the additional observation, medication, and evidence code lists may be added in the future after this study is published.
For a surveillance use case, the algorithms need be run regularly (e.g., daily or weekly) to collect batches of historical cases once all the data are available (as opposed to a real-time implementation to collect cases as they are happening). Because the algorithms were created to prioritize simplicity and interoperability rather than maximize total performance (e.g., metrics beyond PPV such as sensitivity and, negative predictive power, etc), this study aimed for improved performance (measured by PPV) to existing AESI claims-based algorithms. Given our knowledge of how some crucial distinguishing information is part of unstructured clinical notes, which are not considered by the algorithms in this study, we expect further analysis is needed to improve accuracy [38,39]. Natural language processing techniques can improve algorithm performance but greatly increase the deployment complexity across health care organizations. Therefore, no natural language processing techniques were used for any phenotypes designed for this study.

**Study Period**

The study period spanned from January 1, 2018, through May 1, 2022, to ensure that the study’s data sampled patients both before and after the FDA issued the EUA and full licensure for COVID-19 vaccines. We also pulled at least 1 year of historical data for all patients; therefore, our data set includes historical information from January 1, 2017, to January 1, 2018, for all patients with medical encounters in the study period. Patients were included even if there were no clinical events in their historical period.

**Data**

The study population came from a single academic health system in the United States, with EHR medical encounter data from >2.6 million patients and >20.7 million medical encounters for the study period. Table 2 shows the demographic breakdown for age, gender, race, and ethnicity of this population.

The entire EHR population during the study period was eligible to be selected by one of our developed phenotype algorithms. There were no age-related, medical condition–related, or other exclusions on the population for the algorithm to select cases. Clinical data necessary to select and validate cases selected by the algorithm were provided to the study team through a series of EHR data extracts for all patients in the study period. The algorithm required the following clinical data categories:

- demographic
- encounter
- condition
- procedure
- medication
- observation

EHR data extracts were mapped and loaded into an OHDSI Observational Medical Outcomes Partnership database [40]. Medication, observation, and procedure data extracts were requested and loaded into the database only for patients who would not be disqualified by other algorithm criteria. For patients selected to be in the validation sample, these data along with the clinical data for allergies, immunizations, and clinical notes were pulled from the EHR’s FHIR API endpoints, patient by patient, using a custom Python script to loop through the patients in the sample. The data were loaded into a Health Level 7 API (HAPI) FHIR server. We only pulled FHIR data for cases not initially disqualified by the vaccination and diagnosis filters to avoid unnecessary large data transfers and storage. The algorithm flagged potential AESIs that met the specified criteria. Samples of these cases were sent to physicians for validation. **Validation Sample**

Once the algorithm identified cases, a random sample was drawn for each AESI for clinician adjudication. We used stratified sampling to ensure cases during pre– and post–COVID-19 EUA periods were represented (Figure 2). This was due to concerns regarding potential confounding introduced by the COVID-19 vaccines, when attention to possible AESIs or medical charting of AESIs may have shifted. Where possible for each AESI, 100 cases were sampled from the pre–COVID-19 EUA period and 35 from the post–COVID-19 EUA period. If there were <100 or <35 cases during these periods, respectively, the sample would contain all cases the algorithm selected. Febrile seizure was the exception, as we believe the COVID-19 vaccine EUA should not affect the algorithm’s performance because febrile seizure AEs are usually associated with pediatric populations, and the COVID-19 vaccine was not approved for these populations during the study period [27].

- Anaphylaxis (n=35)
- GBS (n=35)
- Febrile Seizure (n=N/A)
- TTS (n=35)

Case counts sampled in each period were based on the incidence of diagnosis code occurrence within each period, as well as the period covered. In addition, we added negative controls selected randomly from every encounter in the period to establish a baseline comparison for the case validation process. We included negative controls as a quality control step to reduce the chance of quality issues with the data and to review the methods our clinicians were following and not for the purpose of making inferences about the phenotypes’ performance for non-AE cases (eg, through metrics such as sensitivity, negative predictive power, or an overall metric for performance). This study did not focus on the algorithmic identification of undetected AEs or AEs that were not coded properly. The focus of this study was to determine the phenotypes’ PPV. Given the expense of clinicians’ time for validations and the rarity of the AESIs, there would be minimum benefit to this study to have a negative control sample large enough to draw strong inferences. Furthermore, negative case controls would not further validate the utility of the phenotypes as tools for identifying probable AESIs through distributed surveillance. We added 20 negative controls from the pre–COVID-19 EUA period and 7 from the post–COVID-19 EUA period. Physicians were blinded to which cases were controls and which were not.

**Chart Review Process**

The sample of cases used to validate the algorithm was loaded into a chart review tool for clinician review. This allowed the clinicians to sort through the clinical information for a case and record the determination. Each case was assigned to 2 clinicians for review. The clinical validation used a patient’s full clinical history, which included EHR data, including all clinical notes for each case. The full EHR data used for clinician review included data unused by the detection algorithm described in the Computable Phenotype Development section, including different types of data (eg, allergies and clinical notes) and data filtered out (eg, admitting diagnosis and encounters with different care settings).

For each case, the clinician evaluated whether the clinical data evidence met the specified case definition criteria. Relevant patient data for the case window were available and presented to the clinicians in an easy-to-use, browser-based tool with a custom user interface. In the tool, clinicians were able to group
items by type, search across all items and text, and request additional chart data to expand the window and access any available historical patient data, if desired.

All suspected AEs were validated using published case definitions [21-23,25-27] according to the levels of diagnostic certainty: level 1 (definite), level 2 (probable), and level 3 (possible). If a case did not meet one of the levels in the case definition, it was assigned as level 4 (doubtful) or level 5 (ruled out). “Ruled out” is distinct from “doubtful” in that “ruled out” cases have definitive evidence disqualifying them from being a correct diagnosis. If a case was determined to be “definite” or “probable,” it was considered a positive case of the AESI.

In the event of a disagreement between a positive and negative clinical review, a third clinician made a final determination by reviewing the case EHR data. If the clinicians found the structured or unstructured EHR data was insufficient, they marked this in their review by creating a level 3 (possible, insufficient evidence) designation, where an AESI could have occurred, but where there was not enough documentation to fulfill the requirements of the case definition.

Statistical Analysis

PPV of Algorithms

Each algorithm’s PPV was the proportion of positive AEs the algorithm identified that were confirmed by clinical adjudication. PPVs were calculated for each AESI overall, as well as stratified by pre– and post–COVID-19 EUA periods and care setting (inpatient, emergency department, or outpatient). Sensitivity analyses were performed to evaluate the impact of medication use, different case definitions, and levels of evidence. PPVs were calculated in 2 different ways for each AESI algorithm. The first PPV calculated removed all possible cases with insufficient evidence from the denominator (cases labeled “definite” and “probable”/total cases minus any labeled “possible, insufficient evidence” by clinicians). PPV was then calculated with the cases with insufficient evidence added back into the denominator (cases labeled “definite” and “probable”/total cases). Reporting both PPV calculations can help with understanding the performance for different algorithm uses. Algorithm performance should ideally be compared with past literature of detection algorithms for the same AESI.

CI Values

Because PPV is a binominal proportion, we calculated CIs for the PPV using the Agresti-Coull interval [41], which is the recommended method for estimating accurate CIs for binomial proportions such as PPV [42].

Interrater Reliability

Interrater reliability was used to measure the extent to which 2 physicians agreed in their AESI assessment. It was calculated using Cohen κ between the first 2 reviewers. Cohen κ measures the agreement between 2 raters classifying instances into mutually exclusive groups [43].

Stratification Analysis and Sensitivity Analysis

After validation was completed, we conducted a stratification and sensitivity analysis. We selected 2 stratification variables that could reasonably impact the generalizability of the results. First, we stratified the data by pre- and post-EUA date to confirm that the algorithm behavior did not change for AESIs after the COVID-19 vaccine was approved and administered to a large portion of the population. Ideally, the algorithms would perform consistently across these eras, but there are multiple factors that could impact the performance over these time periods. We also stratified the data by the care setting of the AE diagnosis, given that care settings may be associated with varying EHR data elements (eg, emergency departments compared with inpatient settings). Algorithm performance was computed using PPV within each stratum.

We also completed a post hoc sensitivity analysis where we investigated whether the algorithm could be improved, as measured by PPV, through small changes to it or by updating the process for evaluation. These changes were based on insights from clinicians or data analysts reviewing validation results, so results may not generalize to other data sets. However, we did attempt to limit our analysis to decisions that could have been feasibly made without postvalidation insights. The changes to the algorithms were either removing medications, observations, procedures, or diagnosis codes that are not specific enough to the AESI in question or adding logic to further filter out cases by requiring more supporting evidence (Table 3). The stratification or sensitivity analyses are meant as exploratory analyses to prompt additional research, but subgroups often have too small a sample size that have narrow enough CIs for meaningful results.

We also completed a sensitivity analysis on the GBS algorithm to calculate the PPV if we relaxed some of the specific case definition evaluation criteria and if more general evidence was available. We found that the 2 pieces of evidence that the case definition required were often missing in the chart review tool: lack of cerebrospinal fluid (CSF) white blood cell (WBC) count in cases of elevated CSF protein and limited or inconsistent documentation of diminished or absent reflexes. In some of these cases, we saw evidence that a neurologist was consulted and felt there was strong suspicion of GBS despite the missing documentation for these tests. This could be explained by 2 mechanisms.

First, and most likely, this could be due to data loss during the delivery or translation of EHR data to our chart review tool. Because we did not have direct access to the data, our process for obtaining, translating to different common data models or standards, and presenting the data to clinicians using the chart review tool could cause the data for these tests to be incorrectly mapped.

Second, case definition requirements for GBS are extremely strict, and physicians in this study believed that some of these might have represented valid GBS cases while not meeting every requirement. For example, several of the cases with missing CSF WBC count did mention cytoidalbuminologic dissociation (or similar); in the presence of such a clinical statement, we might infer that CSF WBC count was performed and acceptable to meet the case definition criteria despite a missing test result.

Furthermore, in cases where a neurologist felt strongly that GBS was a likely diagnosis, along with other supporting evidence, it may be acceptable to rely on documented progressive and significant muscle weakness, especially with conflicting reflex findings. In these instances, we placed more weight on the clinician review (which may account for any unforeseen difficulties in data processing and the strictness of the case definition), not relying solely on the available (nonmissing) data types of the algorithm for assigning case diagnostic certainty.

Results

Population Sample

Figure 2 illustrates the identification of the study populations and validation sample. From the study population of 20.7 million medical encounters for 2,666,974 patients over the study period, the algorithm selected 1195 (0.04%) cases of myocarditis/pericarditis, 550 (0.02%) of anaphylaxis, 123 (0.005%) of GBS, 626 (0.02%) of febrile seizure, and 395 (0.01%) of TTS. Of these patient cases (n=2,666,974), a stratified, random sample of 135 (0.01%) cases each was selected from myocarditis/pericarditis, 135 (0.01%) from anaphylaxis, and 395 (0.01%) of TTS. Of these patient cases (n=2,666,974), a stratified, random sample of 135 (0.01%) cases each was selected from myocarditis/pericarditis, 135 (0.01%) from anaphylaxis, and 395 (0.01%) from TTS populations. All 75 pre-EUA cases of GBS and a random sample of 35 post-EUA cases were selected to be validated. A random selection of 100 cases from the pre-EUA period were sampled to validate febrile seizure. An additional 27 negative control cases were sampled for each algorithm from the roughly 20.7 million medical encounters not selected by the algorithm in our study period. In total, 20 of these cases were sampled from the period before the COVID-19 vaccine EUA, and the remaining 7 came from the period after the EUA.
Overall PPV and Interrater Reliability Results

Table 4 presents algorithm performance measured by PPV for each of the 5 AESIs using cases that had sufficient evidence and all cases (ie, including cases unable to be confirmed as positive by clinicians due to insufficient evidence). Counts for the number of cases included in each PPV calculation can be found in Table S3 in Multimedia Appendix 1 [21-23,25-27].

Overall PPVs, when removing all cases with insufficient evidence, were highest for anaphylaxis (93.3%, 95% CI 86.4%-97%) and febrile seizure (89%, 95% CI 80%-94.4%), followed by myocarditis/pericarditis (83.5%, 95% CI 74.9%-89.6%) and TTS at unusual sites (70.2%, 95% CI 61.4%-77.6%). The lowest was for GBS (47.2%, 95% CI 35.8%-58.9%). All negative control cases across the 5 phenotypes were correctly classified by the algorithms.

The PPV results from the chart reviews of the validation sample for each AESI are reported for all cases as well as for only cases with sufficient evidence to make a clear by chart reviewers. The frequencies and percentages for insufficient evidence are presented with the stratification results in Table 5. The interrater reliability scores for clinician chart reviews all showed substantial agreement between the clinicians (Table 6). Interrater reliability, measured by Cohen κ, suggests substantial reliability when the value is >0.61, with many similar texts recommending a higher threshold of 0.80 [43].

Stratification

To evaluate consistency across pre- and post-EUA periods and care settings, we reported true positive and PPV results for each stratum (Table 5).

None of the algorithms had notable differences between the pre- and post-EUA periods since all 95% CIs had some overlap. However, there were some differences between the PPVs for the 2 periods that could be significant with a larger validation sample. The difference in PPV for myocarditis/pericarditis varied from 68% in the pre-EUA period to 51.4% in the post-EUA period, while anaphylaxis showed the opposite pattern with a 70% PPV in the pre-EUA period that increased to 80% PPV in the post-EUA period.

We also reported stratified results by care setting (Table 5). For myocarditis/pericarditis, the PPV of cases with an inpatient care setting (79.1%, 95% CI 69.4%-86.4%) was notably higher than that from the outpatient (38.5%, 95% CI 21.2%-58.8%) or emergency department (22.2%, 95% CI 6.7%-47.9%) care settings.

Anaphylaxis did not have a large difference across care settings, as the 95% CIs overlapped between the 2 care settings. However, they did show better performance with cases in an emergency department (PPV 75%, 95% CI 65.8%-82.4%) care setting over cases with an inpatient care setting (PPV 63%, 95% CI 42.9%-79.7%). The other AESI algorithms filtered for only 1 care setting or had a vast majority of cases in 1 care setting.

Sensitivity Analysis

Medication and Observation Algorithm Changes

We analyzed whether changes to medication code lists for the myocarditis/pericarditis and GBS algorithms could improve performance. For the myocarditis/pericarditis algorithm, removal of nonsteroidal anti-inflammatory drugs from the medication code lists showed no change in PPV at 83.5% (Table 7), but PPV values were higher for cases selected with the pericarditis instead of myocarditis ICD-10 codes.

For the GBS algorithm, when cases were removed where gabapentin (used for post-GBS pain management) was the only supporting evidence, PPV increased to 38.1% (95% CI 28.2%-49.1%) from 30.9% (95% CI 22.9%-40.3%; Table 8).

Our initial febrile seizure algorithm did not use any supporting evidence to filter out possible false positives since we believed we could get adequate PPV without it.

For our sensitivity analysis, we tested requiring supporting evidence in the condition period, such as the presence of medications for reducing fever such as acetaminophen, observation evidence when the patient’s chief complaint was related to fever or seizure, or the presence of both. When filtered to only cases with either medication or observation evidence, febrile seizure PPV increased significantly to 93.3% (95% CI 84.7%-97.6%) from the original algorithm PPV of 73% (95% CI 63.3%-80.9%), with no overlap in 95% CIs and a \(P\) value of <.001 (Table 9). When the algorithm required both medication and observation evidence, it performed even better (PPV 96.9%, 95% CI 88.5%-99.9%).

Diagnostic Code List Changes

We also analyzed if changing diagnostic codes that were used to identify the AESI might lead to higher performance for the myocarditis/pericarditis and TTS algorithms.

For myocarditis/pericarditis, we found that an algorithm only looking for the myocarditis code (PPV 50.9%, 95% CI 37.4%-64.3%) underperformed an algorithm with just pericarditis codes (PPV 72%, 95% CI 61.1%-80.8%; Table 7). For TTS, we found that the main ICD-10 code I81 for “portal vein thrombosis” (73.5%, 95% CI 64%-81.3%) outperformed all other codes in our code list, including G08 (intracranial and intraspinal phlebitis and thrombophlebitis), I82.0 (Budd-Chiari syndrome), I82.3 (embolism and thrombosis of renal vein), and I82.890 (acute embolism and thrombosis of other specified veins), with a PPV of 36.4% (95% CI 21.3%-54.4%; Table 10).
### Case Definition Validation Criteria

Finally, we analyzed whether a small update to our case definition criteria for the GBS algorithms described in the Stratification Analysis and Sensitivity Analysis section would improve reported performance in Table 7. When we applied both changes, the validation criteria change to the algorithm and removal of gabapentin, as discussed in the Medication and Observation Algorithm Changes section, the algorithm achieved a PPV of 57.1% (95% CI 46.2%-67.4%).

### Discussion

#### Principal Findings

#### Overview

The results of this study show that for 4 out of 5 AEsIs, we can build an interoperable computable phenotype with comparable or improved performance to algorithms in the existing literature. These algorithms are developed using a rules-based approach to facilitate their application and increase the generalizability of performance across EHR databases. For the phenotypes with poorer performance, the issues were often that the case definition required documentation of a test that was lost in our data pipeline, or was not completed, or was not recorded by the treating physician or nurse. While these cases are marked as false positives based on our methodology, they may be true AEs that are lacking the documentation to meet the case definition. Some small updates to the algorithms or the case definition evaluation method could be made to potentially improve the algorithms’ performances, but a more important next step would be to validate our algorithms on other data partners to ensure generalizability of the original algorithms and any updates. Given the need for active AE surveillance, this study is still an important first step toward building an algorithm that can be distributed and implemented on health provider EHR databases and can accurately detect AEs.

The PPV results of the phenotypes, negative control groups, and stratification and sensitivity analysis are discussed in more detail in the following sections. Note our negative control groups and many of the stratification and sensitivity analyses have sample sizes too small to draw strong conclusions as illustrated by the width of the 95% CIs for those results. These were exploratory analyses completed as a supplement to the main findings of the study around the PPV of the algorithms.

#### Myocarditis/Pericarditis

The myocarditis/pericarditis algorithm showed strong PPV performance using cases with sufficient evidence. The literature appears to lack good comparison studies against which to evaluate this algorithm’s performance. A meta-analysis from 2013 reviewed myocarditis/pericarditis algorithm studies and found that none of them evaluated their algorithm by calculating PPV [45].

When myocarditis/pericarditis was segmented via care settings, algorithm performance was highest for inpatient settings, with a PPV of 79.1%. This can be attributed to the availability of supporting clinical data needed for accurate case detection in such settings. Given that inpatient testing is necessary to meet the criteria of the case definition, the algorithm performance matches clinical expectations and adds to its public health importance.

In emergency care settings, myocarditis/pericarditis is often diagnosed for patients with a history of inpatient visits to one or more other health systems. This increases the probability of these patients having additional documentation necessary to meet the case definition. This highlights the role of health information exchanges in supporting public health use cases, improving AE reporting, and enhancing postmarket surveillance.

Myocarditis/pericarditis had a notable difference in PPVs for pre- and post-EUA date. The post-EUA date strata of the sample had a higher percentage of cases coming from the emergency department, which had few cases before EUA. This could be explained by patients being diagnosed during previous inpatient stays in other health systems and a lower threshold to provide a preliminary diagnosis with limited information. This category had a lower PPV on average for myocarditis/pericarditis, likely due to less documentation in an emergency care setting than in an inpatient care setting. This highlights the need for further validation of the algorithm in these settings for an effective public health benefit and to gain confidence that our algorithm is fit for purpose. Because the aim of the algorithms is postvaccination AESI detection in support of public health safety surveillance, any potential degradation in performance in the post-EUA period is a concern. If performance decrease

in the post-EUA period is driven by postvaccination myocarditis/pericarditis being more likely to have confounding physical findings that could affect how quickly and in which care setting it gets diagnosed, the PPV from this study may not be applicable to a postvaccination version of the phenotype. There is a small overlap in the 2 periods’ PPV 95% CI, and a 2-sample proportion test returns a P value of .08. This suggests that the difference could also be due to statistical noise. However, given the importance of the post-EUA period to the algorithm’s future task and the size of the difference, we suggest validating additional cases in the post-EUA period to confirm whether the algorithm is actually less effective.

Anaphylaxis

In cases with sufficient evidence, our anaphylaxis algorithm performed strongly with a PPV score of 93.3% (95% CI 86.4%-97%). This shows a possible slight improvement over previous anaphylaxis research, although both results were within the 95% CI [33,34]. When stratified by care setting, the algorithm performed better in emergency department care settings. This can be explained due to the anaphylaxis symptoms and treatment being more likely to be well-documented in this setting. Availability of additional evidence increases the PPV of the algorithm. Since anaphylaxis cases related to vaccination are more likely to culminate in visits to the emergency department, the better performance of the algorithm would provide a better public health benefit.

Overall, the performance of the algorithm was moderate compared with that seen in literature. With no obvious avenues for improvement available, no additional sensitivity analyses were applied.

GBS Algorithm

Our initial GBS algorithm showed weak performance for GBS with a PPV of 47.2% (95% CI 35.8%-58.9%). Given existing research on GBS validations, this result is not surprising, since our result is comparable with a study result showing GBS algorithm validation PPV of 29% (95% CI 24%-34%) [35]. We hoped that our algorithm would improve on this study’s results, allowing us to meet the “moderate” performance threshold defined in the Methods section, given that we added additional logic to require suggested evidence and filter out historical diagnoses. However, we believe that the algorithm’s performance could be improved based on the sensitivity analysis results.

An increase in performance was observed when adjusting the case definition interpretation of GBS to allow for more general written clinical notes or neurology consult evidence to replace specific documented test results. The lack of standardization in laboratory results is fraught with challenges such as inconsistent data. The observed improvement in the GBS phenotype highlighted the need for further standardization to have a better impact on public health benefit.

Furthermore, the performance of the GBS algorithm was improved by the exclusion of nonspecific medications such as gabapentin, increasing its public health benefit. Gabapentin is often used to treat generalized neuropathic pain for a variety of conditions other than GBS, including diabetes, and can confound the results.

With both case definition and medication adjustments to the algorithm, the PPV rose to be closer to the moderate performance threshold and an increase over the cited historical study [35]. Because these changes were informed by the cases in the validation study post hoc, they might be overfitted to this validation sample and may not be generalizable. They should be tested in other EHR systems.

The GBS algorithm performed slightly better in the post-EUA period, but the performance of both periods was well within the 95% CI of the other period. The GBS algorithm only applies to the inpatient care setting; therefore, no care setting stratification analysis was performed.

Febrile Seizure

Our febrile seizure algorithm performed strongly, with a PPV score of 89% using cases with sufficient evidence. This performance is in line with existing febrile seizure algorithm validation research [32], where a febrile seizure validation study on the FDA Sentinel database showed a PPV of 70% (95% CI 64%-76%). Our sensitivity analysis suggests that even better performance could possibly be achieved by adding additional filters to select cases with supporting medication and observation evidence, which are well-documented in EHRs. The better performance of the algorithm provides better public health benefits and further supports the use of EHRs in the detection of AEs. For cases that met either or both criteria, the PPV increased. Since these changes to the algorithm happened after the validation was completed, they overstate the general performance increases when applied to a new EHR setting but offer avenues for a future validation study. Future research can test whether stronger performance is possible with these filters and focus on reviewing the algorithm’s application to AEs following pediatric vaccinations.

TTS Algorithm

The TTS algorithm showed moderate performance for PPV at 70.2% which is similar to a separate FDA TTS validation study which estimated the performance at 76.1% (95% CI 67.2-83.2%) [29]. TTS had consistent performance across both pre- and post-EUA periods and did not have enough cases in the outpatient and emergency department care settings for any defensible findings around diagnosis care setting stratification. Our sensitivity analysis revealed that when the AESI was diagnosed with the ICD-10 code I81 (portal vein thrombosis), the algorithm showed a significant increase when compared with the performance of all other ICD codes (73.5%, 95% CI 64%-81.3%, compared with 36.4%, 95% CI 21.3%-54.4%). Although if an increase to specificity is desired at the cost of some sensitivity, the TTS algorithm could be limited to only select the higher performing I81 diagnosis code.

Limitations

There are several limitations to this study. First, it only evaluates general AESIs and not postvaccination AESIs specifically since the algorithms do not require the evidence of vaccine administration as criteria. While this was necessary due to the...
rareness of the postvaccination AESIs in our data, it is possible that
the algorithms perform worse detecting postvaccination
AESIs specifically since they will often present slightly
differently in different populations when occurring after a
vaccine administration. For example, the major presenting
symptoms appeared to resolve faster in cases of myocarditis
after COVID-19 vaccination than in typical viral cases of
myocarditis [9]. To guard against this, we included both pre–
and post–COVID-19 EUA data with the hope that post-EUA
cases would include some postvaccination AESIs. However,
we did not have enough post-EUA cases available to build a
large enough sample size for a comparison with sufficient
statistical power to provide definitive evidence on this topic.
Another limitation in this vein is the general small sample size
for all stratification, sensitivity, and negative control analyses.
We make sure to state that these analyses are exploratory in
nature, and the reader should not form strong conclusions from
them given their small samples size and large CI range. Future
research could address these concerns by identifying a data
source with enough postvaccination AESI cases to complete a
comparably large validation study.

An additional limitation of this study is that it only measures
algorithms’ PPVs instead of investigating other metrics that
could give a better picture of the algorithm’s holistic
performance such as sensitivity and specificity. Specifically,
these other metrics would estimate how many of the total
positive cases are being identified and how well the algorithm
is able to identify cases without the AESIs. However, we believe
that this limitation is necessary for the following reasons: (1)
the main purpose of this study was to assess the PPV of
phenotypes because it answers the most relevant public health
question, if the algorithms will generate a quality detected set
of AE cases for the public health surveillance and (2) a much
higher cost and more extensive data sharing are needed to
properly estimate sensitivity and specificity because of the
required validation sample size necessary for a negative control
group. To calculate PPV, one only needs a sample of the cases
selected by the algorithm. To estimate the sensitivity and
specificity, however, it would be necessary to also validate an
extremely large negative control group sample since the AESI
conditions that the algorithms try to detect are often rare events.
We would expect it to be even more rare for these conditions
of interest for AESIs to happen and not be recorded with types
of structured data elements that are being used in the phenotypes.
In fact, the lack of structured data elements in some negative
control cases led to a clinician asking the research team if
something was wrong because their case had no relevant charted
events to be reviewed. A much larger validation study would
also expose clinicians to a larger set of patient data for cases
that have a low likelihood of having an AE. This approach limits
the interaction with protected health information data until the
algorithms’ PPVs support continued research with broader
samples and methodologies.

Another limitation is that although they were designed to be
simple to deploy, the algorithms are still time-consuming to
apply to different EHR systems. Although a hallmark of this
algorithm is its interoperability, the algorithm logic still must
be applied to the EHR common data model or extracted and
translated into another common data model as was done for this
study. Interoperable codes should be available for all patients,
given the requirement to provide patient data in an interoperable
FHIR standard. However, given the recency of the requirement,
they might not be available in all systems and require some
code translation on the health organization side, especially when
analyzing at the population level. In addition, since the
interoperable codes will only be available through a FHIR API,
this adds another data pull and integration with the EHR system
to obtain these codes for the algorithm.

In the future, the evolving landscape of health IT may facilitate
the public health use cases of detecting and reporting
postvaccination AESIs in a safe and secure manner that protects
patient privacy. This could be achieved by EHRs supporting
secure querying of patient cohorts with probable postvaccination
AESIs using clinical query language [46] or other interoperable
query language. Reducing the burden of automatic detection of
postvaccination AESIs would help public health organizations
improve AE surveillance with minimal additional burden to
health care organizations and providers.

A final limitation of this study is that the algorithms were only
applied to 1 site. Going forward, algorithm performance should
be validated at other sites to ensure their generalizability.
Although the algorithms were generated without prior input
from the data, the study is still limited to 1 health care
organization, and this method could have different operating
characteristics (PPV, sensitivity, etc) at a second location.
Future research can be performed to improve algorithm accuracy
and as stated previously would require additional partner EHR
data systems. To create a better performing algorithm, machine
learning techniques could be used to train the model to identify
specific patterns of data instead of relying on rules-based
methods that incorporate published case definition criteria and
clinical subject matter expert experience. When given enough
data, machine learning approaches generally outperform
rules-based approaches across domains, and some prior research
suggests that this is true in the medical domain as well [47].
However, machine learning methods will not generalize across
EHR systems because the data patterns that machine learning
identifies could be specific to an individual health care
organization. Trying to build a large data set that combines
multisite data is extremely difficult and costly due to concerns
over infrastructure, regulations, privacy, and data
standardization. A method such as federated learning could be
explored to alleviate this problem. Federated learning allows
multiple sites to collaboratively train a global model without
directly sharing data and has been used to train machine learning
algorithms at EHR sites previously [48].

Conclusions
In summary, this study presents strong initial evidence that
creating simple, interoperable, rules-based phenotypes can detect
AESIs on a new data source and that the phenotypes outperform
the PPV outcomes for historical validations studies for these
conditions. The study validates 5 different AESIs to prove that
this approach can work for a broad range of AESIs, while also
highlighting where the approach might be less successful. For
example, the GBS algorithm was built using ICD-10 codes that previous validation studies have demonstrated are not accurate predictors of a GBS case that meets case definition criteria; subsequently, our GBS algorithm performed poorly. The validation study sample sizes for all AESIs allowed for adequate precision to evaluate algorithm PPV against historical studies.

An active surveillance system can enhance vaccine safety and aid in the development and use of safer vaccines and recommendations to minimize the AE risks after vaccination [49]. The algorithms were developed using a method that should be able to be applied to and generalize performance for new EHR databases, but more research is needed to confirm this. If the methodology can be successfully used to detect postvaccination AESI cases across EHR databases, these algorithms could be deployed widely to inform FDA decision-making, promote public safety, and improve public confidence. Going forward, further research and investigation are needed to enhance algorithm performance and integrate the algorithms across health care organizations for active surveillance in the interest of public health.

Acknowledgments
Development of the manuscript benefitted from significant engagement with the Food and Drug Administration (FDA) Center for Biologics Evaluation and Research (CBER) team members and their partners. The authors thank them for their contributions. Additional feedback on the manuscript was provided by IBM Consulting (Stella Muthuri and Brian Goodness), Accenture Consulting (Shayan Hobbi), and Korrin Bishop (writing and editing). This research was funded through the FDA CBER Biologics Effectiveness and Safety Initiative. Several coauthors hold commercial affiliations with Accenture, IBM Consulting, and MedStar Health Research Institute. Accenture (PSH); IBM Consulting (AAH, JP, JB, AS, EM, LDJ, and MD); and MedStar Health Research Institute (AZH and JB) provided support in the form of salaries for authors but did not have any additional role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Data Availability
The data sets generated during and analyzed during this study are not publicly available, and were only made available to the Food and Drug Administration for the purpose of evaluating algorithms for adverse events of special interest outcomes. For inquiries or questions regarding the data, individual queries should be directed to the corresponding author.

Conflicts of Interest
Authors AAH, JP, JB, AS, EM, LDJ, and MD are or were employed by IBM while participating in the study. PSH is employed by Gevity Consulting, Inc, a part of Accenture. Authors AZH and HJB are employed by MedStar Health Research Institute, and AZH holds an appointment with Georgetown University School of Medicine. These authors have delivered clinical and epidemiology consulting engagement for public and private sector partners. These affiliations did not impact the study design, data collection and analysis, decision to publish, or preparation of the manuscript and do not alter our adherence to JMIR policies on sharing data and materials. The opinions expressed are those of the authors and do not necessarily represent the opinions of their respective organizations. The remaining authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.

The Association Between Personality Traits and Health-Related Quality of Life and the Mediating Role of Smoking: Nationwide Cross-Sectional Study

Jiangyun Chen1,*, PhD; Jiahuan Wan1,*, PhD; Li Gan1, MA; Haomiao Li2, PhD; Yan Zhou3, MA; Siyuan Liu4, PhD; Lan Luo5; Haozheng Zhou4; Xuanhao Yin4; Jinghui Chang1, PhD

Abstract

Background: There are positive and negative correlations in different directions between smoking, personality traits, and health-related quality of life (HRQOL), where smoking may mask the pathway between personality traits and HRQOL. Understanding the masking pathway of smoking between personality traits and HRQOL can elucidate the mechanisms of smoking’s psychosocial effects and provide new ideas for developing tobacco control strategies.

Objective: The purpose of this study was to investigate the correlation between Big Five personality traits and HRQOL and whether smoking mediates the relationship between them.

Methods: This was a cross-sectional study using data from 21,916 respondents from the 2022 Psychology and Behavior Investigation of Chinese Residents survey. Linear regression models were used to analyze the correlations between smoking, Big Five personality traits, and HRQOL while controlling for potential confounders. The mediating role of smoking on the association between Big Five Personality traits and HRQOL was analyzed using the Sobel-Goodman mediation test.

Results: Extraversion (β=0.001; P=0.04), agreeableness (β=0.003; P<0.001), and neuroticism (β=0.003; P<0.001) were positively correlated with HRQOL, whereas openness was negatively correlated with HRQOL (β=−0.001; P=0.003). Smoking was associated with a decrease in HRQOL and mediated the positive effect of HRQOL on extraversion (z=−2.482; P=0.004), agreeableness (z=−2.264; P=0.02), and neuroticism (z=−3.230; P=0.001). Subgroup analyses further showed that smoking mediated the effect of neuroticism on HRQOL in the population with chronic illnesses (z=−2.724; P=0.006), and in the population without chronic illnesses, smoking contributed to the effect of HRQOL on extraversion (z=−2.299; P=0.02), agreeableness (z=−2.382; P=0.02), and neuroticism (z=−2.213; P=0.03).

Conclusions: This study provided evidence that there is a correlation between personality traits and HRQOL. It also found that smoking plays a role in mediating the connection between personality traits and HRQOL. The development of future tobacco control strategies should consider the unique traits of each individual’s personality, highlighting the significance of extraversion, agreeableness, and neuroticism.

(KEYWORDS: Big Five personality; HRQOL; smoking; mediation; tobacco control; China; neuroticism; extraversion; agreeableness; health-related quality of life)

Introduction

A widely recognized theoretical framework in the field of personality psychology is the Big Five personality model, which classifies personality traits into 5 dimensions: openness, conscientiousness, extraversion, agreeableness, and neuroticism [1]. The stability and validity of the Big Five personality theory have been consistently confirmed by previous research, which has conducted long-term follow-up studies, cross-cultural studies, and comparisons across various age groups. Studies have revealed that the Big Five personality traits are significantly correlated with diverse behaviors and adaptations [2], along
with their interplay with genetic and environmental factors [3,4]. Various characteristics of individuals have been discovered to have a strong association with academic success [5], professional pathways [6], interpersonal connections [7], physical well-being, and psychological well-being [8,9]. The extensive applications of the Big Five personality theory span across multiple domains, encompassing talent management [10], mental health research [11], style of behavior [11,12], clinical practice [13], personal growth, and education [14,15]. By evaluating the Big Five personality traits, scientists have gained insights into individuals’ personality characteristics, offering direction and support. Prior research has additionally indicated that although a person’s character attributes remain relatively consistent, the manifestation of these attributes is not completely rigid. Moreover, an individual’s encounters, surroundings, and cultural upbringing can also influence their character traits and their overall quality of life in terms of health (health-related quality of life [HRQOL]) [16,17].

The Big Five personality theory is extensively used in the domains of health behavior and psychology to examine how personality traits influence behavioral traits and health outcomes in populations [18,19]. Research has confirmed a robust correlation between aspects of the Big Five personality traits and HRQOL. People who have a strong inclination toward openness are generally more welcoming toward novel encounters, have a wider array of hobbies, and exhibit a sense of curiosity. These traits are linked to increased levels of contentment and overall quality of life [20]. Individuals who possess a strong sense of duty and a proactive attitude toward accomplishing tasks tend to have high conscientiousness. This trait is linked to improved mental well-being, reduced negative emotions, and enhanced HRQOL [21]. Individuals who have a high level of extraversion generally have enhanced social abilities, display optimistic emotional expression, and are more inclined to form and sustain positive interpersonal connections. As a result, they experience increased life satisfaction and happiness [22]. People who possess a strongly agreeable nature tend to pay closer attention to the happiness and welfare of those around them. They demonstrate kindness, empathy, and assistance in social engagements, which are linked to improved HRQOL, increased social support, and reduced feelings of isolation [23]. Individuals exhibiting elevated levels of neuroticism are prone to experience anxiety, tension, and negative emotions, which have been linked to diminished levels of life contentment and overall welfare [24]. However, some studies have proposed the concept of “healthy neuroticism,” which refers to individuals with neurotic traits that do not lead to physical and mental health problems [25,26]. The healthy neuroticism theory suggests that neurotic individuals may pursue perfection, possess higher alertness and introspection, and have higher demands on themselves, which may positively influence health behaviors and thus positively impact HRQOL through high alertness to unhealthy behaviors [27].

Personality is also associated with smoking. For example, people with a high level of extraversion are usually more prone to seeking excitement and engaging in daring pursuits, which increases their susceptibility to the temptation of smoking [28]. On the other hand, people with a strong sense of conscientiousness are inclined to be more accountable and have a greater tendency to follow healthy habits, such as refraining from smoking [29]. People with a high level of agreeableness typically exhibit a compliant and cooperative demeanor. As such, those with higher agreeableness exhibit more positive social and prosocial behaviors [30], but they are also more susceptible to being socially influenced to smoke. People with a high level of openness tend to be more inclined to engage in novel activities and are more susceptible to experimenting with smoking [31]. In contrast, people with a high level of neuroticism are prone to feeling anxious and stressed and experiencing negative emotions, which increases their likelihood of initiating smoking and makes it harder for them to quit [32].

Older adults and individuals with underlying diseases are particularly affected by smoking, as it leads to a decline in HRQOL due to health hazards, mental strain, financial strain, and limitations on social activities [33,34]. Multiple research studies have firmly established a robust correlation between tobacco use and the emergence of diverse ailments, such as increasing the burden of cerebral cancer and mortality [35], underscoring its substantial capacity to jeopardize human well-being. According to the World Health Organization Report on the Global Tobacco Epidemic 2021, tobacco remains a significant contributor to untimely fatalities on a global scale [36]. China, being the biggest manufacturer and user of tobacco on a global scale, bears the sole responsibility for around 1 million tobacco-related deaths [37]. The use of tobacco is a significant contributing factor linked to the greatest load of long-term illness, and a decrease in tobacco consumption can result in decreased occurrences of heart disease, stroke, and additional chronic ailments.

Past studies have confirmed that characteristics of an individual’s personality affect both their HRQOL and smoking habits, where smoking is found to have an adverse effect on HRQOL. Nevertheless, the correlation among these 3 variables remains incompletely comprehended, particularly concerning individuals with long-term illnesses. Examining the mechanisms of interaction between Big Five personality traits, smoking, and HRQOL and conducting tobacco control efforts at the level of individual personality traits can provide new perspectives for improving HRQOL. Based on these reasons, this study formulated the following hypotheses:

- **Hypothesis 1**: The Big Five personality traits influence HRQOL.
- **Hypothesis 2**: Smoking is associated with Big Five personality traits and HRQOL, where smoking plays a mediating role between them.

**Methods**

**Participants**

The information used in this investigation was acquired from the 2022 Psychology and Behavior Investigation of Chinese Residents survey. From June to August 2022, a comprehensive survey was carried out in 148 cities; 202 districts and counties; 390 townships, towns, and streets; and 780 communities and villages spanning 23 provinces, 5 autonomous regions, and 4
municipalities under the central government. To ensure the overall representativeness of the study population, the survey used a multistage sampling technique, incorporating stratified sampling at various levels including provincial; city; district and county; township, town, and street; and community and village. Quota sampling was used at the community and village level as well as at the individual level, using quotas that were determined based on sex and age attributes from the data of the Seventh National Population Census. In every city, there was recruitment of at least 1 enumerator or survey team, where each enumerator had the duty of gathering 30 - 90 questionnaires and each survey team had the duty of gathering 100 - 200 questionnaires. The questionnaires were distributed through the web-based Questionnaire Star platform, and if face-to-face surveys were possible in the area, the investigator filled out the questionnaires on site on a one-to-one basis. In the event that face-to-face surveys were impractical due to the constraints of the new coronavirus outbreak, electronic surveys were individually provided to the participants. Participants provided their responses by clicking on the questionnaire link, and they were required to give their informed consent. The study included individuals who were at least 12 years of age, held citizenship in the People’s Republic of China, and were permanent residents of China with an annual out-of-home time of no more than 1 month. Participants who did not fulfill the criteria for this research were disqualified. A total of 23,414 questionnaires were collected for the study, ensuring high quality and national representativeness of the data. After eliminating duplicates and excluding missing data and logically inconsistent outlier data, 21,916 respondents were finally included in this study, with a valid response rate of 93.6% (21,916/23,414). The survey protocol has been published [38].

Ethical Considerations
This study complied with the ethical review rules of the Health Culture Research Center of Shaanxi (JKWH-2022-02). Informed consent was obtained for the investigation. Respondents completed an anonymous, web-based survey in approximately 30 minutes.

Variables

Dependent Variable
The health status of the population was assessed using HRQOL in this study. The measurement of HRQOL was conducted using the EQ-5D-5L traditional scale, which has been proven to be better than its previous version, the EQ-5D-3L, in terms of practicality, upper limit impact, distinguishing ability, and agreement with other measures [39,40]. The EQ-5D-5L scale consists of 5 aspects: mobility, self-care, daily activity performance, pain or discomfort, and anxiety or depression, as specified in Multimedia Appendix 1. There are 5 levels for each dimension, ranging from 1 (no problems) to 5 (extreme problems). The levels of these questions can describe 243 combinations ranging from 11,111 (perfectly good) to 55,555 (perfectly poor). These health states are assigned an index value, known as the health state index (HIS), which reflects the weighting of society’s preference for the health state. The HIS score varied from below 0 (where 0 represents the health state value of death; negative values indicate a health state worse than death) to 1 (representing perfect health), with higher scores indicating better health utility [40]. Based on their health preferences, the HIS value estimates for the Chinese population vary between −0.391 and 1, representing the worst and best outcomes. In this study, the final HIS was obtained according to the utility value conversion formula \((X – \min)/(\max – \min)\) of \([0,1]\) [41].

Independent Variable
The assessment of personality involved the use of the Big Five Inventory (BFI)–10, a condensed variant of the comprehensive BFI-44. In this study, the reliability and validity of the BFI-10 were assessed to confirm its suitability for situations where there are time constraints or it is not feasible to conduct a personality assessment (eg, telephone surveys, etc). The scale consists of 10 items that assess 5 personality dimensions: extraversion, agreeableness, conscientiousness, neuroticism, and openness. A 5-point Likert scale is used to score each item, with higher scores indicating a stronger trait. Extraversion is assessed by questions 1 and 6, agreeableness is assessed by questions 2 and 7, conscientiousness is assessed by questions 3 and 8, neuroticism is assessed by questions 4 and 9, and openness is assessed by questions 5 and 10. It should be mentioned that questions 1, 3, 5, 7, and 9 are scored in the opposite direction [42].

Mediation Variables
Smoking behavior was assessed by asking respondents about their current smoking habits. Specifically, they were asked, “Do you currently smoke?” Responses were categorized into 5 levels: 0=“No”; 1=“Yes, regular cigarettes”; 2=“Yes, e-cigarettes”; 3=“Yes, both”; and 4=“Ever (quit).” For this study, smoking was divided into 2 categories depending on whether participants were presently smoking or not: 0=never smoked or used to smoke but have stopped, and 1=currently smoking.

Covariates
The variables examined in this research consist of the socioeconomic background of the participants (including sex, age, group, area of residence, ethnicity, political status, religion, household income, educational level, occupation, and social status); family attributes (marital status and family type); lifestyle elements (smoking habits and alcohol intake); and mental health status related to perception of stress, perception of social support, self-confidence, and health knowledge. Detailed information on the definitions and categorization of these variables can be found in Multimedia Appendix 2. The choice of covariates was determined by their correlation with the independent variables, as well as their impact on the association between the independent variables and the dependent variable. Age group and sex were adjusted as fixed covariates. If the other covariates changed the dependent variable by more than 10% with the independent variable or were significantly associated with the dependent variable, they were included as potential confounding factors in the final model. The Empower software (X&Y Solutions) was used to test the selected covariates, which were chosen based on established associations or plausible biological relationships. These covariates include...
ethnicity, political status, religion, area of residence (a special Chinese identifier that impacts various aspects of life in China, such as purchasing a house or a car, public health insurance reimbursement rate, and welfare benefits), household income, education level, occupation, social status, marital status, family type, alcohol consumption, stress perception ability, social support appreciation ability, self-efficacy, and health literacy. Multimedia Appendices 3 and 4 contain detailed findings.

Statistical Analysis

The basic study population description included the presentation of chronic diseases characteristics (yes, no, and total) as mean (SD) for continuous variables and as frequency (%) for categorical variables. To examine variations in the attributes of chronic diseases, a 2-tailed Student t test was used for continuous factors, whereas the χ² test was used for categorical factors. The correlation between smoking, Big Five personality traits, and HRQOL was measured using linear regression models. This was done before and after adjusting for covariates, and the findings were presented as β coefficients along with 95% CIs. The Sobel-Goodman mediation test was used to examine the impact of smoking on Big Five personality traits and HRQOL while taking into account all covariates [43]. Statistical significance was determined using 2-sided P values, with α<.05 as the threshold. The analysis of data was conducted using Stata (version 17; StataCorp).

Results

General Characteristics

The sample analyzed in this study consisted of 21,916 cases. There was an equal distribution of sexes, with 10,958 (50%) participants identifying as male and 10,958 (50%) identifying as female. A total of 71.4% (n=15,647) of the participants fell within the age group of 18 - 59 years, and 56.75% (n=12,437) of them were married. The vast majority of respondents were of Han nationality (n=19,970, 91.12%), had no religion (n=21,058, 96.09%), and had “the masses” as their political status (n=13,912, 63.48%). Over half (n=11,811, 53.89%) of the participants lived in urban regions, with a greater proportion belonging to the high-income bracket (n=8032, 36.65%). The majority (n=15,214, 69.42%) of the respondents reported never drinking alcohol, and the largest proportion (n=9773, 44.59%) had tertiary education. In all, 34.68% (n=7601) were employed, with over half (n=11,574, 52.81%) of the family type being a core family. The prevalence of smoking was 14.87% (n=3258). The average social status of the respondents was close to the upper-middle class (mean 4.35, SD 1.30; out of a total score of 6). Among individuals with chronic illnesses, there was a notable decline in HRQOL (mean 0.92, SD 0.10), which was significantly lower than that of the overall sample (mean 0.96, SD 0.10; P<.001). Individuals with chronic illnesses exhibited a diminished level of extraversion (mean 6.14, SD 1.61; P<.001) compared to that of the overall sample (mean 6.23, SD 1.62). The average rating for agreeableness was 7.00 (SD 1.48). The average score for conscientiousness was 6.76 (SD 1.65), and individuals with chronic diseases exhibited a higher level of conscientiousness (mean 6.98, SD 1.65; P<.001). The average score for neuroticism was 6.27 (SD 1.56). Individuals with chronic illnesses exhibited a diminished level of openness (mean 6.20, SD 1.61), which was significantly lower than that of the overall sample (mean 6.46, SD 1.55; P<.001). The average rating for perceived stress capacity was 6.55 (SD 2.54), indicating an increase among individuals with chronic illnesses (mean 6.63, SD 2.57; P=.02). Moreover, the population with chronic illnesses experienced a decrease in their corresponding competencies, specifically in comprehending social support (mean 15.03, SD 3.78), self-efficacy (mean 7.79, SD 2.42), and health literacy (mean 27.55, SD 5.30), suggesting a decline in these abilities (P<.001). Table 1 contains comprehensive details.

Correlation Analysis

Before accounting for covariates, the linear regression model revealed a detrimental association between smoking and HRQOL ($\beta=-.028; P<.001$). Additionally, HRQOL exhibited significant correlations with extraversion ($P<.001$), agreeableness ($P<.001$), conscientiousness ($P<.001$), neuroticism ($P<.001$), and openness ($P=.001$). After making adjustments for various factors such as sex, age range, ethnicity, political status, religion, area of residence, household income, place of residence, education level, occupation, social status, marital status, family structure, alcohol consumption, ability to perceive stress, ability to appreciate social support, self-confidence, and health knowledge, the findings indicated that smoking still had a negative association with HRQOL ($\beta=-.016; P<.001$). Additionally, extraversion ($\beta=.04$), agreeableness ($\beta=.003; P<.001$), neuroticism ($\beta=.003; P<.001$), and openness ($\beta=.001; P=.003$) were all significantly linked to HRQOL. However, in the population with chronic illnesses, the findings of the model, after accounting for covariates, indicated that only tobacco use ($\beta=-.021; P<.001$), agreeableness ($\beta=.003; P=.005$), and neuroticism ($\beta=.005; P<.001$) exhibited a correlation with HRQOL. Table 2 provides the comprehensive details.

Before accounting for covariates, the initial linear regression analysis revealed that smoking had a negative correlation with...
agreeableness ($\beta = -0.107; P < 0.001$), neuroticism exhibited a positive correlation with smoking ($\beta = 0.185; P < 0.001$), and openness displayed a negative correlation with smoking ($\beta = -0.247; P < 0.001$). The findings after accounting for covariates indicated that extraversion ($\beta = 0.077; P = 0.02$), agreeableness ($\beta = 0.059; P = 0.04$), and neuroticism ($\beta = 0.089; P = 0.004$) exhibited a positive association with smoking. After accounting for covariates, the model demonstrated a noteworthy impact of neuroticism ($\beta = 0.155; P = 0.004$) within the group of individuals with chronic illnesses. Table 3 provides a comprehensive overview of the detailed information.

Figure 1. Mediating model of smoking in the association between Big Five personality traits and health-related quality of life (HRQOL).

Subgroup Analysis

In Table 5, the subgroup analysis revealed that smoking acted as a mediator between Big Five personality traits and HRQOL in individuals with chronic diseases. In particular, among individuals with chronic diseases, there was a positive correlation between neuroticism and smoking ($\beta=.012; P=.001$), whereas smoking showed a negative correlation with HRQOL ($\beta=-.020; P<.001$). Additionally, neuroticism exhibited a positive correlation with HRQOL ($\beta=.005; P<.001$). Smoking mediated $-5.1\%$ of the effect HRQOL had on neuroticism ($z=-2.724, P=.006$). Smoking mediated $-13.6\%$ of the effect HRQOL had on extraversion ($z=-2.299; P=.02$), $-1.7\%$ of the effect HRQOL had on agreeableness ($z=-2.382; P=.02$), and $-1.5\%$ of the effect HRQOL had on neuroticism ($z=-2.213; P=.03$) among the population without chronic illnesses. The extent to which smoking behavior mediated the relationship between agreeableness and HRQOL was slightly greater than that of neuroticism, whereas smoking behavior was the least relevant on the relationship between extraversion and HRQOL. Figure 2 displays the ultimate mediation model for the subgroup of the population with chronic diseases.

**Discussion**

**Principal Findings**

Prior research has established robust connections between tobacco use and HRQOL [44], along with the correlations between personality traits and both smoking and HRQOL [45,46]. Nevertheless, there has been no research conducted so far that has investigated the correlation among these 3 variables. The impact of smoking on the relationship between the Big Five personality traits and HRQOL was investigated in our research. We used data from a nationwide cross-sectional survey conducted in China, which encompassed 32 provinces, including autonomous regions and centrally governed municipalities.

Through the process of mediation decomposition, we were able to provide additional evidence that smoking mediates the relationship between Big Five personality traits and HRQOL. The results of our study indicate that there is not only a direct correlation between Big Five personality traits and HRQOL but also an indirect correlation through smoking. Subgroup analyses for people with chronic conditions were also carried out.

The study findings indicated that extraversion, agreeableness, and neuroticism have a positive correlation with HRQOL, whereas openness has a negative correlation. Previous research has demonstrated that the Big Five personality traits impact well-being, life satisfaction, and self-identity, and thus HRQOL, through different personality traits [46]. People who possess...
elevated levels of extraversion and agreeableness have a greater tendency to form enduring and beneficial social connections, which can help reduce psychological strain and feelings of isolation [22, 23]. Moreover, they possess a sunnier perspective on existence and exhibit enhanced resilience in the face of life’s obstacles and stresses [47]. Surprisingly, our research discovered a positive correlation between high neuroticism and HRQOL, which contradicts previous study results. There is a widespread belief that elevated neuroticism is linked to feelings of anxiety, depression, and various other negative emotions [48], ultimately resulting in a diminished quality of life [24, 49]. However, according to the theory of healthy neuroticism, people with healthy neurotic traits aim for flawlessness and exhibit a heightened state of vigilance and self-reflection toward detrimental actions. As a result, their chances of encountering physical and psychological health issues are reduced [25, 26]. Conversely, individuals who possess elevated levels of openness are not constrained by conventional notions and routines, and they might experience remorse for impulsive or erroneous behaviors [50]. Excessive attention to and maintenance of interpersonal relationships can also diminish life satisfaction and happiness [51].

Furthermore, our study provided evidence for the favorable correlations among extraversion, agreeableness, and neuroticism personality traits with smoking. Personality traits that promote social interactions, such as being friendly and reliable, are linked to high levels of extraversion and agreeableness [52]. As smoking is often perceived as a social behavior in some settings, these individuals may be more susceptible to social influence to start or quit smoking [53, 54]. Conversely, people with elevated levels of neuroticism have a greater susceptibility to anxiety and stress [55]. Since nicotine can provide temporary relief from these emotions [56], individuals with high neuroticism may be inclined to use smoking as a coping mechanism, increasing their likelihood of initiating smoking or becoming regular smokers.

The act of smoking has been associated with a decrease in different aspects of HRQOL and the emergence of multiple long-term illnesses [57]. The results of our study indicated a consistent negative correlation between smoking and HRQOL, which was observed in both the entire population and the subgroup with chronic diseases, aligning with previous research. Furthermore, our research suggests that smoking mediates the relationship between extraversion, agreeableness, and neuroticism personality traits and HRQOL. High levels of extraversion and agreeableness are positively correlated with HRQOL, but they are also strongly associated with smoking, as these personality types are more likely to smoke due to a need for social interaction [58]. Smoking has a more significant correlation with HRQOL compared to the favorable correlations of high extraversion and agreeableness, thus smoking’s mediation weakens this positive effect. Furthermore, our research discovered that smoking can mediate the positive impact of highly healthy neuroticism on HRQOL. Prior research demonstrated that high neuroticism can be positively associated with HRQOL by promoting “healthy neuroticism” or introspection; it is also strongly associated with smoking, as people with high neuroticism are more likely to become dependent on tobacco for anxiety relief and experience symptoms of tobacco dependence [32]. The negative effect of smoking on HRQOL is greater than that of high neuroticism. Due to the mediation of smoking, the positive effect of high neuroticism on HRQOL is also weakened.

The findings from the subgroup analysis additionally indicate that smoking plays a mediating role in connecting neuroticism and HRQOL in the population with chronic diseases. However, the mediating effect in the population with chronic diseases remains similar to that of the overall population. The different mediating effects of personality traits in the populations with and without chronic diseases may be due to several factors. For example, the act of smoking is a major contributor to long-term health conditions, and people who have chronic illnesses may experience mental health issues such as neuroticism and anxiety due to their ailment. Furthermore, persistent illnesses frequently necessitate extended periods of therapy and medication, potentially leading to the formation of a neurotic character trait [59]. The findings of this research suggest that although the influence of mediation was minimal for certain traits, the Sobel-Goodman test produced noteworthy outcomes, indicating the existence of mediated routes. Considering the limited impact magnitudes, it is conceivable that alternative mechanisms are at play.

To summarize, our study supports the notion that smoking acts as a mediator in the relationship between the Big Five personality traits and HRQOL. Therefore, using a single tobacco control plan for the entire community may not be the best course of action; instead, tailored smoking cessation tactics based on various personality qualities can be taken into consideration. For individuals with high levels of extraversion and agreeableness, interventions such as smoking cessation environments; legislation; and support from partners, friends, or support groups can greatly increase the chances of successfully quitting smoking [60]. Providing emotional support, actively listening to their emotions and uncertainties, and assisting them in discovering suitable emotion management methods such as deep breathing and relaxation exercises to manage mood fluctuations during the process of quitting smoking could potentially yield greater advantages for individuals exhibiting elevated levels of agreeableness [61]. For people with high neuroticism, it is more important to promote self-reflection among people with high neuroticism and shape healthy neuroticism by sharing the dangers of smoking and health knowledge; provide anxiety management techniques such as deep breathing, meditation, or relaxation training to help them cope with anxiety and stress during the process of quitting smoking; and emphasize internal factors such as self-efficacy in interventions [62, 63]. It is noteworthy that the correlation coefficients between personality traits and HRQOL in this study were small, and that HRQOL may provide a critical research perspective not from a clinical but from a psychosocial point of view, as HRQOL covers a wealth of information and personality traits are a potential factor influencing HRQOL. We initially explored the pathway through which Big Five personality traits influence individual HRQOL, and this pathway does exist. In addition, the mechanisms by which Big Five personality traits acts on HRQOL may be
complex, and some mediating effects may be overshadowed by direct effects.

**Limitation**

Although this study revealed a mediating role of smoking in the relationship between Big Five personality traits and HRQOL, it is important to acknowledge the existence of certain constraints that need to be considered. First, this study has the inherent limitations of cross-sectional studies in inferring causality. Because a cross-sectional study is conducted at a specific point in time, it can only reveal correlations between variables and cannot directly determine causality. Thus, although our cross-sectional study found associations between Big Five personality traits, smoking, and HRQOL, these results were not sufficient to suggest a causal relationship between them. Future research can explore the potential reciprocal association between the Big Five personality traits and HRQOL using longitudinal and prospective studies, thereby further validating and explaining our findings. Second, the correlation coefficients and mediating effects of our study were not very large, and further exploration needs to be made in the future as to exactly how Big Five personality traits affect HRQOL and how smoking mediates the relationship between Big Five personality traits and HRQOL. Finally, since all variables were reported by the participants themselves, there is a possibility of recall and cognitive biases being present, which could impact the precision of factors associated with health and personality. Furthermore, the formation of an individual’s character requires a significant amount of time, and as one matures, their character tends to become more steadfast and influenced by their surroundings. As a result, personality scores may have some bias in their immediate outcomes.

**Conclusion**

This study demonstrated that smoking mediates the relationship between extraversion, agreeableness, and neuroticism personality traits and HRQOL. Additionally, smoking can mediate the effect neuroticism have on HRQOL in a population with chronic illnesses. In the future, when creating tobacco control strategies, it is important to consider the impact of personality, as suggested by these findings. We hope that our study will contribute to increasing the global smoking cessation rate and reducing the incidence of chronic diseases caused by smoking. This could assist in the advancement of campaigns promoting smoke-free initiatives and aid in the creation of a healthier and smoke-free atmosphere.

Abstract

Background: Physical exercise is one of the main nonpharmacological treatments for most pathologies. In addition, physical exercise is beneficial in the prevention of various diseases. The impact of physical exercise has been widely studied; however, existing meta-analyses have included diverse and heterogeneous samples. Therefore, to our knowledge, this is the first meta-analysis to evaluate the impact of different physical exercise modalities on telomere length in healthy populations.

Objective: In this review, we aimed to determine the effect of physical exercise on telomere length in a healthy population through a meta-analysis of randomized controlled trials.

Methods: A systematic review with meta-analysis and meta-regression of the published literature on the impact of physical exercise on telomere length in a healthy population was performed. PubMed, Cochrane Library, SCOPUS, Web of Science, and Embase databases were searched for eligible studies. Methodological quality was evaluated using the Risk Of Bias In Nonrandomized Studies of Interventions and the risk-of-bias tool for randomized trials. Finally, the certainty of our findings (closeness of the estimated effect to the true effect) was evaluated using Grading of Recommendations, Assessment, Development, and Evaluations (GRADE).

Results: We included 9 trials that met the inclusion criteria with fair methodological quality. Random-effects model analysis was used to quantify the difference in telomere length between the exercise and sham groups. Meta-analysis showed that exercise did not significantly increase telomere length compared with the control intervention (mean difference=0.0058, 95% CI −0.05 to 0.06; P=.83). Subgroup analysis suggested that high-intensity interventional exercise significantly increased telomere length compared with the control intervention in healthy individuals (mean difference=0.15, 95% CI 0.03-0.26; P=.01). Furthermore, 56% of the studies had a high risk of bias. Certainty was graded from low to very low for most of the outcomes.
Conclusions: The findings of this systematic review and meta-analysis suggest that high-intensity interval training seems to have a positive effect on telomere length compared with other types of exercise such as resistance training or aerobic exercise in a healthy population.

Introduction

Background

Telomeres are nucleoprotein structures located at the ends of eukaryotic chromosomes and are of critical importance both in the maintenance of genomic stability and in the processes of tumor suppression and aging [1]. In most eukaryotic cells, telomeres consist of tandem repeats of a guanine-rich sequence (TTAAGGG) that develop at the end of chromosomes in the 5’ to 3’ direction, with a complementary cytidine-rich chain [2].

Telomeric sequences may vary between species; however, every organism possesses the same repetitive sequence for all telomeres. At birth, the telomeres of human somatic cells contain approximately 15 kilobases. In the absence of telomerase, an average of 25 to 200 bases are lost from the telomeric ends at each cell division [3]; when the length of the telomere reaches below a critical limit, cell division ceases, and the cell ages and dies [4]. The main function of telomeres is to protect the ends of chromosomes and prevent their degradation and fusion while maintaining genomic stability [5,6].

Several studies have suggested that short telomere length is associated with progressive acceleration of aging, including an increase in age-related diseases such as osteoporosis, cancer, and dementia [7-9]. Therefore, it seems evident that controlling telomere length could be a key factor in the aging process and health care.

Regular physical exercise is one of the main nonpharmacological strategies used to prevent the onset of age-related diseases. Physical exercise is defined as planned, structured, repetitive, and purposeful physical activity, that is, for the improvement or maintenance of one or more components of physical fitness [10]. Werner et al [11] observed that endurance athletes have a larger telomere size than inactive controls. Moreover, physically active middle-aged twins have longer telomeres than inactive siblings [12]. Therefore, it seems clear that regular physical exercise is essential for healthy aging and supporting positive mental health. It can help delay, prevent, or manage many costly and difficult chronic diseases faced by older adults [13]. It can also reduce the risk of premature death and moderate or severe functional limitations in older adults [14].

However, few prospective studies have evaluated the effect of physical exercise on telomere length. In addition, these studies had large methodological differences, such as heterogeneous samples, different physical exercise modalities, and varied time and duration of the interventions. To date, only one meta-analysis [15] has studied the relationship between different physical exercise modalities and telomere length; however, the populations analyzed in the qualitative and quantitative analyses were heterogeneous. Therefore, the results should be cautiously interpreted.

Objective

This systematic review and meta-analysis aimed to study the impact of different physical exercise modalities on telomere length in prospective studies (clinical trials and randomized controlled trials [RCTs]) in which the study sample comprised a healthy population without any type of pathology.

Methods

This systematic review and meta-analysis was conducted in accordance with the guidelines of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses; Multimedia Appendix 1) [16].

Literature Search

To identify relevant studies on the impact of physical exercise on telomere length, we conducted a systematic literature search using the following English-language databases (until September 2022): PubMed, Web of Science, SCOPUS, Embase, and Cochrane Library. The search was performed independently by 2 researchers (JLSG and VNL). The search strategy used to identify all potential studies using the following terms is detailed in Multimedia Appendix 2 [17-25].

We also manually searched the references cited in selected articles or reviews to identify relevant studies.

Study Selection

We used the Population, Intervention, Comparison, Outcomes, Time, and Study design as a framework to formulate eligibility criteria (Textboxes 1 and 2) [26].
**Textbox 1. Population, Intervention, Comparison, Outcomes, Time, and Study design framework.**

- **Population**: healthy adults with no neurological disease
- **Intervention**: interventions with exercise as the main focus were selected
- **Compare**: control group not performing physical exercise
- **Outcomes**: telomere length was assessed using both peripheral blood and saliva samples
- **Time**: no temporal restrictions were applied to the duration of the intervention or outcome measures
- **Studies**: only randomized controlled trials (RCTs) and controlled trials were included

**Textbox 2. Inclusion and exclusion criteria.**

**Inclusion criteria**
- **Article type**: Randomized controlled trials or controlled trials
- **Language**: English
- **Population**: Healthy population
- **Type of intervention**: Aerobic exercise, resistance training, or high-intensity interval training
- **Outcome**: Measurement of telomere size by peripheral blood or saliva collection

**Exclusion criteria**
- **Article type**: Case studies, systematic reviews, and meta-analyses
- **Language**: Spanish, Chinese, French
- **Population**: Population with neoplastic processes, neurodegenerative diseases, and cognitive alterations
- **Type of intervention**: Any other type of nonexercise intervention
- **Outcome**: Any other type of measure that purports to measure aging but is not telomeric length

**Data Extraction**

Two investigators (JLSG and VNL) independently extracted data. A standardized methodology was used to obtain data from studies that met the inclusion criteria. Data were obtained for the first author, year of publication, design, patient characteristics, intervention protocol and timing, study outcomes (telomere size before and after intervention), and the telomere size calculation technique. In addition, the means and SDs of the study results were obtained. The authors of the included studies were contacted via email to access potentially unclear data. If no responses were received, the data were excluded from the analysis.

**Interrater Reliability**

Interrater reliability for screening, risk of bias assessment, and quality of the evidence rating were assessed using percentage agreement and Cohen κ coefficient [27,28]. There was strong agreement between the reviewers for the screening records and full texts (98.51% agreement rate and κ=0.91) and the risk of bias assessment (92.86% agreement rate and κ=0.83).

**Risk of Bias and Assessment Methodological Quality of the Studies**

Two reviewers independently assessed the risk of bias of the included studies (SVR and VNL).

The risk of bias in nonrandomized studies of interventions (NRSIs) was assessed using the Risk Of Bias In Nonrandomized
Studies of Interventions (ROBINS-I) [29]. This tool assesses the risk of bias in NRSI results. The types of NRSIs that can be assessed with this tool are quantitative studies that estimate the efficacy (harm or benefit) of an intervention and did not use randomization to assign units (individuals or groups of individuals) to comparison groups. ROBINS-I considers 6 domains: randomization process (D1), bias arising from period and carryover effects (D5), deviations from the intended interventions (D3), missing outcome data (D4), and selection of the reported result (D5).

In contrast, a revised tool was used to assess the risk of bias in randomized clinical trials (risk-of-bias tool for randomized trials; RoB2) [30]. The tool was structured into 5 domains through which bias could be introduced into the outcome. These were identified on the basis of empirical evidence and theoretical considerations. Because the domains cover all types of bias that may affect the results of randomized trials, each domain is mandatory; and no additional domains should be added. The 5 domains for individual randomized trials (including crossover trials) were bias arising from the randomization process (D1), bias due to deviations from intended interventions (D2), bias due to missing outcome data (D3), bias in measurement of the outcome (D4), and bias in selection of the reported result (D5) [31,32].

Overall Quality of Evidence
The overall quality of evidence was based on classifying the results into levels of evidence according to the Grading of Recommendations Assessment, Development, and Evaluation (GRADE), which is based on five domains: (1) study design, (2) imprecision, (3) indirect, (4) inconsistency, and (5) publication bias.

Evidence was categorized into the following four levels accordingly: (1) high quality: further research is very unlikely to change our confidence in the estimate of effect, and all 5 domains are also met; (2) moderate quality: further research is likely to have an important impact on our confidence and might change the estimate of effect, and 1 of the 5 domains is not met; (3) low quality: further research is very likely to have an important impact on our confidence and is likely to change the estimate of effect, and 2 of the 5 domains are not met; and (4) very low quality: any estimate of effect is very uncertain, and 3 of the 5 domains are not met [31,32].

Statistical Analysis
Mean differences (MDs) after the intervention were used to compare values between the exercise and control groups, with a 95% CI. To obtain the effect size, the MD between the groups was converted to the standardized MD with a 95% CI. Statistical significance was set at $P < .05$. The individual effect size of each study and calculation of the overall effect size are presented as forest plots.

The restricted maximum likelihood method estimated the variance of between-study heterogeneity; the presence of between-study heterogeneity was assessed with the Cochran Q statistic test (with $P < .05$ considered significant) and the degree of heterogeneity with the inconsistency index ($I^2$) [33]. An $I^2$ value between 0% and 25% was considered to represent small heterogeneity, between 25% and 75% medium heterogeneity, and >75% large heterogeneity [34]. $I^2$ complements the $Q$ test, although it has the same power problems when the number of studies is small [34]. When the $Q$ test was significant ($P < .10$) and the $I^2$ result was >25%, indicating heterogeneity between studies, the random-effects model was applied in the meta-analysis. When heterogeneity was >25% according to the $I^2$ statistic, outliers (studies whose 95% CI cutoff was lower and greater than the pooled 95% CI upper and lower cutoff) and influential case analysis were performed using the analysis according to the graph of Baujat et al [35] (graph showing the contribution of each study to the overall heterogeneity compared with its contribution to the overall pooled result). The identified studies were flagged as outliers or influential cases and were removed. A subgroup analysis was performed according to the type of exercise used (resistance training, aerobic exercise, or high-intensity interval training [HIIT]). An a priori meta-regression analysis was performed on the variables of exercise intensity and duration, as well as the year of publication and methodological quality, to evaluate whether these variables influenced the overall effect size.

Skewness was assessed using a contour-enhanced funnel plot in analyses consisting of at least 5 studies, indicating the possible publication bias of small studies small studies with negative results. In the absence of publication bias, the plot resembled a symmetrical funnel-shape.

Studies were analyzed with R software (R Foundation for Statistical Computing) [36], using the Metafor package [37] as detailed by Harrer et al [38], and with the computer software Review Manager (version 4.1; The Cochrane Collaboration).

Results
Study Selection and Characteristics
The search found 3102 records, of which 1612 were duplicates and 1490 were screened by title and abstract. We found 30 studies that were potentially relevant and excluded 21 studies after screening their full reports. Finally, 9 studies met the eligibility criteria and were included in the qualitative analysis, and 7 studies, which included 1320 participants, were included in the quantitative analysis. The entire screening process is shown in the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram in Figure 1.
Qualitative Summary of the Included Studies

All 9 studies were intervention studies (RCTs or controlled trials) and were of fair to good methodological quality according to the ROBINS-I or RoB2 scale (Figure 2 [17-20,22-25]). These studies were conducted in Germany [17,18], Canada [19], the United States [20], the United Kingdom [21], Iran [22], Brazil [23], Spain [24] and South Korea [25]. A total of 1320 participants were included, including both men and women, with the latter being represented to a greater extent (98%).

Regarding the type of exercise, 4 studies performed resistance training [17,18,21,25], 4 used aerobic exercises [17,19,20,23], 3 used HIIT [17,22,23], and 1 used combined training (aerobic plus resistance training) [24]. Regarding protocol duration, 1 study conducted a 2-week intervention [22], 1 study conducted a 4-week intervention [23], 4 studies conducted a 6-week intervention [17,18,24,25], and 3 studies conducted a 12-week intervention [19-21]. The intensity information for each protocol is presented in Table 1.

fT/S: telomere/single gene.
gVO2max: Volume of Oxygen Maximum.
hCT: controlled trial.
iMET: metabolic equivalents.

Risk of Bias

Owing to the design of the included studies, 8 were analyzed using the RoB2, and 1 study was analyzed using the ROBINS-I. As assessed by the RoB2 and ROBINS-I, 56% (5/8) of the studies showed a high risk of bias, 33% (2/8) showed some concerns, and 11% (1/8) showed a low risk of bias. The item with the highest risk of bias was “deviations from the intended interventions” in which 45% (3/8) of the studies showed a high risk of bias, and the item “missing data” had 33% (2/8) of the studies that showed a high risk of bias in therapist blinding (Figure 2).

Effects of Exercise on Telomere Length

The meta-analysis showed that overall, exercise did not produce a significant increase in telomere length compared with that of the control groups, which did not exercise (MD 0.02, 95% CI −0.10 to 0.13; P=.77; N=1058; Figure 3 [17-25]). The restricted maximum likelihood method estimated a between-study heterogeneity variance of $\tau^2=0.0034$ and an $\hat{I}^2$ value of 70%, indicating significant heterogeneity among the studies included in the analysis ($P<.01$).

When performing an analysis of influential cases in the heterogeneity and outlier studies (random-effects model), we detected 2 influential cases (Figures 4 and 5) [17-25]: the study by Sánchez-González et al [24] (which was also considered an outlier) and the study by Friedenreich et al [19]. Excluding the influential cases from the meta-analysis resulted in reduced heterogeneity between studies (23%) and did not affect the results of the meta-analysis (Table 2).

The subgroup analysis according to the type of exercise showed significant differences between the groups ($P=.05$). Resistance training (MD −0.02, 95% CI −0.01 to 0.05; $P=.54; \hat{I}^2=16\%$) and aerobic exercise (MD −0.01, 95% CI −0.0 to 0.06; $P=.64; \hat{I}^2=0\%$) groups showed no significant differences compared with the control group, but the HIIT group showed significant differences compared with the control group, with a greater telomere length observed in the HIIT group (MD 0.15, 95% CI 0.03-0.26; $P=.01; \hat{I}^2=0\%$; Figure 6 [17,18,20-23,25]).

Meta-regression analysis showed no relationship between exercise intensity and duration, year of publication, and methodological quality of the included studies ($P<.05$).
Figure 3. Forest plot of the effect of exercise on telomere length. Forest plot of the results of a random-effects meta-analysis is shown as mean differences with 95% CI for the comparison of mean telomere length in the exercise and control groups. The shaded square represents the point estimate for the individual study and the study weight in the high-intensity group. Diamond represents the overall mean difference between studies.

Figure 4. Funnel plot.

$^c$Removed as influential studies: Sánchez-González et al [24] and Friedenreich et al [19].
Figure 6. Subgroup analysis of the effect of exercise on telomere length. Forest plot of the results of a random-effects meta-analysis shown as mean differences with 95% CI for the comparison of mean telomere length in the exercise group and the control group, performing subgroup analyses for each type of exercise included (resistance training, aerobic exercise, and high-intensity interval training). The shaded square represents the point estimate for each study and the weight of the study in the meta-analysis. Diamond represents the overall mean difference between studies.

### Analysis of Publication Bias

The contour-enhanced funnel plot showed asymmetry, which indicated heterogeneity among the included studies. Most of the studies included in this analysis were not significant; therefore, publication bias was ruled out (Figure 7).

Figure 7. Contour-enhanced funnel plot of the included studies. Dispersion of effect size. x-axis: observed effect sizes. y-axis: inverse SE (higher values on the y-axis represent lower SEs). Slight asymmetry, indicating possible publication bias. Inside to outside (0-2). White region $P>.05$; dark gray region $P<.10$; intermediate gray region $P=.05$; outer gray region $P=.001$. 
Quality of Evidence

Table 3 provides the details of the GRADE assessment. Three levels of evidence were downgraded due to the serious risk of bias and high heterogeneity (inconsistency) of the results, which suggests a very small level of evidence regarding the effects of overall physical exercise modalities on telomere length. In the subgroup analysis, inconsistency was rated as not serious for the 3 exercise modalities, and the level of evidence depended on the risk of bias, being moderate for resistance training and small for aerobic exercise and HIIT.

aNo: most information is from results at low risk of bias; serious: crucial limitation for one criterion or some limitations for multiple criteria sufficient to lower confidence in the estimate of effect; very serious: crucial limitation for one or more criteria sufficient to substantially lower confidence in the estimate of effect.
bSerious: I^2>40%; very serious: I^2>80%.
cNo indirectness of evidence was found in any study.
dOn the basis of sample size. “Serious,” n<250 participants; “very serious,” n<250 and the estimated effect is little or absent.
eOn the basis of funnel plots. No publication bias was found. Funnel plots are not shown because the number of trials was less than 10.
fMD: mean difference.

Discussion

Principal Findings

This meta-analysis aimed to examine the effects of different types of exercise on telomere length in healthy individuals. To date, this is the only study to investigate the impact of different physical exercise modalities in a healthy population. Overall, 9 studies with 1320 participants were eligible; of them, 1299 (98%) were female participants and 91 (2%) were male participants. A total of 199 participants performed resistance exercises, 270 performed aerobic exercises, 73 performed HIIT, and 41 performed mixed exercises.

The pooled effect sizes across all telomere length outcomes showed that exercise did not significantly increase telomere length compared with the control conditions (Figure 3). This finding was robust, with little statistical heterogeneity between studies (I^2=23%). Subgroup analysis suggested that HIIT was the only type of exercise that significantly increased telomere length in exercisers compared with the nonintervention group (MD 0.15, 95% CI 0.03-0.26; P=.01; I^2=0%), with a medium effect size (standardized MD 0.41, 95% CI 0.02-0.8; P=.04; I^2=0%). Meta-regression analyses showed that exercise intensity and duration, year of publication, and methodological quality did not influence the observed effect size. Furthermore, when we compared exercise prescription, considering intensity and duration, with LTL gain, no relationship could be established between LT and exercise intensity and duration. The 2 studies that showed the greatest improvement in LT [17,24] were not those in which the exercise prescription was more intense and...
longer in duration. Similarly, the methodological quality of the studies was not related to the LT gain. The study with the highest methodological quality [19] does not show a significant correlation with LT gain. Therefore, we could not establish a causal relationship between exercise prescription, methodological quality, and LT gain.

To our knowledge, this is the first study to conduct a systematic review and meta-analysis of RCTs to investigate the effects of different physical exercise modalities on telomere length in a healthy population. A recent review by Song et al [15] concluded that aerobic exercise for ≥6 months had a significant effect on the rate of telomere length shortening. However, that review included studies with heterogeneous study populations (breast cancer, polycystic ovarian syndrome, or healthy individuals). This difference in results with our study is probably because in our review, we have only included healthy populations to try to better clarify the possible impact of different physical exercises on telomere length. Telomeric shortening can be accelerated by factors that induce oxidative stress and inflammation [39]; neoplastic processes [40]; psychological disorders [41]; and chronic diseases, such as diabetes or cardiovascular disease [7,42]. Therefore, it seems clear that it is necessary to study the impact of physical exercise in specific populations because of the large number of factors that can influence telomere length.

As previously discussed, our results indicate that HIIT is the type of exercise that appears to have the most beneficial effect on LT. HIIT is characterized by short intermittent bursts of vigorous exercise interspersed with periods of low-intensity recovery [43]. This type of training has sufficient evidence to show that it is a good option for improving cardiovascular health in both healthy individuals and individuals with cardiometabolic diseases [44,45]. However, according to our results, this type of physical exercise significantly increases the length of telomeres, as intense exercise causes an increase in the total oxidative state and external production of free radicals that can lead to oxidative stress [46]. Some studies have suggested that the effects of physical exercise on LT may be represented by an inverted U-shaped dose-response [47,48]. High- or low-intensity levels (too much or too little) may have deleterious effects on the immune system and produce free radicals, thereby accelerating the aging process [49].

The different methodologies used (type of exercise and intensity), time of intervention, lack of homogeneity in the populations studied, and large number of variables that can influence LT could be the cause of the differences in the results of the different studies. Therefore, it is necessary to continue investigating the role of different modalities of physical exercise on LT in different populations by having as much control as possible over the variables that can influence telomere size in RCTs.

Limitations and Recommendations for Future Studies

This study has several limitations. The main limitation was the small number of studies with a small sample size that performed a physical exercise intervention to assess telomere length compared to that of a control group. The included studies were heterogeneous in several aspects. The participants who underwent the interventions were healthy individuals of various ages, the vast majority of whom were women, and this might have influenced the results. The intervention protocol was heterogeneous and included exercise protocols of different intensities and application times (times/wk), some of which were incomplete. Heterogeneity was also present in the main outcome measures, showing disparities among the included studies both at baseline and postintervention measurements, although the methods used for assessing telomere length were the same.

Future research is recommended to evaluate the effects of high-intensity exercise interventions in various healthy age groups to evaluate the effect of these interventions in people with different pathologies and to establish the clinical relationship between the increase in telomere length and variables of clinical relevance.

Recommendations for Clinical Practice

The recommendation to incorporate regular exercise, particularly through HIIT, at least 3 times a week for a sustained period, emphasizes the commitment to the preservation of health and prevention of premature aging.

Conclusions

The findings of this systematic review and meta-analysis suggest that HIIT seems to have a positive effect on telomere length compared to other types of exercise, such as resistance training or aerobic exercise, in a healthy population. The results should be interpreted with caution because of the low quality of evidence.

Data Availability

The original contributions presented in the study are included in the article and supplementary material, and further inquiries can be directed to the corresponding author.

Authors’ Contributions

JLSG and JLSR designed the study, participated in the research, drafted the manuscript, and supervised the study. SVR participated in the operation and drafted the manuscript. RJV participated in the study, revised the article, and supervised the manuscript. RGS participated in the operation and revised the manuscript. CITG contributed to study design, participated in the research, and drafted the manuscript. CRP participated in the operation and drafted the manuscript. VNL and JMV participated in the operation, drafted the manuscript, collected data, and performed the analysis.

Abstract

Background: Myocarditis is characterized by high disability and mortality, and imposes a severe burden on population health globally. However, the latest global magnitude and secular trend of myocarditis burden have not been reported.

Objective: This study aimed to delineate the epidemiological characteristics of myocarditis burden globally for optimizing targeted prevention and research.

Methods: Based on the Global Burden of Disease Study 2019, the myocarditis burden from 1990 to 2019 was modeled using the Cause of Death Ensemble tool, DisMod-MR, and spatiotemporal Gaussian regression. We depicted the epidemiology and trends of myocarditis by sex, age, year, region, and sociodemographic index (SDI). R program version 4.2.1 (R Project for Statistical Computing) was applied for all statistical analyses, and a 2-sided P-value of <.05 was considered statistically significant.

Results: The number of incident cases (1,268,000) and deaths (32,450) associated with myocarditis in 2019 increased by over 1.6 times compared with the values in 1990 globally. On the other hand, the age-standardized incidence rate (ASIR) and age-standardized mortality rate (ASMR) decreased slightly from 1990 to 2019. The disability-adjusted life years (DALYs) decreased slightly in the past 3 decades, while the age-standardized DALY rate (ADSR) decreased greatly from 18.29 per 100,000 person-years in 1990 to 12.81 per 100,000 person-years in 2019. High SDI regions always showed a more significant ASIR. The ASIR slightly decreased in all SDI regions between 1990 and 2019. Middle SDI regions had the highest ASMR and ADSR in 2019. Low SDI regions had the lowest ASMR and ADSR in 2019. The age-standardized rates (ASRs) of myocarditis were higher among males than among females from 1990 to 2019 globally. All ASRs among both sexes had a downward trend, except for the ASMR among males, which showed a stable trend, and females had a more significant decrease in the ADSR than males. Senior citizens had high incident cases and deaths among both sexes in 2019. The peak numbers of DALYs for both sexes were noted in the under 1 age group in 2019. At the national level, the estimated annual percentage changes in the ASRs had significant negative correlations with the baseline ASRs in 1990.

Conclusions: Globally, the number of incident cases and deaths associated with myocarditis have increased significantly. On the other hand, the ASRs of myocarditis showed decreasing trends from 1990 to 2019. Males consistently showed higher ASRs of myocarditis than females from 1990 to 2019 globally. Senior citizens gradually predominated in terms of myocarditis burden. Policymakers should establish targeted control strategies based on gender, region, age, and SDI; strengthen aging-related health research; and take notice of the changes in the epidemic characteristics of myocarditis.
myocarditis; global burden; temporal trend; systematic analysis; incidence; mortality; disability-adjusted life years

Introduction

Cardiovascular diseases can lead to high disability and mortality, which impose severe burdens on population health globally [1,2]. Among cardiovascular diseases, myocarditis has variable clinical presentations and outcomes, including chest pain with uncomplicated clinical manifestations, new onset or worsening heart failure, chronic dilated cardiomyopathy, and sudden death [3]. Myocarditis caused up to 9% of sudden deaths among cardiovascular events in athletes in the United States [4]. Moreover, 16% to 20% of cases of sudden infant death syndrome were documented to be associated with myocarditis [5-7]. Globally, 46,490 deaths were estimated to be due to myocarditis in 2017 [8]. Myocarditis characterized by high mortality represents an enormous public health burden.

Data for specific clinical settings are available to estimate the burden of myocarditis. Data showed that 3% of cases of chest pain in the emergency department were attributed to acute myocarditis and pericarditis [9]. In a prospective registry of northeastern Italy, autopsy studies showed a 12% incidence of myocarditis among young people who died suddenly [10]. The prevalence of myocarditis was reported to be 1.14% among patients with advanced cancers after therapy with immune checkpoint inhibitors (ICIs) [11]. The prevalence rate of myocarditis in hospitalized patients infected with COVID-19 was reported to be 2.4 per 1000 patients, considering definite or probable cases [12]. Hospital mortality was found to be much higher among patients with myocarditis and COVID-19 than among those with myocarditis but without COVID-19 [13]. The nationwide incidence of myocarditis in Israel due to the BNT162b2 mRNA COVID-19 vaccine was 2.7 per 100,000 persons [14]. In the last 2 decades, the diagnosis of myocarditis has become reasonably accurate among patients, including those from low-risk populations, through the use of noninvasive examinations, including high-sensitive troponin levels and cardiac magnetic resonance imaging (CMRI) [15,16]. In the United States, the incidence of myocarditis showed a gradual increase from 95 (in 2005) to 144 (in 2014) per 1 million persons [17]. It is quite clear that many factors can influence the global burden of myocarditis.

The Global Burden of Disease Study (GBD) 2019 is the most recent data set for evaluating the epidemiological levels and trends of 369 diseases along with 87 risk factors globally, and it has incorporated new data sets and modeling strategies compared with the GBD 2017 [18,19]. For example, the only country-level covariate of myocarditis used for the GBD 2019 was the Healthcare Access and Quality Index on excess mortality, which differs from the GBD 2017. Since the evaluation of the global burden of myocarditis using data from the GBD 2017, no comprehensive statistics on the global epidemiological trend of myocarditis have been calculated [8]. Due to the inclusion of more raw data and the application of more robust statistical methods in the GBD 2019, the results for myocarditis burden in the GBD 2019 differ dramatically from those in the GBD 2017, indicating that new statistics and analyses of the global burden of myocarditis need to be reported timely to guide its prevention and control. This research summarizes the latest epidemiological characteristics of myocarditis, including incidence, death, disability-adjusted life years (DALYS), and changing trends by sex, age, and sociodemographic index (SDI), in 204 countries and territories from 1990 to 2019, using data from the GBD 2019. Our results will help to optimize the niche-targeting prevention and intervention of myocarditis that rely on concrete characteristics across the world.

Methods

Data Source

Previous studies have described the primary data explanations and analytic approaches of the GBD 2019 in detail [18-20]. Researchers can extract the reproducible statistical codes and analysis process online [21]. We briefly introduce the estimation methods specific to myocarditis. The Guidelines for Accurate and Transparent Health Estimates Reporting (GATHER) were followed to analyze the GBD database in every step (Report Checklist)[22]. Myocarditis was defined as a clinical diagnosis for the GBD 2019 estimation [2,19]. The International Classification of Diseases version 9 (ICD-9) and version 10 (ICD-10) codes were adopted to identify myocarditis. The determination of myocarditis was based on the disease codes 422-422.9 in ICD-9 and B33.2, I40-I41.9, and I51.4 in ICD-10. To assess the myocarditis burden, more than 250 primary data sources were screened out according to the GBD inclusion criteria. The myocarditis burden from 1990 to 2019 was modeled using the Cause of Death Ensemble tool, DisMod-MR, and spatiotemporal Gaussian regression. Data were obtained from the Institute for Health Metrics and Evaluation to characterize the global burden of myocarditis by sex and 5-year age group across the world in the past 3 decades. According to the SDI (a comprehensive index based on income per person, years of education, and fertility), the world is divided into 5 SDI regions (high, high-middle, middle, low-middle, and low) for assessing the myocarditis burden across different geographies. Furthermore, 204 countries and territories were divided into 21 GBD regions, including Western Europe, Tropical Latin America, and East Asia.

Ethical Considerations

The GBD 2019 is a publicly available database, and all data were anonymous. Our study protocol was approved by the Institutional Review Board of Qilu Hospital of Shandong University with approval number KYLL-202011(KS)-239.

Statistical Analysis

The burden of myocarditis was appraised based on the age-standardized incidence rate (ASIR), age-standardized...
mortality rate (ASMR), and age-standardized DALY rate (ASDR) by calendar year, sex, and region. The estimated annual percentage change (EAPC) was determined based on a regression calculation by fitting the natural logarithm of the age-standardized rate (ASR) with the historical year to characterize the long-term trend in the ASR of myocarditis burden [23]. The calculation formula is as follows:

\[
\ln(\text{ASR}) = \alpha + \beta \times \text{historical year} + \epsilon \tag{1}
\]

The EAPC can be used to depict the changing trends of the ASR in a specific population and a certain time interval. The EAPC and its 95% CI are calculated using the following formula:

\[
100 \times (\exp(\beta) - 1) \tag{2}
\]

An increasing trend was recognized when the EAPC and the minimum of the 95% CI were positive. On the contrary, a decreasing trend was recognized when the EAPC and the maximum of the 95% CI were negative. Otherwise, the trend of the ASR was considered to be stable. The Spearman rank correlation with \(\rho\) coefficient was used to estimate the influence of the baseline ASR in 1990 and the SDI in 2019 all over the world on the EAPC in myocarditis burden. R program version 4.2.1 (R Project for Statistical Computing) was used for all statistical analyses, and a 2-sided \(P\)-value of < .05 was considered statistically significant.

**Results**

**Global Burden and Temporal Trend of Myocarditis**

Across the world, the number of incident cases of myocarditis increased from 780,400 (95% uncertainty interval [UI] 620,600-951,200) in 1990 to 1,265,800 (95% UI 1,021,700-1,531,500) in 2019, with an increase of 62.20%. On the other hand, the ASIR decreased slightly from 16.74 (95% UI 13.46-20.34) to 16.00 (95% UI 13.01-19.28) per 100,000 person-years over the 3 decades, with an EAPC of −0.23 (95% CI −0.26 to −0.21) (Table 1; Figure 1). Simultaneously, the number of worldwide deaths caused by myocarditis increased from 19,620 (95% UI 15,690-26,770) in 1990 to 32,450 (95% UI 23,160-37,090) in 2019, with an increase of 65.39%. On the other hand, the ASMR decreased marginally from 0.46 (95% UI 0.38-0.60) to 0.43 (95% UI 0.31-0.50) per 100,000 person-years over the 3 decades, with an EAPC of −0.09 (95% CI −0.39 to 0.21) (Table 2; Figure 1). Globally, the DALYs decreased slightly. However, the ASDR decreased greatly from 18.29 (95% UI 13.81-27.58) per 100,000 person-years in 1990 to 12.81 (95% UI 10.53-14.72) per 100,000 person-years in 2019, with an EAPC of −1.19 (95% CI −1.33 to −1.04) (Table 3; Figure 1).
