regions from 1990 to 2019 (Table 1). The largest 3 increases in myocarditis changed slightly or remained stable across all GBD regions. The ASIR of myocarditis was always the highest in high and high-middle SDI regions from 1990 to 2019: 18.72 and 16.58 per 100,000 person-years in 1990, and 17.75 and 16.01 per 100,000 person-years in 2019, respectively (Table 1). The leading ASMR in 2019 was recorded in the United States, with an EAPC of 0.13. On the contrary, the fastest decline in the ASIR was noted in Qatar, with an EAPC of −1.52 (Table 3).

The ASMR of myocarditis was always the highest in high and high-middle SDI regions from 1990 to 2019: 18.72 and 16.58 per 100,000 person-years in 1990, and 17.75 and 16.01 per 100,000 person-years in 2019. The ASIR of myocarditis was always the highest in high and high-middle SDI regions from 1990 to 2019. The ASIR slightly decreased in all SDI regions between 1990 and 2019 (Table 1). The ASIR was noted in the United States, with an EAPC of 0.13. On the contrary, the fastest decline in the ASIR was noted in Qatar, with an EAPC of −1.52 (Table 3).

The ASMR of myocarditis was always the highest in high and high-middle SDI regions from 1990 to 2019: 18.72 and 16.58 per 100,000 person-years in 1990, and 17.75 and 16.01 per 100,000 person-years in 2019. The ASIR was noted in the United States, with an EAPC of 0.13. On the contrary, the fastest decline in the ASIR was noted in Qatar, with an EAPC of −1.52 (Table 3).

Variation in the Myocarditis Burden at Regional and National Levels

The ASIR of myocarditis was always the highest in high and high-middle SDI regions from 1990 to 2019: 18.72 and 16.58 per 100,000 person-years in 1990, and 17.75 and 16.01 per 100,000 person-years in 2019, respectively (Table 1). Low SDI regions had the lowest ASIR of 15.29 per 100,000 person-years in 2019. The ASIR slightly decreased in all SDI regions between 1990 and 2019 (Table 1). The leading ASMR in 2019 was observed in middle SDI regions at 0.59/100,000, and high-middle SDI regions ranked second at 0.56/100,000. Low SDI regions had the lowest ASMR of 0.24/100,000 in 2019. The largest increase in the ASMR was observed in low-middle SDI regions, followed by high SDI regions. On the other hand, the other 3 regions presented downward trends in the ASMR (lowest EAPC of −0.97 in low SDI regions) (Table 2). The highest ASDR in 2019 was observed in middle SDI regions, and the lowest was observed in low SDI regions. The ASDRs in 5 SDI regions all dropped from 1990 to 2019, with the highest decrease in middle SDI regions (EAPC=−1.52) (Table 3).

With respect to 21 GBD regions, high-income Asia Pacific, high-income North America, and Eastern Europe were the top 3 regions with the highest ASIRs in 2019 (range from 17.74/100,000 to 20.07/100,000). On the contrary, the North Africa and Middle East, Andean Latin America, and Caribbean GBD regions had the lowest ASIRs in 2019 (range from 12.05/100,000 to 14.19/100,000) (Table 1). The ASIR of myocarditis changed slightly or remained stable across all GBD regions from 1990 to 2019 (Table 1). The largest 3 increases in the ASMR were observed in Central Asia, high-income North America, and Western Europe. On the contrary, the largest 3 decreases in the ASMR were observed in Andean Latin America, Western Sub-Saharan Africa, and Eastern Sub-Saharan Africa (Table 2). The changing trends in the ASMR were different across all GBD regions (Table 2). The highest 3 ASDRs in 2019 appeared in Central Asia, Central Europe, and East Asia (range from 25.17 to 26.70 per 100,000 person-years). On the contrary, the lowest 3 ASDRs in 2019 appeared in Andean Latin America, Central Latin America, and South Asia (range from 3.49 to 6.64 per 100,000 person-years) (Table 3). There were significant regional differences in the trends of ASDRs across all the GBD regions, with the most obvious increase in Central Asia (EAPC=2.05) and the largest decrease in Andean Latin America (EAPC=−3.16) (Table 3).

In 2019, there were 3 countries with an ASIR exceeding 20/100,000, including Austria, Japan, and Sweden, while Lebanon had the lowest ASIR (Multimedia Appendix 1; Figure 2). The difference in the ASMR of myocarditis was nearly 60 times across the world in 2019, with Romania showing the highest value (3.32/100,000) and Tajikistan showing the lowest value (0.05/100,000) (Multimedia Appendix 1; Figure 3). Similarly, the difference in the ASDR of myocarditis was nearly 30 times across the world in 2019, with Romania showing the highest value and Tajikistan showing the lowest value (Multimedia Appendix 1; Figure 3). From 1990 to 2019, 100 out of 204 countries and territories showed a rising ASIR. The largest annual increment in the ASIR was noted in Qatar, with an EAPC of 0.13. On the contrary, the fastest decline in the ASIR was noted in the United States, with an EAPC of −0.93.
(Multimedia Appendix 2; Figure 2). The EAPC in the ASMR was the highest in Kazakhstan (EAPC=9.93) and the lowest in Ghana (EAPC=−4.94) from 1990 to 2019 (Multimedia Appendix 2; Figure 3). The EAPC in the ASDR was the highest in Kazakhstan (EAPC=8.70) and the lowest in Serbia (EAPC=−4.70) from 1990 to 2019 (Multimedia Appendix 2; Figure 3).

**Figure 2.** Maps of the global incidence and temporal trends of myocarditis in 204 countries and territories. (A) ASIR of myocarditis around the world in 2019; (B) EAPC in the ASIR from 1990 to 2019. ASIR: age-standardized incidence rate; EAPC: estimated annual percentage change.
Variation in the Myocarditis Burden in Both Genders and 5-Year Age Groups

From 1990 to 2019, the ASIR of myocarditis among men was higher than that among women (19.06/100,000 vs 13.01/100,000 in 2019) (Table 1). Similar to the finding of the ASIR, the ASMR and ASDR of myocarditis were higher among men than among women. Over the past 3 decades, all ASRs among both sexes had downward trends, except for the ASMR among males, which showed a stable trend (EAPC=0.07) (Table 2). Markedly, the decrease in the ASDR from 1990 to 2019 was greater among females (EAPC=−1.54) than among males (EAPC=−0.91) at the global level (Table 3).
In 2019, the incident cases displayed a bimodal distribution with age and peaked the highest in the 65-69 age group. A relatively lower peak was shown in the 30-34 age group with incident cases (Figure 4). The number of deaths peaked in the 80-84 age group among males and in the 85-89 age group among females. The under 1 age group among both sexes had the largest number of deaths younger than 20 years (Figure 4). The number of DALYs in 2019 peaked in the under 1 age group among both sexes (Figure 4).

Figure 4. Age-standardized counts and rates of the myocarditis burden by sex/SDI region in 2019. (A) Incidence; (B) Mortality; (C) DALYs. DALYs: disability-adjusted life years; SDI: sociodemographic index.

The incidence and mortality rates per 100,000 person-years all showed approximately increasing trends with age among both sexes in 2019 (Figure 4). The DALY rate per 100,000 person-years showed a decreasing trend before the 10-14 age group and an increasing trend after the 10-14 age group with age among both sexes (Figure 4). Over the past 3 decades, the ASIRs among males and females were decreasing over all ages (EAPC<0) (Multimedia Appendix 3). From 1990 to 2019, the population older than 69 years among both sexes showed increasing trends in the ASMR and ASDR with age (EAPC>0) (Multimedia Appendix 3).

From 1990 to 2019, all SDI regions showed an increasing tendency in the absolute incident cases among the population over 30 years old (Multimedia Appendix 4). On the other hand, the ASIR showed a decreasing trend in high SDI regions among the population over 50 years old. Over the past 30 years, the ASIR in the other 4 SDI regions changed slightly across all age groups (Multimedia Appendix 4). Deaths were obviously rising in 5 SDI regions among the residents over 40 years old, especially in high-middle and middle SDI regions. Conversely, the number of deaths was decreasing in all SDI regions among the residents younger than 4 years, especially in high-middle, middle, and low-middle SDI regions (Multimedia Appendix 5). From 1990 to 2019, the ASMR in all SDI regions was steadily rising across all age groups over 85 years, except in low SDI regions where there was a decrease (Multimedia Appendix 5).
The number of DALYs was decreasing in all SDI regions among the population younger than 14 years, especially in high-middle, middle, and low-middle SDI regions (Multimedia Appendix 6). The ASDR showed a similar trend as the ASMR in 5 SDI regions across all age groups over 85 years. The ASDR was obviously decreasing in the under 1 age group in all SDI regions over the past 30 years (Multimedia Appendix 6).

The EAPCs in myocarditis ASIRs varied largely among age groups in the 5 SDI regions during the past 30 years. The highest EAPC in the ASIR in high SDI regions was noted between the ages of 14 and 19 years. In the other 4 SDI regions, the highest EAPC in the ASIR was noted in the age group of older than 95 years (Multimedia Appendix 4). Globally, the EAPCs in the ASMR and ASDR showed rising trends with age, and similar trends could be found in low-middle, middle, and high-middle SDI regions. The highest EAPCs in the ASMR and ASDR in high SDI regions were noted between the ages of 44 and 54 years. The EAPCs in the ASMR and ASDR in low SDI regions were always negative at all ages (Multimedia Appendices 5 and 6).

Potential Factors of Changing Trends

We found negative correlations between the EAPC and the ASIR ($\rho = -0.15; P = 0.03$), ASMR ($\rho = -0.23; P < 0.001$), and ASDR ($\rho = -0.28; P < 0.001$) in 1990 (Multimedia Appendices 7-9). On the other hand, there were no correlations between the EAPCs in the ASIR, ASMR, and ASDR and the SDI (Multimedia Appendices 7-9). The analysis of the annual ASIR of myocarditis from 1990 to 2019 and the SDI across all 21 GBD regions indicated that the ASIR in most GBD regions increased or decreased slightly, except for high-income North America that showed an obviously increasing trend first, a substantial decrease next, and an increase again (Multimedia Appendix 7). The ASMR and ASDR in Central Asia, Central Europe, and Southeast Asia changed significantly, while that in the other GBD regions changed slightly (Multimedia Appendices 8 and 9).

Discussion

Principal Findings

The study estimated the global burden of myocarditis from 1990 to 2019 systematically and comprehensively, which indicated the progressive and prominent influence on public health due to myocarditis. Compared with 1990, the numbers of incident cases and deaths of myocarditis both increased by above 1.6 times across the world, while the global DALYs decreased. All ASRs showed declining trends with negative EAPCs over the past 30 years. The myocarditis burden will certainly increase because of the increasing number of cases and deaths. Myocarditis is a kind of myocardial inflammatory disease diagnosed by established criteria [15,24,25]. The clinical manifestations of severe myocarditis are often fulminant, with sudden onset, extensive myocardial damage, and accompanied by fatal arrhythmia, contributing to a high risk of sudden death [26-30]. The burden of myocarditis is a public health problem of widespread concern, particularly under the background of SARS-CoV-2 infection and mRNA vaccines [31-33]. Since the pandemic, many epidemiological studies have concluded that SARS-CoV-2 increased the incidence of myocarditis. Studies also showed that the use of novel mRNA platforms led to a higher number of reported cases than with previous platforms. Hence, fundamental data on the burden of myocarditis is helpful for investigating the burden induced by SARS-CoV-2 [34,35].

Analyses based on the differences in sex, age, year, SDI quintiles, GBDR regions, and nations depicted the heterogeneities of myocarditis burden. Health policymakers should take notice of the significant implications on public health related to myocarditis globally.

This research found that higher SDI regions always showed a more significant ASIR from 1990 to 2019, which was not analyzed in a previous study of the GBD 2017 [8]. The high incidence of myocarditis in high and high-middle SDI regions may be related to better health care infrastructure and medical resources, population aging, the introduction of highly sensitive troponin and CMRI examinations, and extensive use of ICIs and vaccines [36]. Middle SDI regions accounted for the largest ASMR and ASDR in 2019, and low-middle SDI regions had the largest increase in the ASMR. The main reasons for high mortality and disability in middle SDI regions and the fastest increase in low-middle SDI regions may be delayed diagnosis, imperfect health care systems, and limited medical resources. Ventricular assist devices or extracorporeal membrane oxygenation (ECMO) need to be urgently applied in patients with cardiogenic shock or severe ventricular dysfunction due to myocarditis [37,38]. However, mechanical support devices have not been widely applied in middle and low-middle SDI regions. We also found that all ASRs in low SDI regions were the lowest, which may be due to insufficient health care infrastructure and resources. Definitely, the medical health care system and quality of data sources need to be improved in lower SDI regions for reducing the burden of myocarditis.

At the GBD level, high-income Asia Pacific, high-income North America, and East Asia accounted for the top 3 highest ASIRs in 2019. At the national level in 2019, the ASIR in Austria, Japan, and Sweden exceeded 20/100,000. The EAPCs in the ASMR and ASDR were the highest in Kazakhstan in the past 3 decades. Furthermore, there were significant negative correlations between the EAPCs in ASRs and the baseline ASRs in our results, which demonstrated that countries and territories with higher ASIRs, ASMRs, and ASDRs in 1990 went through more rapid decreases or slow increases in the ASRs of myocarditis from 1990 to 2019. Policymakers of countries and territories with higher ASRs were more likely to attach importance to the prevention of myocarditis and facilitate more reasonable policy formulation and resource allocation. In 2019, there were significant regional differences in the trends of ASRs, which provided accumulating evidence for the epidemiological transition of myocarditis across all GBD regions, nations, and territories. Policymakers should facilitate country-specific health research to allocate limited medical resources more reasonably based on the national information on the myocarditis disease burden.

The ASRs of myocarditis were higher among males than among females from 1990 to 2019 globally. Over the past 3 decades, all ASRs among both sexes showed downward trends, except for the ASMR among males, which showed a stable trend, and
females had a more significant decrease in the ASDR than males at the global level. Previous studies have already displayed a slightly higher incidence rate of myocarditis in men [8,29]. More recently, mRNA-based COVID-19 vaccines were reported to be responsible for an increased risk of myocarditis on the basis of passive surveillance reporting in the United States, especially among adolescent boys and young men after the second vaccine dose [39]. Men were more likely to experience a severe myocarditis developmental trajectory. Differences in innate immunity between men and women may contribute to a different prognosis. Testosterone and estrogen play important roles in the immune response. Testosterone can increase the affinity of the virus to myocytes and trigger a T helper type 1 immune response [40], inhibit the quantity of anti-inflammatory cells, and upregulate cardiac fibrotic remodeling genes [41]. Men with myocarditis have been found to have higher levels of heart failure biomarkers, creatine kinase, myoglobin, and T helper 17–associated cytokines [42]. On the other hand, women can develop a better regulatory immune response. Estrogen can promote the differentiation of T cells to T helper 2 cells and reduce the T helper type 1 immune response [43].

For estimating the age characteristics of the burden of myocarditis more accurately, we adopted a more refined age grouping scheme than that in the previous study of the GBD 2017 [8]. We found that the highest peak of deaths occurred in the under 1 age group among those aged younger than 20 years, and the number of DALYs in 2019 peaked in the under 1 age group among both sexes. There were 2 peaks in the incidence of myocarditis in childhood, and a high incidence was found in infancy and adolescence, with infants having poor prognoses [44]. Infantile myocarditis was more prone to causing severe ventricular dysfunction, which led to a higher probability of requiring mechanical circulatory support compared with that among patients of other ages. Myocarditis was proved to have caused 9% of cases of sudden infant death syndrome on autopsy [6]. It is noteworthy that infants are more susceptible to enteroviruses characterized by direct myocardial injury. The virus can trigger a cascade of hyperinflammatory responses and induce more robust immune responses among adolescents and young adults, especially among males. Previous research indicated that children and young adults had a higher incidence of myocarditis and mortality attributed to myocarditis compared with middle-aged and older adults [8,45]. However, our data showed that the incidence and mortality rates had increasing trends with age, and the DALY rate had a decreasing trend before the 10-14 age group and an increasing trend after the 10-14 age group with age in 2019. Differences in etiology, pathogenesis, and diagnosis strategies may be important reasons for the differences in the burden of myocarditis among children, adults, and elderly people. Senior citizens had high ASRs and numbers of cases in 2019, which demonstrated that elderly people gradually predominated in terms of the burden of myocarditis. The burden of myocarditis shifted to elderly people mainly due to population aging, ICI therapy, hypoinnununity, and more concomitant underlying diseases. Policymakers should be aware of the high DALYs in infants and the shifting of the burden to elderly people.

Limitations
This study has several limitations. First, the study may be prone to sampling bias. The GBD model of myocarditis was reconstructed based on a large number of varying quality, sparse, or limited scope data sources. This can affect the accuracy and applicability of the findings across all regions and populations. The possibility of missed cases of myocarditis, which are either undiagnosed or unreported, could also lead to an underestimation of the actual disease burden. Therefore, the estimation of the burden of myocarditis may deviate from the actuality to some extent, especially in some underdeveloped regions with scarce prior information. Second, longitudinal data were lacking in this study. The absence of data extending beyond the timeframe limits the understanding of recent trends and the ability to evaluate the effect of newer developments in the diagnosis, treatment, and prevention of myocarditis, especially after SARS-CoV-2, with some studies reporting its relation to an increased risk of myocarditis [34]. Third, the classification of myocarditis was not available in this study. There are many causes of myocarditis, among which viruses are the most common. Multiple types of viruses, including enteroviruses, adenoviruses, erythroparvoviruses, viruses from the Herpesviridae family, and SARS-CoV-2, can lead to myocarditis. Other etiologies include autoimmunity, vaccines, ICIs, and exposure to toxins and drugs. The clinical course of myocarditis caused by different factors may be different, and further investigations are necessary. Finally, the Dallas criteria in 1987 for myocarditis considered endomyocardial biopsy to be the standard diagnosis [46,47]. However, the diagnostic strategy has changed with the introduction of highly sensitive troponin and CMRI examinations in the past 20 years. In routine clinical practice, it is often sufficient to establish the diagnosis of myocarditis with the combination of symptoms and signs, laboratory examinations, and imaging studies [3]. It is unclear if the diagnostic criteria of myocarditis were kept the same among different areas. Further investigations are needed to evaluate the impact of changes and regional differences in the diagnostic workup for the assessment of myocarditis burden.

Conclusions
In general, myocarditis remains an important cause of early death and chronic disability, and it negatively impacted the global disease burden from 1990 to 2019. The numbers of incident cases and deaths associated with myocarditis have increased significantly. On the other hand, the ASRs of myocarditis showed decreasing trends from 1990 to 2019. High SDI regions showed more significant ASIRs, while middle SDI regions showed the highest ASMRs and ASDRs in 2019. Males consistently showed higher ASRs of myocarditis than females from 1990 to 2019 globally. Senior citizens had high incident cases and deaths among both sexes in 2019. Peak numbers of DALYs for both sexes were noted in the under 1 age group in 2019. At the national level, the EAPCs in ASRs had significant negative correlations with the baseline ASRs in 1990. Policymakers should develop targeted control strategies based on gender, region, age, and SDI; strengthen aging-related health research; and take notice of the changes in the epidemic characteristics of myocarditis. Targeted control strategies should be developed to reduce the high DALYs in infants and the
increasing burden of myocarditis in the elderly population based on the diversity of myocarditis burden explicated in our study.

Acknowledgments

We would like to thank the institute for the health metrics and evaluation staff, and its Global Burden of Disease Study collaborators who prepared the publicly available data. This work was supported by the National Natural Science Foundation of China (81970319); Taishan Scholars Program of Shandong Province (tsqn202103170); and Key Research and Development Program of Shandong Province (2019GSF108186). The funders were not involved in the collection, analysis, or interpretation of data, or the writing or submission of this report.

Data Availability

The Global Burden of Disease Study 2019 is a publicly available database [48], and we fully complied with data usage requirements.

Authors' Contributions

QYK, CFZ, and XRY contributed to the conception and design of the work. QYK, XX, ML, XM, CFZ, and XRY contributed to the acquisition and analysis of data for the work. QYK, CFZ, and XRY contributed to the visualization of the results. All authors contributed to the interpretation of the results. QYK and XRY drafted the manuscript. All authors critically revised the manuscript. All authors gave final approval and agreed to be accountable for all aspects of the work ensuring integrity and accuracy. CFZ and XRY are co-corresponding authors.

Abstract

Background: The global population of women of menopausal age is quickly increasing. The COVID-19 pandemic has led to an accelerated increase in the use of telehealth services, especially technological solutions targeting women’s health. Understanding the factors behind midlife women’s help-seeking behaviors amidst the pandemic will assist in the development of person-centered holistic telehealth solutions targeting menopausal and postreproductive health.

Objective: This study aimed to compare the factors underlying help-seeking for menopausal distress among midlife women in the United States and China.

Methods: We conducted 2 web-based panel surveys in the United States using Amazon Mechanical Turk and in China using Credamo between July and October 2022. A total of 1002 American and 860 Chinese women aged between 40 and 65 years took part in the survey. The survey was designed based on the Health Belief Model with questions related to their menopausal knowledge, perceived severity of menopausal symptoms, perceived susceptibility to menopausal distress, perceived benefits of help-seeking, perceived COVID-19– and non–COVID-19–related barriers against help-seeking, self-efficacy, and motivation to seek help. Structural equations models were fitted for the data using full information maximum likelihood to manage missing data.

Results: Knowledge was not directly related to help-seeking motivation in both samples. Among the Chinese sample, knowledge was negatively related to perceived severity but positively related to COVID-19–related barriers; in turn, higher perceived severity, benefits, COVID-19–related barriers, and self-efficacy and lower non–COVID-19–related barriers were related to more motivation to seek help. In the US sample, knowledge was negatively related to perceived severity, susceptibility, benefits, barriers (COVID-19– and non–COVID-19–related), and self-efficacy; in turn, higher self-efficacy, COVID-19–related barriers, and benefits were associated with more help-seeking motivation. The factors explained 53% and 45.3% of the variance of help-seeking motivation among the American and Chinese participants, respectively.

Conclusions: This study revealed disparate pathways between knowledge, health beliefs, and the motivation for help-seeking among American and Chinese midlife women with respect to menopausal distress. Our findings show that knowledge may not directly influence help-seeking motivation. Instead, perceived benefits and self-efficacy consistently predicted help-seeking motivation. Interestingly, concern over COVID-19 infection was related to higher help-seeking motivation in both samples.
Hence, our findings recommend the further development of telehealth services to (1) develop content beyond health education and symptom management that serves to enhance the perceived benefits of addressing women’s multidimensional menopausal health needs, (2) facilitate patient–care provider communication with a focus on self-efficacy and a propensity to engage in help-seeking behaviors, and (3) target women who have greater midlife health concerns in the postpandemic era.

Introduction

The population of women of menopausal age is increasing. According to the United Nations, women aged 50 years or older constitutes 26% of the global female population, compared to 21% 10 years ago [1]. Globally, it is predicted that the population of midlife women will reach 1.65 billion by 2050, from about 980 million in 2020, suggesting a burgeoning global demand for menopausal health care. The European Menopause and Andropause Society therefore proposed a Healthy Menopause [2] framework that links menopausal health to the World Health Organization’s healthy aging framework [3] to empower women to make salutary choices for their postreproductive health through personalized interdisciplinary care. Although menopause is often perceived as having ambiguous temporal boundaries and requiring broad population-based interventions, studies across cultures have revealed discrepancies in the understanding of the menopause experience between women in premenopause and postmenopause, pointing to insufficient knowledge and understanding together with inaccurate expectations [4-6].

Midlife women often manage their symptoms through self-initiated lifestyle modifications, such as relaxation, healthy diet, regular exercises, and supplements, or simply tolerating them; yet, they tended to be conservative with seeking medical help and associated services [7-11]. A study reviewing medical records in the United States found that while most menopausal women eventually saw doctors for their worrisome symptoms [12], 40% and 13% of them had neither medication nor any therapeutic interventions documented, respectively, and about 50% of women delayed seeking medical help for more than 6 months after symptom onset. In a recent study in Shanghai, China, only 36.8% of women who had menopausal symptoms went to see a doctor, and most commonly went to internal medicine, rather than gynecology or a specialized menopausal service [13]. Coupling with the patients’ lack of knowledge about menopause and associated care options, a substantial gap in professional education may lead health care professionals to either feeling uncomfortable or less-than-competent in discussing menopause, lacking a holistic perspective about the multidimensional distress of their patients [14].

The COVID-19 pandemic accelerated the rapid rise and accompanying advances in telehealth services [15], which was documented to have increased 38-fold in the total claims volume in the United States in late 2020 when compared to early 2020 [16], with psychiatry and endocrinology services ranked numbers 1 and 3, respectively. Similarly, in China alone, there has been a 900% increase in users and 800% increase in telehealth visits by new users from December 2019 to January 2020, shortly after the emergence of the COVID-19 pandemic [17]. Reflecting on the first 2 years of the COVID-19 pandemic, a global survey with 293 professionals in different fields revealed increased confidence in telehealth [18]. With respect to improving perimenopausal and postmenopausal women’s well-being, Menotech, as a branch of Femtech that encompasses primarily smartphone apps and telemedicine platforms [19-21] aimed at managing symptoms, hormonal replacement therapy, and triaging low-risk women for regular checkups [22], has flourished in recent years in North America, Europe, and Australia. The increased usage of telehealth presents both opportunities and barriers for midlife women seeking health education and care, underscoring the need to examine the related influencing factors from a cross-cultural perspective.

Both China and the United States witnessed a clear spike in telehealth use during COVID-19 outbreaks [23,24]. Both countries also saw marked increases in their population of women entering menopause in recent years. In China, the total number of women in menopause has already exceeded 200 million and is expected to reach 280 million by 2030 [25]. In the United States, about 1.3 million women are entering menopause annually, with over 51 million women going through or having gone through the transition at present [26,27].

Menopause is a universal phenomenon that ensues similar long-term health consequences across populations, yet with geographical differences in the nuanced experiences of its symptoms [13,28]. Palacios et al [29] found that Asian women reported a lower age of onset (42.1-49.5 years) than their North American counterparts (50.5-51.4 years), but a similar prevalence of overall symptoms (36%-50% in North America and 22%-63% in Asia). Chinese women also tend to experience more irritability and emotional distress instead [30]. In general, Asian women are likely to endorse more nonmedicalized views toward menopause, seeing it as a natural progression of life, yet perceive greater difficulties in disclosing and discussing their symptoms with their families, peers, and health professionals. Compared to their Western counterparts, they have been shown to enlist a repertoire of both Western and traditional Asian coping methods to manage with their physical and emotional symptoms [31]. The use of Chinese medicine to manage menopausal symptoms has been such an established practice among Chinese
women that evidence-based Chinese medicine clinical practice guidelines are already available [32]. The purpose of menopausal health care is 2-fold—relieving the multidimensional distress associated with menopause as well as nurturing holistic health for the postreproductive lifespan [33]. With the life expectancy of women in industrialized countries reaching over 80 years and large populations of women facing the onset of menopause at about 50 years of age, understanding the factors behind menopausal help-seeking is important for fostering midlife women’s health and well-being.

In this light, this study used web-based survey panels to explore the differences in help-seeking motivation and the associated factors among midlife women in the United States and China during the pandemic.

Methods

Design and Sampling

This study involved 2 web-based surveys with samples drawn from the United States and China. The US data were collected from Amazon Mechanical Turk (MTurk), while those from China were collected from Credamo Inc. The 2 platforms were chosen considering they are popular and well-established in conducting survey research in their respective countries at the time of data collection, and that they support a similar range of question types, participant screening procedures, and arrangements for distributing incentives. For MTurk, Robinson et al [34] reported that the panel included about 226,500 individuals based in the United States, while Credamo Inc declared over 3 million individuals on their panel based in China as of January 2023 [35]. The advantages of using web-based panels include efficient screening for participants with the desired demographic characteristics out of a vast pool, as well as ensuring that participants have experience filling in web-based surveys to safeguard data quality. In this study, which was conducted against the backdrop of the increase in telehealth use during the COVID-19 pandemic, we were particularly interested in the help-seeking motivation of midlife women who would be potential patrons of telehealth. For both samples, the inclusion criteria were being female and aged between 40 and 65 years, which was the normative window for menopausal transition ±5 years [36,37]. To safeguard data quality, we requested participants to have a HIT approval rate of ≥98% on Amazon MTurk or a historical approval rate and credibility score of ≥80% on Credamo Inc. These benchmarks were recommended by the respective platforms. On the 2 panels, the surveys were advertised and made available to eligible participants only. Informed consent was collected via the internet prior to the surveys. Participants were reimbursed for their participation at nominal prices according to the recommendations of the panels and handled by the panels.

Ethical Considerations

Ethical approval was obtained from the Human Research Ethics Committee of Hong Kong Shue Yan University (HREC 22-04(1)).

Instruments

Participants’ knowledge about menopause was evaluated on a 23-item scale. The first 22 items were adopted from Noroozi et al [38] and Gebretatros et al [39]. These items covered aspects including age and factors affecting the onset and symptom severity, health impacts, and symptoms. An item on hormonal replacement therapy was added as it frequently appears on surveys about menopausal attitudes and knowledge [5,40,41]. Participants scored 1 for a correct answer and the total score ranged from 0 to 23. Perceived severity of menopausal distress was measured by the Greene Climacteric Scale [42], which has 21 items covering physical, psychological, vasomotor, and sexual symptoms. Participants were instructed to answer on a scale from 0 (not at all) to 7 (extremely) on how bothered they were by these symptoms. The scale score ranged from 0 to 63 with good reliability (US: 0.93; China: 0.95). Items of perceived susceptibility, perceived benefits, perceived barriers, self-efficacy, and motivation to seek suitable help for menopausal needs were constructed with reference to the Champion’s Health Belief Model Scale [43] (Table 1 and Textbox 1). The items were face-validated by an expert group comprising 2 general practitioners, a gerontologist, experts in women’s health and mental health, and a medical social worker. Participants were asked to indicate their agreement on a Likert scale from 1 (strongly disagree) to 7 (strongly agree). We examined the perceived COVID-19–related barriers (ie, concerns about contracting COVID-19 from the clinic and spreading it to family members) and perceived non–COVID-19–related barriers (ie, financial, time, and informational barriers and embarrassment from help-seeking) separately. Understanding midlife and older women’s concerns about contracting COVID-19 from medical clinics, separating these 2 categories of barriers was intended to support finding new ways of providing menopausal services, such as telehealth adaptations during a pandemic like the COVID-19 pandemic.

| • I am confident that I will get the help I need for my menopausal health needs. |  |

Motivation

|  |
|----------------|---|
| • I am motivated to get suitable help for my menopausal health needs. |  |

**Statistical Analysis**

Independent *t* tests were used to compare the factors affecting the motivation to seek help across the 2 samples. A structural equations model (SEM) was used to explore the associations among variables according to the Health Belief Model [44]. A model was fitted for each sample, since there was no prior study suggesting either identical or distinctive patterns of associations among the variables. The model has been fitted with the built-in SEM function of JASP (ver 0.16.4.0, The JASP Team) based on the *lavaan* R package, and the missing data were handled by full information maximum likelihood [45]. Instead of imputing or replacing the missing data, all the data in the sample were used to obtain the population parameters that maximize the likelihood functions. A satisfactory model fit was indicated by a nonsignificant result on the chi-square test, comparative fit index (CFI), and Tucker-Lewis Index (TLI) of over 0.95, as well as a root-mean-square error of approximation (RMSEA) and standardized root-mean-square residuals (SRMR) of 0.08 or less [45,46]. Since a large sample size tends to yield a significant chi-square test result regardless of the model fit, we still accepted the model if it fulfilled the last 4 criteria but with a significant chi-square test result. All tests used *P*<.05 to indicate statistical significance.

**Results**

The sample characteristics are presented on Table 2. The US sample had 1002 women (mean age 48.0, SD 6.3 years) collected in 6 days in late September 2022, while the Chinese sample had 860 women (mean age 48.6, SD 5.5 years) collected on 3 separate dates in July and October 2022. Most participants had tertiary education (US: n=909, 90.7%; China: n=567, 65.9%), were married (US: n=852, 85.4%; China: n=835, 97%), and had full-time occupations (US: n=805, 80.8%; China: n=662, 77%). The median income of the US participants was between US $50,000 and US $75,000 per annum (n=382, 38.1%) and the participants were predominantly White (n=835, 83.3%). The median income of the Chinese sample was between ¥15,000 and ¥20,000 (US $2104.82) and ¥20,000 (US $2806.24) per month (US $23,078-$30,769 per annum; n=217, 25.2%). As for their menopausal statuses, 53.2% (n=533), 35.8% (n=359), and 11% (n=110) of US participants were premenopausal, postmenopausal, and perimenopausal, respectively, while the respective ratios were 37.3% (n=321), 31.1% (n=267), and 31.6% (n=272) for Chinese participants. While the number of self-reported chronic illnesses were comparable across the 2 samples, US participants were more likely to use all categories of health care services except for Chinese medicine and
complementary and alternative therapies, for which Chinese participants reported greater use.

A measurement model was fitted for the 4 subscales with self-created items (perceived susceptibility, perceived benefits, perceived COVID-19–related barriers, and perceived non–COVID-19–related barriers) using confirmatory factor analysis. Satisfactory fit for 4 correlated latent factors was reported for both samples (US: $\chi^2_{59}=128.8$, $P<.001$; CFI=0.99; TLI=0.99; RMSEA=0.037; SRMR=0.017; China: $\chi^2_{59}=203.9$, $P<.001$; CFI=0.96; TLI=0.97; RMSEA=0.055; SRMR=0.041).

The US sample scored lower than the Chinese sample on menopausal knowledge, perceived severity, perceived benefits, self-efficacy, and motivation, but higher on perceived susceptibility and perceived barriers (Table 3). All $t$ statistics were statistically significant ($P<.001$).

Several demographic variables were associated with motivation to seek help. In the US sample, higher motivation was related to lower age ($r=-0.79$, $P=.02$), having a full-time occupation ($t_{914}=4.59$, $P<.001$), being affiliated to a religion ($t_{898}=6.87$, $P<.001$), and being married ($t_{913}=8.42$, $P=.03$). Help-seeking motivation was also related to menopausal state ($F_{2,916}=7.37$, $P=.001$), with significantly higher motivation to seek help among women in premenopause rather than those in postmenopause ($P<.001$), and with those in perimenopause in between the other 2 states. Motivation to seek help was not significantly related to education, income, ethnicity, or the number of chronic illnesses.

In the Chinese sample, higher motivation was related to higher income ($r=0.181$, $P<0.001$), having a full-time occupation ($t_{833}=3.758$, $P<.001$), and being married ($t_{833}=2.168$, $P=.03$). Motivation to seek help was also associated with menopausal state ($F_{2,832}=3.096$, $P=.046$), with the highest motivation among women in perimenopause, followed by those in postmenopause ($P=.04$), and then those in premenopause ($P=.03$). Motivation was not significantly related to age, education, the presence of a religious affiliation, or the number of chronic illnesses.

SEM was used to explore the pathways between knowledge, health beliefs, and the motivation to seek help. The overall fit was satisfactory for the US model ($\chi^2_{95}=320.48$, $P<.001$; CFI=0.96; TLI=0.95; RMSEA=0.053, $P=.24$; SRMR=0.037) despite the significant chi-square test result (Figure 1). The model accounted for 53% of the variance of motivation. Surprisingly, higher knowledge was related to lower perceived susceptibility, perceived benefits, perceived COVID-19– and non–COVID-19–related barriers, and even self-efficacy to seek help. Higher perceived benefits, perceived COVID-19–related barriers, and self-efficacy were related to higher motivation to seek help in American participants.

The overall fit was also satisfactory for the Chinese model ($\chi^2_{95}=320.90$, $P<.001$; CFI=0.96; TLI=0.95; RMSEA=0.053, $P=0.24$; SRMR=0.037) despite the significant chi-square test result (Figure 2). Inspection of the regression paths revealed that menopausal knowledge was associated with higher perceived COVID-19–related barriers and lower perceived severity. Higher perceived severity, perceived benefits, perceived COVID-19–related barriers, self-efficacy, and lower perceived non–COVID-19–related barriers were related to higher motivation to seek help. The model explained 45.3% of the variance of motivation. In both the United States and China models, knowledge was not significantly associated with motivation to seek help. Table 4 illustrates the results of the SEM with the United States and China data.

Discussion

Principal Findings

Midlife women in the United States and China revealed rather different patterns of factors associated with menopausal help-seeking. For the US participants, greater knowledge conferred less perceived severity (indicated by bother about symptoms) but a lower self-efficacy to seek help. Furthermore, knowledge was related to lower perceived susceptibility, perceived benefits, and perceived barriers. In turn, motivation was only related to perceiving more benefits, COVID-19–related barriers, and self-efficacy, as was also the case among Chinese participants. For Chinese participants, higher knowledge was related to lower perceived severity and more concerns over contracting COVID-19 from attending clinics. In turn, greater perceived severity, perceiving more benefits, self-efficacy, and concerns for COVID-19, as well as lower non–COVID-19–related barriers, were related to greater motivation to seek help. Paradoxically for this sample, knowledge appeared to suppress the motivation to seek help by reducing perceived benefits, COVID-19–related barriers, and self-efficacy.

We put forward the following reasons that may explain why knowledge did not impose a direct positive effect on help-seeking motivation. First, a good proportion of menopausal women tend to rely on self-initiated lifestyle modifications rather than formal care for their menopausal symptoms [10,31]; thus, higher knowledge may have helped women tackle some menopausal symptoms on their own and effectively reduce help-seeking motivation. Second, Pimenta et al [47] found greater perceived control was related to fewer symptoms. Likewise, a systematic review by Ayers et al [48] revealed more reported symptoms in women with more negative attitudes toward menopause. If knowledge confers perceived control, it may reduce the experience of distress associated with menopause (which is supported by the negative relationships between knowledge and perceived severity in both of our samples), and eventually lead to lower help-seeking motivation. Third, greater menopausal knowledge may dilute menopause as something that should be tolerated, thereby reducing one’s propensity to seek professional help. In a qualitative study by Steffan [9], working midlife women in Britain exhibited strong self-reliance and personal responsibility either through putting up with or handling their menopausal symptoms and were silently “wanting yet not accepting help.” Knowledge may not only serve to normalize help-seeking behavior but may also dilute the intensity of the menopause experience. However, whether neoliberal individualization, or even trivialization, may have resulted in diminished service-seeking warrants more research into the lived experience of midlife women in different societies. In conclusion, whether knowledge imposes a direct effect on tackling the menopausal concerns or acts as an indirect effect via perceived control on palliating or diluting the distressing menopausal experience, which all in turn may reduce engaging in help-seeking, should be subject to further research. Moreover, the role of knowledge on perceived barriers against help-seeking may be socioculturally dependent. In our Chinese sample, knowledge was related to perceiving more barriers against help-seeking, while the reverse was observed among the American sample. In a culture that emphasizes the importance of “face” and regards the discussion of the female body and sexuality a taboo [49], knowing more about menopause may mean learning more about the stigmatizing details of the health condition, which may in turn hinder help-seeking. Also, in China, since gynecological and menopausal well-being support as well as psychotherapies are not as common as in the United States, knowing more about menopause may be concomitant with large investments of time, money, and effort. Instead, Chinese medicine regards menopause as a manifestation of weakened “kidney” function that may be

enhanced by herbal medicines and acupuncture [50], which serves as an explanatory model of a socially cohesive and culturally accepted mode of intervention. The barriers to seeking formal, “Westernized” or medical help could be amplified when self-care means are relatively accessible. Greater knowledge, however, may infer lower embarrassment and fewer financial, information, and time barriers in a society, like the United States, in which health systems have developed to embrace positive aging, femininity, and sexuality coupled with greater access to established menopausal care.

In terms of demographic factors, only being employed full-time and being married were associated with higher motivation to seek help in both samples. Menopausal state was also related to motivation to seek help, yet the directions of association were different in the 2 samples. While a full-time occupation and being married may confer financial and family support for help-seeking in both societies, other variables did not demonstrate cross-cultural consistency. An in-depth exploration of the demographic impetus of help-seeking is beyond the scope of this paper considering the limitations of our web-based survey panels. Social determinants of health, such as discriminatory and disabling beliefs about menopause, the accessibility of health care systems, the availability of treatments, social support, occupational characteristics, and general literacy, could be strongly related to the menopausal experience and may affect formal help-seeking [11]. Differences in cultural representations of the menopausal experience may also affect practitioners’ understanding of their patients’ distress and needs, especially with women from ethnic minorities [51]. Future studies may adopt a person-in-context approach to thoroughly explore microlevel, mesolevel, and macrolevel factors that influence menopausal help-seeking in midlife women.

Limitations
In developing our survey, we needed to balance the need for a succinct measurement tool that engages the attention of our participants against the requirement for comprehensive coverage of the important constructs of the Health Belief Model. Therefore, most items were constructed specifically for this study. The widely used Champion’s Health Belief Model Scale has been adopted to examining the motivation for breast cancer self-examination, Papanicolaou tests, and other women’s cancer screening programs for women in menopause [45,52-54], but we found no adoption to the context of menopausal care to date. Also, as our survey relied on self-reported measures, the motivation to seek help can hardly be counter-checked with the actual help-seeking behavior.

Although the web-based survey panels, unlike face-to-face survey panels, have efficiently compressed the duration of data collection, which minimized the impacts of unexpected, time-sensitive factors (eg, sudden outbreaks), there are several limitations. First, we have no access to the number of potential participants our advertisements have reached, nor the exact randomization procedures of the panels with their eligible members. Thus, it is not possible to estimate the response rate. Also, although smart devices have become ubiquitous in the United States and China, web-based surveys have often resulted in the overrepresentation of individuals with higher socioeconomic status, those belonging to an ethnic majority, and those with a greater likelihood to have convenient and stable internet access. Our findings, however, could be particularly informative for telehealth development as we have engaged a group of women with good potential of early patronage [55]. Other factors, including distraction through concurrent apps on the smart device, self-selection bias, excessive nonnaive, and social desirability bias, may have also affected the data quality of the web-based survey panels [56].

Implications
Although our study was conducted during the height of the COVID-19 pandemic, our findings could be helpful for developing telehealth services targeting midlife women post the pandemic. Perceived COVID-19–related barriers were positively correlated with perceived severity in both of our samples. Higher levels of COVID-19–related concern may reflect either higher health consciousness [57,58] or an underlying health vulnerability that warrants an enhanced motivation to seek formal help. In this light, we call for expanding the use of telehealth to replace physical visits in menopausal care, especially for women who may be concerned about iatrogenic infection or during peaks of seasonal infectious diseases (eg, flu seasons). In fact, even prior to the COVID-19 pandemic, telehealth had been developed to reduce the direct and indirect costs of clinic attendance (eg, travel time and time off from work), as well as enhance privacy and autonomy by allowing consultation with practitioners at a location comfortable to the patient [59,60]. It is expected that these benefits will continue to prevail for a good proportion of patients even though some remote consultations may have reverted to face-to-face visits after the pandemic. Further research is needed to gather empirical evidence to indicate the proportion of remote consultations that have reverted to physical ones and which populations are likely to continue with remote consultations and telehealth services at-large post the pandemic.

Moreover, recent studies have reported that interventions including cognitive-behavioral-, behavioral-, or mindfulness-based therapies [61,62], walking programs supported by a virtual platform [63], and multidisciplinary clinics [64] may be useful for tackling menopausal symptoms as well as fostering the overall quality of life of women. As our study demonstrates, knowledge alone does not necessarily lead women to seek formal support. We suggest telehealth services focus on relieving psychosocial distress, connecting women to build a supportive and empathetic community, and enabling healthy lifestyles. ALSwayied et al [65] found early evidence that mobile-based physical activity programs are helpful for enhancing moderate to vigorous physical activities among midlife women. Another systematic review by Sediva et al [66] on 13 digital health interventions found that most interventions for midlife women targeted weight loss, lifestyles, and menopausal symptom management and primarily relied on the provision of instructions on healthy behaviors, fostering capability, and motivation. Although the heterogeneity of the studies and their outcomes forbids a conclusion about the general effectiveness of these digital health interventions, it is hoped that these contents may build confidence and familiarity in women with their health care providers, thus connecting women...
in need to more specialized support. Telehealth may be used to facilitate shared decision-making in the treatment of menopausal symptoms. The North American Menopause Society has developed MenoPro, an app that relies on a menopause decision-support algorithm, which can be accessed by both patients and health care providers to make decisions for pharmacologic or nonpharmacologic treatments [67]. The app may support a more transparent and personalized approach for risk stratification and shared decision-making that in turn enhances perceived benefits and self-efficacy of the support, which are 2 facilitators for help-seeking revealed in our findings.

A multistakeholder, participatory design study conducted by Backonja et al [21] found that women with menopause had distinctive concerns compared to their health care providers when it came to their desired Menotech functionality, with the former wanting Menotech to “understand, prevent, and positively reframe their menopause experience” and the latter placing greater emphasis on “tracking and patient-provider communication.” Future Menotech is expected to go beyond symptom tracking and assemble the collected data to predict the onset of bothersome experiences and prevent such experiences by offering personalized, quotidian suggestions, which, in turn, integrate and celebrate this life transition under the expanding occupational lifespan of midlife women. Our study points to the intricate cross-cultural differences in the role of knowledge between American and Chinese midlife women. In this light, we call for the development and testing of culturally targeted Menotech services that may enhance perceived benefits and self-efficacy or even capitalize on the health consciousness of midlife women to foster help-seeking. These culturally sensitive considerations may span from content (eg, inclusion of indigenous therapies, such as Chinese medicine and Qigong, among others) and service mode (eg, collaboration with established telehealth platforms of general practice vs a standalone system) to technologies (eg, apps or devices) and policies about data protection and privacy.

**Conclusion**

This study is the first to compare the factors affecting help-seeking tendencies for menopausal care among midlife women in the United States and China. Our findings reveal disparate pathways of help-seeking. Higher self-efficacy, perceived COVID-19–related barriers, and perceived benefits, but not knowledge, were related to higher help-seeking motivation in both samples. In the Chinese sample, motivation to seek help was associated with higher perceived severity and lower perceived non–COVID-19–related barriers. In the US sample, knowledge had negative associations with all factors. Implications for post–COVID-19 telehealth services for menopausal support have been discussed.

Abstract

Background: Health care authorities often use text messages to enhance compliance with medical recommendations. The effectiveness of different message framings has been studied extensively over the past 3 decades. Recently, health care providers have begun using digital media platforms to disseminate health-related messages.

Objective: This study aimed to examine the effectiveness of some of the most widely used message framings on the uptake rates of medical checkups.

Methods: This study used a large-scale digital outreach campaign conducted by Maccabi Healthcare Services (MHS) during 2020-2021, involving a total of 113,048 participants. MHS members aged 50-74 years were invited to take their recommended medical actions from the following list: human papillomavirus (HPV), mammography, abdominal aortic aneurysm, fecal occult blood test (FOBT), and pneumococcal vaccination. Each member was randomly assigned to receive 1 of 6 message framings: control (neutrally framed; n=20,959, 18.5%), gains (benefits of compliance; n=20,393, 18%), losses (negative consequences of noncompliance; n=15,165, 13.4%), recommendation (a recommendation by an authoritative figure, in this context by a physician; n=20,584, 18.2%), implementation intentions (linking potential outcomes to future reactions; n=20,701, 18.3%), and empowerment (emphasizing personal responsibility for maintaining good health; n=15,246, 13.5%). The time frames for measuring a successful intervention were 14 days for scheduling screenings (ie, HPV, mammography, or abdominal aortic aneurysm), 30 days for performing the FOBT, and 60 days for receiving pneumococcal vaccination. We also examined the effectiveness of media channels (text message or email) on uptake rates and whether the subject-line length is correlated with message-opening rates.

Results: No significant effect of message framing on uptake rates of medical checkups was observed. The rates of appointments for screening ranged from 12.9% to 14.1% across treatments. Based on a chi-square test, there was no evidence to reject the null hypothesis that these compliance rates are independent of the treatments (P=.35). The uptake rates for the FOBT and pneumococcal vaccination ranged from 23.3% to 23.8% across treatments, and we could not reject the hypothesis that they are independent of the treatments (P=.88). We also found that emails are more effective than text messages (P<.001) and that the subject-line length is negatively correlated with message-opening rates.

Conclusions: No evidence was found for an effect of the 5 message framings on uptake rates of medical checkups. To enhance compliance rates, public health officials may consider alternative framings. Furthermore, media channels and the subject-line length should be given careful consideration in the planning stages of health care campaigns.

**Introduction**

Successful preventive care requires high uptake rates of early detection tests. Increasing these rates at relatively low costs is one of the more pressing challenges faced by public health officials. Over the past 3 decades, behavioral insights have been used to nudge individuals and increase their compliance rates with recommendations of their national health care authorities. One common tool used in this line of research is message framing, that is, the content of textual messages sent out by health care providers. Message framing has been used to encourage healthy behavior in various public health contexts, such as smoking cessation [1-3], early-detection cancer screenings [4,5], influenza vaccinations [6-8], and, recently, COVID-19 vaccinations [9-11].

In this large-scale field study, we reexamined some of the most influential and commonly used message framings to shed light on their effectiveness. Specifically, we investigated prospect theory, physician’s recommendations, implementation intentions, and empowerment.

Prospect theory [12-14] incorporates the idea that losses loom larger than gains. Over the past 3 decades, dozens of studies have examined the effect of these types of framings on different medical outcomes. Results have been rather mixed and have led to an important ongoing discussion regarding the usefulness of prospect theory–based frames in medical contexts (see Refs. [5,15,16] for systematic reviews).

Physician’s recommendations have also been examined in the literature, especially with respect to cancer screenings, and have been found to increase uptake rates [17-19].

Implementation intentions [20,21] link potential outcomes (eg, results of medical tests) and reactions (eg, steps to be taken after results are received). Such links in critical situations have been shown to facilitate individuals in reaching their health goals [22]. Implementation intentions have been used in different medical contexts, such as influenza vaccination [7,23], colorectal cancer screenings, and the fecal occult blood test (FOBT), for which some studies have reported positive effects [24,25], while others have found no effect at all [26].

Empowerment messaging is meant to emphasize the individual’s responsibility to take care of their own health. Thus far, it has shown potential to increase breast and cervical cancer screening rates [27-29].

Our study contributes to this literature by examining the large-scale effectiveness of these types of framings. To do so, we made use of a massive digital outreach campaign that was held during 2020-2021 by Maccabi Healthcare Services (MHS), the second-largest health maintenance organization (HMO) in Israel.

In addition to the examination of message framing, we also investigated 2 other topics: the effect of the digital media channel on message-opening rates and the influence of the subject-line length on responsiveness. As health care organizations turn to digital media as their main means of communication with the public, there is growing interest in the role of different media channels in generating positive health outcomes [30-36] and in the impact of the subject-line length on digital marketing campaigns [37-39]. These topics are essential for enhancing the public’s responsiveness to health-related digital communication, and they were addressed in this study.

Although the digital setup of this study allowed us to shed light on these 2 topics of emerging interest in public health, the main aim of our work was to test whether specific types of framings can increase adherence to medical recommendations. More specifically, we tested the null hypothesis: the well-known types of framings of digital messages used in this study have no effect on the uptake rates of medical checkups.

**Methods**

**Study Design**

MHS contacted members aged 50-74 years and invited them to take preventive medical actions according to their age, medical history, and guidelines of the Israeli Ministry of Health. The campaign ran from July 2020 to December 2021 and targeted the following medical procedures: mammography (for women), human papillomavirus (HPV; for women), abdominal aortic aneurysm screening (for men), and the FOBT and pneumococcal vaccination (for men and women).

MHS members included in this campaign were randomly assigned into 1 of 6 groups:

- Control: received an informative message, which was identical to the one used by MHS prior to this study
- Gains: highlighting the benefits of compliance
- Losses: highlighting the potential negative effects of noncompliance
- Recommendation: citing a recommendation by an MHS physician
- Implementation intentions: stating a plan that links outcomes to reactions
- Empowerment: emphasizing the personal responsibility of the members for their own health

We included all members who received a digital message from MHS for the first time. Those who received a digital message prior to the initiation of the study were excluded. (MHS started sending out digital messages about 1 year before the initiation of the study as part of a large digitization process within the organization. These messages used the neutral frame that later became the control group in our study.)

JMIR Public Health Surveill 2024 | vol. 10 | e45379 | p.719

(page number not for citation purposes)
Messages were communicated to members via email unless they lacked a valid email address in the MHS registry, in which case, a text message (SMS) was sent with a link redirecting to a landing page. The email subject line and contents (or the text message and the corresponding landing page) had 6 variations according to the assignment to control or treatment groups. Exact message contents are available in Multimedia Appendix 1.

Members received an invitation to perform 1 (or more) of 5 medical checkups that were recommended for them. These recommendations were based on the following criteria that combine the guidelines of the Israeli Ministry of Health with MHS’s designated target groups of the digital campaign:

- Mammmography: women above the age of 50 years for whom at least 2 years had passed since their last mammography test
- HPV: women aged 50-54 years for whom at least 3 years had passed since their last HPV test
- FOBT: women and men above the age of 50 years for whom at least 1 year had passed since their last FOBT and at least 5-10 years had passed since their last colonoscopy test (the exact number of years since the last colonoscopy that triggers an invitation to perform the FOBT determined by the individual’s specific health risks)
- Pneumococcal vaccination: women and men above the age of 65 years who never received the vaccination
- Abdominal aortic aneurysm screening: men above the age of 65 years with a history of smoking who had never performed the screening

Note that members could have been eligible for more than 1 checkup. In these cases, the invitation message included all the relevant checkups.

**Procedure**

Members who met 1 or more of the aforementioned criteria received a message from MHS in which they were invited to perform all the medical checkups that were recommended for them by the Israeli Ministry of Health. (Members who had already been diagnosed with a specific condition that 1 of the 5 medical procedures was meant to detect did not receive an invitation to test for that specific condition. They were contacted by MHS separately to follow up on their earlier diagnosis and to assess their overall medical well-being.) Following the initial contact, if the member scheduled an appointment or performed the recommended checkups, they did not receive any further messages. If they did not comply with the recommendations for all checkups that appeared on their initial message, they received reminders that followed the same framing theme that appeared in their initial message and included the remaining recommended checkups that the member did not perform or did not schedule an appointment for since the initial message was sent out. The first reminder was sent out 2 days after the first message but only in case the first message was sent via email and was not opened. The second and third reminders were sent out 2 and 4 weeks after the initial message, respectively (+/- a day or two if the reminder was supposed to be sent out on the weekend).

For mammography, HPV, and abdominal aortic aneurysm (which we call “screenings”), we collected data regarding scheduled appointments (we did not have access to the actual performance data of these screenings). For the FOBT and pneumococcal vaccination (which we call “lab tests”), we collected data regarding the actual performance (these procedures do not require appointments, and one can perform them simply by showing up at the clinic). Next to every medical procedure that appeared on a member’s invitation was a link that, once clicked, redirected the member to receive more information about the specific procedure on the website of MHS. Messages with screening recommendations included a link through which members could make the appointment (lab tests require no appointment). A total of 129,070 MHS members participated in this study, of which 113,048 (87.6%) were included in our analysis (the data-cleaning process is described in detail in Multimedia Appendix 2). Of these, 71,140 (62.9%) members received messages that only included lab tests, 30,878 (27.3%) received messages that only included screenings, and 11,030 (9.8%) received messages that included at least 1 lab test and at least 1 screening. Looking at the number of checkups that were included in the first invitation message of members who participated in the analysis, we found that 100,125 (88.6%) received a message that referred to only 1 recommended checkup, 10,416 (9.2%) received a message that included 2 recommended checkups, and 2507 (2.2%) received a message with 3 recommended checkups.

**Outcome Variables**

We analyzed the data separately for screenings and for lab tests since each of the 2 has a different outcome measure (appointment scheduling vs actual performance, respectively). In addition, since each message may have included more than 1 recommended medical action, we defined a “screening success” as a case in which a member scheduled an appointment to at least 1 of their recommended screenings. Similarly, a “lab test success” was a case in which a member performed at least 1 of their recommended lab tests. Members who received a message that included a recommendation for a screening and a lab test were included in both groups for analysis purposes. Such members could count as a success in screenings or in lab tests or in both, depending on their actions. Following the criteria set by MHS, the time frame considered for measuring a success was 14 days from the last contact date for screenings, 30 days for the FOBT, and 60 days for pneumococcal vaccination (setting different time frames had no effect on the qualitative results and conclusions).

The time frame that we considered for opening a message was 45 days from the initial contact date. (Since the final reminder was sent roughly 4 weeks after the first message, this time frame ensured that we essentially examined all members who made the minimal effort to respond to the messages by opening at least 1 of them.) A text message was considered opened if a member clicked the link that appeared in the text message that redirected the member to the landing page with the content of the invitation message (an email was considered opened if the member viewed the body of the email).
Covariates

In addition to the type of treatment (control, and 5 more treatment arms), we used the following covariates in our analysis:

- Gender: male or female.
- Age group: 50-54, 55-59, 60-64, 65-69, and 70-74 years.
- Socioeconomic status (SES): an index that is constructed by the Israel Central Bureau of Statistics (CBS), which incorporates information at the household level (education, income, employment, etc), alongside information regarding the geographical place of residence of the household and its local municipality. The index ranges from 1 to 10, where 1 reflects the weakest status and 10 the highest.
- Existing medical conditions (3 distinct covariates): indicating a previous history of (1) cardiac illness, (2) diabetes, or (3) a chronic condition of other type, such as being diagnosed with other chronic illnesses or receiving medication over a long duration of time.
- History of previous checkups: indicating whether the patient underwent any of the screenings or lab tests in the past.
- Media type: indicating whether the patient received an email message or an SMS text message.
- Periphery: indicating whether the patient resided in a geographically peripheral area (ie, based on the patient’s residence area relative to the central district of Israel).

Statistical Analysis

We examined the effectiveness of the different framings for members who opened 1 of their messages, including reminders. To test the significance and effect of the treatment groups on either screenings or lab tests, we used 2 logistic regression models, respectively. The dependent variable was a dummy variable that received 1 if that observation was a success and 0 otherwise. The independent variables of interest were the treatment dummies. Our full set of covariates was added to the logistic regressions as control variables. We also tested for independence of the compliance rates versus association with each of the groups using a chi-square test (ie, independence test). In addition, we reported 95% CIs (via the proportion test) for the compliance rates with screenings and lab tests for the control and treatment groups.

We explored the relationship between the SES and message-opening rates, using visualization and computation of correlation coefficients. Logistic regression was then run to examine whether the effect of sending a message by email on the message-opening rate was positive even when the SES was controlled for. The dependent variable was a dummy variable that received 1 if the member opened the message and 0 otherwise. The independent variables of interest were media channels (email received 1, and text message received 0) and the SES.

We compared the opening rates of messages (proportion of email messages read vs proportion of text message link clicks) using a 2-sided proportion test. We also compared the proportion of test compliance, given message opening (again, using a 2-sided proportion test). These comparisons were performed for various subgroups of the population (ie, controlling for demographic characteristics).

We used 2-sided proportion tests (95% CI) to compare the opening rates of short-subject-line messages versus long-subject-line messages.

Ethical Considerations

This research was approved by the Helsinki Committee of MHS (study number 0099-20-MHS) and by the Ethical Research and the Protection of Human Participants Committee, Faculty of Social Sciences, University of Haifa (approval number 369/21). Approvals included a waiver of consent. Identifying information was not shared with the researchers (ie, the researchers received anonymized data). No compensation was paid to participants.

Results

Sample Characteristics

Table 1 shows the demographic characteristics of our sample across treatments. (The table includes only members for whom we had all demographic variables and the SES, for a total of 112,802 members.) The treatment arms were well balanced on all observable characteristics, which included gender, age group, the SES, and existing medical conditions. Note that the age of the target group in the study and the broad definition of the “existing medical conditions” variable explain the high percentages of members who were classified as having a chronic condition.

*SES: socioeconomic status. This is an index defined by the Central Bureau of Statistics (CBS), ranging from 1 to 10, where 1 reflects the weakest status and 10 the highest.

Main Findings
Approximately 60% of the 113,048 participants in the study, totaling 67,772 MHS members, opened 1 of their messages within the 45-day time frame.

The first 2 columns in Table 2 report success rates (conditional on opening 1 of the messages) by treatment arm. There were no significant differences in success rates across treatments for screenings and for lab tests. Chi-squared tests did not allow us to reject the null hypothesis that compliance rates are independent of treatments ($P=.37$ for screenings and $P=.88$ for lab tests). The last 2 columns of the table relate to the message’s subject-line length (ie, number of words) and the respective message’s opening rate. Table 3 includes logistic regressions with our full set of covariates added as controls (members who had missing values for any of the covariates were omitted from the regressions). Our null result is reflected in the table, as none of the framing versions had a significant effect on success rates. This null result held when we ran the same type of logistic regressions with interactions between the treatment variables and each of our controls (given the large number of interactions, we did not report the results of these regressions in the paper, but they are available upon request).

**Effectiveness by Media Channel**

We compared the effectiveness of the media channels through which messages were sent (69,777, 61.7%, members received emails, and 43,271, 38.3%, members received text messages). Table 4 shows that these groups differed in terms of their demographic characteristics: Members who received text messages were older on average, had a lower SES, and were more likely to be males. More details are provided in the Limitations section. Therefore, we compared the performance of the different media channels within subgroups of the population with similar demographic characteristics. Table 5 provides the opening rates of email messages, text messages, sample sizes, and the P value comparing the 2 rates.
for subgroups of the population with similar demographics. It is evident that text messages were disregarded more often than emails for every subgroup.

Table 6 provides for the same subgroups a comparison of the compliance rates of emails and text messages, given that a message was opened (rates, sample sizes, and $P$ values). In most subgroups examined, and overall, text messages exhibited a slightly higher (but significant) conditional-compliance rate.

Table 7 shows the overall effectiveness of media channels (ie, the overall unconditional success rates of emails vs text messages). Email messages outperform text messages in all subgroups and overall.

SES: socioeconomic status. This is an index defined by the Central Bureau of Statistics (CBS), ranging from 1 to 10, where 1 reflects the weakest status and 10 the highest.

We now provide results concerning the robustness of the findings reported in Table 5, according to which emails were opened more frequently than text messages. First, Figure 1 shows a strong positive relationship between email availability and the SES (correlation coefficient=0.298, $P<.001$). Next, Figure 2 visualizes a positive relationship between the message-opening rate and the SES for both media channels (correlation coefficient=0.079 and 0.13 for emails and text messages, respectively; $P<.001$ in both cases). Moreover, Figure 2 shows that emails had higher message-opening rates compared to text messages for each SES.

In Table 8, we report the results of regressing, in a logistic model, the message-opening rates on the media channel being email and the SES. The email media channel positively affected the message-opening rates even when the SES (which had a positive effect of its own) was controlled for. Table 8 reports this result without controls and while controlling for the entire set of covariates.
Figure 1. Email availability as a function of socioeconomic status (SES).

Figure 2. Message-opening rates as a function of the socioeconomic status (SES) for email and text messages (SMS).
Table 8. Two logistic regression models for message-opening rates, with no controls and controlling for all available demographic characteristics and chronic conditions.

**Message-Opening Rates and Subject-Line Length**

Figure 3 shows the relationship between message-opening rates and the subject-line length for the different media channels and overall (see Table 2 for 95% CIs). As the length of the subject line increased, the message-opening rate decreased. For emails, the average opening rate of the 2 messages with the shortest subject lines (8 and 11 words) was 68.2% and the average opening rate of the 2 messages with the longest subject line (15 and 16 words) was 66.3%. For text messages, these rates were 54.1% and 48%, respectively (both differences were significant, with $P<.001$).
**Figure 3.** Message-opening rates as a function of the subject-line length, with a linear regression fit for email (dashed line), text messages (dotted line), and overall (solid line).

**Discussion**

**Principal Findings**

Our main findings do not allow rejecting the null hypothesis according to which uptake rates of medical checkups are independent of the message framing. Compliance rates (whether appointment scheduling or actual performance) are relatively similar across treatments, and this finding holds even after controlling for different demographic and health-related covariates.

We identified several variables that have a significant effect on compliance: conducting a medical procedure in the past increases the chances of compliance, as expected. Text messages seem to increase uptake rates, conditional on opening the message—a finding that is also robust when examining subgroups with similar demographic characteristics. It is interesting to note that age has a significant effect on success rates but the direction of the effect changes depending on the type of checkups (the reference age group in the regressions was 50-55 years).

The reason for these directional effects is likely the following: Older members may find it more difficult to schedule appointments through the online interface—hence the negative coefficients for the older age groups when we measured screening success. By contrast, lab tests only require a visit to the clinic and no appointments. Older members tend to visit their local clinic more regularly than younger members, which leads to the observed positive effect of age on lab test success. The variable for the SES also showed opposing effects, depending on the type of checkup. As one might expect, appointments made through the online interface increased with higher SES. By contrast, a higher SES leads to lower levels of performance of lab tests. Although we cannot delineate a clear explanation for this finding, it may be that, similar to older adults, individuals of a lower SES tend to visit their local clinics more often than those with a higher SES and therefore have higher performance rates of lab tests.

Regarding the effectiveness of media channels, we conducted this analysis for subgroups of the population with similar demographics, since there was no random assignment to media channels and the 2 groups apparently had different characteristics. For message-opening rates, we found highly significant differences favoring emails for every subgroup (Table 5).

Within each media method, we found that shorter subject lines increase the likelihood of opening messages. Given our main finding of no effect of framing on appointment scheduling/actual performance, we believe that this pattern suggests that shorter subject lines, rather than the subject line’s content, increase the likelihood of opening a message.
Conditional on message opening, we observed that text messages had a significant edge for 8 of 10 subgroups, as shown in Table 6. The overall effectiveness (ie, unconditional success rate) of each channel showed that emails outperform text messages and significantly so for all subgroups (Table 7). We concluded that the high message-opening rates for emails compared to text messages is the driving force behind this media channel’s increased success in our study.

The observation that text messages are disregarded more often than emails may be because text messages are considered more intrusive than emails. However, once opened, members are more likely to actually make an appointment or take the recommended medical action in the case of a text message than when reading through an email (Table 6). It may be that those who are willing to open a text message rather than disregard it have a more positive attitude toward health care recommendations than those willing to read through an email.

There was a positive relationship between the message-opening rate and the SES for both media channels. Moreover, emails had higher message-opening rates than text messages for each SES. These observations suggest that message-opening rates are positively affected by both the SES and the media channel being email.

These findings may be valuable for future public health campaigns as they provide information about the potential of different media channels to fulfill their designated purpose. However, the lack of random assignment into the different media channels prevents us from drawing firm conclusions on this matter. More research needs to be conducted (specifically with random assignment to media channels) in order to substantiate these findings.

**Relation to the Literature and Contribution**

Two of the framings used in our study, gains and losses, which are based on prospect theory [12-14], are the most commonly studied in the literature on framing of health-related communication. Dozens of studies have examined their effectiveness in nudging individuals toward desired healthy behaviors, including early-detection screening tests for different types of cancer. In the past 3 decades, evidence has amounted and has shown mixed results with respect to the empirical validity of these findings (see Refs. [5,15,40,41] for systematic reviews). As a result, conceptual concerns regarding their use in health-related behavior change have been raised [16]. Furthermore, it has recently been suggested that there is not much difference between the effectiveness of the 2 types of messages as far as persuasiveness is concerned [42], even when accounting for different moderating factors. Our study fits right into this discussion and allows testing this paradigm, and the other types of message framings that we have taken from the literature (implementation intentions, recommendation, and empowerment), in a large-scale field study. As mentioned before, we found no evidence that these types of framings are more effective in increasing compliance rates with medical checkups than a standard neutrally framed invitation message. These results suggest that new framings may need to be devised to attract individuals’ attention to important health recommendations.

Our 2 additional findings indicate that more research should be put into the exploration of the effect of the method of delivery of digital messages on uptake rates of medical checkups. The literature on the effect of the delivery medium on preventive health care outcomes has, thus far, been unable to clearly point toward a specific medium that is superior to the rest [43]. Findings to date suggest that all types of mediums are generally successful at encouraging behavior change, but there is no clear emerging pattern linking the type of medium and the type of message to adherence with specific health behaviors [33,34,36,44]. Moreover, a recent review of the potential effects of text messages in promoting health behavior change has called for large-scale implementations of text messages in order to better assess their pros and cons [45]. Our study contributes to this literature as we found that each communication medium in our study surpasses the other along a different dimension:

- **Message-opening rates:** The percentage of email recipients who opened their emails surpassed the percentage of SMS text message recipients who clicked the enclosed link in the text message.
- **Compliance conditional on message opening:** Among those who opened their invitation message (email or SMS text message), we observed higher compliance rates (ie, higher success rates) in SMS text message recipients compared to email recipients.

Given the unique strengths of each communication channel, our goal was to evaluate and compare their overall effectiveness (specifically, to measure compliance rates among recipients of each communication type). Our findings showed higher compliance rates among email recipients in comparison to the compliance rates of those receiving SMS text messages. Consequently, we concluded that the increased rates of email-opening rates elevate the overall compliance beyond what is observed for SMS text messages.

We think that examining these 2 media channels more carefully could be an exciting topic for future research. It also entails clear policy implications regarding tailoring the preferred media channel and combining the channels in specific campaigns. Messages that call for action and are expected (in advance) to have high opening rates due to their high relevance (eg, COVID 19–related messages during the recent pandemic) may benefit from text messages. However, messages that refer to routine checkups and ongoing recommendations, as those that appeared in our study, may benefit from being sent by email, as they may be opened more frequently and consequently will receive more attention than if they are delivered by SMS.

Regarding the subject-line length, it has received increasing attention in recent marketing literature [37-39], but we are unaware of any studies that examine this topic in relation to health behavior. Our suggestive finding that the subject-line length is negatively correlated with message-opening rates may trigger future research on the topic. Designing a field experiment that examines the effect of additional words/characters in messages’ subject lines on message-opening rates and the overall compliance of health-related messages may have important implications for the success of future health behavior campaigns in reaching their target audience.
Limitations

One limitation of our study is that there was no random assignment to media channels. Members with no valid email address in the registry of MHS received a text message. To deal with this limitation, we conducted the relevant analysis for subgroups with similar demographic characteristics. However, it is possible that there are also unobserved characteristics that differ across the 2 groups. This prevented us from drawing firm conclusions regarding the effectiveness of the different media channels. More research needs to be conducted (specifically with random assignment to media channels) in order to substantiate these findings. Another potential limitation, as in many text message interventions, is the lack of control over whether members who opened their message actually read it. It is possible that some skim through their messages without paying much attention to the content (see Ref. [46] for a recent pilot study regarding patients’ reading rates of emails sent by their physicians). The random assignment to different groups should attenuate the potential effects of this limitation. To further address this issue and strengthen the effect of the framing, we included the main theme of each framing, not only in the body of the message, but also in the subject line. However, one should acknowledge the fact that in the era of digital messaging, limited attention of recipients is likely and should be considered. In this respect, our field study realistically mirrors the potential difficulties that future digital campaigns are likely to encounter. Specifically, it may be more difficult to generate a specific state of mind by framing in the digital era compared to the traditional communication methods (eg, brochures, fliers, post).

Policy Implications

Our findings have important policy implications since message framings are frequently used by health care providers to increase individuals’ compliance rates with health recommendations. Taking a broader perspective, it raises questions regarding the ability of specific textual nudges to increase the public’s adherence and compliance rates with different types of government regulations and professional recommendations. It has been recently argued that accounting for publication bias, these nudges may have a small or no effect in different contexts [47,48]. Our findings add to this ongoing discussion and may suggest that there is room for novel framings or other types of behavioral nudges in order to increase compliance rates with preventive care recommendations. It also sheds light on the seemingly large potential effect of the choice of media through which messages are delivered and the subject-line length. These choices may seem of low consequence at first glance, but our suggestive findings imply otherwise. Future research that carefully examines these topics on a large scale may prove useful for the success of future digital health care campaigns.

Conclusion

This study provides evidence regarding the usefulness of well-known framings from health communication research in a large-scale digital field experiment held in Israel. Our main finding is that compliance with recommendations is not affected by the types of framings we used. We believe that this evidence, coming from a wide outreach campaign, shows that digital messaging may require new framings in order to enhance compliance in the digital era. We also report suggestive evidence on significant differences between the effectiveness of the media channels used in our study (email and SMS) and on the effect of subject-line length on message-opening rates.

Data Availability

The code will be made available on a public GitHub repository. The pre-registration is available through the American Economic Association’s (AEA) randomized controlled trial (RCT) registry [49]. The individual-level data sets used in this study are not publicly available, as we do not have legal permission to publish them due to Maccabi Healthcare Services (MHS) policy. MHS considers these to be sensitive health data that contain individual-level information regarding health. These type of data are not made available even if they are deidentified (as it may still be possible to reidentify patients from such data). To keep transparency as high as possible, given this limitation, we have posted our code for the analysis to a public GitHub repository. In addition, some of the tables in the paper provide aggregated data for different variables (eg, Tables 1, 4-7). In special cases of interest, a request may be sent to the corresponding author, who will submit a special inquiry to MHS for partial or full access to the data. Access may still be denied as the decision will be made by MHS in compliance with its data sharing policy.

Authors’ Contributions

AM was responsible for conceptualization, formal analysis, methodology, supervision, validation, visualization, writing—original draft, and revising the manuscript. AS was responsible for formal analysis, methodology, software, visualization, and writing and revising the manuscript. Abstract

Background: Burnout is a multidimensional psychological syndrome that arises from chronic workplace stress. Health care workers (HCWs), who operate in physically and emotionally exhausting work contexts, constitute a vulnerable group. This, coupled with its subsequent impact on patients and public economic resources, makes burnout a significant public health concern. Various self-care practices have been suggested to have a positive effect on burnout among HCWs. Of these, physical activity stands out for its ability to combine psychological, physiological, and biochemical mechanisms. In fact, it promotes psychological detachment from work and increases self-efficacy by inhibiting neurotransmitters and neuromodulators, increasing endorphin levels, enhancing mitochondrial function, and attenuating the hypothalamic pituitary-adrenal axis response to stress.

Objective: Our objective was to conduct a systematic review of the evidence on the association between physical activity and burnout among HCWs.

Methods: We considered HCWs, physical activity, and burnout, framing them as population, exposure, and outcome, respectively. We searched APA PsycArticles, MEDLINE, and Scopus until July 2022. We extracted relevant data on study design, methods to measure exposure and outcome, and statistical approaches.

Results: Our analysis encompassed 21 independent studies. Although 10% (2/21) of the studies explicitly focused on physical activity, the remaining investigations were exploratory in nature and examined various predictors, including physical activity. The most commonly used questionnaire was the Maslach Burnout Inventory. Owing to the heterogeneity in definitions and cutoffs used, the reported prevalence of burnout varied widely, ranging from 7% to 83%. Heterogeneity was also observed in the measurement tools used to assess physical activity, with objective measures rarely used. In total, 14% (3/21) of the studies used structured questionnaires to assess different types of exercise, whereas most studies (18/21, 86%) only recorded the attainment of a benchmark or reported the frequency, intensity, or duration of exercise. The reported prevalence of physically active HCWs ranged from 44% to 87%. The analyses, through a variety of inferential approaches, indicated that physical activity is often associated with a reduced risk of burnout, particularly in the domains of emotional exhaustion and depersonalization. Furthermore, we compiled and classified a list of factors associated with burnout.

Conclusions: Our comprehensive overview of studies investigating the association between physical activity and burnout in HCWs revealed significant heterogeneity in definitions, measurements, and analyses adopted in the literature. To address this issue, it is crucial to adopt a clear definition of physical activity and make thoughtful choices regarding measurement tools and...
methodologies for data analysis. Our considerations regarding the measurement of burnout and the comprehensive list of associated factors have the potential to improve future studies aimed at informing decision-makers, thus laying the foundation for more effective management measures to address burnout.

### Introduction

#### Background

Burnout is a multidimensional psychological syndrome resulting from chronic workplace stress. It is characterized by feelings of energy depletion or exhaustion, increased mental distance from one’s own job or cynicism, and reduced professional efficacy [1].

Burnout is gaining attention as a major public health concern for the mental health challenges of health care workers (HCWs) [2]. It poses a threat to the quality of care delivery, especially in terms of patient safety [3], and results in high resource consumption to face its consequences [4,5]. This became even more evident during the COVID-19 pandemic [6], which tightened physicians’ work conditions [7,8], which highlighted the frailty of health care systems in emergency management [11]. Although COVID-19 no longer constitutes a public health emergency [12], HCWs continue to be particularly vulnerable to burnout [13,14], with weakened abilities to manage the typical difficulties of care work and increased exposure to emotionally challenging situations [15]. This is especially true for those directly engaged in patient care given the demanding nature of their roles [16]. They often work long hours, experience sleep deprivation, contend with irregular schedules, and are exposed to emotionally challenging situations. In addition, they face the pressure to master a vast body of clinical knowledge [17]. Furthermore, HCWs are at high risk of workplace injuries [18] and assaults [19,20]. These challenges are compounded by common life stressors such as work-home conflicts, educational debts, relationship status, the age of their children, and the employment status of their partners [21]. As reported in a literature analysis [6], burnout can result in various negative outcomes and criticalities for HCWs, including anxiety, depressive disorders, alcohol abuse or dependence, and suicidal ideation. Burned-out workers experience poor mental health even without a clinically diagnosable disorder, as also proved by the fact that, within this group, there are more mental health problems than in most other occupational groups [22].

Within the broad spectrum of possible public health options to address burnout in HCWs, prioritizing measures to promote mental well-being has become paramount [23,24]. This entails addressing cultural factors, particularly those related to stigma; ensuring protected access to mental health care services; and implementing active policies to encourage healthy lifestyles [25,26]. Among these, physical activity is recognized worldwide as a key strategy for promoting mental well-being [27,28] in addition to helping prevent and manage noncommunicable diseases. However, unlike physical health [29], determining the “optimal dose” of physical activity—considering the combination of intensity, duration, and frequency [30]—for mental well-being remains uncertain and dependent on the specific domain of investigation [27].

A preliminary search of previous systematic reviews on the effects of physical activity on burnout was conducted in Scopus, PubMed, and PROSPERO and resulted in 2 different studies. Naczenski et al [31] found that physical activity was an effective strategy to reduce burnout among workers from various sectors. Regarding health professionals specifically, Bischoff et al [32] identified a potential beneficial effect in health professionals of mind-body practices such as yoga or qigong on occupational stress, one of the conditions for burnout [1].

#### Objectives

Our study systematically investigated how physical activity was incorporated into studies on burnout among HCWs. Recognizing that strategies created without evidence lead to ineffective programs, wasted resources, and persistently poor health outcomes [33], our ambition was to contribute to the development of evidence-based public health policies.

First, we aimed to provide insights into the reported level of participation in physical activity and the extent of participants at high risk of burnout. We also intended to verify whether a correlation emerges between levels of physical activity and burnout and whether a dose-response association exists.

Our second purpose was to thoroughly assess the quality of the available evidence in terms of collecting, compiling, managing, analyzing, and using health data. This assessment could also offer indications to generate hypotheses for further research to strengthen the body of evidence.

These are essential steps along the road that leads to shaping public health strategies and resource allocation for HCWs’ well-being.

### Methods

As recommended for systematic reviews of association studies [34,35], we adopted the population, exposure, and outcome (PEO) approach by considering physical activity habits as the exposure factor and burnout as the outcome. To ensure accuracy and transparency, we followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) [36] and the PRISMA-S (PRISMA literature search extension) [37] guidelines.

JMIR Public Health Surveill 2024 | vol. 10 | e49772 | p.736

(page number not for citation purposes)
Eligibility Criteria

The eligibility criteria are detailed in Multimedia Appendix 1. We included studies that examined the association between physical activity and burnout in health personnel directly involved in the provision of care services, such as physicians, nurses, and technicians, with no restrictions on demographics or workplace context. We considered both qualitative and quantitative measures of physical activity as eligible for inclusion. As we were interested in the association between physical activity and burnout, interventional studies were included regardless of the presence of a control group. A validated assessment tool for burnout (a general work-related stress outcome was not of interest) was mandatory for inclusion.

Our search was not limited by geographic context, funding source, or time horizon. We excluded studies in which physical activity was not distinct from other supportive strategies aimed at managing stress or building resilience or from other mindfulness practices. In addition, studies that focused on yoga or qigong were excluded as these are classified as meditation practices with only a light-intensity component of physical activity when performing respiration and poses [38-40].

Following the recommendation by Munn et al [35] to clearly report the exposure or risk factor and how it was measured or identified, we excluded studies that proposed only a simple question on physical activity without any reference to its frequency (eg, a generic “Yes/No” question on practicing “exercise” or even “regular exercise”). Furthermore, we excluded literature reviews, gray literature, conference proceedings, and unpublished material. Finally, we excluded studies that lacked a quantitative evaluation of the association.

Information Sources

We searched the following electronic databases up to July 2022: MEDLINE through the Ovid platform, APA PsycArticles, and Scopus. Using a “snowballing” approach, we manually screened the reference lists of included articles and conducted systematic citation tracking in Scopus, PubMed, and Google Scholar.

Search Strategy

In total, 2 authors, CGL and PM, developed search strings using the PEO framework to structure the research question. We selected search terms to identify HCWs, physical activity interventions, and burnout. Regarding burnout, to increase search sensitivity, we also considered terms related to the assessment instruments indicated by Rotenstein et al [41] and those identified in the more recent works by Edú-Valsanía et al [42] and Shoman et al [43]. Moreover, to further increase the sensitivity of our search, we used the National Library of Medicine–controlled vocabulary thesaurus (Medical Subject Headings) with entry terms and synonyms. We limited the search to articles published in English. The complete search strategy can be found in Multimedia Appendix 2 [41-43].

Duplicates were removed by PM using an automatic procedure based on PubMed ID and digital object identifier, and this was performed in Microsoft Excel (Microsoft Corp).

Selection Process

Search results were retrieved from the databases and double screened independently by all the authors. The initial screening was based on the title and abstract using Rayyan (Rayyan Systems Inc) [44] for support. To refine and clarify the eligibility criteria, ensure consistency when applied by different reviewers, and train the team, a pilot phase was carried out on 500 works. The potentially relevant articles were retrieved for full-text screening, and their eligibility was determined as described in the previous step. Any disagreement was resolved through plenary discussion among all the authors until a consensus was reached.

Data Collection Process

Each selected study was randomly assigned to and independently evaluated by 2 authors to extract relevant data. Any disagreement was addressed as mentioned previously.

Data Items

We extracted 3 different types of information. First, we recorded the general characteristics, such as aim, context (country, workplace, and period), and population (type of HCW, number, and gender mix). Second, we summarized the methods used to measure burnout, the criteria used to quantitatively summarize the phenomenon in the study population, and a possible definition of severity. When possible, we included the frequency distributions of categorical outcomes and means of total scores with SDs. Third, we noted the methods adopted to measure physical activity, including the assessment of frequency, time, or intensity of activity and the percentage of participants practicing physical activity. Finally, we reported the adopted measures of the association between physical activity and burnout along with its strength (P values, odds ratios, and their 95% CIs), eventually derived by AB from published data, and a synthesis of the reported evidence. In addition, factors other than physical activity that are significantly associated with burnout were listed. A first list was drawn from bivariate analyses and reported only variables that were significantly associated (P<.05) with burnout. The consideration of even weak associations was hampered by the often incomplete presentation of these analyses. A second list came from multivariable analyses and included all the variables considered in the final (or presented) models regardless of whether physical activity was included in the model itself.

Synthesis of Evidence

The data are presented in a tabular form. A narrative approach was adopted to provide an overall summary of the findings of the included studies and their biases, strengths, and limitations, with an in-depth discussion of the causes of heterogeneity.

Quality

The quality of the studies included in the analysis was assessed using the Joanna Briggs Institute Critical Appraisal Checklist for Cross-Sectional Studies [45]. This checklist consists of 8 items that are rated as “yes,” “no,” “unclear,” or “not applicable.” To further refine our judgment, we added “partial” as a fifth option.
Owing to the eligibility criteria adopted, 2 issues were always rated positively: item 1 (“Were the criteria for inclusion in the sample clearly defined?”), as we only considered studies that clearly reported associations in health personnel directly involved in the provision of care services, and item 4 (“Were objective, standard criteria used for measurement of the condition?”), as we only included studies that used validated questionnaires for burnout.

Item 2 allowed us to register whether a complete description of the participants and setting was provided. We assigned a score of “partial” or “no” if some or all the information was missing.

To assess whether the outcomes were measured in a valid and reliable way (item 7), we verified that the burnout measurement tools were used consistently with the dictates expressed by their developers.

We evaluated the validity and reliability of the exposure measurement (item 3) by positively appraising the use of structured questionnaires (eg, the International Physical Activity Questionnaire–Short Form [IPAQ-SF]) or automatic measurement devices such as pedometers, whereas the use of ad hoc questions to register the frequency or intensity of physical activity was considered a partial achievement.

Concerning the confounding factors, we did not assess how they were considered (item 5) and addressed in the statistical analyses (item 6) in studies exploring multiple wide-scope associations with burnout. On the other hand, we applied these items in studies that focused on a specific exposure factor (either physical activity or another variable of interest). In such cases, the use of statistical modeling, such as multivariable regression analysis, was considered a partial achievement in the absence of an advisable dedicated discussion on confounding factors.

For the appropriateness of the statistical analysis (item 8), a partial quality level was assigned if multivariable regression analysis, though possible, was not conducted or when it was conducted without an adequate method of model selection. Moreover, we assigned a partial level of quality if it was not possible to clearly understand all the details of the analyses because of omissions or results not being clearly reported.

Each study was evaluated for quality by 2 authors, and AB, a statistician, also reviewed items pertaining to statistics.

Discrepancies were resolved through plenary discussion among all authors until a consensus was reached. The quality assessment was not taken into account for eligibility purposes.

Results

Selected Studies

A total of 8937 records were identified, and after removing 2422 (27.1%) duplicates (Figure 1), 6515 (72.9%) publications remained following the initial screening. Of these 6515 publications, 6427 (98.65%) were excluded based on the title and abstract. These records were disregarded as they did not address physical activity, burnout, or health care personnel or because they were conference proceedings, reviews, or nonoriginal research (eg, letters or commentaries). Of the 88 studies selected for potential inclusion, 3 (3%) were not retrieved as they were published in journals not accessible through our organizations even after writing to the authors to request the accepted versions of their manuscripts [46-48]. Following full-text screening, 75% (64/85) of the records were excluded. Consequently, 21 independent studies involving 15,782 HCWs were included in this review (see Table 1 for details).

hACEP: American College of Emergency Physicians.
iPGY-1: postgraduate at year 1.
jPIMR: Pediatric Integrated Medicine in Residency.
kThe 10-hour PIMR curriculum is designed in part to help pediatric programs meet new resident well-being requirements. The topics covered include self-nutrition and physical activity, mind-body therapies, dietary supplements, whole systems of medicine, and clinical applications.
lThe location of the conference where the survey was administered was considered to determine the country.

Although 10% (2/21) of the studies explicitly focused on exploring the association between physical activity and burnout [62,67], the remaining studies investigated the association among several factors, including physical activity. Most of the studies were conducted in America (10/21, 48%) and Asia (9/21, 43%), with only 10% (2/21) of the studies [49,52] being conducted after the spread of COVID-19. In total, 43% (9/21) of the studies [51,54-56,59,60,62-64] focused on residents. All the studies included in this review (21/21, 100%) had a cross-sectional design.

Demography of Study Populations
The study populations consisted of diverse groups of HCWs with varying proportions of women individuals, ranging from 5.6% to 96.3%. The professional categories represented included physicians, nurses, and technicians from different specialties, which were present in 90% (19/21), 38% (8/21), and 14% (3/21) of the studies, respectively. The sample sizes ranged from 60 to 7197 participants. The mean age varied from 27.2 (SD 1.83) years to 49.9 (SD 12.0) years, with a few studies (5/21, 24%) reporting the median ages, ranging from 29 to 53 years.

Measurement of Burnout
In terms of burnout measurement, the 22-item Maslach Burnout Inventory (MBI) was the most commonly used questionnaire. Some studies (3/21, 14%) used MBI-related measures based on fewer items [63-65]. In total, 10% (2/21) of the studies used different questionnaires: the Professional Fulfillment Index [54], which is designed to measure physician well-being [70], and the Copenhagen Burnout Inventory [61], which was proposed as an alternative tool to the MBI for measuring burnout [71] (see Multimedia Appendix 3 [49,51-53,55,56,58-63,66-69,72,73] for details).

The severity of the condition in the investigated population was reported in all the studies (21/21, 100%), albeit with differences in terms of the dimensions considered and the criteria used for deriving a summary assessment of burnout across the dimensions and, in some cases, by providing measures of location and scale parameters. Further details are provided in Table 2.

Study, year | Measure of burnout (MBI\(^{a}\)) | Frequency distribution | Location and scale parameters
---|---|---|---
Reed et al [64], 2020 | 1 single question [76] | EE\(^{c}\) | N/A | N/A | N/A | N/A | 50% | N/A | N/A | N/A | N/A | N/A

\(^{a}\)Frequency distribution from high to low. Independent of the way the authors reported the frequency distribution for PA, in accordance with Maslach et al [72], we considered low PA as a condition characterizing burnout. The numbers in the frequency distribution are rounded to percentage units.

\(^{b}\)MBI: Maslach Burnout Inventory. In total, 3 categories were defined: emotional exhaustion, depersonalization, and PA. Most recent edition: Maslach et al [77].

\(^{c}\)EE: emotional exhaustion.

\(^{d}\)DP: depersonalization.

\(^{e}\)PA: personal accomplishment.

\(^{f}\)Italics indicate critical values for burnout.

\(^{g}\)The burnout dimension is in the high range (+) or low range (−).

\(^{h}\)When referring to MBI and not otherwise specified, critical levels in burnout dimensions mean high in EE and DP and low in PA.

\(^{i}\)Authors’ interpretation.

\(^{j}\)N/A: not applicable.

\(^{k}\)NR: not reported.

\(^{l}\)The proposed burnout score does not consider that PA should be interpreted in the opposite direction from EE and DP as a low degree of burnout is reflected in high scores on PA [72].

\(^{m}\)aMBI: abbreviated Maslach Burnout Inventory.

\(^{n}\)Raw data from the MBI used to divide the burnout process into 8 phases, with phases I-III representing a low degree and phases IV-V and VI-VIII representing moderate and high degrees, respectively [78].

\(^{o}\)MBI adapted.

\(^{p}\)MiniZ (adapted).

In two studies, authors adopted tools not referable to BMI. Ng et al [61] adopted the Copenhagen Burnout Inventory [71], which comprises 3 categories: personal, physical, and psychological exhaustion, work-related physical and psychological exhaustion, and patient-related physical and psychological exhaustion. The reported frequency distribution among study participants is 63%, 56%, and 35% respectively. No specific criteria were defined for burnout.

Eckstein et al [54] used the Professional Fulfillment Index [70], which consists of three response categories: Professional Fulfillment (PF), Interpersonal Disengagement, and Work Exhaustion (WE), employing 5-point Likert scales (“not at all true” to “completely true” for PF items and “not at all” to “extremely” for WE and Interpersonal Disengagement items). All responses are scored from 0 to 4. However, in the considered study, the PF domain was not taken into account. A binary classification (presence vs absence of burnout) is adopted according to the following criterion: the average score of Interpersonal Disengagement and WE ≥1.33 [70]. Participants meeting this criterion for burnout comprise 38%. Regarding Location and scale parameters, the median score for WE, Interpersonal Disengagement, and burnout is respectively 1.50, 0.83, and 1.00.

With due caution regarding the aforementioned heterogeneity of definitions and cutoffs, the percentage of participants classified as burned out varied from 7% to 83%.

**Measurement of Physical Activity**

None of the included studies used objective measurement tools, such as pedometers, to assess physical activity (Table 3).

Structured questionnaires that distinguished among different typologies of physical activity or ad hoc items were considered to investigate the habits of HCWs. The IPAQ-SF, the Ricci-Gagnon scale, and the Arizona Lifestyle Inventory were used in the studies by Olson et al [62], Chokri et al [52], and McClafferty et al [60], respectively. The IPAQ-SF was the only validated tool used, although it tends to overestimate actual physical activity levels [84]. A total of 33% (7/21) of the studies [50,53,61,63,67-69] used an ad hoc question to assess the achievement of a given benchmark, with a threshold frequency ranging from 1 day every 2 weeks [63] to every day [53]. In the remaining studies, physical exercise was measured in terms of frequency and intensity [65], frequency and time [57], only frequency [49,51,54-56,58,59,66], or only time [64]. When it was possible to report a distribution of frequencies or times, we considered the lowest category that did not indicate “no physical activity at all.” Whenever possible, we adopted the most widely used benchmark of physical exercise of “at least 1 day per week” to define physically active participants. Using this criterion, we found that the percentage of active workers ranged from 44% to 82% for residents and from 46% to 87% for the other categories.

### Methods of Association Assessment

Bivariate associations between physical activity and burnout were assessed using usual methods. Table 4 provides further details. All studies except those by Olson et al [62], Vinnikov et al [67], Ghoraiashian et al [56], Feng et al [55], and Tiwari et al [66] also conducted a multivariable regression analysis. In all 5 cases, a multivariable analysis could have been conducted to obtain adjusted odds ratios. Logistic and linear regression were equally used in 43% (9/21) and 33% (7/21) of the studies, respectively.

*(page number not for citation purposes)*
Table 4 also presents the evidence of the association between physical activity and burnout. Owing to the high heterogeneity of the studies, a direct comparison of the results was not feasible. As previously mentioned, the 2 sources of heterogeneity were the diverse and sometimes vague definitions of physical activity used in the studies and the variations in the definitions and cutoffs for measuring burnout. A total of 14% (3/21) of the studies [49,57,64] reported a few results that were not consistent with the data, and in one case [58], the authors referred to supplementary material that was not available on the journal web page. In total, 80% (4/5) [55,56,62,66] of the studies that presented only bivariate analysis were consistent with the data. Compliance with CDC aerobic exercise and muscle strength training recommendations was not independently associated with burnout. Physical activity was not significantly associated with burnout. The definition of burnout adopted in the logistic regression was not clear. It was also a significant predictor of lower values of personal accomplishment. Participants with moderate burnout in the dimension were excluded from the analysis. The result was reported for completeness even though we believe that the burnout score was meaningless as it did not consider that personal accomplishment should be interpreted in the opposite direction from EE and DP.

**Existence and Degree of Association**

Participants conforming with DHHS guidelines were significantly less at risk of having high subscores in burnout (OR 0.38, 95% CI 0.147-0.99) than noncompliant HCWs. Physical activity was not significantly associated with burnout. Participants who performed any physical activity for fitness at least once in 2 weeks were significantly less at risk of high values of burnout (OR 0.41, 95% CI 0.22-0.77) than those who did not perform physical activity. Compliance with CDC aerobic exercise and muscle strength training recommendations was not independently associated with burnout. Physical activity was not significantly associated with burnout. Participants who did not regularly exercise ≥3 d/wk were significantly more at risk of having high EE (aOR 9.91, 95% CI 2.92-27.2) than the other participants. Participants who did not regularly exercise were at higher risk of high EE (OR 5.02, 95% CI 2.25-12.42) and high DP (OR 2.37, 95% CI 1.20-4.74) than those who regularly exercised. Adjusted for other covariates, exercising every week was a significant predictor of lower values of EE and burnout. It was also a significant predictor of lower values of personal accomplishment.

**Study, year** | **Data analysis method** | **Bivariate analysis** | **Multivariate regression analysis**
--- | --- | --- | ---
Olson et al [62], 2014 | Chi-square test and univariate logistic regression | Participants compliant with DHHS guidelines were significantly less at risk of having high subscores in burnout (OR 0.38, 95% CI 0.147-0.99) than noncompliant HCWs | NP
Panse et al [63], 2020 | Univariable and multivariable logistic regression | Participants who performed any physical activity for fitness at least once in 2 weeks were significantly less at risk of high values of burnout (OR 0.41, 95% CI 0.22-0.77) than those who did not perform physical activity | Physical activity was not significantly associated with burnout
Reed et al [64], 2020 | Chi-square test, ANOVA, and multivariable logistic regression | Results of association analysis were inconsistent with the data | Physical activity was not significantly associated with burnout
Shanafelt et al [65], 2012 | Multivariable logistic regression | Participants who lacked exercise at least 1 d/wk were at higher risk of burnout (OR 5.00, 95% CI 1.3-18.5) than participants who exercised | NP
Tiwari et al [66], 2020 | Univariable logistic regression | Participants who lacked exercise at least 1 d/wk were at higher risk of burnout (OR 5.00, 95% CI 1.3-18.5) than participants who exercised | NP
Vinnikov et al [67], 2019 | Bivariate analysis | Physical activity was not significantly associated with any MBI dimension | NP
Vinnikov et al [68], 2021 | Bivariate analysis and multivariable logistic regression | Participants who did not regularly exercise were at higher risk of high EE (OR 5.02, 95% CI 2.25-12.42) and high DP (OR 2.37, 95% CI 1.20-4.74) than those who regularly exercised | Participants who did not regularly exercise ≥3 d/wk were significantly more at risk of having high EE (aOR 9.91, 95% CI 2.92-27.2) than the other participants
Yang et al [69], 2018 | Multivariable linear regression | Participants who lacked exercise at least 1 d/wk were at higher risk of burnout (OR 5.00, 95% CI 1.3-18.5) than participants who exercised | Adjusted for other covariates, exercising every week was a significant predictor of lower values of EE and burnout. It was also a significant predictor of lower values of personal accomplishment

**Notes**

- **EE**: emotional exhaustion.
- **DP**: depersonalization.
- **HCW**: health care worker.
- **Derived by the authors.**
- **Participants with moderate burnout in the dimension were excluded from the analysis.**
- **OR**: odds ratio.
- **aOR**: adjusted OR.
- **NP**: not performed.
- **CBI**: Copenhagen Burnout Inventory. In total, 3 categories were defined: personal physical and psychological exhaustion, work-related physical and psychological exhaustion, and patient-related physical and psychological exhaustion.
- **PeE**: personal physical and psychological exhaustion.
- **PaE**: patient-related physical and psychological exhaustion.
- **WrE**: work-related physical and psychological exhaustion.
- **DHHS**: US Department of Health and Human Services. Its guidelines [80] set a benchmark of 150 minutes per week of physical activity.
- **CDC**: Centers for Disease Control and Prevention. It set recommendations for aerobic exercise and muscle strength training [83].
- **The definition of burnout adopted in the logistic regression was not clear.**
- **MBI**: Maslach Burnout Inventory.
- **The result was reported for completeness even though we believe that the burnout score was meaningless as it did not consider that personal accomplishment should be interpreted in the opposite direction from EE and DP.**
analyses indicated that a lack of physical activity was associated with high values of at least one component of the MBI. Similar results were reported by half (8/16, 50%) of the other studies that presented bivariate analyses regardless of the measure of burnout adopted.

In studies in which bivariate analysis was preparatory to multivariable regression analysis [50-54,58,61,63,68], physical activity may not have emerged as a predictor in the multivariable models [51,52,54,63,68]. This is sometimes due to the lack of a significant (albeit weak) association already in the bivariate analyses [52,54]. However, this result is also influenced by the different approaches to variable inclusion and selection. When conducting a bivariate analysis as a preliminary step for variable selection in the multivariable model, a less stringent significance criterion than P<.05 should be considered. Variables that show weak individual associations can become important predictors when considered jointly (eg, the study by Hosmer and Lemeshow [85]). Unfortunately, the selected studies used very different criteria, ranging from P<.05 for each variable to no preselection at all. In addition, methods for model selection were not always applied or clearly stated.

In cases in which physical activity was found to be a significant predictor in multivariate analyses, a protective effect was observed, especially against emotional exhaustion [50,59,61,68,69] and depersonalization [50,51,53,59]. This held true across a range of activity frequencies, from as little as 1 session per week to daily engagement.

For the sake of completeness, factors other than physical activity that showed a statistically significant association with burnout have been listed in 2 separate tables: one for bivariate analyses and the other for multivariable analysis (Tables S1 and S2 in Multimedia Appendix 4). The predictors were grouped by topic (demography, health conditions, lifestyle, personal attitude, work-life balance, work organization and environment, work profile, and self-perception at work) and ordered within each class according to their frequency.

Quality Evaluation
The risk of bias was assessed using the Joanna Briggs Institute tool, and the details are presented in Multimedia Appendix 3 [45,49-69].

All the studies provided detailed descriptions of participants and settings, with the exception of the studies by Eckstein et al [54], in which gender specifications were missing, and Reed et al [64], in which the period of the survey, gender mix, and age were not reported.

Regarding the assessment of physical activity, only a minority of studies (3/21, 14%) [52,60,62] adopted structured questionnaires and, therefore, received a positive evaluation. Most studies (18/21, 86%) only partially fulfilled this criterion, either relying on simple ad hoc questions to assess the activity frequency, time, or intensity or referring to meeting a threshold of activity. This limitation was observed even in studies that claimed to have a specific focus on physical activity [55,67]. Confounding was never explicitly addressed. As mentioned in the Methods section, we applied the dedicated items to the 14% (3/21) of studies that focused on a specific exposure [62,67,69]. All these papers touched on this issue through their conducted analyses and, therefore, obtained a “partial” rating for item 5. Of these studies, 33% (1/3) conducted only a bivariate analysis and, thus, did not comply with item 6 [62].

As for the use of the MBI, only a few studies (9/21, 43%) received a positive evaluation for item 7. Contrary to the explicit indications of the MBI developers [86], the authors of most studies (11/21, 52%) [50,51,55-58,62,63,66-68] adopted a categorical classification of participants based on burnout dimensions for descriptive as well as inferential purposes. Moreover, Yang et al [69], although correctly adopting the score to assess each MBI dimension, defined and adopted an overall burnout score as the raw sum of the scores in each dimension (as reported in Table 4, even without considering that personal accomplishment should be interpreted in the opposite direction from emotional exhaustion and depersonalization). In all these cases except the studies by Ghoraishian et al [56] and Panse et al [63], we assigned a partial achievement of the item. Indeed, these 2 studies were ranked with a “no” as they did not even provide the rationale behind their choice of ranges of scores in each dimension. Except for 14% (3/21) of the studies—Ajab et al [49] and Vinnikov et al [67,68]—all the other studies referring to the MBI or related multi-item measures introduced a definition of overall burnout. Despite this, studies that also adopted the total score of the burnout dimensions in their inferential analyses [52,53,59,60] were ranked with a “yes.” Ng et al [61] and Eckstein et al [54] were classified as “yes” as they correctly adopted the measurement tools—Copenhagen Burnout Inventory [73] and Professional Fulfillment Index [54], respectively.

Regarding item 8, statistical analysis was not considered appropriate in 10% (2/21) of the studies [50,58], in which the significant differences between physicians and nurses in the dimensions of the MBI were not adequately handled in the multivariable analysis. The analyses conducted in another 14% (3/21) of the studies [49,56,64] were rated as unclear either because the presented results were not coherent with the declared statistical methods [64] or because of unexplained methods [49,56]. Goldberg et al [57], Bin Dahmash et al [51], Shanafeh et al [65], Vinnikov et al [68], Porterio de la Cruz et al [53], and Chokri et al [52] clearly explained their statistical methods and conducted comprehensive analyses, receiving a positive quality assessment. In the other cases, a better statistical methodology could have been applied by conducting a multivariable analysis, considering more suitable criteria to include the explanatory factors in the multivariable analysis, or again by applying model selection methods to obtain more parsimonious and general models.

Discussion
Principal Findings
The COVID-19 pandemic has taken a heavy toll on HCWs in terms of physical and mental health, and the long-term effects of the pandemic will further increase the burden of HCWs’ mental health disorders and burnout [87,88]. It has been argued that addressing burnout could serve as a nonstigmatized and
systemic approach to address a long-standing issue in medicine through mental health initiatives, whether prevention oriented or treatment focused [89].

In addition to the personal consequences for HCWs experiencing burnout, it is important to consider its impact on patient care and resource consumption. Emotionally and physically healthy HCWs are among the most relevant factors influencing health care service quality [90]. All these considerations emphasize the importance of implementing strategies to prevent and manage burnout at an individual, organizational, and cultural level. The literature on burnout management primarily presents fragmented solutions that are infrequently tested in practice. These solutions often align with 1 of 2 predominant lines of intervention: one emphasizes strengthening individual capabilities to navigate the inherent challenges of health care work, whereas the other acknowledges work organization as a contributing factor and attempts to intervene at that level. However, there is a growing realization that individual and organizational well-being are intricately interconnected, thus necessitating systemic solutions. These comprehensive approaches encompass organizational interventions, instilling a culture of well-being in the workplace, and integrating well-being into health care education for true efficacy [24,91].

A recent meta-analysis of 20 controlled trials found that the most effective existing interventions for reducing burnout were those targeting multiple facets of well-being [92]. Regrettably, these systemic solutions are complex and often come at a significant cost [93-95]; therefore, it is particularly relevant for research to precisely identify the characteristics that specific interventions must have to succeed. This review focused on physical activity as an effective factor in fostering a culture of well-being among HCWs, which is crucial for tackling the physical and mental consequences of work-related stress [24]. Physical activity has enormous potential to mitigate the physical and mental impacts of work-related stress [96,97]. Indeed, it is suggested that it facilitates psychological detachment from work and enhance self-efficacy [53], providing an opportunity to divert attention from stressful thoughts [50]. It has also been shown that moderate-intensity exercise training programs improve feelings of vigor, energy, and vitality [98]. In particular, greater effects occurred when combining resistance exercise with aerobic exercise compared with aerobic exercise alone [98]. This finding is consistent with the World Health Organization recommendations for physical activity, which underline the importance for adults of regularly performing both aerobic and muscle-strengthening activities to support health, including mental health outcomes [96]. With this review, we aimed to systematically assess the strength of the evidence and, eventually, the dose-response association between physical activity and burnout in a physically and emotionally exhausting work environment. However, it is essential to note that all studies included in our review had a cross-sectional design. As is well known, randomized controlled trials with a longitudinal perspective are the gold standard to highlight any potential cause-effect relationship between an exposure and an outcome. Nevertheless, the cross-sectional approach is useful in highlighting potential relationships between burnout and related factors, aiding in the identification of a multiplicity of risk factors and mitigation strategies, as the complexity of the phenomenon requires. This is particularly true in our case as most of the included studies (19/21, 90%) were exploratory investigations that examined various aspects potentially related to burnout rather than focusing specifically on physical activity.

As shown in Tables S1 and S2 in Multimedia Appendix 4, a wide range of variables were considered in bivariate analyses (74 issues) and included in multivariable models (58 issues), reflecting the interplay between burnout and demographic characteristics, health, lifestyle, personal attitude, self-perception at work, work organization and environment, job profile, and work-life balance.

As mentioned previously, physical activity is considered a potential tool to cope with distress, and the PEO approach adopted in this study was specifically structured in this direction. However, it is important to recognize the possibility that high levels of burnout negatively influence the level of physical activity [99]. According to the study by Olson et al [62], the “lack of energy” among burned-out residents suggests that high levels of burnout lead HCWs to reduce the time dedicated to leisure activities, including physical exercise. Stults-Kolehmainen and Sinha [99] found a similar result in the literature, stating that stress hinders individuals from being more physically active and has a negative influence on other health behaviors, including smoking, alcohol, and drug use. We suggest that future studies include sections dedicated to exploring the reasons for individuals’ inability to meet their desired level of physical activity. Factors such as time constraints, lack of interest, or underlying health conditions should also be accounted for. The Barriers to Being Active Quiz developed by the US Centers for Disease Control and Prevention [100] is an example of a tool that may support the exploration of the dynamic interactions among personal, socioenvironmental, and behavioral factors, serving as a knowledge base for promoting more active and healthy lifestyles.

This study confirms that the dose-response relationship between physical activity and psychological well-being and health-related quality of life is far from being established. Significant mental health benefits could be achieved even at physical activity levels below the public health recommendations [101,102]. This also emerged from our study and has direct implications on healthy lifestyle recommendations, especially for inactive HCWs for whom incorporating brief bouts of physical activity into daily activities may be a more realistically achievable goal than meeting the guideline-recommended physical activity levels. This can be crucial to promote physical activity and, therefore, trigger a virtuous circle with benefits for burnout. In addition, it may have broader implications for the general population as there are indications that physicians’ involvement in physical activity is linked to their propensity to advise patients on the advantages of exercise [103,104]. Recognizing that any physical activity is better than none and considering engagement in physical activity as a modifiable behavior, adopting a strategy of gradually increasing activity through small habit changes is deemed effective for establishing a consistent exercise routine. This approach can be facilitated by the use of activity trackers [105,106].

This systematic review highlighted another general challenge in quantifying the strength of the physical activity–burnout phenomenon.
association and establishing the dose-response curve, primarily as various methods were used to detect burnout. Different self-reporting tools are indeed available grounded on different theoretical bases [42]. Most of the studies in our review (19/21, 90%) proposed the 22-item MBI or MBI-related questionnaires (Table 2), confirming the substantial monopoly of this tool in burnout research. All these studies fell into some form of misuse of the index. The 3-factor structure of the MBI implies, on the one hand, that each dimension must be treated separately and, on the other hand, that none of them should be ignored. In contrast, in some studies where it would have made sense (3/17, 18%) [59,60,62], personal accomplishment was excluded from the analysis. This practice is not uncommon as several authors consider personal accomplishment not as a reaction to stressful situations but rather as a personality trait or coping resource and, therefore, as not contributing to the comprehensive concept of burnout [107]. Another misuse of the MBI is its diagnostic application, which erroneously considers the MBI dimensions as symptoms of burnout [71]. The 7-point scale (from Never to Every day) used to report the feelings experienced by the respondents was intended by Maslach and the coauthors of the tool as an operational simplification of the measurement of a dynamic phenomenon evolving continuously over time rather than as the assessment of a dichotomous condition (absent or present) defined through an arbitrary cutoff. Considering MBI scores for diagnostic purposes would inevitably invoke the wrong concept of burnout as a disease or disability, ignoring decades of research and the recent statement from the World Health Organization [1]. The MBI was not designed as a diagnostic tool [86], and the cutoff scores established to classify people at low, moderate, and high levels of burnout were “intended primarily as feedback for individual respondents.” These scores were published up to the third edition of the MBI Manual [72] accompanied, however, by a strong recommendation to use the original total scores for any statistical analysis. In the fourth edition released in 2018 [77], the categorization was finally removed. Therefore, it is surprising that, despite the extraordinary diffusion of the MBI, there was a failure to implement the correct instructions for its use. In fact, all studies except the one by Goldberg et al [57] considered some classification of the severity (sometimes referred to as risk) of burnout in each of the 3 MBI dimensions also for inferential purposes. Furthermore, a variety of classification criteria, even when taken from the same reference [72], and algorithms for combining dimensions into a single overall burnout indicator, typically a high score in at least one dimension and sometimes in all dimensions (reversing personal accomplishment, if considered), further increased the heterogeneity of the analyses. These methodological considerations become even more crucial in future research, particularly now that apps providing burnout self-diagnosis are available and transparency is needed in the adopted assessing algorithms [108].

Moving on to the evidence on the association between physical activity and burnout that emerged from this review, the most compelling results came from multivariable analyses that considered emotional exhaustion and depersonalization as the outcome. In these analyses, physical activity appeared to be associated with a reduction in critical conditions. However, it is still unclear whether this association depends on the type, intensity, duration, or frequency of physical activity, as previously mentioned. Some of the included studies (2/21, 10%) suggested that exercising for at least one day per week is sufficient to see a positive effect [58,69], whereas others (2/21, 10%) suggested a frequency of 3 days per week [50,68]. Lebensohn et al [59] observed that, the more frequently HCWs engaged in physical activity, the greater the positive effect.

It is worth noting that, in a few of the studies that considered a multivariable analysis (2/15, 13%), physical activity was not included among the predictors. However, this can sometimes be related to strict variable selection methods.

One limitation of most of the included studies (18/21, 86%) was related to the modality of physical activity measurement. Future studies should consider using objective measurement tools such as pedometers or validated questionnaires such as the International Physical Activity Questionnaire [79] even in its short version [84]. These approaches enhance the accuracy and reliability of data collection. On the other hand, relying on simple questions about regular physical activity or adherence to recommendations for a healthy lifestyle, although suitable for preliminary exploratory investigations, limits the comparability of studies.

The use of precise and detailed definitions to collect measures of intensity and frequency can prove to be a valuable strategy to delve deeper into the dose-response relationship.

Limitations

Our systematic review has some limitations that warrant consideration. First, our search was confined to 3 databases and only considered English-language articles. Moreover, we did not perform a rerun of the search shortly before submission. However, to mitigate the risk of overlooking relevant papers, we used forward and backward citation tracking, including the use of Google Scholar.

Another potential limitation arises from our eligibility criteria as we considered only HCWs in direct contact with patients and excluded practices with only a light component of physical exercise.

Finally, the heterogeneity in measurement methods and statistical analyses, which we have extensively covered in the Results section, made a meta-analysis inappropriate and precluded the determination of any pooled effect size.

Conclusions

Our comprehensive overview of studies exploring the association between physical activity and burnout in HCWs revealed a significant level of heterogeneity in definitions, measurements, and analyses adopted in the literature. Our work aimed to advance effective public health practices by addressing this critical issue in the existing evidence. It is important to adopt a clear definition of burnout and physical activity and make thoughtful choices regarding measurement tools and methodologies for data analysis. This becomes particularly crucial when considering that burnout is not a diagnosable disease but rather a multifaceted psychological syndrome that
emerges in response to chronic interpersonal stressors in the workplace.

Our findings strongly emphasize the beneficial connection between physical activity and burnout when a statistically significant association is present in the analyses. However, they also highlight the importance of a more in-depth investigation of the specific dependencies on exercise type, intensity, duration, and frequency, knowledge that currently represents a research gap in the field of burnout studies. Moreover, our considerations regarding the measurement of burnout and the comprehensive list of associated factors have the potential to enhance the quality of future studies. Our findings have significant implications for policy makers and health care professionals, underlining the importance of promoting physical activity as an easily accessible mitigation strategy for the well-being of the workforce and the overall effectiveness of the health care system.

Acknowledgments

The authors would like to thank Roberto Guarino (National Research Council of Italy—Institute of Clinical Physiology, Lecce) for his technical support (informatics tools for document management and title and abstract screening). This study was conducted within the research agreement between the National Research Council of Italy—Institute of Clinical Physiology, National Research Council of Italy—Institute for Applied Mathematics and Information Technologies, “E. Magenes,” and National Research Council of Italy—Institute for Research on Population and Social Policies and the Brindisi Local Health Unit (CNR-IRPPS-547/2022; deliberazione ASL-BR-1027/2022). The agreement was executed for free.

Data Availability

All data generated or analyzed during this study are included in this published paper (and its supplementary information files).

Authors' Contributions

Conceptualization involved contributions from CGL and PM. Methodology development was the responsibility of AB, PM, and CGL. All the authors participated in conducting the literature search and extracting data. AB, CGL, and PM were involved in preparing the original draft of the manuscript. Reviewing and editing the manuscript was a collaborative effort among all the authors. Throughout the research process, supervision was provided by CGL and PM. All the authors have read and agreed to the published version of the manuscript.

Abstract

Background: The increasing annual global deaths are attributable to noncommunicable chronic diseases (NCDs). Adhering to healthy lifestyle behaviors is associated with lower NCD risk, particularly among individuals with ample movement, enough sleep, and reduced sedentariness. Nevertheless, there are only few prospective assessments on the association of interactions between daily activities with NCD prevention, while the associations between adhering to Canadian 24-Hour Movement Guidelines (24HGs) for adults and NCD risks are still unknown. Compared to the general population, obese and overweight populations are at a higher risk of developing NCDs. Currently, it is unclear whether the health benefits of adhering to 24HGs differ between the general population and the obese population.

Objective: This study explores prospective associations between adherence to 24HGs and NCD risks by weight status among overweight and obese adults in China.

Methods: This decadal study consists of 9227 adults aged 35 years and older without any major NCDs at enrolment in the China Health and Nutrition Survey (2004-2011) and followed up until 2015. The exposure of interest was the overall score of compliance with 24HGs measured by participants’ self-report, wherein 1 point was assigned for compliance to each component, resulting in an aggregated score ranging from 0 to 3. The primary outcome was the first occurrence of major NCDs (high blood pressure, stroke, diabetes, cancer, and acute myocardial infarction). Log-binomial regression models were used to evaluate the associations.

Results: Overall, 4315 males and 4912 females, with 25,175 person-years of follow-up, were included in our analyses. The average baseline age was 50.21 (SD 11.04) years. Among the overweight and obese groups, those adhering to 1 (risk ratio [RR] 0.37, 95% CI 0.19-0.74; P=0.04), 2 (RR 0.37, 95% CI 0.19-0.72; P=0.03), and 3 (RR 0.32, 95% CI 0.14-0.73; P=0.06) recommendations of 24HGs had a significantly lower NCD risk than those not adhering to any of the activity guidelines. Among the normal or underweight groups, those adhering to 1 (RR 0.49, 95% CI 0.27-0.96; P=0.03) and 3 (RR 0.40, 95% CI 0.17-0.94; P=0.03) components had a significantly lower NCD risk than those not adhering to any of the activity guidelines.

Conclusions: In this prospective study, we found that active adherence to recommendations of 24HGs was associated with lower risks of NCDs, especially among overweight and obese participants. Additionally, overweight and obese individuals who...
met at least 1 component of 24HGs were at a significantly lower risk for NCDs, but this protective effect was not found among individuals in the normal and underweight groups. Individuals with excess body weight who tend to be more susceptible to health risks may gain greater health benefits than the general population by adhering to the recommendations of 24HGs.

Introduction

In 2021, 71% of deaths worldwide (41 million) were attributable to noncommunicable chronic diseases (NCDs) [1]. Premature deaths due to NCDs were due to cardiovascular disease (17.9 million), cancer (9.3 million), respiratory diseases (4.1 million), and diabetes (1.5 million). Individuals with NCDs have a shorter life expectancy, struggle with disability, and experience a lower quality of life [2]. Several studies have shown that adhering to healthy lifestyle behaviors contributes to a reduced NCD risk. For example, 2 recent longitudinal studies [2,3] revealed that adhering to healthy lifestyle behaviors at midlife is associated with longer life expectancy and living free from NCDs, particularly if individuals practice at least 3 healthy lifestyle behaviors (ie, ample movement, enough sleep, reduced sedentari ness). Among modifiable lifestyle factors, physical activity, limited leisure screen time, and adequate sleep duration have been consistently shown to have a protective effect against NCDs [4-7]. A meta-analysis evaluating the association between the levels of physical activity and the incidence of breast cancer showed that the relative risk of developing breast cancer was only 0.88 among women with the highest level of daily physical activity compared to those with the lowest level of daily physical activity [4]. Regarding sleep, either short or long sleep duration have been correlated with an increased risk of cancer, cardiovascular disease, and diabetes [5-7]. The available evidence from the UK Biobank has suggested that daily screen viewing, particularly television viewing and computer use, is associated with a modest, but significant, increase in the risk of esophageal and colon cancers [8]. Although the association between NCD risk and physical activity, sleep traits, or leisure screen time has been well-documented, only few longitudinal investigations have assessed the onset of NCDs in relation to long-term patterns of daily movements.

The global population has more than 19 billion overweight and 650 million obese individuals as of 2016 [9]. Overweight and obese individuals are at a higher risk of NCDs, losing at least 3.9 years of life expectancy compared with the general population [10]. Additionally, obesity is linked to immunologic dysfunction, which is detrimental to both innate and adaptive immune responses [11,12]. As such, strategies to reduce overweight and obesity could have a positive impact on the health of billions of individuals at risk of NCDs.

There are daily movement patterns associated with obesity and NCDs. For instance, exercise may help prevent NCDs by controlling blood pressure, preventing impaired glucose tolerance, and improving C-reactive protein levels [13]. Although some studies have investigated the association between the time spent on daily movement and risks of NCDs in overweight and obese populations, it remains unclear as to what extent adhering to recommendations on daily movement facilitates long-term benefits in preventing NCDs. Moreover, it is currently unclear whether the health benefits of adhering to recommended behaviors differ between the general population and obese populations.

To address these research gaps, this study prospectively assesses the association between the reports of overweight and obese patients on their behavioral patterns and their risk of NCDs by using the data of Chinese adults enrolled in the China Health and Nutrition Survey (CHNS). As a metric of behavioral patterns, we used the Canadian 24-Hour Movement Guidelines (24HGs) for adults, which measures participant compliance to physical activity, screen time, and sleep duration.

Methods

Study Population

Data were collected from CHNS, which is an ongoing, longitudinal, nationwide survey initiated in 1989 among a sample of Chinese residents aged ≥22 years from 9 provinces, with follow-ups every 2-4 years. Structured questionnaires were used to obtain data, including demographic, lifestyle, and health factors, from study participants by trained staff. A physical examination was conducted to collect anthropometric data. Details on the full questionnaire and methodology of data collection have been described elsewhere [14]. The survey methodology and data collection procedures were approved by the institutional review board of the University of North Carolina and the National Institute for Nutrition and Health, Chinese Center for Disease Control and Prevention (2015017). A longitudinal cohort analysis of the 2004-2015 CHNS data with complete publicly available daily movement and health data was chosen because it was after 2004 that the CHNS was used to collect sedentary time data in front of the screen. All NCD-free adults (age≥35 years) with complete data on height, weight, physical activity, screen time, chronic disease data, and sleep duration in a survey year were considered eligible participants. Only 1 baseline timepoint was used for the exposure variables to maximize the sample sizes and time intervals between exposure and potential outcomes. The final analyses included 9227 eligible participants.

Measurement of Adherence to 24HGs

The exposure of interest was the overall scores of compliance with the Canadian 24HGs for adults (age 18-64 years) and older adults (65+ years), which were measured at baseline for all participants. Compliance was measured through adherence to 3 components of 24HGs: (1) adequate moderate to vigorous physical activity (MVPA) (≥150 min/week), (2) limited screen
time (≤3 hours/day), and (3) recommended sleep duration (7-9 hours for adults aged 18-64 years and 7-8 hours for those older than 65 years). Using these baseline 24HGs data, we calculated an aggregated adherence score for each participant, ranging from 0-3 depending on how many of the aforementioned 24HGs components were met. Participants’ average daily time on MVPA was calculated using the reported time they spent on physical activities, commuting, and housework per day. We used the Compendium of Energy Expenditures for Adults to describe the absolute intensity of physical activities and estimate the metabolic equivalents for different kinds of exercises. The compendium defines activities involving energy expenditure >3 metabolic equivalents as MVPA. Participants in this study were classified as meeting physical activity guidelines when they accumulated an average of at least 150 minutes of MVPA per week, and 1 point was assigned to them. For sleep duration, participants reported the whole time spent on bed, covering daytime and nighttime. The total hours of all-day sleeping were recorded on average per day. According to 24HGs, uninterrupted sleep of 7-9 hours (age 18-64 years) and 7-8 hours per night (age ≥65 years) is considered as meeting the sleep duration recommendation, and 1 point was assigned to them. To measure leisure screen time, participants reported the average time spent on different recreational screen activities on a typical weekend and on a weekday. Participants were classified within the “recommended screen time” group if they spent less than 3 hours/day both on weekends and weekdays.

**Measurement of Weights and BMI**

Weight and height were measured by trained staff following standardized protocols and performed at the same location as well as by following the same protocol at each survey visit. Weight was measured to the nearest 0.1 kg by using a calibrated beam scale while wearing lightweight clothing. Height was measured to the nearest 0.1 cm without wearing shoes by using a portable stadiometer. BMI was calculated as weight (kg) divided by the square of height (meter). The Working Group on Obesity in China proposed a threshold value for Chinese adults to judge the degree of overweight and obesity in 2003. This overweight and obesity metric is based on large-scale survey data of the Chinese population, wherein overweight was defined as BMI≥24 kg/m² and obesity was defined as BMI≥28 kg/m² [15].

**Assessment of Covariates**

Demographic characteristics consisted of age, sex (male/female), household register (rural/urban), region (northern, southern, western, eastern, and, central China), baseline year (2004/2006, 2009/2011), energy intake (kcal), regular intake of sugar-sweetened beverage (more than 3 times per week or not), regular intake of tea (more than 3 times per week or not), regular intake of coffee (more than 3 times per week or not), smoking status (yes/ever/never), drinking alcohol status (yes/ever/never), light physical activities, family net income (in yuan; ¥1= US $0.15), and highest education level (graduation from lower middle school degree or lower/upper middle school degree, technical or vocational degree/university or college degree or higher). According to the level of economic development and regional characteristics, we divided the regions into 5 groups: eastern region (Shanghai, Jiangsu, and Shandong), western region (Chongqing and Guizhou), southern region (Guangxi), northern region (Beijing, Liaoning, and Heilongjiang), and central region (Henan, Hubei, and Hunan). Family income was inflated to 2015 and adjusted for regional differences.

**Ascertainment of NCDs**

The primary outcome was the first occurrence of major NCDs, including high blood pressure, stroke, diabetes, cancer, and acute myocardial infarction. In each wave, participants were asked, “Have you ever been diagnosed with high blood pressure/stroke/diabetes/cancer/acute myocardial infarction?” Thus, in each survey wave, participants self-reported their health status, drawing from their recollection of hospital diagnoses and medical records. We obtained information pertaining to the presence of chronic diseases among individuals in the current wave. We considered participants to have NCDs as long as they had at least one of these NCDs.

**Ethics Approval**

Written informed consent was obtained from all the study participants, and the CHNS received institutional review board approval from the University of North Carolina (No.2015017). The CHNS data sets are openly accessible, and the data are freely available to scholars in the CHNS official websites after submitting applications. Our research was based on approved deidentified data, and this study was approved by the medical ethics committee of the Department of Psychological and Behavioral Sciences at Zhejiang University (approval 2022060).

**Patient and Public Involvement Statement**

Patients or the public were not involved in the design, conduct, reporting, or dissemination plans of our investigations. The CHNS data sets and published papers are available to the public online [16].

**Statistical Methods**

Baseline characteristics were described using frequencies (percentages) and mean (SD). The characteristic differences of the study population were compared across meeting 24HGs by using Poisson regression, log-binomial regression models were used, which offer better convergence and directly provides us with the risk ratio (RR). RRs and 95% CIs for NCDs associated with 24HGs were estimated with the use of log-binomial regression models. We evaluated the associations of adhering to recommendations with the incidence of NCDs by using log-binomial regression models with stepwise adjustment of confounding variables. Multivariate models were adjusted for age, age*age, and sex in model 1. Additionally, these were adjusted for the type of household register, province, survey year, smoking status, alcohol status, frequency of drinking sugar-sweetened beverages/tea/coffee, family net income, and light physical activity in model 2, and adjusted for the whole movement time in model 3. We imputed missing data by using multiple
imputations [17] for continuous variables and the mode for the missing data of categorical variables. Adding the square of the variable allows us to model more accurately the effect of age, which may have a nonlinear relationship with our independent variable [18]. We applied component analysis—the ratio of the time spent to the recommended time for each activity based on the Physical Activity CoDa Regression Model and code [19].

In the sensitivity analysis considering the influence of specific recommendations, we assessed the association between adhering to a specific combination of 24HGs and the onset of chronic diseases among overweight/obese participants. In addition, we repeated the analysis after excluding underweight individuals at baseline. We also conducted subgroup analyses by using negative binomial regression analysis to explore whether the corresponding associations varied by age (35-49 years/≥50 years), sex (male/female), education level (low/high), and family income (low/high). We also tested the moderation effect of adhering to guidelines and the group variables. Analyses were performed with the R statistical package (version 4.2.2) [20]. All $P$ values were 2-sided, with statistical significance set at <.05.

Results

Baseline Characteristics of the Study Population

Overall, 9227 participants (4315 males and 4912 females), with 25,175 person-years of follow-up, were included in our analyses, and the average baseline age was 50.21 (SD 11.04) years, with the majority of the participants being normal or underweight (5459/9227, 59.2%), living in rural environments (6124/9227, 66.4%), from Central or Eastern regions (4854/9227, 52.6%), and surveyed in 2004 and 2006 (6159/9227, 66.7%). As shown in Table 1, in terms of compliance with the guidelines, 112 (1.2%) participants did not meet any of the recommendations at baseline, and 2171 (23.5%), 6716 (72.8%), and 228 (2.5%) participants met 1, 2, and all components of the 24HGs, respectively. Compared to participants who met none, those who adhered to the overall recommendations of the guidelines were more likely to be older, live in urban environments, have lower energy intake, drink less coffee, never smoke, never drink alcohol, have a higher family net income, and have higher education.

<sup>a</sup>Age*age and sex were adjusted; per score increase = 1.03 (95% CI 0.89-1.20); P=.68.<br><sup>b</sup>The type of household register, province, survey year, smoking status, alcohol status, frequency of drinking sugar-sweetened beverage/tea/coffee, family net income, and light physical activity were additionally adjusted; per score increase = 1.03 (95% CI 0.89-1.20); P=.66.<br><sup>c</sup>The whole movement time was additionally adjusted; per score increase = 1.01 (95% CI 0.87-1.18); P=.90.

Additionally, we performed a compositional analysis with proportions of ratios of the actual time spent on each kind of activity and recommended time (the constituent ratios of 3 movements for each participant) to compare the results more comprehensively. Figure 1 shows the proportions of sleep, MVPA, and screen time, which are displayed using dotted blue and red lines, surrounded by 3 vertices in the heatmap. We observed a positive association between the proportion of screen time and risk of NCDs and a negative association between the proportions of MVPA the risk of NCDs.

Figure 1. Heatmap ternary diagrams of expected risk ratios based on model 3 against different percentage time allocation of the movement behavior time-use composition in the (A) normal/underweight group and (B) overweight/obese group. MVPA: moderate to vigorous physical activity.

**Stratified Analyses and Sensitivity Analyses**

For the specific combination of 24HGs, after fully adjusting for all covariates, we also observed an inverse association between adhering to 24HGs and risk for NCDs across specific combinations of the guidelines in the overweight and obese group. Compared with participants not adhering to any of the activity guidelines, those adhering to meeting screen time guideline (RR 0.34, 95% CI 0.18-0.69; P=.002), meeting screen time + MVPA guideline (RR 0.19, 95% CI 0.06-0.54; P=.002), meeting screen time + sleep guideline (RR 0.37, 95% CI 0.19-0.72; P=.003), and meeting all (RR 0.32, 95% CI 0.14-0.72; P=.006) had a significantly lower risk of NCDs (Table S1 of Multimedia Appendix 1). Moreover, in the subgroup analysis, we observed a similar inverse association between adhering to 24HGs and risk for overweight and obesity across age, sex, highest education level, and family net income subgroups in the fully adjusted model. We did not observe a significant interaction effect between these groups and adherence to 24HGs (Figure 2, Table S2 and Table S3 of Multimedia Appendix 1).
Figure 2. Subgroup analysis of the association between the number of 24-hour movement guidelines met at baseline and the onset of chronic diseases in the (A) normal/underweight group and (B) overweight/obese group.

Discussion

Principal Findings

In this prospective cohort study, we found that compliance with 24HGs had a protective effect against major chronic diseases such as high blood pressure, stroke, diabetes, cancer, and acute myocardial infarction. These associations were independent of the potential confounding effects of age, sex, and socioeconomic status. Compared with individuals who met none of the recommendations, overweight or obese individuals who met 1, 2, or 3 recommendations had a 63%, 63%, and 68% lower risk of being diagnosed with NCDs, respectively. Restricted leisure screen time was observed to have a strong protective effect on chronic disease prevention. Among normal weight or underweight individuals, adhering to 1 or all components of 24HGs were linked with 51% or 60% lower risk of NCDs, respectively.

Although previous studies have performed several investigations regarding association between lifestyle behavior and life expectancy without chronic diseases [21,22], only few studies have assessed the compliance to 24HGs. Findings from a prospective multicohort study of 116,043 European adults aged 40-75 years showed that individuals who followed all the healthy lifestyle behaviors gained about 9 additional disease-free years of life compared to those who did not adopt any healthy behavior [23]. Nevertheless, the Nurses’ Health Study and Health Professionals Follow-Up Study did not observe significant improvements in life expectancy upon adherence to more risk-reducing lifestyle behaviors [2]. This inconsistency in past evidence may be due to the inconclusive combination of healthy lifestyle behavior assessments [24,25]. In our study, 24-hour daily movements were considered an essential part of a healthy lifestyle, and the rationale for recommending 24HGs is already supported by evidence from past randomized controlled trials [26]. Furthermore, independent associations among adequate physical activity [4], limited leisure screen time, sleep duration [6,27], and NCD prevention have also been observed in previous observational and experimental investigations. However, previous studies have not been able to comprehensively assess the association between daily movements and NCDs, and only very few studies have evaluated the association between daily movements and the onset of major NCDs [28]. Our prospective
The association between obesity and the onset of NCDs has potential biological significance and noticeable health improvements. The association of obesity with COVID-19 hospitalization [33] is due to the vulnerability of the overweight/obese group, which are at greater risk due to chronic diseases [10], and face greater risks of NCDs [28], experience more substantial declines in quality of life due to chronic diseases [3].

Despite following the same recommendations of 24HGs, the normal/underweight and overweight/obese groups experienced different health benefits, as indicated by the point estimates. This divergence may be attributable to the particular vulnerabilities of the overweight/obese group, which are supported by well-established biological mechanisms. In comparison to the general population, obese individuals are at an increased risk. They are more susceptible to environmental risk factors for health, have a higher prevalence of mental health disorders [28], experience more substantial declines in quality of life due to chronic diseases [10], and face greater risks of COVID-19 hospitalization [33]. Due to the vulnerability of the obese population, even minor changes could lead to more significant and noticeable health improvements. The association between obesity and the onset of NCDs has potential biological mechanisms. A recent review [34] reported that groups with obesity and adiposity had long-term higher leptin or lower adiponectin concentrations, which might cause dysregulation of the immune system response that leads to abnormally higher concentrations of proinflammatory cytokines. Obesity is usually a situation of chronic low-grade systemic inflammation that leads to numerical and functional alterations of lymphocytes [35]. In the basal state, B-cell and T-cell responses are impaired in individuals with excess body weight, and these alterations may upsurge vulnerability to viral infection [35]. In addition, because several inflammatory components inhabit the tumor microenvironment and foster the phenotype of cancer, adipose inflammation is also considered to be a mediator of cancer development.

In addition, the higher level of concentrations of adipocytokines are associated with fluctuations in the levels of angiotensinogen, plasminogen activator inhibitor-1, interleukin-6, and resistin, which might progress the onset of insulin resistance and atherosclerotic lesions [35,36]. Compared with general population, individuals with adipose inflammation and metabolic dysfunction exhibit higher cancer and cardiovascular disease risk [35,36]. For individuals who are overweight or obese, setting achievable goals and performing daily movements to intentionally lose weight not only reduce the levels of chronic disease-related factors but also reduce the risks of comorbidity incidence and disease progression. Adhering to physical activity recommendations may induce the beneficial effects of decrease in the levels of inflammatory biomarkers and improved endothelial function in obese children and adolescents [36].

Based on the analysis results of 59,005 adults in an English and Scottish Health Survey, vigorous-intensity leisure-time physical activity showed a significant effect on decreasing the cardiovascular disease mortality risk in the obese group [37]. Compared with active females with excess body weight, inactive females were exposed to 20%-41% higher risk of the onset of type 2 diabetes, while inactive males were exposed to 36%-38% higher risk than active overweight and obese males [38]. In addition, we found that meeting MVPA and leisure screen use recommendations would decline 81% risk of chronic diseases. Besides the salutary benefits conferred by physical activity, our analysis revealed the concurrent reduction in the risk of NCD onset when leisure screen time is curtailed, particularly when combined with adequate sleep duration. The nonsignificant values observed in the results for the association between MVPA and NCD risk may be attributable to the smaller sample size rather than a lack of association between MVPA and the prevention of NCDs. A smaller sample size can diminish the statistical power of the study, potentially leading to a type II error, where a true effect is present but not detected. Thus, the observed significance value should not be interpreted as definitive evidence of no relationship between MVPA and NCD prevention. Further research with a larger sample size is warranted to accurately determine the extent of this association.

Future research is needed to investigate the mechanisms that link adhering to 24HGs with NCD risk as well as to explore effective daily movement interventions needed for substantial NCD risk reduction.

**Strengths and Limitations**

One strength of our study was that our analysis was based on a large nationwide sample size of adults with long-term follow-up.
data, which provided high statistical power and the ability to infer temporality. Another important strength was that the data collection of CHNS was conducted under robust quality control management and performed by qualified staff.

There are, however, several limitations to our study. First, the data on lifestyle behaviors were collected via self-reported questionnaires, which might be subject to misclassification or self-report biases. Nonetheless, the results of our study were largely consistent with past research [2,23-28], supporting the validity of our findings. Second, there are likely various potential unmeasured factors related to daily activities or NCD status that could not be adjusted for in the analyses. Third, in the CHNS, sleep duration was collected through self-reported questionnaires. Therefore, we were unable to assess participants’ sleep quality, as sleep quality is typically measured by electroencephalography monitoring, which would not have been feasible in a population-based survey, given its complexity and cost. Thus, in our study, for meeting the guidelines, we were primarily concerned with the duration rather than quality. Fourth, the outcome data on NCDs were collected through self-reported questionnaires. Although participants reported health conditions based on their recollection of hospital diagnoses and medical records, the staff did not have access to the exact diagnosis dates. As a result, the ascertainment of NCDs relied on self-reported data, which may have introduced recall biases. Finally, as we enrolled only Chinese adults in our cohort study, our estimates may not be generalizable to other population subgroups with different social structures and characteristics.

Conclusion
Based on the CHNS data from the 2004 to 2015 waves, our study shows that actively following 24HGs was associated with lower risks of NCDs, especially among overweight or obese individuals. Furthermore, overweight and obese individuals who met at least 1 component of 24HGs were at a significantly lower risk of NCDs. However, this protective effect was not observed in normal or underweight groups. Individuals with excess body weight who tend to be prone to greater health risks may gain larger health benefits by adhering to these recommendations compared to the general population.

Acknowledgments
This investigation received financial support from Zhejiang Provincial Natural Science Foundation of China Funding (LY18C110001) and Fundamental Research Funds for the Central Universities and institutional support from the Department of Sport and Exercise Science, College of Education, Zhejiang University. We express our gratitude to all the staff and participants in the China Health and Nutrition Survey (CHNS) whose efforts made this study possible and thank CHNS for making their large data set available to us. We greatly appreciate guidance from Professor Huijie Qiao in R language, Associate Professor Luis E Escobar in manuscript writing, and Professor Huakang Tu in statistics. This work was supported by the Zhejiang Provincial Natural Science Foundation of China Funding (grant LY18C110001) and Fundamental Research Funds for the Central Universities. The funders had no role in study design, data analysis, data interpretation, writing of this report, or in the decision to submit this paper for publication.

Data Availability
The data sets generated and analyzed during this study were sourced from the China Health and Nutrition Survey. Researchers can access the data on the official China Health and Nutrition Survey website [39] after submitting an application. The data sets used in this study are also available from the corresponding author upon reasonable request.

Authors’ Contributions
SH and YG are credited as co-first authors for their significant contributions. XW (wenxu@zju.edu.cn) and RZ (rhzhang@cdc.zj.cn) are recognized as co-corresponding authors. They supervised the manuscript's completion process, including task allocation, manuscript writing, and budget management. Both have dedicated an equal amount of time and effort to the writing of this article and to overseeing the project that funded the article processing charges. SH and YG jointly worked on the study's concept and design. SH also took on the analysis and interpretation of data, as well as its organization into tables. The drafting of the manuscript was a joint effort by SH and YG, with guidance from XW and RZ, and with additional support from SHA and JX. YG, SH, SHA, and JX concentrated on assessing the results, especially focusing on the methods and analytics. All authors participated in critically revising the manuscript for important intellectual content, had full access to all the study's data, reviewed and revised the manuscript drafts, and gave their final approval for the version to be published.

Conflicts of Interest
None declared.

Abstract

Background: Mass testing campaigns were proposed in France during the first wave of the COVID-19 pandemic to detect and isolate asymptomatic individuals infected by SARS-CoV-2. During mass testing in Saint-Étienne (February 2021), we performed a survey of the general population.

Objective: We evaluated, on the scale of a city’s population, the literacy level about SARS-CoV-2 transmission, barrier gesture respect, and isolation acceptability or possibility in case of SARS-CoV-2 infection.

Methods: We used the validated CovQuest-CC questionnaire. Data were analyzed and correlated with volunteer characteristics and their SARS-CoV-2 screening results using multivariate analysis.

Results: In total, 4707 participants completed the CovQuest-CC questionnaire. Multivariate analysis revealed that female sex was a determinant of a higher score of knowledge about SARS-CoV-2 transmission (adjusted β coefficient=0.14, 95% CI 0.04-0.23; corrected P=.02). Older ages of 50-59 years (adjusted β coefficient=0.25, 95% CI 0.19-0.31; corrected P<.001) and ≥60 years (adjusted β coefficient=0.25, 95% CI 0.15-0.34; corrected P<.001) were determinants of a higher score on barrier gesture respect compared to ages 20-49 years considered as reference. Female sex was also a determinant of a higher score on barrier gesture respect (adjusted β coefficient=0.10, 95% CI 0.02-4.63; corrected P<.001). The knowledge score was correlated with the score on barrier gesture respect measures (adjusted β coefficient=0.03, 95% CI 0.001-0.004; corrected P=.01). Older ages of 50-59 years (adjusted β coefficient=0.21, 95% CI 0.13-0.29; corrected P<.001) and ≥60 years (adjusted β coefficient=0.25, 95% CI 0.1-0.38; corrected P<.001) were determinants of a higher score on isolation acceptability or possibility compared to the age of 20-49 years considered as reference. Finally, the knowledge score regarding SARS-CoV-2 transmission was significantly associated with a lower risk of RT-PCR (reverse transcriptase–polymerase chain reaction) positivity (adjusted odds ratio 0.80, 95% CI 0.69-0.94; corrected P<.03), implying that a 1-point increase in the knowledge score lowers the risk of positivity by 20% on average.
Conclusions: This study identified factors associated with health literacy regarding SARS-CoV-2 infection in asymptomatic individuals in a large French city’s population. We can confirm that in the context of the COVID-19 pandemic, the determinants of better health literacy are not the same as in other contexts. It seems critical to obtain a more detailed understanding of the determinants of individual citizens’ behavior, as part of a strategy to combat the large-scale spread of the virus. The harsh experience of this pandemic should teach us how to nurture research to structure customized interventions to encourage the adoption of ad hoc behaviors to engage citizens in adapting behaviors more favorable to their health.

Introduction
Since the beginning of the COVID-19 crisis, and independent of the wave of the pandemic, one of the main goals of scientists and governments has been to reduce the burden of SARS-CoV-2 infection [1].

Mass Testing Campaign to Contain the Spread of SARS-CoV-2
Among the different strategies used worldwide, mass testing was proposed early [2], with the aim to detect highly infectious individuals who are asymptomatic or presymptomatic, allowing their isolation together with the rapid identification and testing of their close contacts to reduce virus spread [3]. The performance of this strategy is influenced by the prevalence of active infection in the group being tested. Mass testing was then carried out in high-incidence settings with the hope of mitigating the transmission dynamics and avoiding lockdown measures [2]. The impact of such mass testing was considered controversial [2]. Indeed, although the “test, trace, and isolate” strategy has proven effective in suppressing early spread of SARS-CoV-2 [4,5], this strategy has also shown serious limitations as it has been overwhelmed by the increasing number of cases [5] and associated costs [6]. However, if these interventions were used notably before the availability of safe and effective COVID-19 vaccines, with the emergence of variants of concern exhibiting a high level of transmissibility, testing and isolation-based strategies are likely to remain viable tools for the control of epidemic waves.

The Citizen as a Player in the Fight Against the Spread of the Virus
Beyond mass nonpharmaceutical interventions conducted by cities or governments [7], each citizen has also a role, and may be an actor, in controlling the epidemics [8-11]. Indeed, a good understanding and knowledge of the transmission route of SARS-CoV-2, adhesion to barrier gesture respect measures, and having realistic possibilities of individual isolation contribute significantly to fight against the pandemic [10-12]. Moreover, after the launch of mass testing or even after a negative test result is obtained, efforts should continue to further protect oneself and others [13]. As West et al [14] pointed out in May 2020, effective interventions are urgently needed to increase adherence of the general population to the proper implementation of health measures for protecting people individually and collectively.

The Need to Understand Individual Behavior to Tackle the Crisis More Effectively
As Rodon et al [15] point out, assessing health literacy about COVID-19 is crucial to understanding any difficulties individuals may have in adopting protective measures and implementing social distancing measures, bearing in mind that age, education, and the way in which they gather information about COVID-19 are all factors that determine individual behavior. As part of the French health policy in 2021, the city of Saint-Étienne, France (174,082 residents) [16] took part in a French national experiment of city-wide mass testing operations for COVID-19. The campaign took place over 2 full weeks separated by a 5-week interval; the first one occurred from January 13 to 19, markedly after the end-of-year holidays, and the second one occurred from February 22 to 28, when the winter school vacations were over. The city of Saint-Étienne was chosen to be part of this experiment of mass testing since it had high incidence rates, peaking at 1000 cases per 100,000 inhabitants in late 2020 [17,18]. At the time, having been amid this unprecedented crisis, we seized the opportunity of this mass testing operation to survey people about their attitudes and beliefs regarding SARS-CoV-2, which was not undertaken on a city-wide scale. Hence, to our knowledge, this type of evaluation in such a mass testing context among asymptomatic citizens was not performed. While collecting these data may seem outdated at present, given that COVID-19 is no longer a public health emergency of international concern, this large-scale work carried out in a particular situation has enabled us to assess knowledge of, behaviors toward, and opportunities for COVID-19 isolation to better understand our fellow citizens in a pandemic context. At that time, the results of this approach were intended to help develop public health strategies to contain local epidemics using a population approach.

Methods
The study took place during the second week of the mass testing campaign of Saint-Étienne, France, that is, from February 22 to 28, 2021.

Background Concerning the Mass Testing Campaign in Saint-Étienne
Adults and children older than 10 years were eligible for inclusion. People wishing to participate in the study had to be older than 10 years and able to read and understand the French language. For minors, parental permission was required. An
information note was provided to each participant. After obtaining verbal consent of the participant or of his or her guardian, the participant was included in the study. For SARS-CoV-2 screening, saliva samples were obtained from the participants in accordance with the French guidelines of February 2021 on the use of salivary RT-PCR (reverse transcriptase–polymerase chain reaction) tests in the context of large-scale iterative screening in a closed population. Samples were collected and analyzed using quantitative RT-PCR in accordance with the methods described previously [18].

**Recruitment**

Individuals who voluntarily participated in the COVID-19 city-scale mass screening campaign were also offered to complete the CovQuest-CC questionnaire. Screenings were offered free of charge at 12 ephemeral sites, and in parallel, mobile teams were deployed to target populations (adolescents, students, people living in low-income neighborhoods, businesses, etc.). Study participants were provided a paper questionnaire with a pen and asked to complete it while they waited to be tested for the presence or absence of SARS-CoV-2. Everyone then handed in the questionnaire at the time of the screening test. The self-administered CovQuest-CC questionnaire explores 3 main areas: knowledge of SARS-CoV-2, adherence to barrier gesture respect, and the ability to isolate themselves in the event of a SARS-CoV-2 infection. For these 3 concept areas, all response modalities are offered in the form of a Likert scale. The precise content of the CovQuest-CC questionnaire is presented elsewhere [19]. The questionnaire was psychometrically tested and validated in a general population aged 10 years and older. The following age groups were represented: 10-19, 20-29, 30-39, 40-49, 50-59, 60-69, 70-79, 80-89, and >90 years. As explained in a previous report on the CovQuest-CC questionnaire validation process [19], we first carried out a pretest with a representative sample of the target population, to assess the comprehensibility of the questions and their wording. [19] The psychometric validation procedure showed this questionnaire was valid, consistent and reliable. Therefore, our study participants were those who both completed the CovQuest-CC questionnaire and were screened for SARS-CoV-2 infection in the context of the mass screening campaign.

**Information Collected From Participants**

Participants provided information on demographic characteristics, occupation, place of living, and symptoms through a paper questionnaire. The CovQuest-CC questionnaire provided data through a global knowledge score on SARS-CoV-2 transmission ranging from 0 to 6, a score on barrier gesture respect ranging from 0 to 4, and a score on isolation acceptability or possibility ranging from 0 to 4. The highest score for each item corresponded to the best level of response. The French version of the European Deprivation Index (EDI) was also used in this study to approximate the social deprivation level of participants [20]. This score was calculated in 2007 using homogenous clusters for statistical information (called “IRIS” [regrouped statistical information blocks], originally constructed by the organization in charge of the French census) [21]. EDI quintiles were used to group IRIS into 5 deprivation levels [21]. In this study, participants were associated with a deprivation level (increasing from 1 to 5, with 5 being the most deprived) according to the IRIS area they lived in.

**Ethical Considerations**

The CROSS (Checklist for Reporting of Survey Studies) guided the reporting of this survey study [22]. No financial compensation was provided to participants. This study was conducted in accordance with the guidelines set out in the Declaration of Helsinki. The research in which this validation took place was approved by the Ethics Committee of IRB ILE-DE-FRANCE I (I ORG0009918; Protocole No. EudraCT: 2021-A00390-41) and all participants provided their written consent. This study is registered on ClinicalTrials.gov (NCT04859023).

**Statistical Analysis**

**Power**

The margin of error for our sample of 4707 individuals is 1.45% and corresponds to what is expected for survey studies [23], with a recommended margin of error of 1%-10%.

Sample characteristics were described using frequencies and proportions for categorical variables, and mean, SD, and median and IQR for numerical variables.

The relationship between CovQuest-CC questionnaire scores and variables of interest were analyzes using multivariate linear regression models. The models were constructed a priori, without knowledge of the data. One model was developed to analyze the associations between the knowledge score and age, sex, profession, and EDI quintiles. One model was developed to analyze the associations between the barrier gesture respect score and age, sex, profession, EDI quintiles, and the knowledge score. One model was developed to analyze the associations between the isolation possibility score and age, sex, profession, EDI quintiles, and the number of children at home (one or more versus none). The results are presented as multivariate linear $\beta$ coefficients with their 95% CI. Colinearity between variables was systematically assessed using correlation matrices and calculation of the variance inflation factor. Models’ validity and robustness were systematically assessed via graphical residual analysis.

Relations between RT-PCR positivity and age, sex, occupation, global SARS-CoV-2 transmission knowledge score, barrier gesture respect score, number of children at home, and EDI were assessed using a multivariate logistic regression model. The results are presented as odds ratios with their 95% CI. To account for multiple testing, Bonferroni correction was used for adjusting the $P$ value to the number of variables tested in each model. All statistical tests were 2-sided, with $P<.05$ considered significant. Statistical analysis was performed with the R software (version 4.0.3; The R Foundation).

**Data Exclusion**

Interviewees with at least 1 missing value in one of the variables of the different models were excluded from the said model.
Results

User Statistics
Among the 7020 participants in the mass testing campaign, 4707 (67%) responded to the CovQuest-CC questionnaire and were therefore included in this study. The participants’ mean age was 50.3 (SD 18.54) years and their median age was 52 (IQR 36-66) years. Women represented 56.1% (n=2634) of the sample. Among participants, 72.2% (n=3399) lived in the city of Saint-Étienne, and 97.0% (n=4566) of them lived in the Loire or the adjacent Haute-Loire departments; 65.3% (n=2485) of participants lived in areas belonging to the 2 most disadvantaged quintiles of EDI (EDI 4 and EDI 5). Table 1 presents an overview of the sample characteristics.
Table 1. Characteristics of study participants (N=4707).

Evaluation Outcomes

Knowledge Score on the Transmission of SARS-CoV-2 According to the CovQuest-CC Questionnaire

The median score was 5 (IQR 4.5-6). Factors significantly associated with the knowledge score in multivariate analysis are depicted in Figure 1 and Multimedia Appendix 1. Female sex was shown as a determinant of a higher score for knowledge about transmission of SARS-CoV-2 (adjusted $\beta$ coefficient=0.14, 95% CI 0.04-0.23; corrected $P$=.02). Compared to health workers taken as reference, middle and high school students exhibited a lower score of knowledge about transmission of SARS-CoV-2 (adjusted $\beta$ coefficient=–0.57, 95% CI –1.01 to –0.13; corrected $P$=.04).

Figure 1. Adjusted multivariate linear regression exploring the associations between the knowledge global score and the variables of interest, with Bonferroni corrected $P$.

Barrier Gesture Respect Measure Scores According to the CovQuest-CC Questionnaire

The median score was 3 (IQR 2.5-3.5). Factors significantly associated with this score in multivariate analysis are depicted in Figure 2 and Multimedia Appendix 2. Older ages of 50-59 years (adjusted $\beta$ coefficient=0.25, 95% CI 0.19-0.31; corrected $P$<.001) and $\geq$60 years (adjusted $\beta$ coefficient=0.25, 95% CI 0.15-0.34; corrected $P$<.001) were shown as determinants of a higher score on barrier gesture respect compared to ages 20-49 years considered as reference. Female sex also appeared as a determinant of a higher score on barrier gesture respect (adjusted $\beta$ coefficient=0.10, 95% CI 0.02-0.63; corrected $P$<.001). Finally, the level of the knowledge score was also correlated to that of the score for barrier gesture respect measures (adjusted $\beta$ coefficient=0.03, 95% CI 0.001-0.004; corrected $P$=.001). By contrast, higher education was significantly associated with a lower barrier gesture respect score (adjusted $\beta$ coefficient=–0.30, 95% CI –0.43 to –0.17; corrected $P$<.001).
Figure 2. Adjusted multivariate linear regression exploring the associations between the barrier gesture respect score and the variables of interest, with Bonferroni corrected P.

Score for Isolation Acceptability or Possibility According to the CovQuest-CC Questionnaire

The median score was 2.75 (IQR 2.25-3.33). Factors significantly associated with this score in multivariate analysis are depicted in Figure 3 and Multimedia Appendix 3. Older ages of 50-59 years (adjusted $\beta$ coefficient=0.21, 95% CI 0.13-0.29; corrected $P<.001$) and ≥60 years (adjusted $\beta$ coefficient=0.25, 95% CI 0.1-0.38; corrected $P<.001$) were shown to be determinants of a higher score on isolation acceptability or possibility compared to ages 20-49 years considered as reference. In contrast, having at least 1 child living at home versus having none exhibited a lower score on isolation possibility (adjusted $\beta$ coefficient=–0.12, 95% CI –0.19 to –0.05; corrected $P=.006$).

Figure 3. Adjusted multivariate linear regression exploring the associations between the isolation possibility score and the variables of interest, with Bonferroni corrected P.

RT-PCR Positivity Determinants

Results of univariate and multivariate analyses of RT-PCR positivity determinants are presented in Figure 4 and Multimedia Appendix 4. Interestingly, the knowledge score for SARS-CoV-2 transmission was significantly associated with a lower risk of RT-PCR positivity (adjusted odds ratio 0.80, 95% CI 0.69-0.94; corrected $P<.03$), implying that a 1-point increase in knowledge score lowers the risk of positivity by 20% on average.
Discussion

Background

In the middle of a city-wide mass screening campaign, beyond proposing massive SARS-CoV-2 screening for asymptomatic citizens, as accomplished in several other cities [24,25], we were able to assess the knowledge of, behavior toward, and potential for isolation of participants through a validated questionnaire on SARS-CoV-2–related health literacy [19]. It therefore provided a global picture of the determinants of the population’s adherence to a national control strategy in the context of a pandemic at the level of a French semiurban agglomeration of 174,082 inhabitants.

Indeed, the sanitary crisis that has lasted for 3 years now, has been associated with the necessary implementation of social and individual constraints that have not always been accepted or adopted by the general population despite their crucial role to curb the epidemic, reflecting a lack of health literacy in the general population [12]. These deficiencies were further reinforced by discordant messages issued from medical and nonmedical influencers or by deviation of control strategies that were misunderstood because of their complexity [12]. As Hannah Spring pointed out in an editorial on the COVID-19 pandemic, “good health literacy has never been more crucial for survival” [12].

Principal Results

Our results show that female sex was an independent determinant of better knowledge of SARS-CoV-2. We were also able to find evidence that middle and high school status was related to a low score of knowledge about SARS-CoV-2. Same gender and age distribution were also associated with a better knowledge score in a recent study conducted by our Belgian neighbors [26]. Better health literacy among older people seems, however, to be specific to the COVID-19 pandemic, as previous studies have shown that older age is a determinant of lower health literacy [27-30].

According to our findings, the social gradient did not appear as a determinant of better health literacy regarding COVID-19. The same observation was reported by Okan et al [31] in the German population. They suggested that the lack of a social gradient may mean that a great deal of information about the COVID-19 epidemic and SARS-CoV-2 has been made available and understandable, and that the informational environment helps to build health literacy on the topic [31]. It contrasts with other contexts than the COVID-19 pandemic, where better health literacy is usually observed in higher social classes [32]. Our results emphasize that the EDI cannot be settled as a determinant of health literacy, SARS-CoV-2 positivity, or compliance with existing health measures. During the first wave of the epidemic, it appeared that French and Italian citizens—2 populations generally known for their tolerance of deviation from sanitary norms—appeared to be much more disciplined and more respectful of the recommendations issued by public health authorities than Chinese, German, or British citizens, which can be considered as paradoxical [33,34]. Indeed, several studies have suggested that preventive health behavior is strongly influenced by social norms [33,35,36]. We can then hypothesize that, in France, during the beginning of the pandemic, citizens became compliant to sanitary rules as a new normative reference [37].

Factors independently associated with a higher respect of barrier gestures were older age and female sex. Of note, we also found a positive correlation with global knowledge scores. In a recent study on the determinants of preventive behaviors in response to the COVID-19 pandemic in France, we showed that men and young adults were less likely to follow guidelines to contain the spread of COVID-19 [33]. Our results are consistent with this in terms of the age and gender distribution in this study. Other international studies highlighted that better health literacy...
during the pandemic was associated with adherence to preventive behaviors, which is in line with our results [38].

We also had the opportunity to evaluate willingness and the possibility of isolation in case of SARS-CoV-2 infection. Isolation of COVID-19–positive individuals is crucial to contain an epidemic and is a factor that, to our knowledge, has not been well studied before. Our results show that determinants of a higher self-isolation possibility are older age and having no children living under the same roof. Previous literature suggests that socioeconomic status and a fear of loss of income due to home quarantine are the main barriers for adhering to self-isolation [39-41]. It is particularly true among the lowest socioeconomic status quintiles where people are usually unable to work from home [41]. During the pilot study of asymptomatic testing in Liverpool, the United Kingdom, one of the main barriers to adherence to self-isolation was the fear of testing positive and not having sufficient support to implement this individual measure or experiencing a loss of income [42]. In France, home quarantine was not associated with loss of income as the government compensated the loss of salary [43]. In our study, we showed that the major obstacle to the effective implementation of self-isolation was housing conditions, especially with households having more than 1 child. Once again, the EDI was not independently associated with isolation. Self-discipline is, however, not enough: the right conditions must be in place to minimize the risk of disrupting family or social dynamics and thus to produce the expected effects. Practical dispositions such as living conditions, ability to access basic supplies and needs, and access to health care are important factors in individuals’ decisions to comply or not with self-isolation and also possibly participate in a screening campaign [40].

Regarding RT-PCR positivity, it was interesting to observe that a significant determinant of a SARS-CoV-2 infection was the knowledge score regarding SARS-CoV-2 transmission. A 2021 report from the Norwegian Institute of Public Health showed that people with low education and low family income have higher rates of confirmed positive cases [44]. Nevertheless, we cannot make the same claim for our population, given that we did not record the school education level of our respondents. Other studies have confirmed the existence of sociodemographic factors associated with COVID-19 such as deprivation [45]. In our study, belonging to deprived EDI strata or to a low socio-professional category was not independently associated with SARS-CoV-2 infection. However, detection of SARS-CoV-2 infection in the study participants was performed only on 1 day, which was not the case in other studies.

As Schmidt et al [38] recently reported, one of the key elements to be retained from the various recent studies carried out is that the level of health literacy specific to COVID-19 seems to be a strong determinant of the individual’s commitment to adopting preventive attitudes and behaviors toward the virus [38].

Limitations

Our study has some limitations. First, Saint-Étienne ranks 14th among France’s 75 most populous cities, and 17th among 50 of France’s main urban areas. So, despite its position in the top half of France’s most populous cities, it is by no means representative of all French cities [16,46]. Second, we used EDI and IRIS to determine socioeconomic status and geographic areas. We were, therefore, unable to classify individuals by rural, periurban, or urban catchment area since EDI was created in 2007 and the urban landscape has been reshaped. Thus, it was not possible for us to verify whether there is a difference in the level of health literacy according to urban or rural areas. However, it is important to note that the literature is mixed on this specific issue [47-51]. Moreover, EDI is an area indicator and its transposition at an individual level may not be representative of the true deprivation status in numerous cases. Recording the socioeconomic status of individuals would have been more precise but would have increased the length of the questionnaire and may have stigmatized people; hence, we did not make this choice.

We excluded participants with missing values, which can limit the representativeness of the study sample relative to the target population. The most frequent reason for exclusion was the impossibility to determine the IRIS area where participants lived. A proportion of exclusions was also due to incomplete filling of the questionnaire, resulting in an impossibility to calculate scores for 4% to 8% of participants, depending on the score. We cannot rule out a bias of social desirability in the declarative responses to questions about respondents’ behavior with respect to their adherence to existing barrier practices. Moreover, we cannot exclude a representation bias as volunteer participants self-presented to take part in a mass screening campaign and were probably already aware of strategies deployed to contain the epidemic, and their behaviors were perhaps not representative of those of the general population. Especially since the demographic characteristics of our population are slightly different from those of the French general population, we had a notably higher proportion of older individuals [52]. However, we analyzed their behaviors according to their sociodemographic characteristics. Nevertheless, the context, the population surveyed led us to acknowledge that the results of this study have limited generalization. Furthermore, the results obtained were not used to implement public health interventions since the epidemic situation improved. However, our results could help customize specific avenues in case of a future emergency.

Comparison With Prior Work

Added Value of This Study

To our knowledge, this is the first study to assess the knowledge of, behavior toward, and isolation for COVID-19 in a large-scale population during a mass city-wide testing using a validated questionnaire (CovQuest-CC questionnaire) [19]. This evaluation was correlated with the results of the SARS-CoV-2 RT-PCR testing performed for each individual during the mass city-wide testing. A correlation was found between knowledge scores and positive findings on RT-PCR testing among asymptomatic people. In the setting of the COVID-19 pandemic, determinants of better health literacy were not the same as those in other contexts. Other works have evaluated such types of data on a large scale but never in the context of city-wide mass testing and with a lower number of respondents [26,31,33].
Implications of all Available Evidence

As pointed out by Mühlbacher et al [53], restrictive measures in the event of a pandemic can only be successful if they are accepted by the population and if political decision makers can count on the approval of a large with the majority of citizens.

In this way, knowledge of behavioral determinants can help to implement appropriate nonpharmaceutical interventions, supported by public commitment, in the event of a large-scale health threat.

Thus, assessing health-related knowledge about SARS-CoV-2 is crucial, particularly in a large population, in order to transition to public health intervention research, which will provide essential multilevel responses at organizational, societal, and individual levels, while enabling the implementation of structured, individualized interventions aimed at different typologies of individuals.

Conclusions

In conclusion, this study identifies factors associated with health literacy regarding SARS-CoV-2 infection in asymptomatic individuals in a large French population. We can confirm that, in the context of the COVID-19 pandemic, the determinants of better health literacy are not the same as those in other contexts. In particular, we were able to establish a significant relationship between a low health literacy score on SARS-CoV-2 and positivity in an asymptomatic population. We were also able to highlight that female gender is an independent determinant of a better level of health literacy regarding SARS-CoV-2, and that middle and high school status signaled a low level. It seems extremely important to obtain a more detailed understanding of the determinants of individual citizens’ behavior as part of a strategy to combat the large-scale spread of a virus. The harsh experience of this pandemic should teach us how to nurture research to structure customizable interventions to encourage the adoption of ad hoc behaviors to engage citizens in adapting behaviors more favorable to their health.

Abstract

Background: Community engagement plays a vital role in global immunization strategies, offering the potential to overcome vaccination hesitancy and enhance vaccination confidence. Although there is significant backing for community engagement in health promotion, the evidence supporting its effectiveness in vaccination promotion is fragmented and of uncertain quality.

Objective: This review aims to systematically examine the effectiveness of different contents and extent of community engagement for promoting vaccination rates.

Methods: This study was performed in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. A comprehensive and exhaustive literature search was performed in 4 English databases (PubMed, Embase, Web of Science, and Cochrane Library) and 2 Chinese databases (CNKI and Wan Fang) to identify all possible articles. Original research articles applying an experimental study design that investigated the effectiveness of community engagement in vaccination promotion were eligible for inclusion. Two reviewers independently performed the literature search, study selection, quality assessment, and data extraction. Discrepancies were resolved through discussion, with the arbitration of a third reviewer where necessary.

Results: A total of 20 articles out of 11,404 records from 2006 to 2021 were retrieved. The studies used various designs: 12 applied single-group pre-post study designs, 5 were cluster randomized controlled trials (RCTs), and 3 were non-RCTs. These studies targeted multiple vaccines, with 8 focusing on children’s immunization, 8 on human papillomavirus vaccine, 3 on hepatitis B virus vaccine, and 1 on COVID-19 vaccine. The meta-analysis revealed significant increases in vaccination rates both in pre-post
comparison (rate difference [RD] 0.34, 95% CI 0.21-0.47, \( I^2 = 99.9\% \), \( P < .001 \)) and between-group comparison (RD 0.18, 95% CI 0.07-0.29, \( I^2 = 98.4\% \), \( P < .001 \)). The meta-analysis revealed that participant recruitment had the largest effect size (RD 0.51, 95% CI 0.36-0.67, \( I^2 = 99.9\% \), \( P < .001 \)), followed by intervention development (RD 0.36, 95% CI 0.23-0.50, \( I^2 = 100.0\% \), \( P < .001 \)), intervention implementation (RD 0.35, 95% CI 0.22-0.47, \( I^2 = 99.8\% \), \( P < .001 \)), and data collection (RD 0.34, 95% CI 0.19-0.50, \( I^2 = 99.8\% \), \( P < .001 \)). The meta-analysis indicated that high community engagement extent yielded the largest effect size (RD 0.49, 95% CI 0.17-0.82, \( I^2 = 100.0\% \), \( P < .001 \)), followed by moderate community engagement extent (RD 0.45, 95% CI 0.33-0.58, \( I^2 = 99.6\% \), \( P < .001 \)) and low community engagement extent (RD 0.15, 95% CI 0.05-0.25, \( I^2 = 99.2\% \), \( P < .001 \)). The meta-analysis revealed that “health service support” demonstrated the largest effect sizes (RD 0.45, 95% CI 0.25-0.65, \( I^2 = 99.9\% \), \( P < .001 \)), followed by “health education and discussion” (RD 0.39, 95% CI 0.20-0.58, \( I^2 = 99.7\% \), \( P < .001 \)), “follow-up and reminder” (RD 0.33, 95% CI 0.23-0.42, \( I^2 = 99.3\% \), \( P < .001 \)), and “social marketing campaigns and community mobilization” (RD 0.24, 95% CI 0.06-0.41, \( I^2 = 99.9\% \), \( P < .001 \)).

Conclusions: The results of this meta-analysis supported the effectiveness of community engagement in vaccination promotion with variations in terms of engagement contents and extent. Community engagement required a “fit-for-purpose” approach rather than a “one-size-fits-all” approach to maximize the effectiveness of vaccine promotion.

KEYWORDS

community engagement; community-based participatory research; vaccination rate; health promotion; vaccine.

Introduction

Vaccination stands as one of the top 10 great public health achievements of the last century. It has made significant strides in eliminating and controlling various vaccine-preventable diseases, as evidenced by the reduction in morbidity, mortality, and disability caused by these diseases [1,2]. A notable illustration is the use of vaccines as a crucial measure to mitigate the COVID-19 pandemic in the past 3 years [3,4]. A previous study analyzed the economic advantages of vaccination against 10 diseases across 73 countries from 2001 to 2020. It reported that vaccinations have prevented over 20 million deaths and saved approximately US $350 billion in disease costs [5]. A modeling study examined the health implications of vaccination against 10 pathogens across 98 countries from 2000 to 2030. It revealed that vaccinations have prevented 69 million deaths [6].

Both the Global Vaccine Action Plan 2011-2020 and Immunization Agenda 2030 have established strategic objectives to immunize every eligible individual with appropriate vaccines and to ensure equitable coverage of immunization benefits for all. However, the immunization coverage of many vaccines has yet to reach the expected level. For instance, between 2006 and 2014, only 47 million women across 80 countries and territories received the full course of human papillomavirus (HPV) vaccines, representing a mere 1.4% coverage of the total female population [7]. In addition, a study assessing the coverage of childhood vaccines across 136 administrative regions in 43 countries revealed that only one-third of children in 4 countries had fully received routine childhood vaccines [8]. In terms of adult vaccination, only 11 out of 204 countries achieved the World Health Organization (WHO) target of 90% coverage for 11 routine vaccines by 2019 [9]. Various reasons and barriers contribute to the lack of vaccination, with a significant obstacle being vaccine hesitancy. Vaccine hesitancy has been steadily rising worldwide over the past decade [10,11], emerging as one of the top 10 threats to global health listed by the WHO in 2019.

Community engagement is a process that involves engaging and motivating diverse partners to collaborate in harnessing community potential and enhancing community health [12,13]. It first gained prominence in the public health sphere with the Declaration of Alma-Ata and has since become increasingly prominent, particularly with the introduction of the new Sustainable Development Goals [14]. The WHO defines community engagement as “a process of developing relationship which enables stakeholders work together to address health issues” [15]. The United Nations Children’s Fund (UNICEF) defines community engagement as “an action for working with community stakeholders to improve community health” [13]. The definition of community engagement often intersects, competes with, and contradicts definitions of other terms such as community participation and community involvement, among others. Despite the extensive literature on community engagement, there is a lack of comprehensive guidelines to clarify the content and scope of community engagement, including what constitutes community engagement and the extent of its involvement. The levels of community engagement are structured along a continuum that spans from informing and consulting to involving, collaborating, and empowering [16,17]. The elements of community engagement manifest across a spectrum of initiatives, encompassing participant recruitment, intervention development, intervention implementation, and data collection [18,19]. Community engagement is characterized as a dynamic process rather than a singular intervention, operating within diverse contexts to address various issues through multiple mechanisms involving different actors.

A meta-analysis, incorporating 131 individual studies, supported the positive impact of community engagement on health and psychosocial outcomes for disadvantaged groups across various
conditions [20]. It plays a prominent role in global immunization strategies, as it has the capacity to alleviate vaccination hesitancy and enhance vaccination confidence. A systematic review, which included 14 studies, examined the effectiveness of community interventions on HPV vaccine coverage. Of these, 12 studies reported that community interventions led to an increase in the uptake of the HPV vaccine [21]. Another review, spanning across 19 countries, assessed studies indicating that community engagement enhanced the timeliness and coverage of routine childhood immunization vaccines [22]. Despite robust evidence supporting the role of community engagement in promoting health within diverse populations, the evidence for community engagement specifically in vaccination promotion remains fragmented. Thus, we conducted a systematic review and meta-analysis to investigate the effectiveness of various aspects and levels of community engagement in enhancing vaccination rates.

**Methods**

**Overview**
This study was conducted following the guidelines outlined in the Cochrane Handbook for Systematic Reviews of Interventions [23], and the results were reported following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines [24]. The review protocol was registered in the PROSPERO database (CRD42022339081). Two reviewers (ML and YJX) conducted the literature search, study selection, quality assessment, and data extraction independently. Any discrepancies were resolved through discussion, and a third reviewer (LY) was consulted for arbitration when necessary.

**Ethics Approval**
This review paper was a secondary analysis of existing data from original studies published before, rather than a direct collection of new data, and thus, does not require ethical approval.

**Search Strategies**
A comprehensive and exhaustive literature search was conducted across 4 English databases (PubMed, Embase, Web of Science, and Cochrane Library), as well as 2 Chinese databases (CNKI and Wan Fang). The search strategy involved combining terms related to “community engagement” and “vaccination” using specific vocabulary terms (MeSH and Emtree) and their corresponding free-text terms [25,26]. These terms were identified based on key publications in relevant fields, and the search strategy was adjusted to suit each database. Boolean operators, specifically “OR” between terms and “AND” between concepts, were used to combine search terms effectively.

No restrictions were placed on language, study design, country of origin, or publication date. Studies were searched in the selected databases from their inception to April 30, 2023. The initial literature searches were performed in June 2022, with an updated search conducted in April 2023. In addition, the reference lists of relevant articles and previous reviews were manually reviewed to identify any additional relevant studies. The ProQuest Dissertations & Theses Database was consulted to identify unpublished dissertations and theses. Furthermore, Google and Google Scholar were searched to identify gray literature for potential inclusion. Clinical trial registries, including ClinicalTrials.gov and the WHO International Clinical Trials Registry, were also searched to identify trials with outcomes that had not yet been published.

Details of the full search strategy for each database are listed in Table S1 in Multimedia Appendix 1.

**Selection Criteria**
The inclusion and exclusion criteria were established based on the participants, interventions, comparisons, outcomes, and study design (PICOS) strategy [27]. Initially, these criteria were applied to titles and abstracts, and subsequently to full-text articles, to determine their final inclusion status (Table 1).

All records retrieved from the literature search were imported into the bibliographic database EndNote (Clarivate), which was used to manage records and eliminate duplicates. Two reviewers (ML and XL) independently screened the records based on the eligibility criteria. Any discrepancies between the 2 reviewers were resolved through discussion, and a third reviewer (YJX) was consulted if consensus could not be reached. The search terms and selection criteria were designed to provide inclusive flexibility and discretion, considering the various permutations of community engagement.

</tr>
</tbody>
</table>

**Data Extraction**

A data extraction form was developed and piloted on 6 randomly selected sample studies to establish consensus on the data abstraction procedures. Subsequently, 2 independent investigators (ML and XL) extracted information including the first author, publication year, study design, country, participant number, intervention details, control condition, vaccine rates, and effect size of the intervention, where reported. In cases where a study provided data for both vaccine series initiation and completion, only the latter was included in the summary table. If a study evaluated multiple vaccine types and reported a combined vaccination rate, that result was selected; otherwise data for the primary vaccine under focus were presented. In instances where a study reported incomplete data, the authors were contacted via email to obtain the required information.

**Assessment of the Risk of Bias**

The revised Cochrane Tool for Risk of Bias 2.0 (RoB2) was used to assess the risk of bias in randomized controlled trials (RCTs) [33]. For nonrandomized trials and controlled pre-post studies, the Risk of Bias in Non-Randomized Studies-of Interventions (ROBINS-I) tool was used to evaluate the risk of bias [34].

Each study was assessed and categorized as having low, moderate, or high risk of bias for each domain. Studies with low risk in 3 or more domains and moderate risk in any remaining domain(s) were classified as having an overall low risk of bias. Studies with moderate risk in 3 or more domains and low or unclear risk in any remaining domain(s) were classified as having an overall moderate risk of bias. Studies with high risk in 3 or more domains and moderate risk in any remaining domain(s) were classified as having an overall high risk of bias. Studies with moderate risk in 3 or more domains and high risk in any remaining domain(s) were also classified as having an overall high risk of bias.

**Data Synthesis**

Descriptive statistics were used to summarize the key variables of the included studies. Meta-analysis was conducted using Stata version 15.1 (StataCorp LLC) to investigate the effectiveness of community engagement in promoting vaccination.

Vaccination rates were computed as the proportion of vaccinated individuals to the total targeted population. Effect sizes were represented as the rate difference (RD) of vaccination rates, along with 95% CIs [35,36]. Random effects models were used to calculate pooled effect sizes, considering the expected heterogeneity among studies. Standard errors were adjusted for clustering effects when trials used a cluster randomized controlled design.

Forest plots were used to display individual and pooled vaccination rates. Heterogeneity was assessed using the Cochrane $Q$ test ($P_{CQ} < .10$) and the $I^2$ statistics. Subgroup analyses were conducted based on age groups, vaccine types, and immunization. A meta-regression analysis was performed to explore the effects of study design or quality on the pooled effect size [37,38]. Sensitivity analysis using a single-study knockout approach was performed to determine the contribution of each study to the pooled effect size. Publication bias was evaluated through visual inspection of the funnel plot, and the asymmetry of the funnel plot was further assessed using the Egger test [39]. The Egger tests required a minimum of 10 publications to examine the association between SE and effect size in the funnel plot [37]. We classified the evidence quality into different levels according to the recommendations from van Tulder et al [40].
Results

Study Identification and Selection
The flowchart depicting the study selection process is presented in Figure 1. The literature search was conducted across 6 electronic databases from July 5, 2022, to July 12, 2022, yielding a total of 11,404 records. After removing duplicates, 9512 articles remained. Following the preliminary review of titles and abstracts, 83 articles were retained for full-text assessment. Subsequently, after reviewing the full texts, the final selection of 19 eligible articles was made. An additional article was identified through a manual search of reference lists. Therefore, a total of 20 eligible articles published in English were identified that met all inclusion criteria.

Figure 1. The flowchart of study selection. Community engagement is a process that involves engaging and motivating diverse partners to collaborate in harnessing community potential and enhancing community health.

Characteristics of the Included Studies
The characteristics of the included studies are summarized in Table S2 in Multimedia Appendix 1. This review did not restrict the timeframe of the literature search to provide a broad temporal perspective. The included studies were published between 2006 and 2021, with the majority (n=8) in the last 5 years. These studies were conducted in various countries, with the highest number (n=13) conducted in the United States [41-53], followed by Nigeria (n=3) [54-56] and Peru (n=2) [57,58], and 1 each in Pakistan [29] and India [59]. The studies used various designs, with over one-half (n=12) adopting single-group pre-post study designs [41,44,46,48,53,54-56,59], while the rest used cluster RCTs (n=5) [29,45,52,55,59] and non-RCTs (n=3) [49-51]. The studies recruited participants across all age groups, spanning from children (n=8) [29,43,44,46,54-56,59], to adolescents (n=7) [41,49-52,57,58], and to adults (n=5) [42,45,47,48,53]. The sample sizes of pre-post studies ranged from 30 to 12,103, with a median of 323, while the sample sizes of RCTs ranged from 337 to 2598, with a median of 349. These included studies targeted multiple vaccines, with 8 studies focusing on children’s immunization [29,43,44,46,54-56,59], 8 studies on HPV vaccine [41,47,49-52,57,58], 3 studies on hepatitis B virus (HBV) vaccine [42,45,53], and 1 study on COVID-19 vaccine [48]. Vaccination coverage was calculated using either individual-reported or officially recorded data.

Conceptualization of Community Engagement
Community engagement does not neatly fit into predefined typologies, as it encompasses a variety of contexts, extents, and outcomes [60,61]. To address this complexity, a conceptual framework of community engagement was developed. This framework aims to delineate the different contents and extent of community engagement, drawing from the WHO definition of community engagement [62] and the utilitarian perspective...
of community engagement [63]. The contents of community engagement were delineated into 4 main categories: participant recruitment, intervention development, intervention implementation, and data collection. The extents of community engagement were categorized as low, moderate, and high [64]. Specifically, a low extent of community engagement indicated that studies fulfilled 1 or 2 contents of community engagement; a moderate extent of community engagement indicated that studies fulfilled 3 contents of community engagement; and a high extent of community engagement indicated that studies fulfilled all 4 contents of community engagement [64].

Most studies incorporated 2 engagement contents, with the majority engaged in intervention implementation (19/20, 95%) [29,41-46,48-59] and intervention development (13/20, 65%) [41-43,45-50,52-54,56], followed by participant recruitment (12/20, 60%) [41,43-49,51,56-58] and outcome evaluation (11/20, 55%) [29,42-44,46,48,51-53,55-57] (Table 2). Furthermore, most studies fell into the moderate engagement extent category (n=10) [41,42,44,45,49,51,53,54,56,57], followed by low engagement extent (n=7) [29,47,50,52,55,58,59] and high engagement extent (n=3) [43,46,48] (Table 2).

Community engagement in these studies took various forms of intervention strategies, including social marketing campaigns, community mobilization, health education and discussions, health service support, and follow-up and reminders. These interventions were often combined into intervention packages, which included combinations such as health education and discussion with follow-up and reminders, health education and discussion with health service support, health education and discussion with health service support and follow-up reminders, social marketing campaigns and community mobilization with health service support and follow-up reminders, and social marketing campaigns and community mobilization with health education and discussion as well as follow-up reminders. Community engagement varied in geographical coverage, ranging from localized sites in 1 village or city to broader areas encompassing 1 district or more. However, many interventions failed to consider implementation constraints and practicalities on the ground, which in turn limited the fidelity of community engagement and the efficient utilization of community resources.

https://publichealth.jmir.org/2024/1/e49695
**Risk-of-Bias Assessment**

These studies exhibited variable quality across different study designs, with none meeting all the elements of a good quality design. Individual domain ratings and overall bias risk ratings for each study are presented in Tables S3 and S4 in Multimedia Appendix 1.

Two cluster RCT studies [29,59] were identified as having a low risk of bias, 1 [55] as a moderate risk of bias, and 2 [45,52] as a high risk of bias. This variability in the risk of bias may result from incorrect randomization procedures, deviations in intervention implementation, and incomplete outcome reporting. In addition, 6 quasi-experimental studies [44,48,49,53,54,57] were rated as having a low risk of bias, 4 [42,46,47,56] were rated as having a moderate risk of bias, and 5 [41,43,50,51,58] were rated as having a high risk of bias. The sources of bias in these studies may include confounding effects, missing outcome data, and selective reporting of results.

**Overall Meta-Analysis of Community Engagement on Vaccination Rates**

The pooled meta-analysis incorporated usable data from 21 intervention groups across 20 studies. The random effects meta-analysis of pre-post intervention effects revealed a moderate positive effect size of community engagement on promoting vaccination rates (RD 0.34, 95% CI 0.21-0.47, $I^2=99.9\%$, $P_{CQ} < .001$; Figure 2, see also [29,41-59]). Similarly, the random effects meta-analysis of between-group intervention effects showed a small positive effect size of community engagement on promoting vaccination rates (RD 0.18, 95% CI 0.07-0.29, $I^2=98.4\%$, $P_{CQ} < .001$; Figure 2).

**Figure 2.** Meta-analysis of the effects of overall community engagement on vaccination rates. See also [29,41-59]. RD: rate difference.
Meta-Analysis of Community Engagement Contents and Extent on Vaccination Rates

Regarding the contents of community engagement, the random effects meta-analysis revealed that participant recruitment yielded the largest effect size (RD 0.51, 95% CI 0.36-0.67, \( I^2 = 99.9\%, P_{CQ} < .001 \)), followed by intervention development (RD 0.36, 95% CI 0.23-0.50, \( I^2 = 100.0\%, P_{CQ} < .001 \)), intervention implementation (RD 0.35, 95% CI 0.22-0.47, \( I^2 = 99.8\%, P_{CQ} < .001 \)), and data collection (RD 0.34, 95% CI 0.19-0.50, \( I^2 = 99.8\%, P_{CQ} < .001 \); Figure 3, see also [29,41-59]).

![Figure 3](https://publichealth.jmir.org/2024/1/e49695/fig3.png)

Figure 3. Meta-analysis of the effects of different contents of community engagement on vaccination rates. See also [29,41-59]. RD: rate difference.

With regard to the extent of community engagement, the random effects meta-analysis found that high community engagement extent yielded the largest effect size (RD 0.49, 95% CI 0.17-0.82, \( I^2 = 100.0\%, P_{CQ} < .001 \)), followed by moderate...
community engagement extent (RD 0.45, 95% CI 0.33-0.58, $I^2=99.6\%$, $P_{CQ}<.001$) and low community engagement extent (RD 0.15, 95% CI 0.05-0.25, $I^2=99.2\%$, $P_{CQ}<.001$; Figure 4, see also [29,41-59]).

**Figure 4.** Meta-analysis of the effects of different extents of community engagement on vaccination rates. See also [29,41-59]. RD: rate difference.

---

Meta-Analysis of Intervention Strategies on Vaccination Rates

With regard to single types of intervention strategies, the meta-analysis of 4 intervention strategies found that “health service support” yielded the largest effect sizes (RD 0.45, 95% CI 0.25-0.65, $I^2=99.9\%$, $P_{CQ}<.001$), followed by “health education and discussion” (RD 0.39, 95% CI 0.20-0.58, $I^2=99.7\%$, $P_{CQ}<.001$), “follow-up and reminder” (RD 0.33, 95% CI 0.23-0.42, $I^2=99.3\%$, $P_{CQ}<.001$), and “social marketing campaigns and community mobilization” (RD 0.24, 95% CI 0.06-0.41, $I^2=99.9\%$, $P_{CQ}<.001$; Figure 5, see also [29,41-59]).
With regard to combined types of intervention strategies, the meta-analysis of 5 intervention strategy packages found that intervention package 2 yielded the largest increase in vaccination rates (RD 0.64, 95% CI 0.31-0.97, $I^2=99.3\%$, $P_{CQ}<.001$), followed by intervention package 3 (RD 0.58, 95% CI 0.05-1.11, $I^2=99.1\%$, $P_{CQ}<.001$), intervention package 4 (RD 0.31, 95% CI 0.20-0.41, $I^2=99.2\%$, $P_{CQ}<.001$), and intervention package 1 (RD 0.25, 95% CI 0.09-0.41, $I^2=98.6\%$, $P_{CQ}<.001$). However, intervention package 5 had no statistically significant impact on vaccination rates (RD 0.07, 95% CI 0.00-0.14, $I^2=72.7\%$, $P_{CQ}=.03$; Figure 6, see also [41,43-45,47,49-57,59]). Data from 5 studies were not synthesized because of high heterogeneity in their intervention strategies [29,42,46,48,58].
Subgroup Analyses of Age Groups, Vaccine Types, and Immunization Definitions on Vaccination Rates

Subgroup analyses revealed that adults (RD 0.50, 95% CI 0.16-0.85, $I^2=100.0\%$, $P_{CQ}<.001$) exhibited a larger effect size compared with adolescents (RD 0.44, 95% CI 0.18-0.70, $I^2=99.3\%$, $P_{CQ}<.001$) or children (RD 0.18, 95% CI 0.04-0.33, $I^2=99.7\%$, $P<.001$; Figure S1 in Multimedia Appendix 1). HPV vaccination (RD 0.44, 95% CI 0.18-0.70, $I^2=99.3\%$, $P_{CQ}<.001$) exhibited a larger effect size compared with HBV vaccination (RD 0.42, 95% CI 0.12-0.72, $I^2=99.8\%$, $P_{CQ}<.001$) or children immunization (RD 0.18, 95% CI 0.04-0.33, $I^2=99.7\%$, $P_{CQ}<.001$; Figure S2 in Multimedia Appendix 1). Full immunization (RD 0.41, 95% CI 0.30-0.53, $I^2=99.5\%$, $P_{CQ}<.001$) exhibited a larger effect size compared with partial immunization (RD 0.20, 95% CI 0.08-0.33, $I^2=93.3\%$, $P_{CQ}<.001$). However, no significant increase was found in the vaccine rate of up-to-date immunization (RD 0.25, 95% CI –0.10 to 0.60, $I^2=100.0\%$, $P_{CQ}<.001$; Figure S3 in Multimedia Appendix 1).

Sensitivity, Meta-Regression, Publication Bias, and Evidence Level

Sensitivity analysis showed that no significant changes were observed in the effect size of the pre-post intervention effect analysis (Figure S4 in Multimedia Appendix 1). However, the pooled effect size decreased dramatically when eliminating the study of Ma et al [45] in the between-group intervention effect analysis (RD 0.08, 95% CI 0.02-0.20; Figure S5 in Multimedia Appendix 1). Meta-regression analyses did not show any association between effect size and study design or study quality for the pre-post intervention effect analysis ($P=.16$ or $P=.65$; Figure S6 in Multimedia Appendix 1). As evidenced by the funnel plot and Egger test, no discernible signs of publication bias were detected either in the pre-post or in the between-group intervention effect analyses ($P=.25$; Figures S7 and S8 in Multimedia Appendix 1). According to recommendations from van Tulder et al [40], evidence quality in our meta-analysis was graded as moderate in both the pre-post and between-group
intervention effect analyses (Table S5 in Multimedia Appendix 1).

**Discussion**

**Principal Findings**

Community engagement drives interventions operated in a bottom-up manner rather than the traditional top-down approach. This approach supports stakeholders coming together to achieve global vaccination coverage goals from childhood to adulthood.

This study reported that community engagement strategies resulted in a 34% increase in vaccination rates through a pre-post intervention effect analysis and an 18% increase in vaccination rates through a between-group intervention effect analysis. The random effects meta-analyses indicated that participant recruitment exhibited the largest effect size, followed by intervention development, intervention implementation, and data collection. Consistent with previous evidence [64], intervention implementation constituted the primary engagement approach of most included studies and yielded a moderate effect size, while participant recruitment represented the engagement approach of over half of the included studies and yielded the largest effect size. Community partners who possess the knowledge and skills to effectively approach the target population and actively engage in participant recruitment hold the most potential to achieve relatively high recruitment and retention rates for participants. This meta-analysis found that the effect size increased with the extent of community engagement, with the highest community engagement extent exhibiting the largest effect size. Similar to previous evidence [65], a higher extent of community engagement resulted in greater vaccination promotion. Previous systematic reviews, which classify community engagement into different levels from low to high, also reported positive correlations between community engagement extents and intervention effects [65].

Regarding intervention strategies, the meta-analyses showed that health service support yielded the largest effect size, followed by health education and discussion, follow-up and reminder, and social marketing campaigns and community mobilization. Similar to previous studies, health service support increased routine childhood vaccine coverage [66]; health education and discussion increased HPV vaccine coverage among adolescents [21,67] and influenza vaccine coverage among older adults [68]; follow-up and reminder increased HBV vaccine coverage among adults [69]; and social marketing campaigns and community mobilization increased routine childhood vaccine coverage [70]. Health service support, whether used alone or in combination with other strategies, demonstrated effectiveness for vaccination promotion. Consistent with our analysis, previous studies have supported the effectiveness of health service support in the form of free vaccination outreach or mobile clinic vaccination [66,71], and flexible vaccination schedules [72]. Intervention packages that combined health service support with the other 3 strategies resulted in a significant boost in vaccine rates. The intervention packages with adaptability and flexibility, which incorporated diverse intervention strategies, could effectively meet the needs of the community population and maximize intervention benefits.

Meta-analyses across a broad range of topics, populations, and interventions often encounter a disjunction between considerable heterogeneity arising from broad questions and the limited statistical methods available for variance analysis. The limited number of included studies precluded the performance of subgroup analyses and meta-regressions to fully address the sources of heterogeneity. The development of a conceptual framework provided homogeneity at the theoretical level despite the unavoidable nature of situational heterogeneity.

The geographic coverage of the included studies spanned across 5 countries, with most studies located in the United States, which could reflect a type of publication bias along with the skewed nature of global health research. These included studies were published between 2006 and 2021, with the majority in the last 5 years, which could reflect increased academic enthusiasm and enhanced policy support in recent years. However, most studies failed to disclose the social characteristics of community participants, which highlights the reality of known social hierarchies within communities.

Many studies proposed operational definitions of community engagement, and some studies suggested empirical models to explain its connotation. However, few articles made references to definitions or frameworks, reflecting a lack of theoretical basis and critical perspective. The lack of common definitions, along with the absence of conceptual frameworks, has led to diversified procedures and contents of engagement across diverse contexts and practices. Despite the wide acceptance of community engagement in theory and practice, considerable challenges remain in identifying the best engagement approach and evaluating engagement effectiveness [73-75]. Community engagement shares similar spirits but varies in practices, as the extent of engagement spans a spectrum from minimal superficial involvement to fully collaborative participation. Operating community engagement is cost-intensive rather than cost-neutral, requiring labor, capital, and time to establish, develop, and sustain fruitful partnerships, thus posing challenges to its successful and sustainable implementation. These included studies failed to report any analysis of costs, which precluded conclusions about the economic case for community engagement. While studies support the value of community engagement, the evaluation of community engagement has largely focused on health outcomes and ignored economic information. Future studies should incorporate economic analysis to explore the potential cost-utility and cost-effectiveness of community engagement in real-world contexts. This will help close the research-practice gap and facilitate evidence-based policy making.

The inclusion of experimental designs allowed the identification of a clear link between community engagement and vaccination promotion. However, none of these included studies were located at the top level of the evidence hierarchy, which limited the direct contribution of community engagement to vaccination promotion. Future studies with more rigorous designs should be performed to draw more definitive linkages about which participant group benefits the most from which engagement
type in what community context. Randomized trials followed allocation sequence methods to ensure between-group comparability, but most interventions differed from comparisons in more ways than just community engagement. The comparator for community engagement always involved a completely different multicomponent intervention rather than the conventional health promotion activity without community engagement. The lack of a pure comparator in most community engagement interventions could cloud the interpretation of this meta-analysis. Community engagement often operates in nonlinear pathways synergized between various components and multiple outcomes, thus complicating effect evaluation compared with simple dose-response relationships. Community engagement functions as a dynamic process rather than as a discrete intervention, implying that evaluation should fully account for intrinsic complexities rather than simply focusing on outcome indicators. The primary studies should conduct thorough process evaluations to incorporate a spectrum of outcome measures and complement qualitative evaluations to elucidate the active ingredients of community engagement and the potential unintended effects of community engagement.

The effects of community engagement on vaccination promotion did not occur as a linear progression, but rather consisted of complex processes influenced by facilitators or challenges. These included studies identified individual- and community-level factors that facilitated or challenged community engagement in the context of vaccination promotion. At the individual level, the sense of confidence and ownership, along with the development of leadership skills and knowledge, facilitated community partners to engage with participatory processes. Conversely, the lack of interest and capacity, as well as the ambiguity of role and responsibility, challenged community partners to engage with participatory processes. At the community level, trust facilitated effective community engagement, while mistrust inhibited genuine community engagement. Further work should adopt a broader range of study designs that encompass both quantitative and qualitative engagement. Further work should adopt a broader range of study designs that encompass both quantitative and qualitative methodologies to measure these intangible facilitators or challenges in the area of community engagement.

These included studies faced the challenge of measuring the level of community engagement, as engagement levels span a spectrum from more passive involvement to more active participation. This study proposed operationalized extents of community engagement beyond levels of community engagement from a pragmatic perspective. Further studies should be performed to develop tools or standards to measure and evaluate the levels of community engagement effectively.

As most studies narrowly defined community engagement as an intervention program imposed on the community, they framed the effectiveness of community engagement in terms of short-term individual-level outcomes [60] while neglecting multidimensional community-level outcomes. A narrow definition of community engagement, along with a restricted view of effectiveness, excludes a conceptually coherent and methodologically sound evaluation of community engagement [15]. Evaluating community engagement raises a unique set of challenges around conceptual, methodological, and practical aspects [76]. The interaction between the engagement strategy and the community system creates a degree of complexity beyond the detail of intervention implementation [77]. This complexity grows in concert with the delivery of the engagement strategy, which may, in some instances, reshape the intervention and the community context [77]. Future work should focus on intervention theories, logic models, and outcome frameworks to clarify the relationship between community engagement and health outcomes.

Community engagement can function independently or in conjunction with other initiatives. However, when combined with other initiatives, it becomes challenging to isolate the specific contribution of community engagement to health outcomes [78]. On the other hand, some studies treated community engagement as a discrete intervention rather than a dynamic process. This oversight has resulted in a lack of alternative process evaluations to explore how community engagement contributes to vaccination promotion [79-81]. Despite the widespread use and recognized significance of community engagement [82], there are still gaps in measuring and evaluating its implementation. While there is a vast body of literature on community engagement spanning various disciplines, comprehensive guidelines and frameworks for community engagement are lacking. The adoption of consistent guidelines and frameworks can formalize the implementation and evaluation of community engagement efforts.

Limitations
This study faces some challenges and limitations that warrant consideration and point toward future directions. The first challenge was the range of different definitions and terminology referring to engagement versus involvement and participation. The second challenge was the disjunction between the conceptual heterogeneity inherent in such broad questions and the limited statistical methods available to analyze variance. The third limitation was the possibility of study omission due to search deficiencies or publication bias, despite the extensive and rigorous literature search conducted.

Conclusions
The findings of this meta-analysis support the effectiveness of community engagement in promoting vaccination, with variations observed in terms of the contents and extent of engagement. Experimental studies often involve differences between the intervention and comparison groups beyond just community engagement. Studies designed to specifically isolate community engagement as the only differing factor between the intervention and comparison groups are suggested, which allows for a clearer understanding of its added value in vaccination promotion. Comprehensive process evaluations and qualitative evaluations should be used, to provide insights into the active ingredients of community engagement and uncover any unintended effects it may have. A further scientific agenda on community engagement should focus on theory development, framework construction, and effectiveness evaluation. Future studies will benefit from the adoption of standard guidelines and frameworks to enable cross-study or cross-country comparisons of community engagement, promoting effective, sustainable, and appropriate community initiatives.

Abstract

Background: The existing literature reveals several significant knowledge gaps that hinder health care providers in formulating exercise prescriptions for cognitive health.

Objective: This study endeavors to elucidate the relationship between the level of physical activity and cognitive function in older adults in China. Moreover, it seeks to explore the associations between distinct exercise behaviors—such as exercise types, the purpose motivating engagement in exercise, the accessibility of exercise fields, and the inclination toward exercise—and cognitive function.

Methods: Using data from the China Longitudinal Aging Social Survey (CLASS conducted in 2016, cognitive function was meticulously assessed through the modified Chinese version of the Mini-Mental State Examination, encompassing measures of orientation, memory, and calculation. Using self-report structured questionnaires, a myriad of information about physical activity during leisure time, exercise engagement, exercise intensity, primary exercise types, reasons for exercise participation, availability of sports facilities, and exercise willingness was diligently gathered. Robust ordinary least squares regression models were then used to compute coefficients along with 95% CIs.

Results: A discernible inverted U-shaped trend in cognitive scores emerged as the level of physical activity surpassed the threshold of 500 metabolic equivalents of task (MET) minutes per week. Notably, individuals with a physical activity level between 500 and 999 MET minutes per week exhibited a coefficient of 0.31 (95% CI 0.09 to 0.54), those with a physical activity level between 1000 and 1499 MET minutes per week displayed a coefficient of 0.75 (95% CI 0.52 to 0.97), and those with a physical activity level above 1500 MET minutes per week demonstrated a coefficient of 0.45 (95% CI 0.23 to 0.68). Older individuals engaging in exercise at specific MET levels showcased superior cognitive function compared to their inactive counterparts. Furthermore, individuals driven by exercise motivations aimed at enhancing physical fitness and health, as well as those using sports facilities or public spaces for exercise, exhibited notably higher cognitive function scores.

Conclusions: The findings underscore the potential of exercise as a targeted intervention for the prevention and treatment of dementia or cognitive decline associated with aging in older individuals. Leveraging these insights to formulate informed exercise recommendations holds promise in addressing a significant public health challenge linked to aging populations.
Introduction

Cognitive function plays a crucial role within the framework of healthy aging proposed by the World Health Organization [1]. The decline in cognitive function can have adverse effects on social interaction, sense of purpose, independent living abilities, as well as the capacity to recover from illnesses or injuries [2,3]. Approximately 55.2 million people worldwide have cognitive impairments, and this number is projected to rise to 83.2 million by 2030 and further to 152.8 million by 2050 [4,5]. Given the rapid acceleration of global population aging, it has become imperative to identify and address potential cognitive decline. While cognitive decline is an inevitable part of the aging process, evidence suggests that cognitive plasticity can still occur, even in later stages of life [6]. The 2020 Lancet Commission on dementia prevention, intervention, and care indicates that approximately 40% of dementia cases worldwide are potentially modifiable [7], and a significant contribution can be attributed to engaging in physical activity and exercise can potentially reduce the risk of cognitive function [6,7].

Physical activity refers to any movement of the body that requires energy expenditure, such as gardening, shopping, or doing household chores [8], while exercise is a planned and structured form of physical activity that aims to improve or maintain physical fitness components [8]. Both physical activity and exercise have been extensively studied and shown to enhance cognitive performance through various molecular mechanisms, including the stimulation of brain-derived neurotrophic factors, learning, and memory [9,10]. As a result, clinical guidelines and public health recommendations often emphasize the importance of incorporating physical activity and exercise as fundamental strategies for preventing and managing dementia [7,11]. The World Health Organization suggests that older adults should aim for 150-300 minutes of moderate-intensity aerobic activity per week or 75-150 minutes of vigorous-intensity aerobic activity, along with regular muscle-strengthening exercises involving major muscle groups at least 3 times per week [12].

However, the existing literature reveals several significant knowledge gaps that hinder health care providers in formulating exercise prescriptions for cognitive health. First, although some evidence suggests the minimum effective, optimal doses, and maximum safe threshold of physical activity to enhance cognitive function in older adults [13], most of these studies have focused on high-income countries rather than limited-income countries. This discrepancy poses a challenge when attempting to develop exercise prescriptions for cognitive health in limited-income regions. Second, there is a limited number of studies that have distinguished the diverse effects on cognitive function between general physical activity and planned, structured exercise behaviors. Additionally, only a few studies have examined the specific influence of exercise itself on cognitive function while considering the controlling factors of physical activity metabolic equivalents. Third, there is insufficient evidence to determine the most effective types of exercise for improving cognitive function in older adults. Moreover, research is scarce regarding the relationship between different exercise behaviors, such as exercise purpose, chosen venue, exercise willingness, and cognitive function in older adults. However, this information concerning exercise behaviors plays a crucial role in guiding the development of exercise prescriptions aimed at enhancing cognitive health.

Therefore, to fill these gaps, this study used a nationally representative population-based study, the China Longitudinal Aging Social Survey (CLASS), to examine the relationship between exercise and cognitive function and its 3 domains among old adults. Here, we have included the assumptions of this study: first, we assume that there is a statistically significant relationship between the level of physical activity and cognitive function among older adults in China, and then, we assume that the aforementioned relationship will exhibit significant variations across different specific exercise behaviors (including various exercise types, the purpose for engaging in exercise, the availability of exercise fields, and the willingness of exercise).

Methods

Study Design and Participants

For this study, data were obtained from the CLASS conducted from 2014 to 2020. CLASS is a nationally representative survey that encompasses 28 provinces in China. It was designed by the Institute of Gerontology and implemented by the China Survey and Data Center at Renmin University of China. The survey used a stratified multistage probability sampling method to obtain participants from communities which involved 134 counties and 462 communities across the county in China. Participants aged 60 years and older were included in this study, and their demographic information, family and community details, health status, social functioning, physical activity, and retirement information were examined. Specially trained interviewers collected all the information through face-to-face interviews. More comprehensive information about this study’s design of CLASS can be found in a previous publication [14].

In 2016, the collection of metabolic equivalents of task (MET) values and detailed exercise information was limited to that specific year, while cognitive function and other covariates were collected across all 4 waves of data collection. As a result, our analytic sample includes individuals who responded to MET, detailed exercise information, cognitive function, and other covariates in 2016. In the 2016 survey, a total of 11,492 participants aged 60 years and older were involved. Among them, 2027 participants had missing data on cognitive function scores, 18 were missing information on the intensity of physical activity metabolic equivalents, 18 were missing information on the intensity of physical activity metabolic equivalents, and 2027 participants had missing data on cognitive function.
activities, 63 were missing information on exercise behaviors, and 186 were missing information on covariates. Individuals with missing values were excluded from our sample, resulting in a final analysis involving 9198 participants.

Measures

Cognitive Function

The cognitive function of the respondents, including orientation, memory, and calculation, was assessed using the modified Chinese version of the Mini-Mental State Examination (MMSE). Orientation was evaluated using 5 questions that required respondents to provide information such as the current date, the village’s name, the date of National Day, the name of the current president, and the lunar calendar year. Each correct answer was assigned a score of 1, while incorrect answers received a score of 0, resulting in a range of 0 to 5 for orientation. Memory function was measured through immediate and delayed word recall tasks, where respondents were asked to recall 3 simple Chinese words immediately and several minutes later, respectively. The scores for immediate and delayed recall were combined, resulting in a range of 0 to 6. Calculation ability was assessed by having respondents count backwards from 100 by 7 seconds for 5 consecutive times, yielding a score ranging from 0 to 5. The sum of these 3 dimensions provided a representation of respondents’ cognitive functioning, with higher scores indicating better cognitive performance. According to a previous study [15], respondents who correctly answered at least three questions related to orientation were considered to have the cognitive ability to complete the full MMSE test. Therefore, the final cognitive functioning score ranged from 3 to 16.

Physical Activity

The self-report questionnaires were used to collect information on the extent of physical activity during leisure time. The questionnaire consisted of 9 questions that aimed to measure the time taken for different levels of activity, establishing based on the standard MET, which is a physiological measure expressing the energy cost of physical activities. It represents the ratio of the rate of energy expended during a specific physical activity to the rate of energy expenditure at rest. Further, 1 MET is defined as the energy expenditure at rest, typically around 3.5 mL of oxygen per kilogram of body weight per minute (3.5 mL O2/kg/minute). In practical terms, MET values are used to quantify the intensity of various activities. This study translated physical activities to METs involved assigning MET values to various activities based on the standard MET scale according to a previous study [16]. In our study, physical activities, such as light-intensity activities (including reading, playing an instrument, working on a computer, or walking at a slow or leisurely pace), moderate-intensity activities (including brisk walking, slow cycling, or playing tennis doubles), and vigorous-intensity activities (including jogging or running, bicycling, climbing briskly up a hill, or participating in an aerobics class), were involved. MET minutes per week were derived by quantifying the energy expenditure of different activities in terms of MET values and summing these values based on the duration of each activity. According to that, the level of leisure-time physical activity in this study was then categorized into several groups based on the calculated energy expenditure. The categories included: 0 (indicating a completely sedentary lifestyle), less than 500 MET minutes per week, 500 to 999 MET minutes per week, 1000 to 1499 MET minutes per week, and greater than 1500 MET minutes per week.

Exercise Behaviors

We investigated the relationship between exercise behaviors and cognition by examining aspects including whether participants engaged in exercise, the intensity of the exercise, the primary types of exercise, the reasons for engaging in the exercise, the availability of a sports field, and the willingness to participate in the exercise. These aspects were measured by (1) exercise: the presence of exercise behavior was measured by asking the question, “have you participated in physical exercise in the past year?”; (2) the intensity of exercise: the intensity of exercise was assessed using the questions, “how many days per week do you engage in high-intensity physical exercise that lasts at least 10 min and significantly increases your heart rate and sweating?” (frequency of high-intensity exercise per week) and “how many days per week do you engage in moderate-intensity physical exercise that lasts at least 10 min, increases your heart rate, and causes slight sweating?” (frequency of moderate-intensity exercise per week); these variables were measured as continuous variables; (3) the primary types of exercise: the primary types of exercise were determined by asking the question, “what types of physical exercise do you regularly participate in?” and categorized as follows: without exercise, endurance and speed exercises (eg, walking, running, swimming, cycling, badminton, and table tennis), apparent aesthetic exercises (eg, aerobics, dance, martial arts, and yoga), and other; (4) reasons for engaging in exercise: the reasons for participating in exercise were assessed by asking, “why do you engage in physical exercise?” and categorized as follows: without exercise, physical fitness and health enhancement (eg, disease prevention, maintaining physical fitness, and improving health), no specific purpose (ie, engaging in exercise without a specific goal and just for the sake of being active), and other (eg, self-realization and encouragement from children to be active); (5) the availability of sports fields: the availability of sports fields was measured by asking, “have you used the following sports facilities?” and categorized as follows: without exercise, athletic fields (eg, public sports fields and community sports facilities), parks, squares, or community fitness equipment (eg, parks, squares, residential area open spaces, and community fitness equipment), and home’s yard or curbside (eg, roadside and personal residence); (6) the willingness to participate in exercise: the willingness to engage in exercise was measured by asking, “if suitable conditions were provided for your exercise, would you be prepared to participate in exercise?” and categorized as “without willingness,” “uncertainty,” and “willingness.”

Covariates

Age (continuous covariates), gender (men or women), marital status (living without a spouse or living with a spouse), residency (urban or rural), education level (illiteracy, primary school, junior high school, senior high school, and above), working for pay (no or yes), household wealth (Renminbi, yuan), activities of daily living (ADL) impairment (no or yes), and
having cardiometabolic disease (no or yes) were involved as covariates. Of these, cardiometabolic disease was consistent with the combination of diabetes, heart disease, and stroke according to previous studies [17-21], which was determined through the self-reported history obtained through an in-person visit with study personnel via a questionnaire.

Statistical Analysis

Descriptive statistics are presented as means (SDs) for numerical variables and as numbers (%) for categorical variables. Ordinary least squares regression analysis was used to examine whether there is a relationship between the intensity of physical activity and cognitive function which was to calculate β coefficient and 95% CIs while adjusting for various factors including age, sex, marital status, residency, education level, occupation, household wealth, ADL impairment, and presence of cardiometabolic disease. Additionally, we use 8 ordinary least squares regression models to verify the associations between specific exercise behaviors and cognitive function. To examine the robustness of our findings, we conducted a subgroup analysis to explore the association between exercise and cognitive function among different subgroups. Specifically, we analyzed the male and female subgroups, individuals residing in rural and urban areas, individuals with low or high education levels, and individuals with or without cardiometabolic disease. All statistical analyses were performed using Stata (version 15; Stata Corp).

Ethical Considerations

The data collection in CLASS was issued by the Biomedical Ethics Review Committee of Peking University (IRB00001052-11015). All participants were compensated and ethical approval for collecting data on human participants was received and updated annually at Peking University Institutional Review Board.

Equity, Diversity, and Inclusion Statement

Our study embraces diversity by examining the relationship between exercise and cognitive function specifically among Chinese older adults. By focusing on this population, we contribute to the broader understanding of the benefits of exercise across diverse demographics. We strive for equity by ensuring equal representation and access to our study, regardless of socioeconomic background or other factors. We acknowledge that equitable opportunities for participation are essential in producing meaningful and inclusive findings. Inclusion is at the heart of our research, as we value the experiences, perspectives, and contributions of all individuals involved. We recognize that diversity and inclusion enhance the validity and applicability of our findings, promoting a more comprehensive understanding of the topic.

Results

Characteristics of Participants

Table 1 displays the characteristics of participants aged 60 years and older in China. The mean age of the participants was 69.55 (SD 7.21) years. Among the participants, 51.84% (n=4768) of them were men, 50.3% (n=4627) of them resided in urban areas, and 74.36% (n=6840) of them lived with their spouse. Regarding educational background, 23.05% (n=2120) of individuals were classified as illiterate and 13.71% (n=1261) of them were engaged in paid employment. The average household wealth was CN ¥241,267 (SD CN ¥425,622 [US $33,385.6, SD US $58,895.9]). Additionally, 5.97% (n=1414) of participants exhibited ADL impairment and 38.3% (n=3523) had cardiometabolic diseases.

The average global cognition score was 13.47 (SD 3.23), with specific mean scores of 4.67 (SD 0.78) for orientation, 4.90 (SD 1.67) for memory, and 3.90 (SD 1.72) for calculation. Among the participants, 16.37% (n=1507) of them reported engaging in exercise within the past year. On average, participants dedicated 0.20 (SD 0.94) days per week to high-intensity physical exercise lasting at least 10 minutes, which substantially increased heart rate and sweating. Additionally, participants allocated an average of 0.27 (SD 1.07) days per week to moderate-intensity physical exercise. Regarding the primary types of exercise, 14% (n=1288) of participants engaged in endurance and speed exercises, 1.89% (n=174) of them were involved in apparent aesthetic exercises, and 0.49% (n=45) of them fell into other categories. Furthermore, 12.95% (n=1191) of participants exercised for physical fitness and health enhancement, while 1.34% (n=123) of them had no specific purpose for engaging in exercise. In terms of available sports field facilities, 5.74% (528) of individuals had access to athletic fields when participating in exercise, 8.56% (n=787) of them could use parks, squares, or community fitness equipment, and 2.09% (n=192) of them used their home’s yard or curbside. As for willingness to engage in exercise, 40.41% (n=3717) of them expressed uncertainty, while 41.19% (n=3789) of them confirmed their readiness to participate in exercise if suitable conditions were provided.

### Distribution of Cognitive Function Scores According to Physical Activity Levels and Exercise Behaviors

Figure 1 shows the distribution of cognitive function scores according to physical activity levels. While participants with physical activity levels below 500 MET minutes per week exhibited lower cognitive function scores compared to those who were completely sedentary, cognitive function scores increased as the physical activity level increased from 500 to 1499 MET minutes per week (13.44-14.11). However, cognitive function scores started to decline after reaching a physical activity level of 1500 MET minutes per week or higher (13.57). Similar patterns were found in scores of orientation, memory, and calculation.

Regarding the scores of cognition based on the purpose of exercise, individuals with the purpose of exercise focused on physical fitness and health enhancement attained the highest cognitive function score (14.30). Conversely, individuals who exercised without a specific purpose had the lowest cognitive function score among those who engaged in exercise. Moreover, individuals who had access to athletic fields or parks, squares, or community fitness equipment exhibited higher cognition scores (>14.0) compared to those who exercised in their home’s yard or curbside. Lastly, individuals who expressed willingness to exercise if suitable conditions were provided had the highest cognitive function score (13.68), while those with uncertainty about exercise demonstrated a slightly lower score (13.66), and those without a willingness to exercise had the lowest cognitive function score (12.55). Comparable trends were observed in the cognitive domains of orientation, memory, and calculation. More specific details can be found in Figure 2 and Table S1 in Multimedia Appendix 1.
Figure 1. Distribution of cognition score according to physical activity levels.

Figure 2. Distribution of cognition score according to exercise.
Association Between Exercise Behaviors and Cognitive Function Among Older Adults in China

When compared to the cognition scores of individuals who were completely sedentary, there was no significant difference in the cognition scores of individuals with a physical activity level below 500 MET minutes per week (β=−0.04, 95% CI −0.28 to 0.20). However, as the physical activity level increased beyond the 500 MET minutes per week threshold, cognition scores showed an inverted U-shaped trend. The coefficient for individuals with a physical activity level between 500 and 999 MET minutes per week was 0.31 (95% CI 0.09 to 0.54), for individuals with a physical activity level between 1000 and 1499 MET minutes per week, the coefficient was 0.75 (95% CI 0.52 to 0.97), and for individuals with a physical activity level above 1500 MET minutes per week, the coefficient was 0.45 (95% CI 0.23 to 0.68).

Individuals who engaged in exercise within the past year exhibited higher levels of cognitive function compared to those without exercise engagement (β=0.49, 95% CI 0.32 to 0.66). Higher frequency of high-intensity or moderate-intensity exercise per week was associated with higher cognitive function scores (high-intensity: β=0.11, 95% CI 0.04 to 0.17; moderate-intensity: β=0.13, 95% CI 0.07 to 0.19). Specifically, individuals primarily involved in endurance and speed exercises had increased cognitive function compared to those without exercise (β=0.56, 95% CI 0.38 to 0.74). Participants who exercised to improve physical fitness or health demonstrated a coefficient of 0.49 (95% CI 0.30 to 0.68), whereas those with no specific purpose for exercise did not show a significant difference. Additionally, compared to individuals without exercise, the availability of athletic fields, parks, squares, or community sports facilities was associated with higher cognitive function scores. Individuals with exercise willingness or uncertainty if suitable conditions were provided exhibited higher cognitive function scores compared to those without exercise willingness (uncertainty: β=0.68, 95% CI 0.51 to 0.89; willingness: β=0.60, 95% CI 0.43 to 0.78). More details can be found in Table 2.
Table 2. Risk of cognitive function decline associated with exercise behaviors in China, 2016. The models were adjusted for age, sex, marital status, residency, education level, occupation, household wealth, ADL\(^a\) impairment, and having cardiometabolic disease or not.

</table>
Our research has revealed that older individuals who participate in exercise exhibit higher cognitive function levels than those who are inactive, considering a specific level of MET for physical activity. This suggests that purposeful, organized, and planned exercise activities, in contrast to general physical activity, positively influence cognitive function. Physical exercise has been scientifically proven to decrease the risk of various negative health outcomes and positively impact individuals with mild cognitive impairment or dementia. These effects may be attributed to the elevation of neurotrophic proteins, reduction in the accumulation of harmful proteins, mediation of neuroinflammation, or inhibition of neuronal functional deficits [22-24]. Additionally, our findings indicate that endurance and speed exercises exert a more pronounced influence on cognitive function. This aligns with previous research that highlights the significant role of aerobic exercise and low-intensity resistance training in inducing clinically significant cognitive changes [13,25]. Our robust analysis was indicated by similar findings of the main results.

The results of our study reveal a robust link between exercise aimed at improving physical fitness and health and higher cognitive function scores. Furthermore, we noted that individuals who possess exercise motivation tend to exhibit higher cognitive function scores compared to those lacking motivation. These findings underscore the importance of emphasizing the impact of exercise on health through health education, boosting exercise motivation, and amplifying the cognitive benefits of exercise. Moreover, our research indicates a positive correlation between engaging in exercise in sports facilities or public spaces and achieving higher cognitive function scores. This suggests the potential advantages of constructing sports facilities or park areas in the future to maximize the benefits of exercise for the older adult population. In summary, our study represents a significant step toward providing precise exercise recommendations for enhancing the overall cognitive abilities of older individuals in China. It can serve as a valuable resource for developing tailored exercise plans and implementing patient-centered care approaches to enhance cognitive function in limited-income countries moving forward [26,27].

Discussions

Our study is the first study to examine the specific associations of exercise itself (including the purpose of exercise, the choice of exercise place, and the willingness to exercise) with cognitive function while taking into account controls for the metabolic equivalent of physical activity. This study has several limitations. First, those with impaired cognitive function may have a limited capacity to exercise, which may lead to a reverse causal relationship between exercise and cognitive function. However, due to the cross-sectional design of this study, it could not exclude this influence. Subsequent research could use longitudinal designs to explore the bidirectional relationship and the causal impact of exercise behavior on cognitive function. Second, this study only incorporated respondents who completed cognitive function measurements in the CLASS survey, thereby excluding nonrespondents. This may result in an underestimation of the strength of the relationship between exercise and cognitive function. Future research should replicate this issue using a wider array of data sources. Third, due to data limitations, some important variables that could potentially impact cognitive function (such as depression, dementia, or Alzheimer disease) were not included in this study. Therefore, when interpreting our results, it is important to be mindful of this, and we hope that future research can use other data sources to further validate and delve deeper into this study’s findings. Fourth, the physical activity was measured through self-reporting based on the standard MET. Future studies should use more accurate measurement methods, such as accelerometer-measured relative physical activity intensity, to further validate our results. Fifth, this study used the MMSE to assess cognitive function, which may result in a ceiling effect for older adults. Future research should consider using other cognitive function measurement scales, such as the Montreal Cognitive Assessment, to validate our findings.

Conclusions

Our results found that there was a statistically significant relationship between the intensity of physical activity and cognitive function among older adults in China. Our findings suggested that the optimal exercise dose associated with

cognitive changes falls within the range of 500-1499 MET minutes per week. However, the benefits of exercise become less clear beyond 1500 MET minutes per week. Older individuals who engage in exercise at a specific level of MET for physical activity demonstrate higher levels of cognitive function compared to inactive individuals. Moreover, this relationship exhibited significant variations across different specific exercise behaviors: individuals with exercise motivation, aiming to improve physical fitness and health, and those who engage in exercise in sports facilities or public spaces, exhibit higher cognitive function scores than their counterparts. Our findings may offer practical guidance for health care professionals, enabling them to enhance cognitive health outcomes in older individuals through targeted exercise interventions and recommendations. Specifically, health care professionals should recognize that the impact of exercise motivation on cognitive function can be addressed through motivational strategies to encourage older individuals to engage in physical activity. Additionally, physicians or physiotherapists may need to advise older adults to monitor their exercise intensity within the specified range. This approach can optimize cognitive benefits while avoiding the potential diminishing returns associated with exceeding 1500 MET minutes per week. By using these findings to provide informed exercise recommendations, we can better address one of the significant public health challenges we face. Future studies can delve deeper into understanding the nuances of the optimal exercise dose associated with cognitive changes and use longitudinal designs to establish temporal relationships between exercise patterns and cognitive changes over time.

Abstract

Background: Participatory research (PR) involves engaging in cocreation with end users and relevant stakeholders throughout the research process, aiming to distribute power equitably between the end users and research team. Engagement and adherence in previous workplace health promotion (WHP) studies have been shown to be lacking. By implementing a PR approach, the insights of end users and stakeholders are sought in the co-design of feasible and acceptable intervention strategies, thereby increasing the relevance of the research.

Objective: This scoping review aims to explore, identify, and map PR techniques and their impact when used in office-based WHP interventions designed to improve physical activity (PA) or reduce sedentary behavior (SB).

Methods: The reporting of this scoping review followed the PRISMA-ScR (Preferred Reporting Items for Systematic reviews and Meta-Analyses extension for Scoping Reviews). A systematic literature search of 5 electronic databases—Web of Science, PubMed, Scopus, Google Scholar, and OpenGrey—was conducted, searching from January 1, 1995, to February 8, 2023. In total, 2 independent reviewers first screened the retrieved articles by title and abstract, and then assessed the full texts based on the inclusion and exclusion criteria. The search strategy and eligibility criteria were developed and guided by an a priori population (office-based working adults), intervention (a PA WHP intervention that took a PR approach), comparison (no comparison required), and outcome (PA or SB) framework. Data were charted and discussed via a narrative synthesis, and a thematic analysis was conducted. The included studies were evaluated regarding the degree of end user engagement throughout the research process and power shared by the researchers, using Arnstein’s ladder of citizen participation.

Results: The search retrieved 376 records, of which 8 (2.1%) met the inclusion criteria. Four key strategies were identified: (1) end user focus groups, (2) management involvement, (3) researcher facilitators, and (4) workplace champions. The degree of engagement and power shared was relatively low, with 25% (2/8) of the studies determined to be tokenistic, 25% (2/8) determined to be nonparticipation studies, 25% (2/8) determined to be tokenistic, and 50% (4/8) determined to provide citizen power.

Conclusions: This review provides a foundation of evidence on the current practices when taking a PR approach, highlighting that previous office-based PA WHP studies have been largely tokenistic or nonparticipative, and identified that the end user is only engaged with in the conception and implementation of the WHP studies. However, a positive improvement in PA and...
Reduction in SB were observed in the included studies, which were largely attributed to implementing a PR approach and including the end user in the design of the WHP intervention. Future studies should aim to collaborate with workplaces, building capacity and empowering the workforce by providing citizen control and letting the end users “own” the research for a sustainable WHP intervention.

**Introduction**

**Background**

A growing body of literature in occupational health research, and specifically research into individuals with office- and desk-based occupations, has begun to focus on prolonged occupational sitting [1]. The workplace environment and increased use of computers have been associated with a significant reduction in physical activity (PA) and an increased prevalence of prolonged sitting, especially in desk-based office workplaces [2,3]. Sitting is classified as a sedentary behavior (SB), which is a term used to define any waking behavior with an energy expenditure of ≤1.5 metabolic equivalents of task when sitting, reclined, or in a lying posture [4]. The workplace environment and organizational culture can often facilitate and promote prolonged SB [2,5]. Emerging evidence from 2 previous studies that measured sedentary time via accelerometers indicated that office workers were sedentary for a mean of 75.8% [6] to 81.8% (438.8, SD 51.5 min) of their working hours [7].

Previous research has attempted to reduce or interrupt prolonged occupational sitting in the workplace environment to varying degrees of success, by increasing PA. However, these previous workplace interventions or workplace health promotion (WHP) studies can often be characterized as “one size fits all” interventions, which have taken a traditional top-down, research-driven approach where the end users are considered passive subjects [8-10]. In this review, we define an end user as an individual working in a desk-based office environment or communities such as the organization’s workforce as this population is the target (participants) in WHP studies and the population of interest in this scoping review. Furthermore, this scoping review acknowledged the involvement of relevant stakeholders, following the description provided by Leask et al [11] regarding stakeholders as individuals or groups that are interested or involved in the implementation of an intervention but not the direct end users. Example stakeholders in this scoping review context, but not an exhaustive list, may be family of desk-based office employees, employees not in administrative or desk-based roles within the company, office managers, and company owners. While all these stakeholders are not the specific end users, they have lived experience and knowledge of the workplace and the end users and the ability to inform the design of a relevant, feasible, and acceptable WHP intervention from a stakeholder perspective and facilitate or support changes in the workplace culture, practices, and policy.

To shift research away from top-down “one size fits all” interventions, researchers have begun to take a participatory research (PR) approach to conducting studies. PR incorporates the knowledge and expertise of the end users and relevant stakeholders, thereby increasing the relevance of the research [6,12], and was described by Jagosh et al [10] as the coconstruction of research among people affected by the issues under study and researchers, stakeholders, and decision makers who have the capacity to apply the research findings. Therefore, PR allows for the tailoring of interventions by incorporating the relevant end users and stakeholders within the research process, which has been shown to promote a sense of ownership and aid the acceptability of the research when implemented, if conducted well [6,13]. When a participatory approach is not taken, research has shown that the WHP study may lead to an intervention approach, concept, or format that is inappropriate [14].

Previous research has suggested that the workplace is an ideal and valuable setting for the delivery of preventative health interventions when targeting adults, both healthy and especially those at increased risk of developing chronic diseases [15-17]. Earlier WHP interventions have targeted different aspects of the workplace environment, commuting habits, work schedules or implemented behavior change strategies to increase PA or reduce SB. However, studies targeting behavior change that did not take a PR approach have been shown to be weaker in intervention design [18] as it has been demonstrated to be beneficial for the investigating research team to acquire an understanding of the influences on the targeted behavior in the context in which they occur [19]. For example, in the workplace setting, a manager is an important stakeholder and can provide insights into the acceptability and feasibility of potential intervention strategies [20].

A research priority in WHP interventions is to create a sustainable WHP program after the completion of the study and researcher involvement [21]. Furthermore, maintaining end user adherence throughout the WHP intervention can be difficult, with documented high rates of attrition shown in previous WHP studies [21]. For instance, participants who are highly sedentary before an intervention are likely to return to their previous levels of SB due to increasing work pressures [2]. Including end users and relevant stakeholders with the aim of collaboration, education, and community action can promote active ownership of the research process and sustainability [8,22,23].
PR is a distinctive approach to research and not a particular research method that aims to distribute equitably the power between the research team and the research participants [24]. Therefore, PR is not a research method in and of itself and can take multiple forms and use varying methodologies, methods, processes, and tools [25]. When taking a PR approach, end user and stakeholder involvement can vary in intensity at distinct phases of an intervention (eg, conception, planning, conduct, evaluation, reporting, and dissemination). Conventional research methods such as focus groups and surveys can be adapted and applied in a participatory way, and therefore, any method, tool, or activity can be participatory if chosen or used collaboratively among end users, relevant stakeholders, and their academic partners [25]. The level of end user involvement in selecting, adapting, and implementing a method, process, activity, or tool could be considered more important than the method or technique itself in terms of impact on the WHP intervention. This is supported by Andersson [26], who identified that the quality and impact of the research can increase when end users are involved early in the research process, and reinforced by Vaughn and Jacquez [25], who stated that the level of participation is closely tied to the impact that research will have in real-world settings. The level of participation and power shared between researchers and end users can vary, and when power is not shared between the end user and academic partner in the decision-making process, the research cannot truly be “participatory” [8]. Arnstein [27] states that there is a crucial difference between going through an empty ritual of participation and end users being provided with the real power needed to affect the outcome of the process.

Several systematic reviews and meta-analyses have investigated workplace interventions that were designed to improve PA [21,28-30] or reduce SB within the workplace [31]. These reviews have reported positive overall benefits and that workplace interventions are generally effective in improving PA or reducing SB. However, previous systematic reviews investigating PA WHP studies have stated that the evidence is inconclusive [21,32] and called for more research into the elements of WHP studies that are likely to increase adoption and efficacy within the occupational setting [21]. Previous literature has shown that a PR approach can increase efficacy and lead to successful implementation and greater adherence in health promotion studies [13,18,22]. Thus, this scoping review provides evidence on the use of PR in WHP studies that may lead to greater adoption of PR and success of WHP interventions.

Rationale
To the authors’ knowledge, the use of PR in WHP studies has not been synthesized, and by examining how PR is currently incorporated within WHP research, we can identify the current available evidence, key approaches and methods, and the scope of reported impacts of PR, thereby providing an overview and identifying key characteristics of the current research that has used PR in WHP interventions aimed at increasing PA and reducing SB.

Objectives
This study had the following objectives: (1) to identify and map previous literature in which office-based adults have been involved in PR studies and how their involvement shaped the design of the WHP intervention, (2) to identify and discuss the methods implemented in the PR WHP studies, and (3) to discuss the evaluation and outcomes measured in the PR WHP studies included in the scoping review.

Research Question
How have previous PA WHP studies investigating office-based workers incorporated PR and the end user in their studies and to what reported benefit or detriment?

Methods
Protocol and Registration
An a priori protocol was published with BMJ Open and is available for this scoping review [33].

The reporting of this scoping review followed the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews). The PRISMA-ScR consists of a 22-item checklist [34]. The completed checklist for this scoping review can be found in Table S1 in Multimedia Appendix 1 [16,18,35-40].

This scoping review followed the guidelines and framework published previously by Levac et al [41], who expanded and developed the methodology for scoping reviews by Arksey and O’Malley [42], as planned in the published protocol [33]. This scoping review also followed the more recent methodological guidance published by Peters et al [43,44] for conducting and reporting scoping reviews.

Eligibility Criteria
In the planning of this scoping review, the research team a priori developed a population, intervention, comparison, and outcome (PICO) framework to assist in the development of the search strategy and the inclusion and exclusion criteria. The PICO framework, as previously published in the scoping review protocol [33], was as follows: the population was office-based working adults; the intervention was PA WHP interventions that used a PR approach; for comparison, we did not wish to compare interventions or treatments (this is typical in some PICO analysis frameworks, where a comparison is not always present); and the outcome was PA or SB levels.

Articles were screened for eligibility related to our inclusion and exclusion criteria (Textbox 1), excluding non–English-language articles.
Inclusion criteria
- Population: working adults in office environments
- Language: English
- Years considered: January 1, 1995, to February 8, 2023
- Study focus: articles investigating workplace health promotion (WHP) in office-based workplaces that implemented participatory health research techniques that including a physical activity (PA) aspect to the intervention study, for example, increasing PA or decreasing sedentary behavior (SB) using steps or walking, breaks in sitting, exercise, and yoga.
- Publication status: published peer-reviewed journal articles and relevant gray literature, which was defined within this scoping review as theses or dissertations, conference papers, research and government reports, ongoing research, editorials, and textbooks.

Exclusion criteria
- Population: home-based "office" workers
- Language: studies written in a language other than English
- Years considered: studies published before January 1, 1995, or after February 8, 2023
- Study focus: studies conducted within the workplace with the aim of improving health; studies based in the community or home and not in the office environment; and health promotion (HP) interventions measuring and targeting psychological or work performance improvements and not measuring or reporting on PA or SB.
- Publication status: any other literature that was not listed in the inclusion criteria, such as websites

Rationale
- Population: the focus of this scoping review was to investigate participatory research (PR) in WHP studies in office-based participants and workplaces. Children, teenagers, and retired adults would not fit our eligibility criteria of “working adults.” Non-office workers and home-based workers may have different “health” needs related to the working environment.
- Language: the reviewers only speak English, and feasibility considerations (eg, limited resources) prevented the use of translation services.
- Years considered: a wide period was established to capture all relevant WHP research. The years considered were cut off at 1995 as this is when guidance was published by Green et al [45] for the development of PR in HP and, therefore, implemented into research practices following this year.
- Study focus: the focus of the overall research question of this scoping review was specific to PR in WHP research in office-based workplaces. Other work-based environments may carry different health-associated risks, priorities, or safety concerns, which would not be comparable to those of an office-based environment. Including PA or SB as outcome measures would allow for an evaluation of the included studies and a discussion on the effectiveness of taking a PR approach in those WHP studies. We excluded studies that did not measure or reported PA or SB and included those that did to address our research question as these outcome variables were the primary outcome variables of interest. Of the included studies, those that reported further outcome variables such as psychological well-being, diet, or work performance were eligible and included; however, we did not report or discuss these additional outcome variables in this scoping review as they were outside the scope.
- Publication status: the aim of this scoping review was to capture a wide range of literature, so including gray literature ensured a more complete search and minimized publication bias.

Data Sources, Searches, and Study Selection
A total of 5 electronic databases was systematically searched by 2 independent reviewers (AJB and CKL). These databases were Web of Science, PubMed, Scopus, Google Scholar, and OpenGrey. The full electronic search strategy for each database was previously published with the protocol [33].

The first search was executed on January 17, 2022, retrieving articles between this date and January 1, 1995. This criterion was used for all the included databases. These years were considered as part of our inclusion and exclusion criteria (Textbox 1). The second search to ensure all recent and relevant literature was retrieved was executed on February 8, 2023, retrieving articles between this date and January 17, 2022.

The retrieved articles were exported from the 5 electronic databases to EndNote (Clarivate Analytics), where duplicates were removed via the EndNote function and manually when a duplicate was missed by the software.

Following duplicate removal, retrieved articles were reviewed by 2 researchers independently (AJB and CKL); the retrieved articles were screened first by title and abstract based on the inclusion and exclusion criteria and then by full text. Any discrepancy between the 2 reviewers regarding eligibility was discussed until consensus was reached. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram was populated to show the number of articles retrieved, screened, and excluded (with reasons) before reaching our number of included studies (Figure 1).
A comprehensive evaluation of the retrieved articles was conducted, which involved an informal multistep iterative approach and screening system by the lead researcher (AJB) and second reviewer (CKL) assessing whether a retrieved study had taken a PR approach if the article met all other inclusion criteria. The first step or indication that both reviewers would try to identify when screening a retrieved article was the keyword “participatory” or a related synonym; when this keyword (“participatory”) or related synonyms were not present, the reviewers would search for words such as “co-design,” “co-development,” and “co-produced.” If these words were still not present within a retrieved manuscript, a search would be conducted for key terms such as “end user,” “stakeholder,” “manager,” and “volunteer.” Finally, a further screening of the
retrieved articles would then be conducted looking for specific nuances or characteristics of PR, such as focus groups, surveys, meetings or community boards, panels, or groups that were conducted or mentioned to be formed in the retrieved article with the objective of designing, tailoring, or facilitating an intervention. If none of the aforementioned key terms or characteristics of PR were present within a retrieved manuscript, the study was excluded.

No in-depth assessment of whether a study was participatory was completed during the screening phase. For example, studies did not need to meet certain requirements to be considered participatory. However, the level of participation was examined during data extraction and when writing the narrative synthesis of all the included studies in this scoping review.

Data Extraction and Charting Process
Data from the included studies were charted independently by one reviewer (AJB). The second reviewer (CKL) charted 2 randomly selected articles independently to duplicate and confirm the data charting process. It was previously proposed that the second reviewer would independently duplicate 10% of the included articles [29]; due to <10 articles being included, 2 articles were deemed more than the agreed upon 10% and sufficient for confirming the data charting process.

Data were extracted and charted using a Microsoft Excel (Microsoft Corp) sheet table. The Microsoft Excel table had been piloted by the research team and peer reviewed during publication of the scoping review protocol.

Data Items
When charting the data from the included studies, we sought to retrieve, extract, and chart information on variables such as study design, study purpose and aims, PR approach taken, whether oversight was included and whether this oversight was a participatory group or researcher oversight, level of involvement from end users and stakeholders throughout the study, intervention focus, data collection methods, study outcomes (primarily related to PA and SB), data analysis, and whether the studies self-evaluated the PR techniques they implemented. Further information on each of the data items described has been provided within the published protocol of this scoping review [33]. These data items were the headings used in the data extraction and charting process. Each data item had an associated question that was used to retrieve and chart the extracted information from the included articles.

Data Synthesis and Analysis
As is a standard approach when conducting scoping reviews [41,42,46], a critical appraisal of the included studies or data was not conducted. This was decided a priori, as documented in the study protocol [33].

Synthesis of Results
Following data extraction and charting, we summarized our findings via a narrative synthesis, providing a descriptive summary of the included studies and charted data. A qualitative thematic analysis was conducted using Microsoft Excel according to the approach published by Bree and Gallagher [47] and following the guidance of Braun and Clarke [48,49].

The studies were evaluated based on the degree of participation and power shared with end users when making important decisions with the public, end users, and relevant stakeholders from nonparticipation to tokenism to citizen power using the ladder of citizen participation by Arnstein [27], which is an 8-rung ladder. There are 2 rungs (manipulation and therapy) categorized under nonparticipation, 3 rungs (informing, consultation, and placation) that fall within tokenism, and 3 rungs (partnership, delegated power, and citizen control) that form citizen power [27]. Therefore, the ladder by Arnstein [27] allowed the authors to distinguish and compare the level of participation and access to power in the included studies [30]. Each of the 8 different rungs of the ladder relates directly to the extent to which end users have attained decision-making power, with the highest rung signifying complete citizen control [51].

Data from the included studies were charted independently by one reviewer (AJB). The second reviewer (CKL) charted 2 randomly selected articles independently to duplicate and confirm the data charting process. It was previously proposed that the second reviewer would independently duplicate 10% of the included articles [29]; due to <10 articles being included, 2 articles were deemed more than the agreed upon 10% and sufficient for confirming the data charting process.

Data were extracted and charted using a Microsoft Excel (Microsoft Corp) sheet table. The Microsoft Excel table had been piloted by the research team and peer reviewed during publication of the scoping review protocol.

Data Items
When charting the data from the included studies, we sought to retrieve, extract, and chart information on variables such as study design, study purpose and aims, PR approach taken, whether oversight was included and whether this oversight was a participatory group or researcher oversight, level of involvement from end users and stakeholders throughout the study, intervention focus, data collection methods, study outcomes (primarily related to PA and SB), data analysis, and whether the studies self-evaluated the PR techniques they implemented. Further information on each of the data items described has been provided within the published protocol of this scoping review [33]. Each data item had an associated question that was used to retrieve and chart the extracted information from the included articles.

Data Synthesis and Analysis
As is a standard approach when conducting scoping reviews [41,42,46], a critical appraisal of the included studies or data was not conducted. This was decided a priori, as documented in the study protocol [33].

Synthesis of Results
Following data extraction and charting, we summarized our findings via a narrative synthesis, providing a descriptive summary of the included studies and charted data. A qualitative thematic analysis was conducted using Microsoft Excel according to the approach published by Bree and Gallagher [47] and following the guidance of Braun and Clarke [48,49].
Results

Study Selection

The systematic search strategy of 5 electronic databases identified 297 articles upon first search and an additional 79 articles with the updated second search, totaling 376 articles. Following the screening process of all eligible articles, which was conducted independently by 2 reviewers (AJB and CKL), of the 376 studies, 8 (2.1%) met the inclusion criteria (Figure 1). Of the 8 included studies, 2 (25%) provided additional reports, one in the form of a study protocol [52] and the second in the form of a second manuscript reporting findings obtained from the same study [53]; however, these reports were combined and only discussed as the manuscript retrieved and included via the search strategy, and therefore only 8 studies will be referred to.

Study Characteristics

A total of 38% (3/8) of the included studies were pilot studies [35-37] that did not randomize participants and used a pretest-posttest [35,36] or a posteriori quasi-experimental study design [37], whereas 50% (4/8) were cluster-randomized trials [16,18,38,39]. The final study had a longitudinal pretest-posttest study design [40]. In total, 38% (3/8) of the studies took a mixed methods research approach collecting and analyzing both quantitative and qualitative data in the same study [35-37,40]. The duration of the studies ranged from 3 weeks [36] to 18 months [40]. The sample size ranged from 5 [36] to 585 [16] across the included studies, and they were conducted in various countries, such as the United Kingdom [35,36], Australia [18,37], China [38,39], Sweden [40], and Singapore [16]. One of the included studies sampled women only [16], whereas the rest were mixed-sex studies [18,35-40]. Participants’ occupations varied across the included studies, and they were based in large IT organizations [38], telecommunications organizations (administrative and clerical workers) [37], government organizations (clerical, data entry, and call center office workers) [18], and workplaces in sectors or industries that were primarily office based and sedentary in nature (government administration and finance departments) [16]. Some participants were office workers in desk-based occupations (education or research, administration, human resources, accountancy, sales, and IT) [36]; worked within a department in an academic institution (university) [35]; and were part of a singular organization that serviced a municipality with 56,000 inhabitants and carried out assignments such as running and developing schools, providing social services, and conducting urban planning [40]. The final study did not provide specific occupations but stated that the included worksites were located in the Yangtze River Delta in China and comprised primarily desk-based occupations [39]. Further study characteristics can be found in Table 1, and the intervention components and reported outcome variables can be found in Table S2 in Multimedia Appendix 1.

Synthesis of Results

Overview

In this section, we provide a narrative synthesis that focuses on how participants, end users, and relevant stakeholders of the included studies were involved in the WHP studies and how their involvement shaped the design of the WHP intervention. This narrative synthesis was guided by a thematic analysis that identified themes related to how end users, stakeholders, and researchers were involved in the research process when taking a PR approach and what role they played (Table 2). Further information on the PR methods implemented in the included studies, including how they engaged end users and relevant stakeholders, the number and duration of any meetings and activities, how many end users and stakeholders were involved in the PR method or methods, and the content and agenda of any meetings or activities when engaging with the end users and relevant stakeholders, can be found in Table S2 in Multimedia Appendix 1.
Table 2. Components of the thematic analysis of end user, stakeholder, and researcher involvement in the participatory research process and overall conduct of the study. The table highlights primary themes and subthemes and provides a description of each theme with supporting illustrative quotes with references.

</tr>
</tbody>
</table>
This subtheme describes how the managers acted as gatekeepers to the workplace and were used to pass information or study materials from the research team to the participants and workplace.

**Subtheme 2.3: management leading in data collection and setting up intervention components**

This subtheme describes how individuals with managerial roles assisted with data collection and study design and provided support throughout the study.

**Subtheme 2.4: invitation from the management or workplace**

This subtheme describes how invitations to participate in the development of the WHP study were sent via the workplace itself rather than through the research team.

**Theme 3: researcher facilitator**

This theme describes how the research team or lead research facilitator would communicate with team leaders or managers to help with the facilitation of the WHP intervention.

**Theme 4: workplace champions, health inspirers, team leaders, and health strategists**

This theme describes how the studies recruited participants from the workplace for elevated positions within the study to lead by example or provide more in-depth insights when codeveloping components of the WHP study.

**Subtheme 4.1: involved in intervention or implementation delivery or provision of support in increasing PA**

This subtheme describes how participants, managers, workplace champions, health inspirers, team leaders, or health strategists, and stakeholders were involved in the delivery of the intervention and supported WHP and increasing participants’ PA.

---

To evaluate the level of involvement and power shared with the end users and relevant stakeholders in the WHP studies, we used the ladder of citizen participation by Arnstein [27].

**Level of Participation (Ladder of Citizen Participation)**

In this scoping review, we aimed to evaluate the role and level of participation that the end users and stakeholders had in three aspects of the included studies: (1) the conception of the WHP study and intervention, (2) the data collection, and (3) the analysis and reporting of the included studies, as documented a priori in our published protocol [33].

**Conception**

When evaluating the included studies and the degree of participation and power shared with their participants within the conception and design of the WHP studies, 25% (2/8) of the studies were deemed as nonparticipation [38,40]. The studies by Blake et al [38] and Wahlström et al [40] were deemed to be nonparticipation as they stated the following:

---

**a**WHP: workplace health promotion.

**b**Not applicable.

**c**PA: physical activity.

**d**SB: sedentary behavior.
A total of 25% (2/8) of the included studies [16,37] were determined to be tokenistic in how they involved the participants and relevant stakeholders when conceiving and designing their WHP interventions. Gilson et al [37] described that, as researchers, they reached a consensus from the ideas generated by the workers regarding the design and number of strategies in the WHP study. While Tan et al [16] held workshops and participants self-selected their own intervention activities, the individually tailored strategies still needed to meet the prescribed 5 to 10 minutes of exercise breaks as designated by the research team. This level of involvement of the end users could be seen as “consultation” or “placation” on the ladder of citizen participation by Arnstein [27] as the researchers retained the right to judge the end users’ ideas and advice.

In total, 50% (4/8) of the studies were evaluated and determined to have provided citizen power, where the participants discussed and developed the WHP intervention and the planning and decision-making were shared between the researchers and the participants [18,35,36,39]. While the level of participation in 75% (3/4) of these studies was evaluated as “citizen power,” their level of participation was found to be at the lowest rung under “citizen power” of the ladder by Arnstein [27]. They were determined to be at the “partnership” rung as the researcher facilitated the discussions and communicated with team leaders and management concerning the implementation of the WHP study [18]. Kong et al [39] described the intervention as a community-based participation intervention where community (worksite) employees and researchers engaged as equals in a cooperative process; however, the power shared was not clearly documented, and the statement was merely cited as what a community-based participation intervention is, referencing Minkler and Wallerstein [54]. Kong et al [39] did state that they formed employee advisory boards (consisting of 4 to 7 employees), which were established in each worksite from all occupational sectors to “...work closely with the research team to design and implement intervention activities,” whereas Griffiths et al [36] described a “...compromise between the stakeholder input and researchers’ evidence-focused approach” and, furthermore, that they “...were able to include the participants views and opinions within the intervention design.” Finally, Mackenzie et al [35] held a brainstorming session with participants, who identified the strategies to reduce workplace sitting in the WHP study.

Data Collection and Data Analysis and Reporting

When originally planning and proposing our evaluation of the included studies, we had stated that we would evaluate whether participants and stakeholders were involved in data collection and the data analysis and reporting of the study. Upon extracting and charting the data from the included studies, we found that none of the studies included participants or stakeholders within the data collection, analysis, or reporting process. However, participants were included and took part in facilitating and implementing the intervention, and therefore, we retrospectively included a narrative synthesis on how participants were involved in the facilitation of the WHP study.

Facilitation of the Included WHP Studies

The larger components of the WHP interventions can be found in Table S3 in Multimedia Appendix 1. In this section, we provide a narrative synthesis on how end users and stakeholders assisted in facilitating the WHP studies. In this scoping review, the authors use the term “facilitation” to describe methods and processes that are active components of implementation, where individuals, end users, and stakeholders who are defined as facilitators enable and influence the implementation process [55].

One study provided no indication or description of end users assisting with the facilitation [36]. In total, 38% (3/8) of the studies enlisted the workplaces’ assistance in recruiting participants to the study [16,37,38]. Tan et al [16] enlisted their workplace coordinators to facilitate within-cluster recruitment to the study. The workplace coordinators were provided with resources by the research team to aid this recruitment, whereas managers were directly involved and facilitated recruitment by distributing recruitment emails to their administrative and clerical workers in the workplace study conducted by Gilson et al [37]. Management involvement was evident in the remaining 50% (4/8) of the WHP studies [18,35,38,40]. This management involvement ranged from emails [35] to introduce, support, and carry forward the intervention [35] to distributing questionnaires supporting and inspiring a healthy lifestyle, and management was asked to discuss and disseminate messages from the WHP campaigns at workplace meetings [40]. Blake et al [38] described the most involvement from managers, who delivered 30-minute orientations to team leaders on the WHP intervention to demonstrate senior management commitment, with the senior manager randomizing the 2 sites and being involved in the design and development of promotional posters and exercise videos. The management team also provided technical support, including the development and installation of a pop-up window system and web-based exercise log recording system [38]. Though not directly management involvement, the health resources department was responsible for inviting all employees from the worksite to participate in the study via their company intranet web page [38]. Whereas management involvement was not clearly described by Parry et al [18], other than “helped with implementation”.

The most frequent component of facilitation was the empowerment of employees in roles such as workplace champions. This term differed among the studies, with other titles used such as “team leaders” [16,38], and “health inspirers” [18]. Blake et al [38] asked their workplace champions to lead group exercise classes at allocated times, and the champions were involved in the provision of support for PA. This was similarly asked of the workplace champions in the WHP study by Mackenzie et al [35], who asked workplace champions to promote standing and walking meetings or sessions as well as incidental walking (talking and not emailing) and support lunchtime walks. This was further evident in the study conducted
by Wahlström et al [40], who asked the health inspirers to assist with the development of the communication campaign and support and inspire coworkers in attaining a healthy lifestyle. Unfortunately, it was not clear to what extent workplace champions facilitated the study carried out by Parry et al [18] other than that they “helped implementation,” whereas the study by Kong et al [39] was the only one to form an employee advisory board that worked closely to design and implement intervention activities with the research team. However, the extent of involvement of the end users, management, or relevant stakeholders in the implementation of all the intervention activities compared to the research team was not clearly indicated in the study [39], but it was stated that the employees voluntarily set up several exercise teams that monitored and attempted to improve their daily behaviors by recording their daily exercise and reminding each other to exercise daily. These exercise teams would meet regularly to exercise at an agreed time and place together [39].

The final forms of facilitation that we observed in the included studies had to do with the marketing of the interventions. Blake et al [38] formed an organizational committee made up of 2 team leaders and 2 human resources officers, who developed and implemented company policy on the internal marketing of the intervention. In the study by Wahlström et al [40], the organization’s communication department and the internal health strategist distributed all materials via posters, tabletops in meetings, and breakout spaces, along with posts on the workplace intranet.

Impact on PA and SB Levels
Of the 8 included studies, 1 (12%) [35] did not report PA as an outcome variable, but the remaining 7 (88%) studies did so in varying formats and across different intensities. Overall, 86% (6/7) of the studies did report an increase in PA, whereas Griffiths et al [36], who only measured and reported moderate to vigorous PA, found no change in their 2-week pilot study with 5 participants.

When investigating SB, 62% (5/8) of the included studies reported a measure of SB as an outcome variable. A total of 38% (3/5) of the studies reported a reduction in SB, whereas 12% (1/8) of the studies [40] reported no change in sitting time and 12% (1/8) [38] reported an increase in SB. Although Blake et al [38] reported an increase in SB, they did report a significantly lower increase in SB in the intervention group than in the control group.

When reporting the physical behavior outcomes, most studies (5/8, 62%) reported PA or SB during work hours, during which the intervention took place [18,35-37,40], whereas 25% (2/8) of the studies reported PA [16,38] and SB [38] as minutes or hours per week as the intervention could be continued outside of work hours. Furthermore, 12% (1/8) of the studies provided measures of PA daily (steps) and over a week (walking days per week) [39]. Finally, Parry et al [18] reported the physical behaviors as a percentage of accelerometer wear time for work hours and over the workday, and Mackenzie et al [35] provided the SB data during work hours in total and split into morning and afternoon.

The intervention outcomes reported in the included studies related to PA and SB are further outlined in Table S3 in Multimedia Appendix 1.

Reported Benefits of Taking a PR Approach
Many of the included studies (5/8, 62%) provided some context and evaluated how taking a PR approach benefited or hindered the research process and alluded to barriers that were experienced by the participants or researchers. In total, 25% (2/8) of the studies stated that the PR approach used was the key component to the success of the WHP intervention [18,38], whereas 38% (3/8) of the studies stated that taking a PR approach benefited the development of the intervention [18,35,36]. The authors noted that taking a PR approach and including the participants’ views and opinions ensured that the interventions were suitable to the workplace surrounding and, therefore, more likely to be acceptable and feasible for employees [18,35,36]. Mackenzie et al [35] hailed the PR approach for allowing for the development of a “real-world” pragmatic intervention. This point was expanded on further by Griffiths et al [36], who stated that the development group allowed for discussions and refinement of the initial intervention concept, which resulted in an agreed upon evidence-based intervention that was deemed feasible and acceptable by the stakeholders.

Some further benefits of the participatory approach were noted. These were awareness of the intervention [35] and increased communication about PA, suggesting that the information reached the workforce [40]. Managers’ behavior was noted as a motivating factor for employees to sit less and move more [40], and peer support was also identified as an important facilitator of intervention adoption [38]. Participants expressed that they had positive experiences about senior management as they offered great organizational support for the duration of the project and designed and developed the study’s promotional posters, which were regarded as high quality [38].

Reported Barriers of Taking a PR Approach
Despite the several benefits highlighted by the included studies, some barriers were also noted, such as lack of peer support, which reduced engagement [38]; lack of support from management and team leaders [18,38]; and lack of awareness of the intervention components (i.e., workplace champions and Twitter updates) rendering them unhelpful to the participants [35]. Furthermore, Parry et al [18] reported limited success in changing the organizational culture in workplaces even when management and participants were aware of the intervention options, leading to suggestions of stronger external support, such as guidelines.

Griffiths et al [36] presented and reported barriers when taking a PR approach. These were (1) inconsistent stakeholder attendance, which reduced stakeholder input in discussions at meetings; (2) conducting focus group meetings on the web rather than in person as this was thought to lose some of the possible interaction among stakeholders; (3) the fact that attempting to align the research with reality required compromise from both the stakeholders and research team, which did not guarantee resolution for all stakeholders; and (4)
the fact that having a small sample from a few different organizations in the development group and piloting of the intervention facilitated more in-depth discussion and greater input from participants but that whether the intervention translated to other organizations and, subsequently, its applicability and adherence were unknown [36].

A total of 38% (3/8) of the included studies did not evaluate how the PR approach may have benefited or hindered the WHP intervention or its outcomes [16,37,39].

**Discussion**

**Summary of Evidence: End User Engagement**

This scoping review addressed the research question and objectives, which were to identify and understand how previous WHP studies implemented PR with desk-based office workers. The systematic search retrieved 8 studies that met our inclusion criteria. Overall, there is evidence suggesting that taking a PR approach is beneficial to the development of a WHP intervention [18,35,36] and a key component of its success [18,38]. The main reasons cited in the included studies were that, by taking a PR approach, the participants’ opinions and lived experiences were included, which ensured that the intervention was suitable for the workplace and, ultimately, feasible and acceptable to the end users and relevant stakeholders [18,35,36].

A defining characteristic of PR is the degree of engagement and power shared with the end users during the different stages of the research process and decision-making more so than the methods and techniques used [8,56]. A key finding from this scoping review was that, among the 8 identified WHP studies that incorporated end users, the inclusion of the participants ended at the conception of the WHP intervention, with 2 (25%) studies not involving the end users or stakeholders in their conception and only in assisting with the implementation and facilitation of the study [38,40]. An important point to highlight is that, while we use the term conception of the WHP intervention, there was a distinct lack of engagement of end users in the conception of the overall study (ie, none of the included studies commenced due to an end user highlighting their occupational physical behaviors as a health priority and seeking an academic partner). In fact, all the included studies commenced with an academic institute or partner approaching an organization or organizations and recruiting participants and end users to the study before then developing the WHP intervention in collaboration with the end users and relevant stakeholders at varying levels of involvement and shared decision-making. In PR, the research problem should ideally originate from the community or end users [24]; however, in reality, we find that most PR projects are in fact initiated by researchers. Therefore, participatory processes are actively applied to shift ownership and control of the research process toward the end user community [57]. This leads to a more equitable and democratized decision-making process to facilitate the shift in knowledge leadership and support community ownership of the research process and developed intervention [57].

The degree of engagement and power that was shared with end users was evaluated to be low, with 25% (2/8) of the studies determined to be nonparticipation studies [38,40] and 25% (2/8) determined to be tokenistic in how the end users were involved in conceiving and designing the WHP studies [15-34,41-49]. This finding is similar to that of another identified review, which investigated studies that took a participatory action research approach to promote mental health and resilience in youth and adolescents [58]. Raanaas et al [58] identified a distinct lack of authentic involvement of the end users in their included studies, which is similar to our own included studies, with only 38% (3/8) of the studies determined to have provided citizen power at the lowest rung (‘partnership’) [18,35,36]. The similarities, despite the differences in population and outcome measures, can largely be attributed to the PR approach taken by the researchers and the power they shared with the end users.

The evaluation of the included studies via the ladder by Arnstien [27] placed an important emphasis on the level of involvement and shared decision-making, so the evaluation and final “labeling” of the included studies was not impacted by the lack of involvement in the later stages of the research process (data collection, analysis and reporting, and dissemination). However, the evaluation and, therefore, “labeling” was influenced by how the participants were involved in the development of the subsequent WHP intervention, with the included studies labeled as nonparticipatory stating that the research team developed the study without involvement of the end users or relevant stakeholders [38,40] and 25% (2/8) of the studies being labeled as tokenistic as evidenced by the research team tailoring the intervention components to the end users but retaining the overall decision-making power by (1) reaching a consensus from ideas generated by the workers [37] and (2) having a fixed prescribed exercise break of 5 to 10 minutes, which was instructed by the research team [16]. Therefore, 50% (4/8) of the studies demonstrated a lower level of involvement and shared decision-making, as opposed to the 50% (4/8) of the studies that were determined to provide citizen power, which noted a compromise or generated all ideas with the end users. Instead of excluding, tailoring, or retaining the right to draw the conclusions from a consensus of end users’ lived experience.

A goal in PR is that end users should “own” the research process [8], but in this review, we identified a glaring lack of end user involvement in the overall research process. When using the phrase “own the research,” the authors of this scoping review refer to the shift in knowledge leadership and influence from the researcher or academic institute to the community or workplace, which then has ownership and self-determination over the research process and subsequent intervention or interventions [57]. None of the included studies included engagement strategies such as creating a stakeholder board (beyond an advisory board) or council or involving end users as coresearchers in data analysis or research dissemination. These findings are bleak and identify an issue in this emerging field of PR in office-based WHP. One potential reason for the lack of authentic involvement observed in this review may be that 38% (3/8) of the studies were pilots [35-37]. However, authentic involvement was also absent in the remaining 62% (5/8) of the studies, and therefore, future research should strive...
to move beyond using PR to tailor and implement an intervention toward involving end users in the entire research process.

Summary of Evidence: Methods of Involving the End Users and Relevant Stakeholders

In this scoping review, we aimed to discuss how end users and relevant stakeholders were involved and how the participants’ involvement shaped the design of the WHP intervention. To address this aim, we conducted a thematic analysis and charted extracted data on the methods of PR (Table S2 in Multimedia Appendix 1). When conducting the thematic analysis to examine the role of the end users and the level of involvement in the coproduction of the WHP studies, we identified 4 primary themes. The four themes were (1) participant workshops, focus groups, meetings, or brainstorming sessions; (2) manager or management involvement; (3) researcher facilitator; and (4) workplace champions, health inspirers, team leaders, or health strategists. These themes can be compared to the set of themes identified in a previous broader review of end user involvement strategies [59].

The key findings from the thematic analysis in relation to the methods of involving end users were that the included studies invited end users to attend an initial focus group meeting where they were asked to provide their opinions and personal experiences in relation to designing or evaluating a WHP intervention. These focus group meetings were often cited as the conception of strategies that formed or were implemented alongside the WHP intervention. However, this was also often the end of the end user involvement, meaning that the focus groups may have been conducted in a tokenistic manner or tick-box exercise for an intervention that had already been largely planned. Focus groups in and of themselves do not constitute participatory engagement but are simply another form of data collection, which Arnstein [27] rates as tokenistic consultation. One of the included studies noted that compromises were made by the research team, suggesting that power was shared in the decision-making and development of the WHP intervention [36].

Another key finding from the thematic analysis and evaluation of the end users’ level of participation was the use of elevated positions that were created by the research team in the included studies, such as “team leaders,” “health inspirers,” and “workplace champions.” These elevated positions were created and asked end users to take on these positions and lead by example, support, and facilitate the delivery of different intervention components and in some cases provide more in-depth insights or participate in the codevelopment of intervention components [40]. However, barring the latter point, the use of elevated positions is not uncommon in nonparticipatory interventions, which may use members of a research team, intervention facilitators, or participants to assist in the facilitation of an intervention. Whereas a benefit of taking a PR approach is that end users in these elevated positions will remain engaged upon completion of the study and researcher involvement. Thus, these end users in elevated positions have an increased capacity to continue supporting behavior change within the community or workplace.

It is important to note that the lack of reporting on the PR approaches taken in the included studies restricts the conclusions that can be drawn as to whether the end users involved in the conception of the intervention were involved as the intervention facilitators. In some of the included studies (2/8, 25%), it was evident that other or additional employees and not solely the end users involved in intervention design were asked to be the intervention facilitators [38,39]. The potential impact of this is unknown regarding whether it would be a benefit or detriment to the facilitation of the intervention components. The reasons for this were not reported in the included studies but may be related to end user burden, to the end user involved in the PR approach not being an eligible participant, or to increased intervention facilitators being needed when the intervention is rolled out across a large workplace compared to the number of individuals (end users and stakeholders) involved during the commencement of the PR approach and conceptualization.

Summary of Evidence: Effect of PR WHP Interventions on PA and SB

An objective of this scoping review was to discuss the evaluation and outcomes of the included studies. Overall, the PR approach was shown to increases PA in 86% (6/7) and decrease SB in 60% (3/5) of the studies that measured these outcome variables, respectively. These changes were typically reported during occupational hours, which is when the interventions were generally prescribed. Only 12% (1/8) of the studies noted an increase in SB; however, the increase in the intervention group was significantly lower than the increase in the control group, suggesting that the PR approach may have blunted the increase in SB, whereas the final study that investigated SB noted no change. Caution should be taken when interpreting these findings as 38% (3/8) of the included studies [35-37] were pilot studies with no control comparator groups and small sample sizes (ie, not powered to detect a change in physical behavior [PA or SB]). However, the findings of this scoping review and of the included studies do suggest that PR should be investigated further as a research approach within health research due to the numerous benefits identified and the positive results observed overall.

Implications

The included studies and this scoping review provide insights into how PR has been incorporated in office-based PA WHP studies by reporting and evaluating the methods, the degree of engagement and power shared with end users, and the barriers to and benefits of taking a PR approach in the workplace setting. This review identified a lack of authentic and meaningful involvement of the end user, where they were asked to provide input to tailor an intervention but were not provided with the opportunity to “own” the research process. Future research should move beyond piloting PR in WHP interventions and start from the workplace to actively collaborate, identifying the end users’ priorities and developing or tailoring an intervention collaboratively with them to address their priorities. Further recommendations would be to (1) include end users in the published articles, presentations, and reports; and (2) build capacity within the workplace with a stakeholder board, management, or workplace champions that empower the end
users and create a sustainable WHP intervention after researcher involvement. (3) A key recommendation for future WHP studies or any study that wishes to take a PR approach would be to allow adequate time for the coconstruction or collaboration to occur and opportunity for decision-making to be shared and, therefore, for trust to be built [60] between the community or workplace and the research team. Some of the included studies (2/8, 25%) conducted a single “participatory” event, workshop, or focus group, which was often done in a tokenistic manner and to tailor a planned intervention from academia and not from the community. Ultimately, the act of conducting a single “participatory meeting” means that the researchers retain the power or ownership of the research process and decision-making of the research project and do not provide an equitable environment. Researchers should step outside the “normal” confines of research and share power and resources and develop capacity within their relevant community and end users to allow them to appropriately engage in all stages of the research process. This could be in the form of a larger number of participatory workshops (≥3 meetings), earlier engagement with end users to help conceptualize a suitable intervention that addresses their identified health priorities, and training and involvement in all aspects of the research process to increase the capacity of the included end users. These recommendations may facilitate the shift in knowledge leadership and encourage the sharing of power and movement toward end user ownership and self-determination over the research process and subsequent intervention or interventions.

Limitations
While this is the first scoping review to examine how PR is being incorporated in PA WHP studies in desk-based adults working in offices, in which we identified a multitude of common traits regarding how participants and the end users were involved, some limitations should be considered. When evaluating the degree of participation and power shared between participants and researchers in the WHP studies, we used the ladder of citizen participation by Arnstein [27]. Although the ladder by Arnstein [27] is well regarded, our interpretation of the included studies relied solely on self-reported end user involvement details in published literature and associated documents. Reporting standards for patient and public involvement are generally not well followed [61]; therefore, we could only evaluate the studies based on limited reporting, which may have missed details of engagement and shared power. This echoes the limitation of Frankena et al [62], who conducted a structured literature review and found it difficult to evaluate from written text whether the inclusion of their relevant end users (people with intellectual disabilities) was meaningful or tokenistic. Frankena et al [62] stated that more information was often needed regarding the process of inclusion.

Conclusions
In conclusion, the findings from this scoping review provide a foundation of evidence for how PR is currently being implemented in office-based PA WHP studies. We observed that the end user is currently only incorporated in the conception and implementation of the WHP studies and that, largely, the studies were tokenistic or nonparticipative, whereas 50% (4/8) of the studies were evaluated to provide citizen power in the conception of the interventions. Overall, a benefit was observed with positive improvements in PA and reductions in SB across the studies, which was largely attributed to taking a PR approach and involving the end users, which allowed for the design of a WHP intervention that was feasible and acceptable. Future studies should aim to move beyond a pilot and feasibility trial and collaborate with the workplaces, building capacity and empowering the workforce by providing citizen control and letting the end users “own” the research for a sustainable WHP intervention after researcher involvement.

Acknowledgments
This scoping review was funded and supported by the Health Research Institute, University of Limerick, through a PhD Studentship Award. The included sources of evidence were obtained via open-source electronic databases, and the articles were accessed through the University of Limerick library database or open-access publications. The authors would like to acknowledge Liz Dore (Faculty of Education and Health Sciences librarian at the University of Limerick) for the assistance in developing the search string and adapting it for the different databases searched. Generative artificial intelligence was not used in any portion of the manuscript writing or editing process.

Data Availability
Data sharing is not applicable to this paper as no data sets were generated or analyzed during this study.

Authors’ Contributions
All authors made substantial intellectual contributions to the conduct of the scoping review and the development of this manuscript. AJB and JS conceptualized the review approach, and AJB conducted the search, screening of the retrieved articles, and data extraction and drafted the initial manuscript. CKL conducted the search of the electronic databases independently, screened the retrieved articles, and performed checking of the data extraction. BPC and AED contributed to the conceptualization of the review. CKL, BPC, AED, and JS contributed to the writing and editing of the manuscript.
Conflicts of Interest
None declared.

Multimedia Appendix 1
Participatory research methods, intervention components, and reported outcomes of the interventions in the included studies in relation to physical activity and sedentary behavior and completed PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) checklist.

Abstract

Background: The association between lifestyle risk factors and the risk of mortality and chronic diseases has been established, while limited research has explored the impact of healthy lifestyle factors on lifetime health care expenditure using longitudinal individual data.

Objective: We aimed to determine the individual and combined effects of 5 healthy lifestyle factors on life expectancy and lifetime health care expenditure in Taiwan.

Methods: Using data from the National Health Interview Survey cohort, 5 healthy lifestyle behaviors were defined and analyzed: nonsmoking, avoiding excessive alcohol consumption, engaging in sufficient physical activity, ensuring sufficient fruit and vegetable intake, and maintaining a normal weight. We used a rolling extrapolation algorithm that incorporated inverse probability of treatment weighting to estimate the life expectancy and lifetime health care expenditure of the study populations with and without healthy lifestyle factors.

Results: A total of 19,893 participants aged ≥30 (mean age 48.8, SD 13.4) years were included, with 3815 deaths recorded during a median follow-up period of 15.6 years. The life expectancy and per capita estimated lifetime health care expenditures for the overall study population were 35.32 years and US $58,560, respectively. Multivariable-adjusted hazard ratios for all-cause mortality in participants adhering to all 5 healthy lifestyle factors, compared with those adhering to none, were 0.37 (95% CI 0.27-0.49). We found significant increases in life expectancy for nonsmokers (2.31 years; 95% CI 0.04-5.13; P=0.03), those with sufficient physical activity (1.85 years; 95% CI 0.25-4.34; P=0.02), and those with adequate fruit and vegetable intake (3.25 years; 95% CI 1.29-6.81; P=0.01). In addition, nonsmokers experienced a significant reduction in annual health care expenditure (~9.78%; 95% CI ~46.53% to ~1.45%; P=0.03), as did individuals maintaining optimal body weight (~18.36%; 95% CI ~29.66% to ~8.57%; P=0.01). Overall, participants adhering to all 5 healthy lifestyle behaviors exhibited a life gain of 7.13 years (95% CI 4.43%-5.71%; P=0.02) compared with those adhering to one or none, with a life expectancy of 29.19 years (95% CI 25.45-33.62). Furthermore, individuals adopting all 5 healthy lifestyle factors experienced an average annual health care expenditure reduction of 28.12% (95% CI 4.43%-57.61%; P=0.02) compared with those adopting one or none.

Conclusions: Adopting a healthy lifestyle is associated with a longer life expectancy and a reduction of health care expenditure in Taiwanese adults. This contributes to a more comprehensive understanding of the impact of healthy lifestyle factors on the overall health and economic burden.

Introduction
Background
Accumulative epidemiologic studies have investigated the relationship between lifestyle factors and the risk of mortality and chronic diseases. These studies have explored both the individual and combined effects of various risk factors on health. A meta-analysis including 531,804 participants from 17 countries indicated that smoking, inactivity, poor diet quality, and heavy alcohol consumption contributed to approximately 60% of all premature deaths [1]. A healthy lifestyle, which is characterized by regular physical activity, normal weight, nonsmoking behavior, moderate alcohol consumption, and healthy diet intake, is associated with an increase in life expectancy (LE) [2-11], with studies reporting increases of 6.6 years for men and 8.1 years for women in Singapore [2]; 8.8 years for men and 8.1 years for women in China [3]; 10.3 years for men and 8.3 years for women in Japan [4]; 12.2 years for men and 14.0 years for women in the United States [5]; 16.8 years for men and 18.9 years for women in Canada [6]; and 7.4 to 15.7 years for 3 European cohorts (RCPH, ESTHER, and Tromsø) [7], indicating that the beneficial effects of a healthy lifestyle may vary across populations and countries. On the other hand, these healthy lifestyle factors have been found to be associated with an increase in disease-free LE as well [12-17].

In recent decades, a significant increase has been noted in the average LE worldwide. However, whether such improvements translate into an overall reduction in health care expenditures remains uncertain. Studies on the impact of a healthy lifestyle on health care costs have focused primarily on the effects of individual risk behavior [18-28]. A regression analysis revealed that a 10% relative decrease in the prevalence of smoking in the United States would lead to a reduction of approximately US $63 billion in health care costs in the year following this decrease [21]. Another study reported that excessive alcohol consumption results in an economic burden of US $223.5 billion in the United States, with 72.2% of this amount being attributable to lost productivity, 11% attributable to health care expenses, 9.4% attributable to criminal justice costs, and 7.5% attributable to other effects [22]. A systematic review recruited 19 cost-of-illness studies on obesity, identifying substantial economic burdens across countries, with direct medical costs ranging from 0.7% to 17.8% of health system expenditure and total costs ranging from 0.05% to 2.42% of the country’s gross domestic product [23]. Studies comparing the effects of obesity, overweight, smoking, and problem drinking on health care use and costs in the United States have indicated that obesity and overweight are associated with the highest health care costs [26,27]. However, these studies had cross-sectional designs and certain analytical limitations, such as problems related to the unit of observation used at the ecological level or the indirect estimation of risk attributable approach. To date, no study has investigated the impact of both individual and combined healthy lifestyle factors on lifetime health care expenditure based on longitudinal individual data.

Objectives
The objective of this study was to investigate the impact of both individual and combined healthy lifestyle factors on LE and lifetime health care expenditure in a contemporary population. Using a nationally representative cohort with over 19,000 participants, we have proposed a rolling extrapolation algorithm that incorporated inverse probability of treatment weighting (IPTW), which can adjust for the effects of potential confounders, to estimate the lifetime survival function for the study cohort. The lifetime survival functions were used to calculate the LE and lifetime health care expenditure for study populations with and without healthy lifestyle factors.

Methods
Study Design, Settings, and Population
A nationwide longitudinal cohort study was performed. We used data from the Taiwan National Health Interview Survey (NHIS) to define study cohorts with or without healthy lifestyle factors. Then, a rolling extrapolation algorithm was introduced to estimate the lifetime survival function of study cohorts [29]. The LE of a study cohort was calculated according to the corresponding extrapolated lifetime survival function. In addition, the total lifetime health care expenditures of a study cohort were estimated by integrating the product of the lifetime survival function and a medical cost function, which was calculated using reimbursement data obtained from Taiwan’s National Health Insurance Research Database (NHIRD) [29]. Finally, we estimated the effect of each healthy lifestyle factor (individual effects) and the combination of the individual effects (combined effects) on LE and lifetime health care expenditure. The study sample comprised individuals who participated in the Taiwan NHIS in 2001 and 2005, with household response rates of 91.1% and 80.6%, respectively. The NHIS is a cross-sectional survey, which adopted a multistage stratified sampling scheme to obtain a nationally representative sample of the Taiwanese population. For the NHIS, baseline data regarding individuals’ sociodemographic and behavioral factors were collected through in-person interviews. Details of the design and sampling scheme of the NHIS have been reported previously [30]. In this study, 27,631 participants aged ≥30 years were included. We excluded participants who refused to link their NHIS data to NHIRD records (n=5680); who had a missing value for smoking, alcohol consumption, BMI, physical activity, or healthy diet (n=1709); who had an extreme value of lifestyle factor (BMI >60 kg/m² or metabolic equivalent of task [MET] >10,000 min/wk; n=229); or who had missing covariate data (n=327). Finally, 19,893 participants were included in the analysis at baseline and were followed till the end of the study period (December 31, 2020) or death, which was confirmed using data from the vital registry of Taiwan (Figure 1). The reporting of this study adhered to the STROBE
Assessment of Healthy Lifestyle Factors

The following 5 lifestyle factors were analyzed in this study: smoking, alcohol consumption, BMI, leisure-time physical activity, and healthy diet (sufficient intake of fruit and vegetables). Information on lifestyle-related factors was collected from the NHIS data, which were collected through in-person interviews conducted at baseline. We categorized smoking status at baseline into 2 groups: never-smokers (never smoked at all or smoked <100 cigarettes in their lifetime) and current or former smokers (smoked more than 100 cigarettes in their lifetime). We defined alcohol consumption at baseline into 2 groups as well: infrequent or nonconsumers (those consuming alcohol less than once a week) and excess consumers (those consuming alcohol at least once a week). Anthropometric data were self-reported. We used the BMI to categorize baseline body weight status into 2 groups: optimal body weight (BMI: 18.5-25 kg/m²) and nonoptimal body weight (underweight: BMI <18.5 kg/m² and overweight: BMI ≥25 kg/m²). To evaluate leisure-time physical activity, we used individuals’ responses to the following NHIS question: Did you participate in any leisure-time physical activity over the past 2 weeks? Respondents could list more than one type of physical activity; they also reported the exercise frequency (ie, the number of times they engaged in the activity in the previous 2 weeks) and duration (ie, how long they exercised). MET intensity levels were assigned to each activity (eg, Tai Chi, walking, jogging, and swimming) on the basis of a relevant study [31]. Total weekly leisure-time physical activity (MET min/wk) was calculated by multiplying the frequency (times per week), duration (minutes), and the MET values of each activity. The physical activity was classified into 2 groups: insufficiently...
active (<500 MET min/wk) and sufficiently active (≥500 MET min/wk). Diet was assessed using the NHIS data, which were collected using a simplified food frequency questionnaire. We defined a healthy diet as having sufficient fruit and vegetable intake: ≥4 servings of fruits and vegetables per week.

**Covariates**

We obtained data regarding the individuals’ sociodemographic characteristics, lifestyle factors, and disease history from the NHIS database. The NHIS data were obtained through in-person interviews and a structured questionnaire survey [30]. The potential confounders and covariates were taken into consideration, including enrollment year, age at baseline, sex, ethnicity, education level, marital status, religion, monthly household income, and medical history of hypertension, hyperlipidemia or raised cholesterol, cardiovascular disease, diabetes mellitus, cancer, chronic lung diseases (asthma or chronic obstructive pulmonary disease), and chronic kidney diseases (Table S1 in Multimedia Appendix 1).

**Statistical Analysis**

Although the participants of the study cohort were followed with a median duration of 15.6 years, a high proportion of participants were still alive by the end of the follow-up. We therefore applied a rolling extrapolation algorithm to obtain the lifetime survival function for the study cohort [29]. The rolling extrapolation algorithm is one of the new methods to improve the accuracy of survival extrapolation using external evidence [32]. The extrapolation method was successfully applied in many studies for estimating loss of LE of cohorts with specific health conditions [33-36] compared with age- and sex-matched reference cohorts generated from life tables of the general population. In an observational study, the estimates of LE differences among comparative study cohorts (eg, with and without specific healthy lifestyle factors) may be biased due to the effects of some confounders in the samples. In this study, we incorporated IPTW to the rolling extrapolation algorithm to reduce the potential confounding effects on the estimate of LE difference between 2 cohorts.

We described the details of the modified rolling extrapolation algorithm in the following 4 major steps. First, each individual in a study cohort was given a weight equal to the inverse probability of the individual being in the cohort, which is estimated by a multinomial logistic regression model with measured confounding covariates; that is, each study cohort is inflated with the weights of the participants to form a pseudocohort in which confounders are equally distributed across the pseudocohorts [37]. The adjusted Kaplan-Meier estimator was applied to the weighted survival data of individuals in the study cohort to obtain the survival function, denoted by \( S(t) \), for the cohort [38]. We may call \( S(t) \) the confounder-adjusted survival function of the study cohort. Second, Monte Carlo methods were used to generate survival times of referents whose age and sex matched with participants in the study cohort using life tables of the general population. The same weights were assigned for the referents matched with the participants in the study cohort. The confounder-adjusted lifetime survival function of the reference population was obtained by applying an adjusted Kaplan-Meier estimator on the weighted survival times of the generated referents and denoted by \( S_r(t) \). We renamed \( S_r(t) \) as \( S_r(t) \times e^{\delta} > S(t) \) for use as a relevant predictor in extrapolating the survival function of the study cohort when \( S_r(t) > S(t) \) during the follow-up period. If \( S_r(t) \leq S(t) \), a proper hazard value \( \delta \) was subtracted from the reference population to ensure the predictor \( S_r(t) = S_r(t) \times e^{\delta} > S(t) \) [39]. The relative survival function, \( \bar{S}(t) \), is then within 0 and 1. Third, the logit transformation of the relative survival would straighten the curve \( \text{logit}[W(t)] \), which is relatively easy to extrapolate. Fourth, we used restricted cubic spline models to fit \( \text{logit}[W(t)] \) for the observed period \( t = 1, 2, ..., F \) months. The fitted curve was used to predict the \( \text{logit}[W(t)] \) 1 month ahead. The predicted \( \text{logit}[W(F+1)] \) was usually quite accurate because of the approximate linearity property of \( \text{logit}[W(t)] \) and treated as an observation at month \( F + 1 \). We then repeated the extrapolation procedures by rolling the same-length observation periods 1 month ahead, \( t = 2, 3, ..., F + 1 \), and refit the restricted cubic spline models for the updated observation periods to predict the value of \( \text{logit}[W(F+2)] \). By repeatedly performing the abovementioned procedures of extrapolating \( \text{logit}[W(t)] \) month-by-month to a time \( L \) beyond which all subjects of the cohort died, we could then invert transformation of the extrapolated \( \text{logit}[W(t)] \) to obtain an estimate of relative survival function \( \bar{S}(t) \) and lifetime survival function \( S(t) \) of the cohort. The validation analysis of the rolling extrapolation algorithm was performed for study cohorts with and without risk lifestyle factors (Table S2 in Multimedia Appendix 1). The confounder-adjusted LE of each study cohort was obtained by summing the extrapolated confounder-adjusted lifetime survival function, \( \bar{S}(t) \). The loss or gain of LE of a cohort is estimated by the difference of confounder-adjusted LE between the cohort and the comparative cohort.

With the extrapolated lifetime survival function \( S(t) \) of a cohort, we can further estimate the lifetime health expenditures of the cohort using the formula \( C(t) = \text{monthly average of the participant’s weighted expenditures in the subset} \), where \( C(t) \) is monthly average expenditure of living participants at time \( t \) in the study cohort [29]. We retrieved all direct health care costs (including inpatient and outpatient care) from the claims database of the National Health Insurance for the participants of each study cohort. Each participant’s costs were also assigned the same weight as the participant in a cohort. All the reimbursement costs, including treatment, examination, and procedures associated with disease outcomes of the participants in a cohort, were weighted and summed up to calculate the monthly average of the cohort. To extrapolate the monthly mean cost function beyond follow-up, we make one reasonable assumption that medical expenditures start increasing from K months before death [40]. Specifically, we classify the participants alive in each month into subsets of participants who died in the current month, within the next K months, and who lived more than K months. We then calculate mean costs in each month by a weighted average of the K+2 mean costs of these subsets in that month, where the weights were estimated by the extrapolated risk of death and the mean cost of each subset was estimated by the average of the participants’ weighted expenditures in the subset [29]. Estimates of LE, difference in LE between study cohorts, lifetime health
expenditures, annual average health expenditure, and their SEs and 95% CIs were obtained using the R package iSQoL2, which can be downloaded [41].

To estimate the magnitude of hazards associated with an unhealthy lifestyle, we used Cox proportional hazard models to calculate adjusted hazard ratios and corresponding 95% CIs for all-cause mortality associated with each individual health risk factor and a composite of health risk factors (0, 1, 2, 3, 4, or 5). The models were adjusted for the effects of the aforementioned covariates. In addition, dose-response relationships between the lifestyle factors and LE or health care expenditure were analyzed to evaluate the robustness of our findings. We classified smoking status into 4 categories based on smoking history and recent smoking behavior: never-smokers, former smokers, current smokers of 1 to 19 cigarettes per day, and current smokers of ≥20 cigarettes per day. Alcohol consumption was classified into 4 categories based on drinking frequency: never drinkers, infrequent drinkers (those consuming alcohol less than once a week), regular drinkers (those consuming alcohol more than once a week but not to the point of getting drunk), and heavy drinkers (those consuming alcohol more than once a week and typically to the point of getting drunk). Leisure-time physical activity was divided into 4 categories: sedentary (0 MET min/wk), insufficiently active (1-499 MET min/wk), active (500-1499 MET min/wk), and highly active (≥1500 MET min/wk). We classified healthy diet into 4 categories based on the frequency of fruit and vegetable intake: ≤1 serving, 2 to 3 servings, 4 to 6 servings, and ≥7 servings per week. Body weight status was divided into 4 categories: underweight (BMI <18.5 kg/m²), normal weight (18.5≤BMI<25 kg/m²), overweight (25≤BMI<30 kg/m²), and obese (BMI ≥30 kg/m²) [42]. Moreover, a series of sensitivity and validation analyses were conducted. We used the World Health Organization (WHO) Asian BMI risk cut points for BMI classification as part of our sensitivity analysis [43]. To investigate the effect of the number of healthy lifestyle factors on health, we initially designated individuals who adhered to none or one of the 5 healthy lifestyle factors as the reference group in our primary analysis. As a supplementary sensitivity analysis, we also designated individuals who embraced none of the healthy lifestyle factors as an alternative reference group. Furthermore, a subgroup analysis was performed based on different numbers of healthy lifestyle factors, including those with 2 factors, 3 factors, or 4 factors, to present estimations of LE and health care expenditure associated with the combinations of healthy lifestyle factors within each subgroup. In addition, a validation analysis was performed to assess the accuracy of survival function extrapolation (further details are provided in Table S2 in Multimedia Appendix 1). The R package programs mnet::multinom and survival::coxph were used for the analysis. Statistical significance was set at a 2-tailed value of P<.05.

Ethical Considerations

In accordance with Article 5 of the Human Subjects Research Act of the Ministry of Health and Welfare, Republic of China (Taiwan) [44] and the guidelines titled “Management Principles for the Application of Health and Welfare Data” announced by the Ministry of Health and Welfare, Taiwan on September 7, 2017, pursuant to Wei-Bu-Tong-Zi (#1062560770)” [45], the data used in this analysis are subject to the management and regulation by the Health and Welfare Data Science Center, Taiwan [46]. Individual health data managed therein (including NHIS, NHIRD, and Death Registry data) undergo deidentification processing in accordance with the Personal Data Protection Act.

This study was approved by the Taipei Medical University Joint Institutional Review Board (TMU-JIRB-N202009047). The Health and Welfare Data Science Center reviewed the study protocol and institutional review board approval and granted access to confidential data. The requirement for written informed consent was therefore waived because anonymous and deidentified information was used for analysis.

Results

Baseline Characteristics

Of 19,893 participants included in the analysis, 10,311 (51.8%) were men; the mean age was 48.8 (SD 13.4) years. During 317,116 person-years of follow-up, 3815 deaths were recorded (1403 women and 2412 men). Table 1 presents the baseline characteristics of study participants by the number of healthy lifestyle behaviors they adhered to. Individuals adhering to a higher number of healthy lifestyle behaviors were more likely to be women, had received higher levels of education, and had higher household income. At baseline, 68.2% of participants were not current or former smokers, 83.2% did not consume excessive amounts of alcohol, 33.8% were sufficiently active, 89.2% had sufficient fruit and vegetable intake, and 62.1% had a normal weight.

Healthy Lifestyle Factors and Mortality Risk

Each individual healthy lifestyle factor was significantly associated with all-cause mortality (Figure S1 and Table S3 in Multimedia Appendix 1). The risk of mortality decreased with increasing adherence to healthy lifestyle behaviors (in terms of the number of behaviors adopted by the individuals). Individuals adhering to all 5 healthy lifestyle behaviors exhibited a hazard ratio of 0.37 (95% CI 0.27-0.49) for all-cause mortality, compared with those with 0 healthy factors, after adjusting for potential confounding factors.

Impact on LE

Using the rolling extrapolation method, we found that participants with mean ages of 48.8 years who did not smoke had a life gain of 2.31 (95% CI 0.04-5.13) additional years. Not drinking excessively was marginally associated with an additional gain in life years by 1.62 (95% CI -0.15 to 4.59) years. Sufficient physical activity was associated with an additional 1.85 (95% CI 0.25-4.34) life years gain. Sufficient fruit and vegetable intake was associated with a life gain of 3.25 (95% CI 1.29-6.81) years. Finally, having an optimal weight was associated with a nonsignificant increment in life years (0.72 years; 95% CI -1.21 to 2.14) compared with being underweight or overweight. LE increased with the increasing adherence to healthy lifestyle behaviors (Table 2). After covariate adjustment, we note that individuals who adhere to 4 and 5 healthy lifestyle behaviors have a life span increase of 6.58 (95% CI 1.13-10.76) and 7.13 (95% CI 1.33-11.11) years, respectively, compared with LE (29.19 years) for individuals who do not adhere to more than one healthy lifestyle behavior.

\(^a\)Nonoptimal weight: underweight (BMI <18.5 kg/m\(^2\)) and overweight (BMI ≥25 kg/m\(^2\)).

**Impact on Lifetime Health Care Expenditure**

We evaluated the effects of healthy lifestyle factors on lifetime health care expenditure and found that nonsmoking and a healthy weight were significantly associated with reduced lifetime health care expenditure (Table 3). Per capita estimated lifetime health care expenditures were US $60,395 for smokers and US $58,821 for nonsmokers. Notably, individuals with nonoptimal body weight had a significantly higher per capita estimated lifetime health care expenditure compared with those with optimal body weight (US $62,474 vs US $53,336, respectively). The percentage change in annual health care expenditure was calculated by determining the difference in per capita annual health care expenditure between populations with and without healthy lifestyle factors, which was then divided by the annual average health care expenditure per capita of the overall population. We found that never-smokers had a significant reduction in the percentage change in annual health care expenditure compared with current or former smokers (−9.78%; 95% CI −46.53% to −1.45%). Furthermore, individuals with optimal body weight had notably lower average annual health care expenditures compared with those with nonoptimal body weight, with an 18.36% reduction of annual health care expenditures per capita (95% CI 8.57%-29.66%). Overall, individuals who adopted 2, 3, 4, or 5 healthy lifestyle factors demonstrated a dose-response reduction in the percentage change in annual health care expenditure per capita by 16.01%, 18.90%, 18.61%, and 28.12%, respectively, in comparison to those who adopted 0 or only 1 healthy lifestyle factor.

aUS $1=New Taiwan $30.65.
bThe percentage change in annual health care expenditure was calculated as the difference in per capita annual health care expenditure between populations with and without healthy lifestyle factors divided by the annual average health care expenditure per capita for the overall population.
cNonoptimal weight: underweight (BMI <18.5 kg/m$^2$) and overweight (BMI ≥25 kg/m$^2$).

Dose-Response Analysis
The analysis of the dose-response effect of each lifestyle factor on LE revealed that nonsmoking, infrequent alcohol consumption (less than once a week), high physical activity levels, healthy diet intake (intake of ≥4 servings of fruits and vegetables per week), and overweight (25≤BMI<30 kg/m$^2$) were associated with a long LE (Figure 2). Regarding lifetime health care expenditure, individuals who were heavy smokers (≥20 cigarettes per day), were regular and heavy drinkers, had a sedentary lifestyle (0 MET min/wk), and were overweight and obese (BMI ≥25 kg/m$^2$) are more likely to have higher average annual health care expenditures (Figure 3). Regarding healthy diet intake, it is important to note that the exposure group with the longest LE may not necessarily be the same as the group with the lowest health care expenses. In addition, we found that overweight, when compared with normal weight, was associated with an additional 0.69 (95% CI −0.54 to 2.26) life years. However, this increased LE comes with the caveat of incurring additional health care expenses, with an increase of percentage change in annual health care expenditure (21.1%; 95% CI 9.98%–31.17%). Alternatively, we depicted the correlation between LE and lifetime health care expenditures for populations with and without healthy lifestyle factors using a scatter plot. We hypothesized a linear relationship, with a steeper slope indicating higher annual average health care expenditures. Figure S2 in Multimedia Appendix 1 illustrates that, in comparison to populations with 0 or only 1 healthy lifestyle factor, individuals with all 5 healthy lifestyle factors not only experience a longer LE but also have lower annual average health care costs. When examining individual factors, generally, each of the healthy lifestyle factors is associated with a longer LE. However, we found that smoking and nonoptimal body weight are linked to considerably higher annual health care expenses, along with reduced LE.
Figure 2. Estimated life expectancy (LE) and years of life gained according to levels of individual lifestyle risk factors. Red color indicates the estimated value was significantly higher or lower than reference group. MET: metabolic equivalent of task. *: cigarettes per day; #: minutes per week; &: servings of fruit and vegetable intake per week.
Sensitivity and Subgroup Analysis

In addition to using the globally common BMI classification criteria, we conducted a sensitivity analysis by incorporating the WHO Asian BMI risk cut points for BMI classification. The results of the sensitivity analysis align with our primary findings. Compared with individuals with a normal weight (18.5≤BMI<23 kg/m²), those classified as overweight (23≤BMI<27.5 kg/m²) demonstrated significantly improved LE, with an additional gain of 3.36 years (95% CI 1.88-5.76; Figure S3 in Multimedia Appendix 1). Moreover, we also designated individuals who adhered to none of the healthy lifestyle factors as an alternative reference group. A discernible dose-response relationship was identified. Overall, individuals who adopted 1, 2, 3, 4, or all 5 healthy lifestyle factors presented LE gains of 4.37, 4.73, 10.22, 11.85, and 12.39 years, respectively, in comparison to those who adopted none of these 5 healthy lifestyle factors (Table S4 in Multimedia Appendix 1). Furthermore, under stratification by the number of healthy lifestyle factors, noticeable heterogeneity emerged across various combinations of these factors.
Discussion

Principal Findings

Using data from a nationally representative cohort, we found that 5 healthy lifestyle factors were associated with significant gains in LE and reductions in health care expenditure for individuals aged ≥30 years in Taiwan. Our findings revealed that adherence to all 5 healthy lifestyle behaviors was associated with a 7.13-year increase in LE and a 28.12% reduction in the percentage of annual health care expenditure per capita compared with the values noted in individuals adhering to 0 or 1 healthy lifestyle behavior. Furthermore, the lifestyle factors did not exert equal effects on LE. Smoking and diet were the most significant risk factors for a short LE, with current and former smokers having an estimated reduction of 2.31 years in LE compared to never-smokers. In addition, individuals consuming sufficient amounts of fruits and vegetables had a life gain of 3.25 years compared with the LE of individuals with insufficient intake. Individuals regularly engaging in sufficient physical activity had a life gain of 1.85 years compared with the LE of individuals with a sedentary or inactive lifestyle. Individuals who were underweight (BMI <18.5 kg/m\(^2\)) had a shorter LE than did those with a normal weight (18.5≤BMI<25 kg/m\(^2\)); in contrast, individuals who were overweight (25≤BMI<30 kg/m\(^2\)) had a longer LE than did those with a normal weight. Heavy drinkers who consumed alcohol more than once a week and typically to the point of getting drunk had a shorter LE than those consuming no alcohol.

Our findings regarding the individual and combined effects of healthy lifestyle factors on LE are generally consistent with those of other studies. Adhering to a healthy lifestyle is associated with a significant increase in estimated LE by 6.6 to 18.9 years across countries [2-8]. Differences in the definitions of healthy lifestyles and the characteristics of study populations might have contributed to the differences in LE increase among the countries. Additional sources of such heterogeneity should be investigated. For example, living environment has also been linked to LEs [47-49]. Residents of low-income areas in wealthy cities, such as New York and San Francisco, had significantly longer LEs than did those of low-income areas in poor cities, such as Gary, Indiana, and Detroit [49]. Further studies are required to better understand how living environment, as well as socioeconomic status and difference between Eastern and Western populations, influence the health benefits of lifestyle factors across countries.

The global average LE has undergone a significant increase in recent decades. However, the LE in Taiwan, one of the wealthiest nations in East and Southeast Asia, falls behind in comparison to other high-income countries in this region. In 2019, LE at birth in Taiwan was 80.3 years, which was lower than that of Singapore (84.9 years), Japan (84.8 years), and South Korea (82.9 years) [50,51]. This discrepancy can be attributed to Taiwan having a health care system that prioritizes disease treatment over prevention. Our revisit analysis of the 2017 Global Burden of Disease study revealed that 44.3% of the total disease burden in Taiwan was associated with modifiable risk factors, whereas the leading risk factors in Japan, Singapore, and South Korea had lower fractions of attributable disability-adjusted life year rates of 38.0%, 35.2%, and 40.3%, respectively [52]. The successful reduction in risk exposure and unhealthy behaviors in these countries has led to significant improvements in health outcomes. Our findings clearly indicate that a healthy lifestyle can significantly extend a person’s life span. Our estimates can serve not only as materials for promoting health among the public but also as key references for the government when it seeks to develop, implement, and evaluate intervention programs.

Our study showed that nonsmoking, avoiding excessive alcohol consumption, healthy diet intake, normal weight, and regular physical activity were all associated with a low risk of premature mortality. Nonsmoking and healthy diet intake considerably affected the LE of Taiwanese adults. The harmful effects of smoking are well known. Our findings highlight the importance of maintaining nonsmoking behavior. Healthy diet intake has been associated with low risks of morbidity and mortality associated with several noncommunicable diseases [53]. We did not investigate the effects of the intake of various foods and nutrients; nevertheless, the quantity of fruit and vegetable intake indicates the healthiness level of a diet, at least partially. A significant dose-response relationship was noted between fruit and vegetable intake and an increase in LE. Nevertheless, this relationship has not been found in the burden of health care expenditure. One plausible interpretation is that individuals who adhere to a healthy diet may also exhibit a heightened health consciousness, potentially resulting in excessive use of health care resources, particularly within the environment of Taiwan’s National Health Insurance system. Regarding BMI, individuals who were normal weight or overweight had longer LEs than those who had underweight or obesity. These findings are generally consistent with those of a population-based cohort study, which reported a J-shaped association between BMI and mortality, with the nadir at a BMI of 25 kg/m\(^2\) [54]. However, the issue of the obesity paradox necessitates thoughtful consideration when using BMI as an indicator of obesity because of its inherent limitations and the potential for misclassification resulting from arbitrary BMI categorization [55-58]. In our
study, consistent results were observed when applying both the WHO global and Asian BMI classification systems. Importantly, it should be noted that overweight and obesity exerted significant negative effects, as indicated by the noteworthy excess health care expenditure associated with these conditions. Furthermore, our findings revealed a positive correlation between the level of physical activity and an increase in LE, yet this did not translate into a reduction in health care expenditure. Although physical activity has been associated with improvements in overall LE, engaging in regular exercises (particularly those involving outdoor activities) may increase the risk of accidental injury and thereby lead to additional health care expenditure. Our findings revealed that infrequent alcohol consumption (less than once a week) exerted a favorable effect on LE, as well as health care expenditure. Although the cardioprotective effects of moderate alcohol consumption have been reported in large cohort studies [59], current guidelines do not endorse initiating alcohol consumption solely for the purpose of preventing cardiovascular disease. Notably, a systematic review and meta-analysis reported that low or moderate alcohol consumption was not significantly associated with a reduced risk of all-cause mortality [60]. Furthermore, relying solely on alcohol consumption frequency rather than the actual intake amount (in grams) in this study may result in an imprecise exposure assessment. To address this limitation, we used NHIS 2009 and 2013 data, which began collecting information on alcohol intake amounts, to investigate the relationship between consumption frequency and intake amounts. Our additional analysis revealed a significant correlation, with a Spearman correlation coefficient of 0.986 (Table S6 in Multimedia Appendix 1). However, further research is warranted to refine exposure assessment methods and comprehensively explore the impact of alcohol consumption on LE and health care costs. In addition, there could be notable diversity in the effects on LE and lifetime health expenditures across various combinations of healthy lifestyle factors. Our subgroup analysis reveals that the combination of nonsmoking and adequate fruit and vegetable consumption stands out as the most crucial factors associated with increased LE while maintaining an optimal body weight emerges as pivotal for reducing lifetime health expenditures. However, the constrained sample sizes within the strata might have impeded the detection of discrepancies owing to diminished statistical power. Thus, further investigation with larger samples is imperative to elucidate these potential heterogeneities more definitively.

To the best of our knowledge, this study is the first to quantify the lifetime health care expenditure associated with the individual and combined effects of healthy lifestyle factors. Our results showed that healthy lifestyle factors were associated with reduced annual average health care expenditure. Previous studies exploring the effects of risk behaviors on health care costs have revealed that smoking, excessive alcohol consumption, obesity, and overweight may lead to significant economic burdens [20-22,24-27]. However, less research to date has explored the impact of individual and combined healthy lifestyle factors on lifetime health care expenditure using longitudinal individual data. Adherence to a low-risk lifestyle can not only prolong an individual’s life span but also significantly postpone disability [7,12-17,61]. Li et al [14] reported that individuals aged 50 years who had a low-risk lifestyle had a longer LE free of major chronic diseases, with an approximate gain of 7.6 years for men and 10 years for women in the United States and 6.9 years for men and 9.4 years for women in the United Kingdom population [13]. Furthermore, a recent Chinese study unveiled that adults aged 40 years, who embraced 5 low-risk lifestyle factors, could attain an additional 6.3 and 4.2 years of life without cardiovascular diseases, cancer, and chronic respiratory diseases for men and women, respectively, compared with those with 0 to 1 low-risk lifestyle factors [12]. These findings indicate that postponing disability can benefit society by ensuring that health care costs associated with disability are not incurred until individuals reach advanced ages and enabling individuals to work longer. On the other hand, our investigation has revealed that specific lifestyle factors exhibit disparate effects on both LE and health care expenditures. For example, our findings show that individuals who are overweight (25≤BMI<30 kg/m²) experience an extension of 0.69 (95% CI 0.54 to 2.26) years in their LE compared with those with a normal weight (18.5≤BMI<25 kg/m²). However, this increased longevity is accompanied by elevated health care costs, resulting in a 21.1% (95% CI 9.98%-31.17%) increase in annual health care expenditure. By carefully considering the trade-offs between the influences of health behaviors on LE and health care expenditure, our outcomes may yield valuable insights for the comprehensive evaluation of cost-effectiveness in primary prevention initiatives. Nonetheless, these findings also emphasize the urgency of future research endeavors to thoroughly investigate the impact of health factors on both nonfatal and fatal disease burdens. For instance, it would be imperative to examine the effects of health factors on composite metrics such as disability-adjusted life years, quality-adjusted life years, or health-adjusted LE at an individual level to gain a comprehensive understanding.

As nations with aging populations face the associated socioeconomic consequences, they must ensure that the health status of older individuals is maintained. Our findings, derived from the Taiwanese population, indicate that significant health and economic gains can be achieved if individuals adopt low-risk behaviors. Taiwan’s Health Promotion Administration has sought to increase the health promotion awareness and the preventive health capabilities of the population. Their efforts have concentrated on the screening of cancer, regulation of tobacco hazards, and prevention of chronic and noncommunicable diseases. These measures may not only reduce disease risks and extend LE but also alleviate economic burdens. For example, consider the tobacco tax revenue in Taiwan for the year 2022, which amounted to approximately 0.97 billion [62]. Approximately 50% (0.49 billion) of this revenue is allocated to subsidize the National Health Insurance expenditure. According to the estimates in this study, combined with a smoking prevalence of 14% in Taiwan [63], we can estimate that approximately an additional 0.36 billion in health care expenditure was contributed by smokers. However, it is important to note that our study does not account for indirect economic impacts, including indirect health care expenditures and productivity losses. In recent decades, Taiwan’s health care expenditures have steadily increased, and the National Health
Insurance system currently grapples with a budget deficit. To improve the health care system in Taiwan, adjustments in health promotion investment strategies are necessary. The findings from this study hold significant implications for the direction of health promotion strategies and policy formulation. Previous literature suggests the effectiveness of fiscal policies in improving health, such as the implementation of taxes on tobacco, alcohol, and sugar-sweetened beverages and foods. Nevertheless, it is not limited to taxing substances with health risks. Adjustments may include increasing investments in health education and preventive health services, as well as enhancing food and physical environments to support healthy behaviors.

Limitations

Our study has several strengths, including the use of a large sample size derived from national representative survey data, a prospective nature, and an almost complete follow-up. By linking these data with National Health Insurance claims and vital registry data and integrating an extrapolated lifetime survival function, we were able to comprehensively evaluate the impacts of health lifestyle factors on LE and health care expenditure in Taiwan. In addition, we integrated IPTW in our survival function extrapolation algorithm to minimize the effects of potential confounders. This innovative approach enhances the robustness and validity of our findings.

This study has several limitations that should be acknowledged. First, all analyzed lifestyle factors were assessed at baseline; therefore, lifestyle changes over time were not accounted for because no repeated measurement data were available. Second, the lifestyle factors data were self-reported, which may have led to misclassification. Third, although we adjusted the statistical models for a wide range of potential confounders, the likelihood of residual and unmeasured confounding effects cannot be ruled out. Fourth, we might have underestimated the proportion of individuals with an unhealthy lifestyle because individuals with poor health may be less likely to participate in surveys or may even die before participating. Fifth, we did not account for other healthy lifestyle factors that may independently affect LE, including factors such as lack of comprehensive dietary intake frequency information (eg, red or processed meat consumption), which prevented us from adequately exploring the impact of various healthy dietary patterns on overall health and economic burden, as well as factors such as sleep quality and duration, and levels of stress. Finally, lifetime health care expenditures were estimated on the basis of reimbursement data obtained from Taiwan’s NHIRD. Therefore, the estimates did not account for out-of-pocket expenses or costs associated with a loss of productivity. Therefore, from a societal perspective, lifetime health care expenditures might have been underestimated in this study.

Conclusions

Our findings revealed dose-response relationships between healthy lifestyle factors and increased LEs and reduced annual health care expenditures. The findings may have implications for primary prevention and resource allocation. They highlight the need for coordinated multisectorial efforts that target modifiable lifestyle factors to reduce the overall burden of disease. By prioritizing interventions that promote healthy behaviors and mitigate risk factors, health outcomes can be improved and health care costs can be minimized.

Abstract

Background: Colorectal cancer (CRC) is the second most deadly form of cancer, inducing an estimated 1.9 million incidence cases and 0.9 million deaths worldwide in 2020. Despite the availability of screening tests, their uptake remains suboptimal. However, blood-based tests that look for signs of cancer-specific markers in the body are increasingly available as an alternative for more invasive tests for cancer. Compared with existing tests, the benefits of blood-based tests for CRC include not needing pretest preparation, stool handling, and dietary or medication restrictions.

Objective: This study aims to explore the population’s preferences for CRC screening tests, with a focus on blood-based tests, and investigate the factors influencing test uptake.

Methods: We used a mixed methods approach, combining semistructured interviews and a discrete choice experiment (DCE) survey. Interviews were analyzed using thematic analysis to identify salient attributes for CRC screening tests. These attributes informed the design of the DCE survey. The DCE data were analyzed using mixed logit and mixed-mixed multinomial logit models.

Results: Qualitative findings from 30 participants revealed that participants preferred blood-based tests due to their perceived low risk, minimal pain, and ease of sample collection. However, concerns about the test’s lower accuracy were also expressed. The DCE survey was completed by 1189 participants. In the mixed logit model, participants demonstrated a stronger preference for blood-based tests over a 2-day stool-based test. The mixed-mixed multinomial logit model identified 2 classes, strong supporters and weak supporters, for CRC screening. Weak supporters, but not strong supporters, had a higher preference for blood-based tests. Women, ethnic Chinese, and people aged 40 to 60 years were more likely to be weak supporters. Both models highlighted the high influence of cost and test sensitivity on participants’ preferences. Transitioning from a 2-day stool-based test to a blood-based test, assuming a national screening program at a base price of Singapore $5 (US $3.75), was estimated to have the potential to increase the relative uptake by 5.9% (95% CI 3.6%-8.2%).

Conclusions: These findings contribute to our understanding of CRC screening preferences and provide insights into the factors driving test uptake. This study highlights the perceived advantages of blood-based tests and identifies areas of concern regarding their accuracy. Further research is needed to determine the actual increase in uptake rate when blood-based tests are made available.

**Introduction**

**Background**

Colorectal cancer (CRC) is the second most deadly form of cancer, inducing an estimated 1.9 million incidence cases and 0.9 million deaths worldwide in 2020 [1]. Regular screening for CRC, through methods such as colonoscopy and fecal immunochemical testing (FIT), helps detect CRC earlier, reduces the incidence and mortality of CRC, and brings about cost savings compared with not undergoing any screening [2]. Despite the availability of screening as a preventive intervention for the early detection of CRC, screening rates are suboptimal, even within high-income countries [3-5]. Factors that hamper screening include not just individual characteristics but characteristics of the screening tests as well [6].

The emergence of blood-based, early detection tests for cancer has the potential not only for detecting multiple cancers but also for improving patient compliance and acceptance [7]. The discovery of circulating and cell-free tumor DNA in the blood has ushered in new possibilities for the blood-based detection of CRC as well [8]. Epi proColon—a SEPT9 DNA methylation assay—remains to be the only US Food and Drug Administration–approved test [9]. However, there are at least 5 other blood-based tests in various stages of development, with tests ranging from CRC-specific tests to multi-cancer early detection tests. Some candidate analytic targets include cell-free DNA, methylated circulating tumor DNA, and a combination of methylated DNA and proteins [10]. Compared with existing tests, the benefits of blood-based tests for CRC include not needing pretest preparation, stool handling, and dietary or medication restrictions [9].

Challenges to the implementation of blood-based tests for screening include lower specificity relative to one-time FIT [11] and inferior sensitivity compared with next-generation FIT-DNA tests [12]. As a result, blood-based tests for CRC are not recommended for the general population in the health guidelines of the United States, Europe, China, and Singapore [13-16]. While there exist several clinical disadvantages to blood-based tests, it may serve as an alternative for patients refusing screening by colonoscopy or patients self-excluded from stool-based tests due to bleeding conditions such as hemorrhoids radiation proctitis [17]. In fact, the SEPT9 test was found to be more effective and cost-effective compared with no screening [18]. By making screening easier, blood-based tests have the potential to improve uptake if the benefits outweigh the downside of this screening modality [19]. Studies are required to understand how the population will make trade-offs between different procedures and their attributes.

In a randomized controlled trial (RCT) involving average-risk adults that offered blood-based tests and FIT in a clinical setting, higher screening participation rates were observed in the blood-based test arm [20]. The blood-based test was also found to be effective in increasing screening rates among medically underserved populations [19]. However, another RCT reported no statistically significant improvement in the uptake among the population familiar with FIT if a blood-based test was offered upfront as an option [21]. Conversely, studies offering the blood-based test as a rescue option for those who declined colonoscopy and stool-based tests showed an increase in participant rates [21-23].

**Objective**

Building on the existing literature, at least 4 questions are deserving of further investigation. First, what is the population’s inclination toward blood-based tests if the accuracy of blood-based tests can be improved to satisfactory levels akin to the FIT-DNA test? This insight can help assess the potential value of further investment in the test and inform the design of a target product profile [24,25]. Second, what is the general population’s preference for using the blood-based test in routine CRC screening? Results from RCTs may not be generalizable to the general population given the differences in the characteristics between the study participants and the general population. Third, considering heterogeneous preferences for blood-based tests, can we profile the population based on their preferences? Such profiling efforts can inform the crafting of targeted screening programs to cater to the heterogeneous preferences across different groups. Fourth, many preference studies were done in Western countries and very few were done in Asia [26,27]. Cultural and social norms could influence decision-making and outcomes. Studies understanding the acceptance of blood-based CRC tests in Asia are needed.

Acknowledging these gaps, we have designed a mixed methods study to delve into the population’s preference for blood-based testing modalities in Singapore, a multiracial Asian society, and to understand their decision-making process when choosing between blood-based tests and other existing screening methods. A discrete choice experiment (DCE) was used to construct hypothetical scenarios (eg, higher accuracy for the blood-based test). Furthermore, we intend to undertake subgroup analyses to examine potential variations in the preference for blood-based tests within distinct segments of the population, as highlighted by the mixed results of the RCTs. Our investigation will also delve into whether specific screening methods, such as the blood-based test, might positively impact participation rates, particularly in subpopulations identified with lower anticipated adherence based on prevailing screening recommendations.

**Methods**

This is a mixed methods study with interviews and a survey that incorporated a DCE. The methods for the qualitative and quantitative components will first be outlined, and subsequently, the qualitative and quantitative results will be presented.

**Ethical Considerations**

The study was approved by the National Healthcare Group Domain Specific Review Board (2021/00753) before data collection. Participants of the DCE were from a web-based cohort, and their participation in research was approved by the National University of Singapore (NUS) institutional review board (NUS-IRB: H-18-011).
Qualitative Component

Participant and Sampling

The recruitment and interview of participants for the qualitative component took place between December 2021 and March 2022. Convenience sampling was undertaken to include the Singapore population aged ≥40 years with varied engagement with CRC screening services. Recruitment was conducted via the NUS social media platforms and its email blast services, as well as other participant recruitment channels and word of mouth. Interested potential participants contacted the researchers, who verified their eligibility before taking informed consent.

Conducting the Interview

The interviews took place either on the web via a videoconferencing application or in a quiet room within the NUS that was convenient for recording. The interviews adopted a semistructured format using a topic guide. Each interview lasted approximately 30 to 45 minutes and was conducted in English.

Analysis of Interviews

The interviews were transcribed verbatim, and the data were analyzed using thematic analysis. A preliminary codebook with emerging themes of relevance from the first 5 transcripts was developed upon full familiarization of the transcripts. A deductive and semantic approach was used in the clustering of codes into metacodes and categories of interest. The coding framework was subsequently applied to the remaining transcripts. The identified themes were also further reviewed to ensure their usefulness and accuracy in representing the data.

Quantitative Component

Discrete Choice Experiment

DCEs have increasingly become a popular method for investigating and eliciting patient and population preferences for health care [28]. The method is based on consumer choice theory [29], which posits that respondents make choices between hypothetical products or scenarios comprising of ≥2 alternatives based on the importance they place on the characteristics of these attributes. In a DCE, a product or scenario is described with a fixed number of attributes with varying combinations of levels. Per this paradigm, in choosing the ideal product or scenario, the respondent evaluates the overall desirability of the alternatives and makes trade-offs among the attributes. From the respondents’ choice, their preferences are indirectly revealed, determining the attributes that drive the respondents’ preferences as well as the way variations of the attributes and levels may affect the respective preferences [30].

Selection of Attributes and Levels

The selection of attributes and levels must be relevant to the policy process and the study population, while being consistent with the random utility theoretical foundation of DCEs [31]. An initial set of attributes and levels for the DCE was based on a scoping review of the existing literature, which yielded 13 attributes. During the aforementioned qualitative interviews, participants were asked to rank 3 attributes that they valued the most, and the weighted preferences of all participants helped shortlist the final attribute list for the DCE. Following that, a quantitative survey with eligible health care professionals (n=11), who had at least 1-year working experience with patients with CRC or RC screening, was conducted to ensure the validity of the selected attributes and their corresponding levels. After these iterative processes, six attributes were identified and ultimately used in the DCE: (1) procedure, (2) pain level, (3) sensitivity, (4) recommendation, (5) out-of-pocket cost, and (6) risk of test. Each attribute was assigned various levels based on the best information available. The blood-based test was one level of the procedure attribute.

To optimize the choice sets, a pilot study was conducted with 12 participants. Adjustments were then made to the text for the attributes and levels to improve clarity for the participants. The final set of 6 attributes and levels is presented in Textbox 1. The total number of appearances and selections for each attribute and level may be found in Multimedia Appendix 1.

**Experimental Design**

The DCE questionnaire was designed using Sawtooth Lighthouse Studio (version 9.13.2), and a 2-stage design was used. For each task, participants first selected the preferred choice from 2 test profiles and were then asked to choose between taking the test or opting out of it in real life. Correspondingly, the parameter labeled “Opt-Out” represents the utility associated with declining the preferred test in the first stage. A negative value thus indicates a participant’s preference to undergo the screening test. The questionnaire was designed using the random task generation method provided by Sawtooth. The DCE included a total of 20 blocks with 10 choice sets each. Each study participant saw 1 block of choice sets, consisting of 10 choice sets, from the 20 blocks. To test for internal validity, 1 fixed choice set offering 2 alternatives is common across all blocks, of which one is intended to be strictly dominant over the other.

The levels of cost were selected to reflect the costs of different procedures in reality. Participants in qualitative interviews also demonstrated a similar perception regarding the cost of the tests. Certain within-concept prohibitions were also specified to provide combinations of attributes that were realistic. This included prohibiting high out-of-pocket payment costs and the presence of mild pain for stool-based tests. However, we allowed the blood-based test to appear together with a higher cost given that commercial companies may set higher prices [32]. The coverage matrix of the DCE design was examined using Sawtooth Lighthouse Studio to ensure all the parameters can be estimated. In addition, considering the large range of costs, we treated cost as discrete variables rather than a continuous.
variable in our analysis. An example of a DCE choice task is presented in Figure 1.

Participants reported any familial history of CRC and if they had attended any type of CRC screening in the past. Various sociodemographic information was also collected. All variables were coded as categorical variables, and some variables were subsequently recoded as binary or ternary variables to form meaningful subgroups for analyses. Psychosocial inventories—the Zimbardo Time Perspective Inventory [33], the Intolerance of Uncertainty Scale [34], and the Duke UNC Functional Social Support Questionnaire [35]—were also included to measure participants’ degree of present orientation, intolerance of uncertainty, and social support, respectively.

Figure 1. An example of a discrete choice experiment choice task. SDG: Singapore Dollar (SGD 1 = approximately US $0.75).

**Participant and Sampling**

This study was conducted as a web-based survey hosted on REDCap from May 19, 2022, to May 28, 2022. The target population for this study was Singapore citizens and permanent residents aged ≥40 years. The survey was sent to the participants from Singapore Population Health Studies web-based panel. This web-based panel consists of a cohort that is broadly representative of the general Singapore population. Participants gave their implicit consent by participating in the survey and were reimbursed with Singapore $10 (approximately US $7.50) for every successful completion of the survey.

In calculating the minimum sample size, we made use of the proposed formula of \( n > \frac{500 \times c}{(t \times a)} \) by Johnson and Orme [36], where 500 is a fixed variable, \( c \) demotes the largest number of levels for a certain attribute, \( a \) indicates the number of DCE choice sets per block of questionnaire, and \( t \) refers to the number of alternatives per DCE choice set (excluding “Opt-out”). Accordingly, the sample size required for this study should be >125 participants (500*5/(2*10)=125). In addition, Lancsar and Louviere [30] suggested 20 responses per block or questionnaire, which led to a minimum sample size of 400. Considering that the DCE may be relatively difficult to answer, we expected a relatively high nonresponse rate of 20% to 30%. Hence, we set the target sample size to be 600. We subsequently tested the sample size using simulation functions with Sawtooth Lighthouse Studio, which deemed the sample size of 600 as sufficient. Owing to the overwhelming response, our final sample size of 1189 participants not only meets the minimum required sample size but also allows for the possibility of conducting flexible subgroup analyses.

**Statistical Analysis**

A total of 2 models were tested: a mixed logit (MXL) model and a mixed-mixed multinomial logit (MMML) model [37]. The MXL model was selected to account for the correlation introduced by the repeated observations from each participant and to relax the assumptions of independence from irrelevant alternatives [38]. This model assumes that the choices made by the same participant are correlated, and preference heterogeneity exists across the population sample. The interpretation of the mean preference weights is made in relation to the chosen base level, and the SD of each level indicates the variability in the mean preference weights. The MMML model was also selected as it incorporates both MXL and the latent class logit model. Unlike latent class logit where a homogeneous fixed preference is assumed within each latent class, a distribution of random coefficients is specified in the MMML model. Within each class, preference weights and the average probability of each demographic within each class can be derived. The number of classes was chosen by examining the Bayesian information criterion.

In addition, the conditional relative importance (CRI) for a given attribute, defined as the difference between the highest preference weight of the attribute level and the lowest preference weight of the attribute level, was reported. A higher CRI indicates the attribute is more important in designing the CRC screening program. Profile-based normalization was then applied to normalize the sum of CRI of all the attributes to 1.

A left-specific constant was included in each regression, with a statistically significant coefficient indicating a left-right bias in the study [39]. Participants in DCE may take shortcuts and use simplifying heuristics when answering DCE questions, which can introduce an unintended source of variability in the...
data. When using reading order heuristic, study participants may tend to choose the option on one side [40]. Incorporating a variable indicating the position of the choice in the regression can disentangle the associated bias [41,42].

All levels were coded as dummy variables. Reference levels were selected based on the current recommendation for CRC screening for the average-risk adult population. However, we intentionally designated “No Recommendation” as the reference level for the “Recommendation” attribute to investigate the nuanced preferences arising from diverse recommendations made by different individuals. Continuous psychological variables were demedian by subtracting the median value from each data point, resulting in a centered distribution. As for the classification of the continuous sociodemographic variables, age bands were set according to the definition of senior citizen locally, which is at the age of ≥60 years. Household income was grouped to ensure a sufficient sample size in both groups.

Statistical significance was set at P<.05. All quantitative data analyses were carried out using the statistical software R (version 4.2.1; The R Foundation) [43].

Results

Qualitative Component

Sample Characteristics

A total of 30 participants completed the interview. A summary of their sociodemographic characteristics is presented in Multimedia Appendix 2. Of these participants, 14 had undergone a colonoscopy, 20 had taken a stool test, and 6 had taken a blood-based test. A total of 5 participants had not undergone any screening for CRC. Five main themes that elucidated the participants’ motivations and important attributes of CRC screening were identified: (1) accuracy, (2) cost, (3) perceived risk and pain, (4) convenience of the test, and (5) the method of sample collection.

Accuracy

When it came to blood-based tests, many participants were uncomfortable with its inferior accuracy relative to other tests. They saw it as “pointless” due to its possibility of giving rise to many false positives and negatives:

...half the chance of being accurate, then why waste my blood? [P6, female]

If [accuracy is] too low, then it defeats the purpose already...you want to know whether you have cancer or not, you see. [P24, female]

For participants who felt that they had no symptoms, the level of accuracy of the stool-based tests provided sufficient assurance that they felt a colonoscopy was unnecessary. Many cited an approach of escalation—to undergo a colonoscopy only in the event of a positive stool-based test:

I’m not in the high-risk category...I’ll go for the FIT first, and then based on [the results], I’ll go for the colonoscopy. [P22, female]

Participants who had undergone invasive tests such as colonoscopy either (1) were diagnosed with hemorrhoids or (2) had discovered blood in their stools. They had opted for the colonoscopy under their physician’s or friend’s advice, seeing that a colonoscopy was a more “comprehensive” or “complete” test. Many felt that the relatively higher accuracy of the colonoscopy provided them greater ease of mind:

[Colonoscopy] gives a more accurate reading, because you’re able to see...what’s inside. [P19, female]

[Colonoscopy] is not so comfortable, but it’s comfortable to the mind. [P30, male]

Perceived Risk and Pain

The stool-based and blood-based tests were more favorable to most participants as the process was “simple” and “pain-free.” Furthermore, many who had undergone a blood-based test did so as part of their annual comprehensive health check-up and saw little extra risk or pain in doing it:

It’s less traumatic to the patient. That kind of [needle] pain is bearable...no issue. [P1, female]

If it’s part of the blood works, might as well, right? Since they are already drawing blood? I don’t mind testing for [colorectal cancer] as well. [P17, female]

Many of these participants who had no prior experience undergoing colonoscopy were more likely to express fear of the risk of colon perforation from the procedure. Due to its invasive nature, many were also “scared” and “uncomfortable” with the pain the procedure might induce:

I don’t know how big the scope is...how difficult is it to insert? Will it damage anything permanently? [P11, male]

The sort that comes with pain...[I] may get cold feet. [P17, female]

Interestingly, most participants who had undergone colonoscopy had little qualms about the risk and pain of the procedure. Instead, many expressed difficulties adhering to the bowel preparation instead:

The agony part was the bowel preparation. I can’t finish the 4 litres...I gave up at 2 litres. [P14, male]

Method of Sample Collection

While being relatively easy to conduct, some participants shared reservations about the collection of stool samples. They saw the process as “dirty,” “disgusting,” or “troublesome,” especially when 2 separate stool samples were required. While some complained about the uncomfortable experience of stool collection, some expressed personal concerns about improper collection:

...because you have to do it on your own, especially when you have to dig the stool, I’m not sure whether we are doing correctly or not. [P28, male]
Nevertheless, participants who have done it across many years expressed little of such concerns, seeing it as a routine exercise that was necessary:

> You’ve done it once and then you make it an annual exercise...it’s not a big deal. [P10, female]

**Convenience of Test**

As colonoscopies and blood-based tests require medical professionals to perform them, some participants felt that the need to arrange a doctor’s appointment was time-consuming. This was especially true for colonoscopies, where a referral from a primary care physician is required to receive a subsidized rate for the colonoscopy:

> ...you have to go to the [primary care] polyclinic and then get a referral, see the specialist and then wait for the appointment...you know, so it’s a bit more cumbersome. [P25, male]

However, participants shared that stool-based tests were relatively more accessible, with kits being easily obtained at pharmacies or mailed to them on request. Even when returning stool samples, some participants shared that mailing services to the laboratory were available, which saved them the shame and hassle of dropping them off at a clinic:

> [It's] kind of a deterrent because you have a book an appointment...compared to FIT test, you can just drop by any of the pharmacies...it's a lot more convenient. [P20, female]

**Cost**

Many participants were aware of the stark difference in cost between a colonoscopy and a stool-based or blood-based test. While many participants, especially those younger and working, had employer and private insurances to subsidize a colonoscopy procedure, they highlighted that out-of-pocket cost was still substantially higher. Many cited that a higher willingness to pay must come in tandem with either higher accuracy and lower frequency of testing:

> If the colonoscopy is 70-80% [accurate], and the other tests are also 70-80% [accurate], of course I will choose the simple one. No point to go for a colonoscopy...pay so much, go through the hassle... [P24, female]

> [If] you do this scope, one time, last you for 10 years, [because them you] don’t have to collect stool sample at the next medical check-up. [P29, male]

**Quantitative Component**

**Sample Statistics**

A total of 1189 participants completed the study. Of these, 127 (10.7%) participants did not have complete sociodemographic information, while 44 (3.7%) participants failed the fixed choice task. This led to 168 (14.1%) participants dropping out, leaving a sample of 1021 participants for analysis. The demographic characteristics of all participants are presented in the Multimedia Appendix 2.

**MXL Model**

The main results of the MXL model are presented in Table 1. All mean coefficients were significant at $P<.05$. On average, participants exhibited a higher preference for blood-based tests relative to a 2-day stool-based test (coefficient=0.40, 95% CI 0.24-0.55). Participants also exhibited a higher preference for a 1-day stool-based test relative to a 2-day stool-based test (coefficient=0.27, 95% CI 0.10-0.45). The preference for these 2 procedures were however not statistically different from each other (coefficient=0.12, 95% CI –0.04 to 0.29).

The profile-based normalized CRI of the 6 attributes based on the MXL model is presented in Figure 2. Ranking the attributes, participants were most concerned with the cost and sensitivity of the screening test. This is followed by the procedure type, the risk level, the pain level, and ultimately the recommendation received for the screening test.

\(^a\)Log-likelihood: -8353, Akaike information criteria: 16,777, and Bayesian information criteria: 17,054.

\(^b\)Mean refers to the population mean. SD measures the individual preference heterogeneity. A significant value means that the preference for the corresponding level is heterogeneous at the individual levels.

\(^c\)Not applicable.

\(^d\)CT: computed tomography.

\(^e\)Singapore $1=approximately US $0.75.
**MMML Model: Preference Analysis**

The results from the MXL model suggested preference heterogeneity across the participants, with the SDs of several preferences being statistically significant. Thus, we ran an MMML model while also estimating the posterior class membership probabilities. A 2-class MMML model was the most appropriate based on the BIC. The classes were labeled post hoc as (1) strong supporters and (2) weak supporters, based on the coefficient value for “None.” A more negative coefficient value means people are more willing to take the screening test in real life. The class shares for strong supporters and weak supporters are 38.09% (n=339) and 61.91% (n=632), respectively. The main results of the MMML model are presented in Table 2. The full table with SD is presented in Multimedia Appendix 3.

Strong supporters did not exhibit a higher preference for blood-based tests relative to a 2-day stool-based test. However, weak supporters had a higher preference for blood-based tests compared with a 2-day stool-based test (coefficient=0.66, 95% CI 0.44-0.88). Similar to the results in the MXL model, strong and weak supporters were most concerned with the cost and sensitivity of the screening test. Weak supporters were more likely than strong supporters to be concerned with the procedure, pain level, and risk of test. Compared with an existing national screening program that is 2-day stool-based, has no pain, 80% sensitivity, recommended by the government’s Health Promotion Board, costs Singapore $5, and has no risk, the relative uptake rate of a blood-based screening test with all else constant will increase by 0.2% (95% CI 1.2% to 1.6%) for strong supporters and increase by 5.9% (95% CI 3.6% to 8.2%) for weak supporters.

**MMML Model: Analysis of Demographic Information**

Weak supporters were more likely to be women, ethnic Chinese, and people aged 40 to 60 years. However, strong supporters were more likely to be working, have higher income levels, and live in private housing. Strong supporters were also more likely to have a family history of CRC and to have opted for CRC screening in the past. Compared with weak supporters, strong supporters were also found to have higher scores for the perceived safety of CRC screening tests, social support, present orientation, and intolerance of uncertainty.

**Discussion**

**Principal Findings**

For every screening program to be successful, it is important to identify patterns in the population’s choice for CRC screening test to encourage uptake. By using a sequential exploratory mixed methods design and using a web-based cohort that is designed to be representative of the general Singapore population, our study is able to identify salient attributes of screening among participants to inform our understanding of the population’s preference. Furthermore, controlling for some of the salient attributes in our DCE allows for a better...
interpretation of the preference of specific procedures, which is likely to encompass the value of convenience and method of sample collection that is otherwise not considered in the DCE.

Our DCE results suggest that most participants preferred a blood-based test over a 2-day stool-based test and colonoscopy after accounting for the other attributes (eg, sensitivity). A blood-based test was perceived to be pain free, with a method of sample collection that was relatively simpler, compared with a colonoscopy. This pattern of aversion to aspects of pain and risk that comes with colonoscopy is supported by several studies [44,45]. Furthermore, studies have also supported the convenience and ease of the blood-based tests as compared with colonoscopy, as no preparation is involved [44,46]. Stool-based tests were regarded as unpleasant and disgusting to some participants in line with studies from the United States [47], Australia [48], and Germany [49], wherein participants expressed a preference for blood over stool sampling. However, comparing a blood-based test with a 1-day stool-based test, the utility for a blood-based test was not statistically significantly higher. This suggests that the requirement of testing twice was a key contributor to the perceived inconvenience and disutility of a stool-based test.

One advantage of DCE is its ability to profile the population and understand the preference and estimate the uptake in different subpopulations. We profiled the population into 2 classes, the strong supporters for CRC screening who were indifferent between the 2-day stool-based test and blood-based test, and the weak supporters for CRC screening who preferred the blood-based test over the 2-day stool-based test. Our results suggest that the sensitivity of tests was a key consideration of participants. For example, a 2-day stool-based test with a sensitivity of 80% was preferred by both strong supporters and weak supporters compared with a blood-based test with a sensitivity of 60%. Unfortunately, the shortcoming of existing blood-based tests lies in the relatively inferior sensitivity and specificity [11,12], which was a concern for participants based on the qualitative interviews as well. In reality, while the procedure of blood-based tests itself is preferred, the low sensitivity and specificity rate is unlikely to appeal to the masses. However, if blood-based tests can achieve the same sensitivity as 2-day stool-based tests, by offering blood-based tests to weak supporters, there is a potential to increase the relative CRC screening uptake by approximately 6%. The impact is likely to be significant as weak supporters make up approximately 62% of the population. Hence, further investment in research and development to improve the accuracy of blood-based tests could be beneficial to society.

The weak supporters identified in the study were less likely to do CRC screening in real life, but showed a higher preference for blood-based tests. Several observable demographic factors were associated with being weak supporters, including being female, ethnic Chinese, and younger and having lower income. The government may thus use targeted information campaigns to strong supporters should focus on better accuracy (eg, a blood-based test with high accuracy). Both strong supporters and weak supporters valued the recommendation from the Health Promotion Board [50] most, the governmental agency driving preventive care under the Ministry of Health in Singapore.

While DCEs can inform patients’ preferences on specific tests, a proper health technology assessment should be performed on whether blood-based tests are appropriate in each country. Unfortunately, cost-effectiveness studies on SEPT9 were rarely included in systematic reviews of the cost-effectiveness of CRC screening strategies [51,52]. All found studies that included SEPT9 as a screening strategy discovered that an annual SEPT9 screening was more cost-effective than no screening [18,53,54]. A total of 2 studies that relied on test characteristics of the earlier version of SEPT9 found that annual screening with FIT dominated the SEPT9 strategy [18,54], meaning that using FIT provided superior outcomes at a lower cost compared with using SEPT9. However, a more recent study using test characteristics of the improved version of SEPT9 with higher sensitivity and specificity found that the strategy resulted in higher quality-adjusted life years gained, CRC cases adverted, and CRC deaths adverted compared with other screening strategies [53]. Nevertheless, the strategy of using SEPT9 remained more costly than FIT as it resulted in a 63% higher referral for colonoscopy than FIT, increasing the cost by 26%. As a result, the strategy of FIT was still more cost-effective than SEPT9. However, these conclusions were based on perfect adherence of strategies. On the basis of our findings, the blood-based tests like SEPT9 are more likely to have higher adherence than stool-based tests such as FIT if similar accuracy can be achieved. Indeed, 2 studies that considered imperfect uptake found that when the uptake rate of FIT fell below 70% relative to that of SEPT9, FIT was no longer more cost-effective than SEPT9 [18,54]. Thus, the possibility of SEPT9 being more cost-effective than FIT likely hinges on (1) an improved version of SEPT9 with higher sensitivity and specificity and (2) a significantly higher uptake for SEPT9 over FIT. 

Policy Implications

It is inevitable that the next frontier of cancer screening will be the adoption of blood-based tests [8]. Multiple such tests are being evaluated or studied currently [7]. Hence, it is no longer far-fetched that policy makers need to decide whether and how to include blood-based tests in the national cancer screening program. In the overall landscape of cancer screening, different stakeholders have different views on the matter. Patients and clinicians alike will want any patient with cancers to be diagnosed earlier, while developers and manufacturers of the test will ultimately focus on monetary returns as a primary consideration. Policy makers and government agencies have to determine the cost-effectiveness of such tests and be mindful of all the additional subsequent more invasive and expensive tests that would be performed in the presence of a positive test result, all of which can compound health care costs. Aside from
the financial aspect, the other downsides of screening, such as patient anxiety and lead-time bias, will all need to be considered seriously. Most of the existing studies examining the attitude and preference for blood-based CRC tests were conducted in Western societies [26,27]. Preference of the technology in Asia is understudied. Therefore, studying preferences in Singapore, with its mix of East, South, and Southeast Asian cultures, provides a valuable addition to the literature.

Screening test only serves as the first step—follow-up diagnostic tests are required to complete the process. The gaps between stool-based tests and follow-up colonoscopies have been documented in the literature [55,56], which compromises the benefit of the screening program. Nonetheless, blood-based tests give policy makers another option to improve CRC screening. While blood-based tests in themselves may result in higher colonoscopy referral rates, blood-based tests may be combined with the existing screening methods rather than replacing them. This potentially improves on current CRC screening program by reducing the burden of colonoscopy through a 2-step screening approach that triages positive stool-based test patients [37] and serves as an alternative for people who reject stool-based tests [22]. Additional research is required to address these practical issues and understand the value brought by blood-based tests before advocating for the inclusion of blood-based cancer screening tests into the national guidelines.

**Limitations**

We acknowledge several limitations in this study. First, the DCE could not encompass the entirety of decision attributes pertinent to CRC screening, potentially limiting the comprehensive representation of individual decision matrices. However, we prioritized the most salient attributes of the population through qualitative interviews. Moreover, the qualitative interviews helped furnish and provide supplementary perspectives beyond the finalized attributes. Second, it is imperative to note that our study was conducted within a relatively affluent nation, thereby limiting the generalizability of economic considerations, such as income sensitivity and trade-offs to settings with lower income levels. In addition, the availability, accessibility, and quality perception of essential infrastructure, services, and resources may be influenced by local contexts, and their differential manifestations in various settings could yield disparate research conclusions.

Nevertheless, this study advances our understanding of the preferences of the population for CRC screening tests with respect to the type of procedure. The quantified value of the population’s preferences can help in the design of more targeted policies to promote optimal screening behavior and improve screening rates. Given the constrained available resources, more resources can be allocated in the short term to (1) increase the awareness of noninvasive tests and (2) the accessibility of noninvasive tests. Given that stool-based tests are nationally recommended in Singapore, efforts addressing the emotional barriers of embarrassment and disgust of stool collection should be promoted to encourage the collection of stool as something fundamental and shameless. In the long-run, policy makers should consider investing in research and development to improve the accuracy of blood-based tests, as they are generally preferred over invasive tests and may lead to greater uptake. With an improved blood-based test that yields higher sensitivity and specificity rates, institutionalizing CRC screening alongside other routine blood works is likely to be widely acceptable.

Abstract

Background: It is important for health organizations to communicate with the public through newspapers during health crises. Although hospitals were a main source of information for the public during the COVID-19 pandemic, little is known about how this information was presented to the public through (web-based) newspaper articles.

Objective: This study aims to examine newspaper reporting on the situation in hospitals during the first year of the COVID-19 pandemic in the Netherlands and to assess the degree to which the reporting in newspapers aligned with what occurred in practice.

Methods: We used a mixed methods longitudinal design to compare internal data from all hospitals (n=5) located in one of the most heavily affected regions of the Netherlands with the information reported by a newspaper covering the same region. The internal data comprised 763 pages of crisis meeting documents and 635 minutes of video communications. A total of 14,401 newspaper articles were retrieved from the LexisNexis Academic (RELX Group) database, of which 194 (1.3%) articles were included for data analysis. For qualitative analysis, we used content and thematic analyses. For quantitative analysis, we used chi-square tests.

Results: The content of the internal data was categorized into 12 themes: COVID-19 capacity; regular care capacity; regional, national, and international collaboration; human resources; well-being; public support; material resources; innovation; policies and protocols; finance; preparedness; and ethics. Compared with the internal documents, the newspaper articles focused significantly more on the themes COVID-19 capacity ($P<.001$), regular care capacity ($P<.001$), and public support ($P<.001$) during the first year of the pandemic, whereas they focused significantly less on the themes material resources ($P=.004$) and policies and protocols ($P<.001$). Differences in attention toward themes were mainly observed between the first and second waves of the pandemic and at the end of the third wave. For some themes, the attention in the newspaper articles preceded the attention given to these themes in the internal documents. Reporting was done through various forms, including diary articles written from the perspective of the hospital staff. No indication of the presence of misinformation was found in the newspaper articles.

Conclusions: Throughout the first year of the pandemic, newspaper articles provided coverage on the situation of hospitals and experiences of staff. The focus on themes within newspaper articles compared with internal hospital data differed significantly for 5 (42%) of the 12 identified themes. The discrepancies between newspapers and hospitals in their focus on themes could be attributed to their gatekeeping roles. Both parties should be aware of their gatekeeping role and how this may affect information distribution. During health crises, newspapers can be a credible source of information for the public. The information can also be valuable for hospitals themselves, as it allows them to anticipate internal and external developments.

Introduction

It is important for health organizations to communicate with the public during health crises [1-4]. Newspapers, both print and on the web, form an important mode of communication, given their relatively high perceived credibility, frequent use, and agenda-setting role [5-8]. Newspapers can inform the public of recent developments, including the extent of the crisis and threats, and preventive measures [3,9,10]. This enables the public to be well informed, can reduce fear, and stimulates the public to adopt the behavior needed for crisis mitigation [11-14]. However, communication can also induce public anxiety and make people refrain from appropriate behavior [14-16]; misinformation, an overabundance of information, or a wrongful depiction of certain issues or phenomena can be contributing factors [15,17,18]. Therefore, it is essential that both health organizations and newspapers facilitate the distribution of information that is accurate, timely, and valid [9,19,20].

Traditionally, governments and public health organizations have been the main organizations involved in communication during a health crisis [21-23]. However, the COVID-19 pandemic has been recognized by health communication scholars as the first large-scale health crisis to occur in a new media context, characterized by, among other elements, a deluge of information and misinformation [15,23,24], relatively high rates of skepticism toward media reporting [23,25], and new organizations involved in sharing information [23]. Hospitals emerged as such a new organization because of the central role they played during the crisis in ensuring the treatment of patients with COVID-19 [26-28], often being on the front pages of newspapers [29]. Furthermore, hospitals experienced firsthand the effects of misinformation and skepticism toward media reporting, including continued pressure on hospital functioning owing to low vaccination rates [30,31] and increased aggression toward hospital workers [32]. In light of the new media context and the negative effects associated with flawed communication, scholars have emphasized the importance of gaining a better understanding of information distribution through media [19,33].

Studies analyzing communication through newspapers so far have shown mixed results. Some studies have suggested adequate information distribution, for example, during the SARS-CoV-1 outbreak [34] or the H1N1 influenza pandemic [35,36]. However, other studies have been indecisive or deemed that communication could be improved, including those focusing on the West Nile virus outbreak [37], the H1N1 influenza pandemic [9,38,39], and the COVID-19 pandemic [8,40,41]. Although these studies provide valuable insights, some aspects remain understudied because most studies focused on epidemiological information [34-37,39] or included a short time frame (ie, <6 months) [8,40,41]. Furthermore, in light of the new media context, it remains unclear how information from new key stakeholders, such as hospitals, is being presented to the public. Overall, there is a need for further insights into how information from health organizations is presented to the public by newspapers during health crises [19,33,42]; therefore, scholars have specifically called for studies using both qualitative and quantitative components to understand this phenomenon [19].

Given this need, this paper presents a longitudinal mixed methods study examining the representation of hospital information in (web-based) newspaper reporting during 12 months of a health crisis in the Netherlands. Specifically, this study aimed to (1) explore the situation of hospitals during the first year of the COVID-19 pandemic, (2) determine the degree to which the representation of the identified themes in internal documents aligned with what was presented to the public in newspaper articles, (3) examine the extent to which hospital actors were included in newspaper articles reporting on hospitals, and (4) assess whether newspaper articles contained misinformation. The results of this study deepen our understanding of the portrayal of organizational information in the media and the role of both media and health care organizations in facilitating effective communication, especially during health crises [19]. Moreover, these insights can help optimize communication strategies and facilitate improved information distribution during a health crisis [19]. As such, this study contributes to health emergency preparedness [43].

Methods

Overview

This longitudinal mixed methods study compared internal hospital data with newspaper coverage over time using thematic, quantitative, and manifest content analyses. We focused on (web-based) newspaper reporting because in the Netherlands and many other European countries, both regional and national newspapers still form an important source of information for the public, especially during health crises [44]. This is contrary to some other countries, such as the United States or Argentina, possibly because of lower trust in newspaper reporting in these countries [44]. We focused on the first year of the pandemic to encapsulate the most pressing period in terms of hospital admissions and deaths within the Netherlands [45,46]. This study was part of a larger research project investigating hospitals’ responses to the COVID-19 crisis.

Ethics Approval

Ethics approval was obtained for this study by the Faculty of Health, Medicine and Life Sciences Research Ethics Committee of Maastricht University (FHML-REC/2020/110).

Setting

This study focused on the Dutch province of Limburg, one of the most heavily affected provinces in the country during the first year of the COVID-19 pandemic [47]. The province had 1,115,872 inhabitants as of January 1, 2021 [48]. During the first year of the pandemic (February 27, 2020, to February 28, 2021), the province experienced 71,348 confirmed COVID-19 cases and 1438 COVID-19–related deaths [46,49,53].
There are 5 hospitals located in the province of Limburg. These 5 hospitals vary in size, ranging from one of the smallest in the country to one of the largest in the country in terms of the number of available beds, the number of patients treated, and the number of staff. One of the hospitals is an academic hospital, whereas the other 4 are general hospitals, of which 2 are top clinical centers. Geographically, the hospitals are equally spread across the province. All included hospitals provide both inpatient and outpatient care and have a 24-hour emergency ward. All hospitals are members of the same regional acute care network; regional acute care networks are networks through which Dutch healthcare organizations coordinate crisis responses [54].

The province of Limburg has 1 major regional newspaper covering the entire province, namely De Limburger, with a daily circulation of >120,000 newspapers [55]. The newspaper has no specific political leaning and is considered neutral [56,57]. The newspaper is available both web-based and in print.

Data Collection

This study used 2 data sources: internal data from all 5 hospitals and all related media coverage from the main newspaper of the province. On March 4, 2020, the province had the first confirmed COVID-19 case [58]; therefore, the time frame was set from March 1, 2020, to February 28, 2021.

Regarding the hospital data, each of the 5 hospitals provided us with in-depth organizational data from the first year of the COVID-19 pandemic in the Netherlands. Specifically, we were given crisis meeting minutes (action and decision lists) from all meetings held between March 1, 2020, and February 28, 2021, and internal communication videos posted during the same time frame. Ultimately, 763 pages of written documents were collected, together with 635 minutes of video communications. The documents and videos contained a variety of content, including detailed information on discussions held within the crisis teams, purchases made, and department-level issues.

The regional newspaper De Limburger was selected as a data source, as it is a large regional print newspaper, also available on the web, that covers the entire province where all the 5 hospitals are located. We included a regional newspaper as opposed to a national newspaper because, in light of gatekeeping theory, the regional newspaper would likely contain more articles about the hospitals [59,60]. We used the LexisNexis Academic (RELX Group) database to collect articles published about the hospitals [59,60]. To retrieve relevant articles, the keywords used were as follows: “COVID-19,” “corona,” “care” (zorg), “hospitals” (ziekenhuizen), or “hospitals” (ziekenhuis), and “COVID-19,” “corona,” “care” (zorg), “hospitals” (ziekenhuis), or “hospitals” (ziekenhuizen). In total, 14,401 newspaper articles were identified and screened for relevance based on title and preview. Articles were deemed relevant when they included information on ≥1 of the 5 hospitals and contained information on anything related to COVID-19 in these hospitals. When in doubt of relevance, the articles were fully read and included if relevant. Of the 14,401 articles, 194 (1.3%) were included in the data analysis. The reasons for the exclusion of a large number of articles include the fact that many did not relate to COVID-19 or any of the hospitals. In part, this has to do with the fact that we used a broad search string (using “OR” instead of “AND”), as we did not want to miss any relevant articles. Furthermore, the keyword “care” (zorg) also means “ensure” in Dutch, leading to the inclusion of articles with this keyword but not related to COVID-19 and hospitals.

Data Analysis

To assess newspaper reporting of the situation in hospitals, content and thematic analyses were performed [61,62]. All coding was done by hand, as opposed to computer-aided searches for certain terms, as this is more likely to lead to a more accurate interpretation of data [63].

Regarding the internal data (ie, the action and decision lists and communication videos), FvdB used thematic inductive coding to identify themes that characterized organizational reality during the pandemic [64]. This approach was deemed most suitable because through this technique, common themes revolving around a certain phenomenon (ie, the COVID-19 pandemic) can be identified [65]. It involved pattern recognition within the data, requiring constant careful rereading of the data and construction of themes based on the characteristics of the data [64]. The coding continued until no new themes emerged. Throughout the process, FvdB engaged in ongoing discussions with RG and DW regarding the emerging codes and identified themes and presented identified codes, grouped themes, and other updates. Through these discussions, the authors, for example, distilled public support as a main theme. This theme emerged through codes related to signs of public support and appreciation (eg, bringing gifts, care bonuses, and support through social media) and codes related to public aggression and frustration (eg, verbal assault of employees, impatient patients, and downplay of the severity of the crisis on social media). In total, 12 main themes were identified, which were used to create a codebook. Multimedia Appendix 1 includes the codebook with the definition of each theme and examples of quotes. This study was part of a larger project aimed at identifying hospitals’ challenges during the COVID-19 pandemic and related responses. For the project, interviews were conducted by FvdB and RG with hospital employees from all layers of the organization (eg, medical staff, managers, and chief executive officers [66,67]). This provided a certain safeguard that the main themes identified through the coding resonated with what was experienced in practice.

Quantitative thematic content analysis was used to determine the degree to which the representation of themes in the internal documents aligned with that in the newspaper [61]. The created codebook was used to deductively code the 194 newspaper articles and 763 pages of internal documents. For each newspaper article, sentences, paragraphs, or passages that encapsulated a certain theme from the codebook were coded [64]. For example, in one of the articles, the code human resources was assigned to the following paragraph:

Bottleneck in all hospitals remains the availability of people. Who also drop out. “Absenteeism is high,” says the hospital spokesperson. Many employees have [been] infected, many more than in the first wave. Moreover, the second wave lasts longer than the first.

Articles not covering any of the themes from the developed codebooks were assigned the code “miscellaneous” (6/194,
If an article covered multiple themes, it was given multiple codes. The same approach was used for the internal documents (i.e., each hospital’s action and decision lists per day). That is, sentences, paragraphs, or passages were deductively coded. For example, in one of the documents, the code ethics was assigned to the following passage:

When the corona law takes effect on Dec. 1, wearing a mouth mask will be mandatory in all public places. ...[But] we will not enforce this law because we have a care duty.

FvdB, RG, and DW engaged in initial deductive coding of the newspaper articles and internal documents. Differences in coding were discussed to reach a consensus on the coding procedure. FvdB coded the rest of the data and consulted with RG and DW in case of doubt. After the proportions of themes for the internal documents and newspaper articles were identified, chi-square tests were conducted to calculate differences between theme proportions of the internal documents and newspaper articles. Chi-square tests were performed using SPSS Statistics for Windows (version 27; IBM Corp). \( P \) values <.01 were considered statistically significant.

To assess the presence of misinformation in the newspaper articles, manifest content analysis was performed, which is a form of qualitative content analysis [62,68]. This method of content analysis regards the direct examination of text with a low level of abstraction and a low degree of interpretation [68]. This was considered an appropriate approach because we wanted to directly compare the text in newspaper articles (e.g., statements on absenteeism rates, intensive care unit capacity, or change in visitor policies) with the text of the internal documents to assess whether the information in the newspaper articles aligned with the information in the internal documents.

### Results

#### Identified Themes and Quantitative Differences in Coverage

The internal data revealed 12 themes regarding hospitals’ situation during the first year of the COVID-19 pandemic. The themes included COVID-19 capacity; regular care capacity; regional, national, and international collaboration; human resources; well-being; public support; material resources; innovation; policies and protocols; finance; preparedness; and ethics (refer to Multimedia Appendix 1 for a full description of themes and exemplary quotes). Table 1 shows the number of times the code of a theme was found in the internal documents and newspaper articles, the proportions of themes compared with the total amount of codes, and whether the proportions of the internal documents differed significantly from those of the newspaper articles. As can be seen, over the course of the year, the newspaper articles covered significantly more about COVID-19 capacity (\( P < .001 \)), regular care capacity (\( P < .001 \)), and public support (\( P < .001 \)). The articles covered significantly less about material resources (\( P = .004 \)) and policies and protocols (\( P < .001 \)). No significant differences were found in the other themes.

#### Changes in Reporting Over Time

During the first year of the pandemic, the attention toward themes in both the internal documents and newspaper articles fluctuated and showed both similarities and differences (Figures 1-3). During the first wave of the pandemic (March to May 2020), the attention given to the themes was largely similar. The content of both the internal documents and newspaper articles mainly related to COVID-19 and regular care capacity, the change in policies and protocols, forms of collaboration to accommodate the large influx of patients with COVID-19, and human resources needed to handle the crisis.
Between July and September 2020, some differences in attention toward themes arose. Specifically, the internal documents mainly covered the themes of policies and protocols and preparedness. The documents revealed that the hospitals reflected on the experiences of the first wave and the lessons learned. This was done to be able to better accommodate a potentially expected new wave after the summer, whereby policies and protocols were adjusted accordingly. The hospitals seemed to have had difficulty in making decisions on certain issues, given the uncertainty of a potential new wave and the lack of clarity on the effectiveness of certain policies. For example, the internal documents contained discussions on whether policies and protocols should be adjusted for staff and patients coming from countries with a high prevalence of infections. Suggestions were made to impose a 2-week quarantine for individuals returning from holidays in these countries. Ultimately, it was decided to follow the national recommendations. The newspaper reported on the themes of policies and protocols and preparedness at a more aggregate level. Instead, the articles focused largely on regular care capacity. The articles described the large backlash of regular care that occurred owing to most care practices being canceled during the first wave. Moreover, the articles described how hospitals aimed to catch up with regular care and the difficulties associated with that owing to, for example, staff being on holidays.

As depicted in Figure 2, a large proportion of the newspaper articles published between July and September 2020 also focused on staff well-being. This was ahead of the attention given to that theme in the internal documents. The newspaper articles described the physical and emotional impacts of the first wave on hospital staff, the insufficiency of a 2-week holiday for full recovery, and staff concerns regarding a potential new wave after the summer period. Similarly, public support became a focal point in the newspaper articles from August onward, before receiving attention in the internal documents. The articles highlighted the decline in public support after the first wave, with the hospital staff increasingly experiencing (verbal) aggression. Moreover, the articles reported on government plans to offer a bonus to health care workers as a sign of appreciation and the ensuing backlash owing to strict eligibility criteria.
From October 2020 onward, the attention toward themes largely aligned again. The main exception was coverage of the themes well-being and public support during January and February 2021, when the third wave of admissions of patients with COVID-19 declined. During this period, the internal documents frequently covered the well-being of staff. The documents showed that the hospitals sought ways to show appreciation and deemed it important to pay attention to the mental well-being of staff, as the work started to take its toll. Instead, the newspaper articles increasingly focused on public support. The articles described the growing tension in society, whereby skeptics, for example, called hospitals to check whether intensive care units were indeed occupied with patients with COVID-19. Furthermore, the newspaper articles described how hospital staff had to deal with increasing aggression.
Types of Articles

We distinguished 3 types of newspaper articles (refer to Table 2 for an overview of the types and number of newspaper articles). The first type regarded articles that included stakeholders as a source in the reporting. This included, for example, interviews with the chief executive officers or other types of hospital staff or reporting on specific issues such as having to deal with a large influx of patients with COVID-19 and the perspectives of stakeholders on this. The second type regarded articles that did not use stakeholders as a source or where this at least was not stated. This mainly entailed more general reporting, such as the use of eHealth services or changes in hospital visitor policies. As a third type, the newspaper published diary articles in which staff from the hospitals wrote about their personal experiences of working during the crisis. Staff, for example, wrote about the struggle of having to deal with increased emotional and work pressure whereas part of the general public believed COVID-19 to be comparable with the flu. The theme well-being was covered predominantly in diary articles in the newspaper (10/27, 37%).

Table 2. The types and number of articles published in the newspaper related to the hospitals’ situation during the first year of the COVID-19 pandemic (March 1, 2020, to February 28, 2021).

Comparison of Content

All the newspaper articles were assessed for the presence of misinformation. For 7 (3.6%) of the 194 newspaper articles, the content could not be compared with the content of the internal documents because the internal documents did not contain related information. This was, for example, the case for an article published on April 4, 2020, stating that the hospitals in the studied province had the most hospital admissions in the entire country. This could not be verified, as the internal documents did not contain data on admissions in other regions. For all other newspaper articles (187/194, 96.4%), the content could be compared with the internal documents. No indication of the presence of misinformation was found. Multimedia Appendix 2 provides an example for every theme of information described in the newspaper compared with the internal documents. No indication of the presence of misinformation was found in any of the newspaper articles.

The discrepancies between newspapers and hospitals in their focus on themes can be attributed to their gatekeeping roles [59,60]. Media are faced with a plethora of events that could be covered and, therefore, have to decide which events will eventually be reported on and how [60]. During this process, several factors are considered, including timeliness, importance, proximity, and novelty [60]. Regarding our findings, the consideration of importance for readers (ie, the general public) could explain why newspaper articles covered significantly more about COVID-19 capacity, regular care capacity, and public support. Especially during the summer of 2020, the focus on regular care capacity in the newspaper deviated from the hospitals’ focus on policies and protocols and preparedness. Considering the growing need for regular care to be scaled up again after being largely canceled during the first wave [28], it could be that the newspaper deemed it necessary to frequently report on this issue, given the implications it had for the general population. The newspaper’s increased focus on public support from September 2020 onward may have been driven by societal debates on the appropriateness of public health measures and the related decrease in public support over time [69,70]. Moreover, the lower emphasis on policies and protocols and material resources could reflect the newspaper’s perception that these topics were of less importance to the readers, as they mainly had implications for hospitals and staff. However, the role of hospitals as frontline gatekeepers could also have contributed to this disparity [59,60]. As the primary source of information, organizations can decide which information is being shared with the media [60]. The hospitals may have provided less information regarding material resources and changes in policies and protocols because they deemed it irrelevant or wanted to keep it private.

Discussion

Principal Findings

This study aimed to examine newspaper coverage of the situation in hospitals in the Netherlands during the initial 12 months of the COVID-19 pandemic. Previous research found that hospital information was frequently included in media reporting during the COVID-19 pandemic [8,29]. However, our study specifically examined how hospitals navigated the first year of the pandemic and how this reality was communicated to the public through (web-based) newspaper articles. In total, we identified 12 themes that characterized the situation. We observed significant differences in the extent of coverage between internal organizational documents and newspaper articles for 5 (42%) of these 12 themes, namely COVID-19 capacity, regular care capacity, public support, material resources, and policies and protocols. An analysis of changes over time mainly revealed discrepancies in the attention paid to these themes between the first and second waves (May to September 2020) and at the end of the third wave (January and February 2021). Three types of articles could be distinguished, namely those that included stakeholders as a source, those that did not include stakeholders as a source, and diary articles. No
actors, the public, and news media are coproducing and responding to messaging [2,71]. In contrast to the more unidirectional flow of information, where public health actors disseminate information to the public through media, the current context involves a greater exchange of information between these entities. Studies have, for example, shown how public health actors monitor (social) media to assess the response to and the potential effectiveness of communication [2,71]. Our results suggest that the multidirectional nature of information should also be considered for hospitals. That is, not only do hospitals form an important source of information to promptly inform the public about recent developments, but newspaper articles can also yield relevant information for hospitals. For example, the themes well-being and public support gained attention in newspaper articles before gaining attention in the internal documents of hospitals, which shows that newspapers can be a means for those leading the crisis response to become aware of issues that might affect the organization. Moreover, the type of information found in articles, including details on available capacity, absenteeism rates, and experiences of frontline staff working during the crisis, can both meet the information needs of staff [72] and help those leading the crisis to assess and compare their internal situation with the situation of others. Although the extent to which newspapers provide new information and act as agenda setters might vary depending on the context [41], our results thus suggest that taking stock of media reporting can be valuable for hospital staff, and organizational leaders in particular, to be aware of changes occurring in both the external and internal environments and how these might impact the organization.

Contrary to what the public or stakeholders might perceive [5,6,73] and what some studies during prior health crises found [37,74], we did not find any indication of the presence of misinformation in any of the newspaper articles. Therefore, in line with previous research, our findings suggest that newspapers can be a credible source for those seeking valid information during a health crisis [35,36]. One explanation for not finding misinformation compared with previous studies could be that the study focused on hospital information instead of risk information, the latter being potentially characterized by more uncertainty [18,37]. Another explanation is that the studied newspaper was a regional newspaper. Previous studies found that compared with national newspapers, regional newspapers tend to have higher quality in reporting a local event because of audience considerations (i.e., a local audience prefers more details of a local event than national audiences) and better access to local sources [75,76]. Given the frequent inclusion of local sources, including diary articles written by hospital staff, our findings seem to support these studies. The large inclusion of sources supports the notion that during health crises, health systems would benefit from good relationships between stakeholders and traditional media [42,73,74].

**Practical Implications**

Our findings have several implications for crisis communication and health emergency preparedness. First, in light of the ongoing debate surrounding fake news and media distrust, our findings suggest that newspapers can be a valuable source of valid information during health crises [35,36]. Second, health care organizations should reflect upon and be aware of their role in informing the public and how this can be done through the media. Furthermore, health care organizations should be aware that newspapers can provide valuable information to them, allowing them to anticipate the developments occurring in both their external and internal environments. For newspapers, the inclusion of sources forms an important aspect for providing coverage that is reflective of organizational reality [76]. The use of nontraditional forms of reporting, such as diary articles, can be valuable in this regard. Furthermore, using a variety of reporting styles enables newspapers to cater to a diverse audience. The general public, as recipients of news, encompasses groups with diverse characteristics, including differences in sex, education level, and socioeconomic status [77]. These differences can influence the perceived relevance of information and subsequent behavioral responses [78]. By diversifying communications toward different groups of recipients, the effectiveness of communications can be enhanced [77]. Furthermore, newspapers need to be aware of their gatekeeping role, as this can explain deviances in the attention given to certain aspects. Although relevance to readers can justify these deviances, a decreased focus on relevance could make reporting more reflective of organizational reality. Ultimately, the public benefits from health organizations and the media collaborating in crisis communication [42,73]. By fostering relationships before a crisis occurs, both parties can ensure the rapid spread of valid information to the public [42,73].

**Limitations**

This study is subject to several limitations. First, the hospital theme proportions were constructed based on the content found in the action and decision lists. These sources reflect the outcome of a larger process, whereby it could be that verbally or via other means, such as email, more attention toward certain themes was given than was observed in the action and decision lists. Therefore, the actual focus of hospitals on themes throughout the year could differ from what we identified through our analysis. Nevertheless, considering the extensiveness of these documents (763 pages from 5 hospitals) and that these documents captured all aspects on which the hospitals needed to decide or take action, the focus derived from the action and decision lists would likely reflect the overall attention to a large extent. A second limitation regards the fact that in our study, we focused on a regional print newspaper, which could differ in reporting from national newspapers and other types of traditional media, including (local) radio and television. However, for local issues, the local newspaper can often be the agenda setter that other media follow, meaning that how the local newspaper reports on an issue can influence how it is presented in other media [76]. Moreover, considering that a substantial part of the population still accesses local newspapers as a source of information [44], studying this type of media itself could be considered still of value to health communication research.

**Conclusions**

The COVID-19 pandemic constituted a health crisis in which hospitals were a main actor and source of information. The situation of hospitals could be categorized into 12 themes, and
there was a significant difference in focus between the internal hospital documents and newspaper articles for 5 (42%) of the 12 identified themes. Newspaper articles focused significantly more on COVID-19 capacity, regular care capacity, and public support and significantly less on material resources and policies and protocols. The deviations seem to have mainly occurred between the first and the second COVID-19 waves and at the end of the third wave. The gatekeeping roles of the media and stakeholders could explain the deviations in focus. Some themes gained attention in the newspaper articles before gaining attention in the internal hospital data, supporting the notion that the flow of information can be multidirectional. Regarding newspaper reporting on hospital reality, no indication of the presence of misinformation was found. Overall, our findings suggest that newspapers can be a valuable source of information for both the public and health organizations during a health crisis.

Abstract

Background: Despite the growing accessibility of web-based information related to spinal cord stimulation (SCS), the content and quality of commonly encountered websites remain unknown.

Objective: This study aimed to assess the content and quality of web-based information on SCS.

Methods: This qualitative study was prospectively registered in Open Science Framework. Google Trends was used to identify the top trending, SCS-related search queries from 2012 to 2022. Top queried terms were then entered into separate search engines. Information found on websites within the first 2 pages of results was extracted and assessed for quality using the DISCERN instrument, the Journal of the American Medical Association benchmark criteria, and the Health on the Net Foundation code of conduct certification. Website readability and SCS-related information were also assessed.

Results: After exclusions, 42 unique sites were identified (scientific resources: n=6, nonprofit: n=12, for-profit: n=20, news or media: n=2, and personal or blog: n=2). Overall, information quality was moderate (DISCERN). Few sites met all the Journal of the American Medical Association benchmark criteria (n=3, 7%) or had Health on the Net Foundation certification (n=7, 16%). On average, information was difficult to read, requiring a 9th- to 10th-grade level of reading comprehension. Sites described SCS subcategories (n=14, 33%), indications (n=38, 90%), contraindications (n=14, 33%), side effects or risks (n=28, 66%), device considerations (n=25, 59%), follow-up (n=22, 52%), expected outcomes (n=31, 73%), provided authorship details (n=20, 47%), and publication dates (n=19, 45%). The proportion of for-profit sites reporting authorship information was comparatively less than other site types (n=3, 15%). Almost all sites focused on surgically implanted SCS (n=37, 88%). On average, nonprofit sites contained the greatest number of peer-reviewed reference citations (n=6, 50%). For-profit sites showed the highest proportion of physician or clinical referrals among site types (n=17, 85%) indicating implicit bias (ie, auto-referral).

Conclusions: Overall, our findings suggest the public may be exposed to incomplete or dated information from unidentifiable sources that could put consumers and patient groups at risk.

Introduction

Background
Spinal cord stimulation (SCS) is an emerging therapeutic approach that has been used as an intervention to address chronic pain [1,2], paralysis, and autonomic dysfunctions [3,4] resulting from injury and disease. SCS delivers electrical stimulation to the spinal cord using invasive or noninvasive interfaces. Groundbreaking pilot studies involving individuals with paralysis after spinal cord injury have demonstrated the potential benefits of SCS for improving functional recovery [5,6], resulting in a growing demand for information related to SCS among various consumer or patient groups, their caregivers, and the general public [7]. In the absence of evidence-based guidelines and standardized treatment options, people living with long-term disease and disability are likely to turn to other sources of information (eg, web-based search results), and potentially alternative treatment options (eg, advertised devices and surgical procedures), to help manage their condition. However, web-based information on SCS has not been evaluated in depth.

Currently, the US Food and Drug Administration [8] has only approved the use of epidural spinal cord stimulation (ESCS; ie, surgically implanted) to manage failed back surgery syndrome, refractory angina pectoris, peripheral arterial disease, complex regional pain syndrome, painful diabetic neuropathy as well as nonsurgical low back pain. Whether publicly accessible websites curating information on SCS provide clear indications (or contraindications) for the intended use (or potential risk) of this therapeutic modality remains unknown. Over the next decade, medical consumerism is projected to grow as people seeking treatment become more knowledgeable and active in their care through the expansion of web-based resources and the availability of medical information [9]. As the marketing of SCS to treat or manage various conditions expands concomitantly with the fragmentation of web-based medical information [10] and the gradual erosion of routine patient-to–health care provider interactions [11], patients may become more vulnerable to predatory marketing strategies that inflate the benefits of SCS while obscuring or underreporting its potential harms [12]. This market-driven shift by which medical information is being provided and subsequently accessed may engender patient consumerism and potentially alternative treatment options (eg, advertised devices and surgical procedures), to help manage their condition. However, web-based information on SCS has not been evaluated in depth.

The objectives of this qualitative study were (1) to systematically map web-based resources containing SCS-related information using common search methods that are openly and freely available to the general public and (2) to assess the content and quality of information regarding the use of SCS for the treatment or management of health conditions or symptoms.

Methods

Ethical Considerations
Ethics approval was not required for this study, as it did not involve human participants.

Search Strategy and Inclusion Criteria
This study was prospectively registered in Open Science Framework [28]. A pilot search was conducted to identify the most popular search terms (worldwide) within the last decade (2012 to 2022) for the topic “spinal cord stimulator” using Google Trends (Figure 1). All searches were performed using a United States IP designation to standardize the country-specific origin of returned results for each search engine [17]. A detailed description of the search strategy using the highest trending search queries (ie, “spinal stimulator” and “spinal cord stimulator”) is provided in the Search Strategy section in Multimedia Appendix 1 [17,28-77].
Figure 1. Search term identification. (A) Search terms with relevance to spinal cord stimulation were identified using Google Trends. Topic search using the term “spinal cord stimulator” was used to identify the top related queries: 1=spinal stimulator, 2=spinal cord stimulator, 3=spinal stimulation, and 4=spinal cord stimulation. Among the top queried terms, 1=spinal stimulator and 2=spinal cord stimulator ranked the highest in terms of relative search term popularity. (B) Search interest for the topic term “spinal cord stimulator” by global region indicated the United States (n=100), followed by Ireland (n=53), Laos (n=45), Australia (n=45), and United Kingdom (n=30) had the highest proportion of all queries (ie, not the highest number of queries) for this topic term within the specified timeframe (2012-2022).

This study considered publicly accessible websites providing information on SCS. Websites were categorized as scientific resources (ie, academic institutions and government organizations), nonprofit or foundations or advocacy organizations, for-profit or private sector or industry, news or media, or independent sources or personal blogs in accordance with subcategorizations previously outlined by Fisher et al [17]. Sites were not excluded on the basis of origin or date. Peer-reviewed papers or book chapters hosted by journal publisher websites were not included in the data extraction. Evidence suggests the general public may be unable to interpret or understand all scientific content found within peer-reviewed literature (ie, accessibility or readability of information) [78]. As this content has already been subjected to professional scrutiny from subject-area experts and editorial revision of considerable rigor or is altogether inaccessible (eg, paywall restricted), this information was not evaluated. Advertisement sites that did not include information relevant to SCS were also excluded.

Data Extraction
Data were extracted by 2 independent authors, and discrepancies were resolved through discussion or consensus with a third author. Extracted data included website type [17], characteristics (ie, site title, address [URL], publication date or most recent update, author names and credentials, country of origin or geographical designation, alternate accessibility options [format], and number of peer-reviewed reference citations), and SCS-related information provided (ie, SCS definition or summary, indications, contraindications, side effects or risks, device considerations, follow-up, outcomes, intended audience [consumer or caregiver, researcher or clinician, or both], and referral to a health care professional [eg, physician and therapist] or clinic).

Quality and Readability
In accordance with methods described in previous studies [17,18], the quality of the information provided on each website was assessed by 2 independent authors using the DISCERN instrument [29], the Journal of the American Medical Association (JAMA) benchmark criteria [30], and Health on the Net Foundation (HON) code of conduct certification [31]. Readability for each site was determined using the Flesch-Kincaid indices [32]. These assessments are described in detail in the Quality and Readability Assessments section in Multimedia Appendix 1.

Data Synthesis
Data extracted from websites were tabulated and aggregated according to site type. Websites were also explored for
high-frequency keywords. Webpages were imported as PDF to NVivo software (version 12; QRS International Pty Ltd) and archived for further analysis using the NCapture extension in Google Chrome. Website text from imported PDF files was then used to generate word clouds and frequency tables. Descriptive analyses were performed using SPSS software (version 28; IBM Corp). Average scores and ratings for each site type are expressed as mean and SD, median and IQR, or frequencies (n) and proportions (%) for continuous, ordinal, and dichotomous levels of data, respectively.

**Results**

**Screening and Search Term Frequency**

Using the term “spinal stimulator” in the first search and “spinal cord stimulator” in the second search (Figure 1), a total of 202 results were returned (Google: n=56, Baidu: n=39, Yahoo: n=58, and Bing: n=49). After exclusions (ie, duplicates, advertisements, and sites unrelated to SCS), a total of 57 unique websites were identified. Of these, 15 were host sites for peer-reviewed journal papers (n=8), book chapters (n=4), or patent applications (n=3) and were thus excluded from the main synthesis. Of the remaining 42 sites, the majority were categorized as for-profit (n=20) followed by nonprofit (n=12), scientific resource (n=6), news or media (n=2), and personal or blog site types (n=2). A flow diagram outlining the screening procedure is provided in Table 1.

Word frequencies for each search term used (ie, spinal, cord, and stimulator) are provided in Table 2 and Figure S1 in Multimedia Appendix 1. Word cloud and word frequency summaries are also provided in Figure S1 in Multimedia Appendix 1. Word frequency summaries showed that the occurrence of individual words comprising the search topic (ie, “spinal,” “cord,” and “stimulator”) was among the most frequent. This suggests the returned search results are likely to be an accurate representation of the web-based resources and SCS-related information that consumers would encounter irrespective of the search engine used [79,80]. Average occurrence (ie, frequency) of all 3 search terms was highest for scientific resource sites (spinal: mean 25.7, SD 16; cord: mean 23.7, SD 14.5; and stimulator: mean 13.8, SD 13.3), while proportional usage (ie, relative to all other words) was highest among personal or blog sites for the terms “spinal” (mean 4.4, SD 2.7) and “stimulator” (mean 3.5, SD 3.2) and news or media sites for the term "cord" (mean 5.4, SD 6.8).

**Readability**

A summary of readability is provided in Table 2 and Table S1 in Multimedia Appendix 1. Readability indices across all sites indicated that information was difficult on average and required a 9th- to 10th-grade level of reading comprehension (reading ease: mean 48.4, SD 10.8 and grade: mean 9, SD 2.7). News or media required the highest level of reading comprehension (mean 15.2, SD 9.3), and personal or blog sites required the lowest level of reading comprehension (mean 6.7, SD 3.5).

---

*a* JAMA: Journal of the American Medical Association.

*b* HON: Health on the Net Foundation.
Quality
A summary of information quality (ie, DISCERN, JAMA scores, and HON code of conduct certification) is provided in Table 2 and Figure S2 in Multimedia Appendix 1. Based on DISCERN rating criteria, just over one-third of all sites were rated as having high overall quality (n=16, 38%), with the remainder rated as having moderate (n=19, 45%) or low (n=7, 16%) overall quality. Scientific resources (median 3.5, IQR 2-3) and news or media sites (median 2, IQR 2-2) showed the highest and lowest overall DISCERN scores, respectively. Few sites met all 4 JAMA benchmark criteria (n=3, 7%). Nonprofit (median 2.75, IQR 2-3) and for-profit sites (median 1.25, IQR 1-1.9) showed the highest and lowest benchmark totals, respectively. HON code of conduct certification was present in less than a quarter of all sites (n=7, 16%), with the majority attributed to nonprofit sites (n=4, 9%).

Website Characteristics
Tabulated website characteristics are summarized in Tables S3 and S4 in Multimedia Appendix 1. Publication dates (or latest revision date) were reported for less than half (19/42, 45%) of all websites and was proportionately lowest among for-profit sites (5/20, 25%) compared to other site types. Author names, aliases, and credentials were provided in less than half of all sites (20/42, 47%), and authorship disclosure was also proportionately lowest among for-profit sites (3/20, 15%) compared to others. Site addresses included designation in the United States (30/42, 71%), Canada (1/42, 2%), and Australia (1/42, 2%) or did not provide a location (10/42, 23%). Relative to other site types, the proportion of sites that provided a geographical designation was highest among for-profit sites (19/42, 45%). Just under half of all websites provided alternate content accessibility options (ie, PDF, audio, and video; 20/42, 47%). Some sites also featured pop-up notifications and advertisements (9/42, 21%). On average, nonprofit sites contained the greatest number of reference citations (mean 11.1, SD 27.1) followed by scientific resources (mean 1.2, SD 2.9).

Website Information
Website information is summarized in Tables S3 and S5 in Multimedia Appendix 1. Most websites were intended for consumers and caregivers (n=27, 64%), with the remainder intended to serve as resources for clinicians and researchers (n=1, 2%) or both (n=14, 33%). Site information pertaining to the use of ESCS (n=37, 88%), both transcutaneous SCS and ESCS (n=2, 4%), or did not define SCS type (n=3, 7%). Sites also provided summary information or a definition of SCS (n=37, 88%) and described SCS subcategories (n=14, 33%), indications (n=38, 90%), contraindications (n=14, 33%), side effects or risks (n=28, 66%), device considerations (n=25, 59%), follow-up (n=22, 52%), and outcome-related information (n=31, 73%). Most sites featured physician or clinical referral (n=26, 61%). Relative to other site types, for-profit sites showed the highest proportion of referrals (17/20, 85%).

Discussion
Principal Findings
This study provides a novel qualitative synthesis of publicly available web-based information on the topic of SCS. For-profit websites were the most commonly encountered. Website quality ratings varied between site types suggesting that the reporting (or omission) of important quality criteria (eg, authorship, information source, and publication date) was site-type dependent. For-profit sites were rated as having relatively lower quality than nonprofit or scientific resource sites based on quality criteria (ie, JAMA benchmarks and HON code of conduct certification). The proportion of for-profit sites reporting authorship was comparatively less than nonprofit and scientific resource sites. The average number of peer-reviewed reference citations identified within for-profit sites was also comparably less frequent than that of nonprofit and scientific resource sites. These findings are largely consistent with other studies of web-based information that report similar discrepancies in the provision of authorship and information sources [17,18]. This suggests that consumers may be exposed to web-based information on SCS that originates from unidentified authors and sources. While two-thirds of all websites mentioned potential risks or side effects of SCS, only one-third described possible contraindications for SCS. Moreover, the majority of websites specifically targeted consumers or their caregivers and featured clinical or physician referral for SCS. Relative to other site types, for-profit sites constituted the largest proportion of referrals indicating potential information bias and consumer-directed marketing of SCS [13]. This is a cause for concern, as the selective provision of SCS-related information from undisclosed sources may potentially place consumers and patient groups at unnecessary risk and consequently diminish their capacity to make informed health care decisions.

Limitations
This study has several limitations. First, returned search results were limited by geographical location (ie, IP designation within the United States based on geographical trends for the search topic “spinal cord stimulator”) and may lack generalizability across regions and therefore introduce bias unintentionally. This study also incorporated the use of Baidu, the second-most commonly used search engine by international ranking at the time the search was conducted, in conjunction with other common search engines (ie, Google, Bing, and Yahoo). Although Baidu is the most commonly used web-based resource for medical information seekers following the withdrawal of Google from China in 2010 [81], the additive benefit of using this search engine and associated indices (eg, Baidu Index) to include a broader user demographic and potentially enhance search result generalizability remains inconclusive. For-profit websites were the most commonly encountered site type, representing approximately half of all included sites (n=20, 48%). However, it is unclear whether the developers of these sites allocated funding and resources to increase user traffic and enhance website visibility through the use of strategic search engine optimization techniques (eg, content management systems; schematic data structuring; and technical optimizations.
to improve URL structure, loading, navigation, and internal linking). Although the results of the word frequency summary potentially suggest the use of word frequency–based ranking algorithms, the way these search engines ultimately select which resources to display in a given list of returned search results remains unknown. Future studies may investigate whether academic institutions and government and nongovernment organizations (ie, scientific resources) that curate high-quality, evidence-based medical information actually benefit from devoting funds and organizational resources to increase website user traffic and visibility via technical optimization (eg, site content and search engine compatibility) or by other means (eg, endorsement by influential people and use of slogans, catchphrases, logographic designs, and multimedia to enhance site awareness and recognition and to demonstrate expertise, authority, and trustworthiness).

Several tools were used to provide a robust quality assessment of the information encountered on various websites (ie, DISCERN, JAMA, and HON code of conduct). Although this approach is largely consistent with previous studies of web-based medical information, among these assessments, there are both redundant components (eg, authorship, attribution, and disclosure) as well as quality criteria that are unique to each of the tools used (eg, financial disclosure and advertising). Future studies may consider the use of more recent assessments comprising these and other essential criteria for evaluating the quality of information encountered on websites and web-based resources.

Additionally, the data extracted reflects publicly accessible information from the first 2 pages of returned results for 2 top trending search terms. Though not exhaustive (ie, all possible websites providing information on SCS), the search methodology used was intended to simulate scenario-specific consumer behavior (ie, seeking SCS-related information). Future studies may consider an alternate methodological approach involving divergent user-behavior scenarios.

Conclusions
Publicly available web-based information on SCS mainly targets consumers and their caregivers. We found that almost all sites focused on surgically implanted SCS with less than half providing authorship details and publication dates. Most websites mentioned risks or side effects of SCS, yet few websites described possible contraindications. Sites curated by for-profit entities featured clinical or physician referral for SCS more often than other site types indicating implicit bias. This suggests that the public is likely to be exposed to incomplete, potentially misleading, or out-of-date information from unidentified sources regarding the use of SCS. For-profit sites were also encountered more frequently than nonprofit and scientific resource sites, suggesting the content and technical format of sites featuring higher-quality medical information are not optimized to enhance user traffic and search engine visibility. To avoid the spread of misinformation that could potentially harm certain consumer or patient groups, sites featuring evidence-based information on the current use of SCS should declare authorship, ensure the evidence is frequently updated, and consider using search engine optimization techniques that enable preferential site positioning for commonly used search terms.

Abstract

Background: Smoking ban policies (SBPs) are potent health interventions and offer the potential to influence antismoking behavior. The Korean government completely prohibited smoking in indoor sports facilities, including billiard halls, since the government revised the National Health Promotion Act in December 2017.

Objective: This study aimed to examine the impact of the SBP on the economic outcomes of indoor sports facilities, particularly billiard halls.

Methods: This study used credit card sales data from the largest card company in South Korea. Data are from January 2017 to December 2018. Monthly sales data were examined across 23 administrative neighborhoods in Seoul, the capital city of South Korea. We conducted the interrupted time series model using the fixed effects model and the linear regression with panel-corrected standard errors (PCSE).

Results: The sales and transactions of billiard halls were not significantly changed after the introduction of the SBP in the full PCSE models. The R2 of the full PCSE model was 0.967 for sales and 0.981 for transactions.

Conclusions: The introduction of the SBP did not result in substantial economic gains or losses in the sales of billiard halls. In addition to existing price-based policies, the enhanced SBP in public-use facilities, such as billiard halls, can have a positive synergistic effect on reducing smoking prevalence and preventing secondhand smoke. Health policy makers can actively expand the application of SBPs and make an effort to enhance social awareness regarding the necessity and benefits of public SBPs for both smokers and the owners of hospitality facilities.

KEYWORDS
smoking ban policy; indoor sports facility; South Korea
Introduction

Background

It is well-known that exposure to secondhand smoke causes illness and death. The World Health Organization has estimated that tobacco smoking kills 7 million people per year globally, of which 890,000 are due to secondhand smoke [1]. In the United States, the prevalence of secondhand smoke exposure among nonsmokers diminished between 1988 and 2014, from 87.5% to 25.2%. However, there was no change in exposure between 2011-2012 and 2013-1014 periods, and about 1 in 4 nonsmokers were still exposed to secondhand smoke during the 2013-2014 period [2].

Previous studies have reported that South Korea has a high prevalence of tobacco smoking [3,4], but the prevalence of smokers had markedly decreased by 2021 [5]. However, the prevalence is still high compared to other Organisation for Economic Co-operation and Development member countries [6], which means that people are considerably exposed to health threats and risks of secondhand smoke.

Between 2007 and 2018, the exposure rate to secondhand smoke among Korean adults decreased by 10.7%, and the exposure rate to secondhand smoke in indoor working areas decreased by 34.5% [6]. The reduction in the exposure rates to secondhand smoke in indoor working areas and public regions was especially prominent after 2012, most probably due to the continuous expansion of nonsmoking zones [7].

The smoking ban policy (SBP) is a potent health intervention, offering the potential to influence antismoking behavior. There has been an increase in the number of SBPs in countries globally, including Australia, England, and the United States, aligning with an increase in knowledge about the risk of secondhand smoke [8]. Indeed, the introduction of SBP leads to a decrease in exposure to secondhand smoke, improves indoor air quality, protects workers, reduces adult and youth smoking levels, decreases hospitalizations for acute myocardial infarctions, and promotes respiratory health [9-11]. Notwithstanding the benefits of SBP, owners of hospitality facilities, including restaurants, bars, and billiard halls, have vigorously opposed the policy to curb smoking in these places, arguing that SBPs will result in economic hardship for them. This argument suggests that a complete ban on smoking in these places would discourage people from dining out, potentially negatively affecting sales. However, there is much evidence from the United States, Korea, Australia, and European countries indicating that economic performance was not affected by SBPs [12-15].

In accordance with the global trends of implementing SBP, indoor sports facilities (eg, billiard halls) in South Korea were regulated by the SBP as completely nonsmoking areas since the Korean government revised the National Health Promotion Act to prohibit smoking in all indoor spaces in December 2017 [16]. This change in SBP has led owners of indoor sports facilities to feel that the policy may negatively influence their economic profit, despite no significant change in sales. The effectiveness of SBPs has been evaluated by studies in other countries, demonstrating whether SBP affects economic profit. Previous works have consistently highlighted the impacts of SBPs on sales in various indoor places, such as restaurants and bars. For example, a previous study that included a sample of all 88 counties in the state of Ohio demonstrated that there was no significant difference in bar and restaurant sales following a statewide SBP between border regions in Ohio and nonborder areas [17]. The SBP in Ohio did not differentially influence the sales revenue for bars and restaurants located in counties where the border is shared with 5 other non–smoke-free states, compared to those in nonborder counties. Another study [18] supported the evidence that the SBP did not significantly affect facility sales, as the overall impact on sales in bars was negligible. The SBP was related to an increase in sales in medium to large bars in the rural region of Ireland and a small reduction in sales among large bars in the urban areas. These findings from previous works support the evidence for justification of continued use of SBPs to prevent the general public from exposure to secondhand smoke. However, there is a lack of evidence of the effects of SBP on business revenues in indoor sports facilities, even though many studies have been steadily involved in such research based on other indoor places. Moreover, it is crucial to assess the effect of the SBP, determining whether it resulted in a positive or negative economic impact. The results of the economic impact are important to provide evidence to visitors and owners of indoor sports facilities.

Objective and Hypotheses

To date, there has been little study on changes in business revenues of indoor sports facilities, especially billiards halls since the introduction of the SBP in South Korea. This study aimed to examine the impact of the SBP on the economic outcomes of indoor sports facilities, specifically billiard halls, using actual revenue data from the largest card company in South Korea. Based on the evidence that hospitality facilities’ sales were not affected by SBPs [14,19,20], we hypothesized that the introduction of the SBP does not significantly affect billiard halls’ sales.

Methods

Data

This study used sales data from the Shinhan Card Big Data Center. The data included Shinhan’s credit, debit, and check card sales information from January 2017 to December 2018. Shinhan Card holders were 12 million in 2015, representing 44.6% of the economically active population in South Korea [21,22]. Shinhan Card has the largest market share (21.7%) in South Korea as of 2017 [23]. In 2016, a total of 80% of all private consumption in South Korea was made through card payments. A payment method survey in South Korea reported that 94% of Seoul citizens had 1 or more debit or check cards in 2013 [24]. The cash transactions were not included in our data, but the correlation between sales information provided by Shinhan Card data and the retail sales information of Statistics Korea was 0.92 [25]. The correlation between the sales information from all card companies in South Korea and the data of Shinhan
Card was 0.97 [25]. Our data are suitable for assessing the effect of the policy.

In total, 3 districts in Seoul were selected for this analysis; Nowon district (533,498 population in 2019; 35.44 km²), Secho district (430,697 population in 2019; 46.98 km²), and Songpa district (675,843 population in 2019; 33.88 km²). The population in Seoul was 9,729,107 in 2019, and the 3 districts selected for this study account for 16.9% of Seoul’s population and cover 19.2% of Seoul’s total area. Regional experts at the Seoul Institute selected the districts considering various factors, including the percentage of the population aged 20-59 years, health behaviors (eg, smoking, drinking, and obesity rates), income level, environmental factors (eg, park space per capita and the number of designated smoking areas), and the similarity of z score for each factor with the average values for Seoul.

The unit of analysis for this study was neighborhood-month. Neighborhood in South Korea is referred to as “dong,” which is a submunicipal-level administrative unit of a city. We aggregated the individual billiard hall data into the neighborhood level. As the unit of analysis does not involve human subjects, this study does not require approval from an institutional review board.

Ethical Considerations
This research used aggregated sales data from billiard halls by region. It is not subject to ethical considerations.

Variables
The dependent variables were sales per neighborhood-month and transactions per neighborhood-month. The total sales information was aggregated from credit, debit, and check card use. A total of 1100 Korean won (KRW) was exchanged for US $ 1.

Based on previous studies on retail sales [14,26,27], the following factors were considered as the independent variables: socioeconomic factors of customers and region, seasonal factors, weather factors, employee factors, and overall economic status. The data consisted of neighborhood-month, making it impossible to consider the characteristics of individual customers and specifics of the store. Therefore, regional socioeconomic factors, seasonal factors, and economic factors were included as the independent variables in our study. The research model and control variables are shown in Figure 1.

Neighborhood total sales size represented the overall economic size of the neighborhood. It summarized all monthly credit, debit, and check card use in all business types except for online shopping, university tuition, insurance fees, taxes, and utility bills. As revenue is largely influenced by the total sales size of the neighborhood, it is an important covariate to analyze the billiard halls’ sales. Season and number of holidays per month were included as seasonal factors. Seasons were classified into spring, summer, fall, and winter because customers prefer to visit indoor facilities during summer and winter. Some billiard halls close on holidays, while others are crowded on holidays. The Composite Index of Business Indicators was included to adjust the overall economic condition in South Korea [28].

Figure 1. Research model and control variables of this study.

Statistical Analysis
The Wilcoxon signed rank test was used to assess the mean difference between before and after introducing the policy. Our data were balanced panel data. Data constituted time-series–cross-section (TSCS) data, consisting of 24 months and 23 panels. Although the fixed effects (FE) model is commonly applied to analyze TSCS data, the assumptions of independence and identical distribution are prone to violation due to panel heteroskedasticity, contemporaneous correlation, serial correlation, and nonstationarity [29]. To identify these violations, we used various tests, including the Wooldridge test for serial correlation, the Pesaran cross-sectional dependence test for contemporaneous correlation, and the likelihood ratio
test using Wiggins and Poi’s method [30] for panel heteroskedasticity. With the results of these tests, panel heteroskedasticity, serial correlation, and contemporaneous correlation were observed to be significant.

Therefore, a regression model with panel-corrected standard errors (PCSE) was the most suitable approach for our data [31]. The PCSE model is known to provide robust estimation for TSCS data when \( T \geq 15 \). Since the number of panels and the number of time points are almost the same, we conducted an FE model with robust standard errors to assess the robustness although there was a contemporaneous correlation.

The interrupted time series model, a quasi-experimental analysis, was used in the analysis [32]. Interrupted time series is a well-known method to analyze the effects of policies. It provides a policy effect by comparing the actual outcome with the potential outcome assuming that the baseline trend would be extended if the policy were not introduced [33].

The full regression model is as follows:

\[
Y_{it} = \beta_0 + \beta_1 t + \beta_2 \text{policy} + \beta_3 D_{it} + \epsilon_{it}
\]

where \( Y \) is the dependent variable; \( t \) is the time period (month); \( \text{policy} \) is an indicator for the introduction of the policy introduced (0: before the introduction of the policy; 1: after the introduction of the policy); \( D \) is the dummy variables for neighborhood FEs; and \( \epsilon \) is the error term. \( \beta_2 \) and \( \beta_3 \) represent the effects of the policy. \( \beta_2 \) represents the level change due to the policy, and \( \beta_3 \) represents the trend change after the policy was introduced, compared to the baseline time trend (\( \beta_1 \)). The effects of the policy can be calculated by considering both \( \beta_2 \) and \( \beta_3 \) after the time point when the policy was introduced. For example, the 1-year effect of SBP is calculated as follows: 

\[
\beta_2 + \beta_3 \times 12.
\]

### Results

The general characteristics of the study data are shown in Table 1. The changes in sales information and neighborhood total sales size of billiard halls were insignificant in all 3 districts. Only the transactions of billiard halls in the Secho district significantly decreased, implied in the number of card payments. Since the sales in the Secho district did not change significantly, customers might be paying more per visit (Table 1).

Figure 2 shows the monthly sales trends of districts. The trends of billiard halls’ monthly sales in the 3 districts were almost flat (Figure 2).

Figure 2. The trends of the monthly sales of billiard halls from January 2017 to December 2018.

Table 2 shows the results of FE and PCSE regressions. PCSE regression with FE terms and control variables showed the highest $R^2$ results in both the sales and transactions models. Our variables of interest were SBP and the month after the policy. In model 5, with the highest $R^2$, the SBP’s coefficient ($\beta_2$) was 0.0767. It shows that the dependent variable increased by 0.0767 constantly after the SBP implementation. The coefficient for the month after the policy ($\beta_3$) was –0.0123. It showed that the dependent variables decreased by 0.0123 every month after the policy was introduced. However, neither variable was significant in all models for sales. The month after the policy, variables in transaction models were significant in models 1 and 2 (FE) as well as model 4 (PCSE), but they were not significant in model 5 (full PCSE). There was little evidence that the sales were affected by the SBP in billiard halls.

The Composite Index of Business Indicator was not significant for both sales and transactions, but it showed a positive relationship. This suggests that there may have been no significant macroeconomic issues from 2017 to 2018. The log of the neighborhood total sales size was significant for both sales and transactions; it showed that the billiard hall business was strongly affected by the economic status of its location. Compared to spring, only sales in winter were significantly higher. However, transactions were not significant in winter, compared to spring. It meant that people were likely to visit billiard halls and stay longer in the winter season. Transactions in summer were significantly higher than in spring ($P=.049$). The number of holidays did not significantly impact both sales and transactions.

Discussion

**Principal Findings**

Despite the concerns of many people about the negative impacts of the SBPs on sales of indoor working areas [14,34], this study found that the sales and transactions in billiard halls were not affected by the SBP introduced in 2017 in South Korea. This finding supports previous research demonstrating that SBPs had no negative economic impact on sales of restaurants and bars in South Korea and other countries [14,34,35].

The first of the 3 reasons for no negative economic impacts on sales of billiard halls is that the social awareness of the need for public SBPs to prevent the harms of secondhand smoke has been increased due to mass media campaigns among both smokers and nonsmokers [36-39]. As smoking in public places becomes increasingly stigmatized, smokers may increasingly...
become aware that nonsmokers have the right to object to exposure to harmful passive smoking [36,40,41]. The second reason may be due to changes in the smoking population and increased preferences for no-smoking areas. The smoking prevalence among Korean adults aged 219 years decreased from 27.5% in 2010 to 20.6% in 2020 [42]. Smoking prevalence among men aged 30-50 years, who were the dominant population of smokers, decreased especially after 2015, when tobacco prices were raised from KRW 2500 (US $2.1) to KRW 4500 (US $3.8) and indoor smoking was banned in all businesses and restaurants [42-44]. A study found that Korean smokers in 2016 reported more positive perceptions of the effectiveness of expanded smoking bans and smoke-free policies compared to smokers in 2010 [40]. Therefore, the number of smokers who may complain regarding SBPs in billiard halls has decreased, and smokers who prefer smoke-free environments may still visit the billiard halls despite knowing that they are nonsmoking areas.

The third reason may be related to the indoor smoking room. According to a study conducted between 2018 and 2019, a total of 87% of billiard halls have indoor smoking rooms [41]. Based on the National Health Promotion Act in Korea, smoking rooms can be installed inside and outside of facilities, even if the facilities are smoking-free areas. Most smokers could use indoor smoking rooms despite the SBP in billiard halls, which may have resulted in no change in the sales of billiard halls. If there are no indoor smoking rooms or if rooms are far away from the playing area, smokers may decide not to smoke and focus on playing. The Ministry of Health and Welfare in South Korea reported that nonsmokers are more likely to be exposed to secondhand smoke in indoor public places with indoor smoking rooms and recommends closing indoor smoking rooms in all public facilities by 2025 [45]. Future research should examine the economic impact on indoor facilities and the consequences of secondhand smoke following the closure of indoor smoking rooms.

There are several additional benefits related to the SBP in billiard halls. First, SBPs reduce exposure to secondhand smoke, improve health outcomes, and reduce mortality due to smoking-related illnesses for both smokers and nonsmokers [36,46]. Second, smoking restrictions may lead to changes in smoking behavior among smokers, as they should spend additional time smoking due to SBPs, leading to an increase in quit attempts [46]. Third, the SBPs in billiard halls can lead to enhanced positive perceptions of the effectiveness of expanded smoking-free areas. A study found that past smokers and nonsmokers among owners, workers, and users in billiard halls and indoor golf clubs were more in favor of smoke-free areas after the SBP in 2017 compared to before the SBP was implemented [41].

Previous studies stressed price-based policy as the most effective means of reducing the consumption of tobacco [38,44], but the level of price increase in 2015 was insufficient to lead to a noticeable difference in South Korea [44,47]. Therefore, SBPs in public facilities, such as billiard halls, together with price-based policies, have positive synergistic effects in reducing smoking prevalence and preventing secondhand smoke [35,38,40,41]. This study has the strength of examining the impact of the SBP on billiard halls’ economic outcomes using actual revenue data from the largest card company in South Korea to provide a basis for enhancing the SBP.

However, there are some concerns in interpreting the findings of this study. First, this study could not adjust for the presence of indoor smoking rooms in billiard halls, which may be related to sales and transactions in these establishments. Future studies could compare sales between the billiard halls with and without indoor smoking rooms, or, in the case of closing indoor smoking rooms, compare sales before and after closure to provide a more robust evidence base for smoke-free policies. In addition, the inability to control for individual preferences and accessibility to indoor smoking rooms is one of the limitations of this study. Smokers might prefer to play pool rather than smoke, even though they are aware of the ban in billiard halls. Alternatively, smokers may not be aware of the existence of an indoor smoking area, or even if they are, they may choose not to use it while playing pool. Therefore, future studies should include individual preferences and adherence to smoking and smoke-free areas as well as environmental constraints, such as the presence and accessibility of indoor smoking rooms, in their analyses to determine if smoke-free policies have an impact on sales.

Conclusions
This study examines the effects of the SBP in indoor sports facilities on billiard halls’ economic outcomes. Despite the worries of the owners of hospitality facilities, the SBP does not affect the sales of billiard halls. In addition to existing price-based policies, enhancing SBP in public use facilities, such as billiard halls, can have a positive synergistic effect on reducing smoking prevalence and preventing exposure to secondhand smoke. Based on this finding, health policy makers can actively expand the application of SBPs and make efforts to enhance social awareness of the need and benefits of public SBPs among both smokers and owners of hospitality facilities.

Religion, Geography, and Risky Sexual Behaviors Among International Immigrants Living in China: Cross-Sectional Study

Yuyin Zhou1, MD; Feng Cheng2,3, PhD; Junfang Xu1, PhD

Corresponding Author:
Junfang Xu, PhD

Abstract

Background: Behavioral differences exist between countries, regions, and religions. With rapid development in recent decades, an increasing number of international immigrants from different regions with different religions have settled in China. The degrees to which sexual behaviors—particularly risky sexual behaviors—differ by religion and geographical areas are not known.

Objective: We aim to estimate the associations of religion and geographical areas with sexual behaviors of international immigrants and provide evidence for promoting the sexual health of international immigrants.

Methods: A cross-sectional study was conducted via the internet with a snowball sampling method among international immigrants in China. In our study, risky sexual behaviors included having multiple sexual partners and engaging in unprotected sex. Descriptive analysis was used to analyze the basic characteristics of international immigrants as well as their sexual behaviors, religious affiliations, and geographical regions of origin. Multivariate binary logistic regression analyses with multiplicative and additive interactions were used to identify aspects of religion and geography that were associated with risky sexual behaviors among international immigrants.

Results: A total of 1433 international immigrants were included in the study. South Americans and nonreligious immigrants were more likely to engage in risky sexual behaviors, and Asian and Buddhist immigrants were less likely to engage in risky sexual behaviors. The majority of the Muslims had sexually transmitted infection and HIV testing experiences; however, Muslims had a low willingness to do these tests in the future. The multivariate analysis showed that Muslim (adjusted odds ratio [AOR] 0.453, 95% CI 0.228 - 0.897), Hindu (AOR 0.280, 95% CI 0.082 - 0.961), and Buddhist (AOR 0.097, 95% CI 0.012 - 0.811) immigrants were less likely to report engaging in unprotected sexual behaviors. Buddhist immigrants (AOR 0.292, 95% CI 0.086 - 0.990) were also less likely to have multiple sexual partners. With regard to geography, compared to Asians, South Americans (AOR 2.642, 95% CI 1.034 - 6.755), Europeans (AOR 2.310, 95% CI 1.022 - 5.221), and North Africans (AOR 3.524, 95% CI 1.104 - 11.248) had a higher probability of having multiple sexual partners.

Conclusions: The rates of risky sexual behaviors among international immigrants living in China differed depending on their religions and geographical areas of origin. South Americans and nonreligious immigrants were more likely to engage in risky sexual behaviors. It is necessary to promote measures, including HIV self-testing, pre-exposure prophylaxis implementation, and targeted sexual health education, among international immigrants in China.

religion; geography; risky sexual behaviors; international immigrants; China; sexual behavior; immigrant

Introduction

Culture is a complicated phenomenon, and there are important cultural differences between different countries, regions, and religions. International immigrants undergo an acculturation process, which influences how well they can live a new life in their new country and may result in differences in individual sexual behaviors [1]. Traditionally, in most countries, religious individuals have conservative attitudes toward sexual behavior [2,3]. For example, Christianity prohibits adolescents and unmarried ones from having sexual intercourse [4,5]. Similarly, Muslims are only permitted to have sex within marriage [6]. Some international immigrants have strong and deep-rooted religious beliefs derived from their motherland, and some of these beliefs may influence their sexual behaviors. Consequently, some international immigrants may be less likely to engage in risky sexual behaviors compared to local nonreligious people. However, some studies have found opposite results, indicating that religion may be a risk factor for engaging in risky sexual behaviors. Many world religions promote doctrines that include negative views toward homosexual
behavior, multiple sexual partners, and premarital sexual behaviors. These doctrines may cause sexual guilt in individuals engaging in nonmonogamous sexual activity, which is associated with reduced contraceptive use [7,8]. In addition, a meta-analysis [9] focused on youths identified that religion was a protective factor for age at sexual debut and the number of sexual partners but had no association with contraceptive use. Individuals’ geographical region of origin also has associations with their sexual behaviors. It was reported that polygamy was one of the main factors contributing to risky sexual behaviors and HIV infection among Haitian immigrant women living in America [10]. Additionally, single Latina women were likely to have multiple sexual partners in America [11]. Moreover, Huang [12] indicated that the migration process, especially from middle- and low-income countries to high-income countries may increase the possibility of risky sexual behaviors.

With rapid development in recent decades, an increasing number of international immigrants have settled in China. The National Bureau of Statistics reported that approximately 845,697 international immigrants lived in China in 2020, representing an increase of 251,865 compared to 2010 [13,14]. However, international immigrants tend to be exposed to sexual vulnerability [15] for several reasons. The totally new living environment, including historical and cultural differences, huge language barriers, and lack of solid social networks among international immigrants can lead to social isolation, so they may engage in risky sexual behaviors to relax and spend spare time [16]. Meanwhile, the lack of community supervision brings sexual freedom among these immigrants, which may also increase their risky sexual behaviors as they seek mental and physical pleasure [17]. For instance, a previous study found that risky sexual behaviors among homosexual/bisexual male migrants from Central and Eastern Europe living in London had been significantly influenced by the process of migration. Specifically, disentangled from the conventional frameworks of social regulation prevalent in their countries of origin and with expanded access to gay venues in London led to a notable escalation in their sexual engagement [18]. Therefore, it has also been reported that migrants are an at-risk population vulnerable to contracting sexually transmitted infections (STIs) or HIV [19-21]. However, rates of engagement in risky sexual behaviors may differ by religion and geographical region of origin. This study investigated the associations of religion and geographical region of origin with the sexual behaviors of international immigrants living in China. Findings from this study can generate evidence to assist the promotion of sexual health and implement programs for target populations at high risk of sexual behaviors.

**Methods**

**Participants**

A cross-sectional study was conducted via the internet during the COVID-19 pandemic between January 2021 and September 2021. Considering the cultural differences and sensibility of sexual issues, the respondent-driven sampling method was used to access international immigrants living in China. First, 3 - 6 international immigrants with plenty of social contacts living in different cities in China were chosen as the initial seed participants, and these seed participants had different occupations, ages, geographical regions of origin, and genders. After introducing the inclusion criteria of participants to every seed participant, they were required to recommend 1 - 3 international immigrants. If a seed participant did not recruit any other participants within 2 weeks or recruited fewer than 5 participants over 2 months, a new seed participant corresponding to its sociodemographic characteristics would be developed to ensure survey continuity and seed diversity.

Guangdong province, Zhejiang province, and Beijing were chosen as the study sites. We selected these sites because the Seventh Population Census of China in 2022 showed that these provinces or municipalities were included in the top 10 provinces or municipalities in terms of the size of international immigrants in China [22]. Guangdong is the province with the largest number of international immigrants in China, with more than 410,000 international immigrants residing there. Guangdong’s open policy and diverse social environment provide good living and working conditions for international immigrants. Zhejiang Province has a developed economy, convenient transportation, and many private enterprises, with more than 46,000 international immigrants living there. Moreover, Yiwu in Zhejiang province is one of the largest commodity trading cities, attracting nearly half a million international immigrants every year [23]. Beijing is the capital and the political, economic, and cultural center of China, with over 62,000 international immigrants. Foreign embassies, offices of major foreign companies in China, commercial and trade organizations, and foreign students are all gathered in Beijing.

The inclusion criteria of the participants were the following: (1) their home country is not China, but they currently live in China for more than 3 months; (2) aged ≥18 years; (3) able to read in English; and (4) willing to participate in the study. The exclusion criteria were the following: (1) short stay in China for business, travel, and other purposes and (2) failure to pass the “attention check” in the questionnaire, which was set to identify the careless respondents and improve the data quality. PASS 2021 (NCSS LLC) software was used to calculate the sample size. Previous studies [24,25] showed that the prevalence of HIV among international immigrants was 1.70% - 62.0%, so the prevalence of HIV was selected as 31.85% in this study with an α error set at .05, implying a 3% margin of error. To ensure the validity of the questionnaire, we increased the sample size by 20%, which required 1150 participants. Finally, 1460 participants were surveyed, and 1433 eligible participants were included in this study.

**Data Collection**

All participants completed a web-based questionnaire in English, which included sociodemographic information (eg, home country, gender, age, marital status, religious beliefs, and education level), sexual behavior–related items, and the willingness to undergo testing.

The geographical regions of origin included sub-Saharan Africa, North America, South America, Europe, North Africa, Asia, and “others.” The religious beliefs included Christianity, Islam,
Hinduism, Buddhism, and “others,” and a group of participants who identified as nonreligious were also included.

Sexual behavior–related items included whether one had participated in sexual behavior before, sexual orientation, number of sexual partners, and the frequency of condom use. Risky sexual behaviors included having multiple sexual partners and unprotected sexual behaviors. Multiple sexual partners referred to engaging in sexual behaviors with at least 1 other person in addition to their spouse or stable partner within the last year. Unprotected sexual behaviors referred to ever having sex without a condom. The questions regarding sexual behaviors were designed based on the guidelines for the prevention of HIV/AIDS issued by the China Center for Disease Control and our previous studies [26-28].

The willingness to undergo testing included STI/HIV test experiences (ie, whether they had had an HIV test in the past), perceived risk of being infected with STIs/HIV, and willingness for STI/HIV testing in the future.

Statistical Analysis
The basic characteristics of international immigrants, and their sexual behaviors, religious beliefs, and geographical regions of origin were analyzed using descriptive statistics with frequencies and percentages. Multivariate binary logistic regression analyses were used to identify religion-related and geographical origin-related factors significantly associated with risky sexual behaviors among international immigrants. Additionally, in logistic regression analysis, we took having multiple sexual partners and unprotected sexual behaviors as the dependent variables. We considered age, gender, marital status, education level, employment status, annual disposable income, STI/HIV testing experience, perceived risk of being infected with HIV, and willingness for STI/HIV testing in the future variables as covariates for conducting a multiplicative and additive interaction analysis to further explore the interaction between religion and geography. The statistical software R (version 4.2; R Foundation for Statistical Computing) and SPSS (version 23.0; IBM Corp) were used to analyze all data, and \( P < .05 \) was considered to indicate statistical significance.

Ethical Considerations
The study protocol and consent procedure were approved by the Ethics Review Committee, School of Public Health, Zhejiang University (#2019 - 064). Informed consent information was provided before the questions; participants had the option to exit the survey after reading the informed consent information or to provide consent to continue. The confidentiality of individuals was properly protected in the management of the investigation and the processing of data.

Results

Basic Characteristics of International Immigrants
As shown in Table 1, a total of 1433 international immigrants living in China were included in the study, with the mean age of 24.97 (SD 4.57) years. The majority were male (n=973, 67.90%), and more than half were unmarried (n=1263, 88.14%). Participants who had completed over 12 years of education (n=831, 57.99%) and their annual disposable income was at most 50,000 yuan (n=1040, 72.58%) accounted for the largest percentage in all groups. The participants’ religions included Christianity (n=641, 44.73%), Islam (n=565, 39.43%), Hinduism (n=73, 5.09%), Buddhism (n=47, 3.28%), and others (n=11, 0.77%), and 95 (6.63%) had no religion. The geographical regions of origin included sub-Sahara Africa (n=665, 46.41%), North America (n=44, 3.07%), South America (n=23, 1.61%), Europe (n=40, 2.79%), North Africa (n=14, 0.98%), Asia (n=610, 42.57%), and others (n=6, 0.42%). Moreover, 37.68% (n=540) of the participants had risky sexual behaviors before.

Sexual Behaviors Among International Immigrants by Religion and Geography

Table 2 shows the distributions of risky sexual behaviors among international immigrants by religion. The rates of participants with multiple sexual partners were as follows: 30.53% (n=29) among nonreligious individuals, 27.93% (n=179) among Christians, 16.64% (n=94) among Muslims, 16.64% (n=12) among Hindus, and 8.51% (n=4) among Buddhists. The rates of unprotected sexual behaviors were as follows: 22.11% (n=21) among participants without religion, 17.63% (n=113) among Christians, 8.32% (n=47) among Muslims, 5.48% (n=4) among Hindus, and 4.26% (n=2) among Buddhists. Table 3 shows the distributions of risky sexual behaviors among international immigrants by geographical region of origin. The rates of participants who reported having multiple sexual partners were as follows: 52.17% (n=12) from South America, 35.71% (n=5) from North Africa, 32.50% (n=13) from Europe, 22.73% (n=10) from North America, 27.22% (n=181) from sub-Saharan Africa, and 15.74% (n=96) from Asia. Engaging in unprotected sexual behaviors was reported as follows: 30.43% (n=7) in those from South America, 20% (n=8) in those from Europe, 16.99% (n=113) in those from sub-Saharan Africa, 15.91% (n=7) in those from North America, 14.29% (n=2) in those from North Africa, and 7.87% (n=48) in those from Asia.

The Willingness to Undergo Testing Among International Immigrants by Religion and Geography

Table 4 shows that 378 (58.97%) Christians, 469 (83.01%) Muslims, 58 (79.45%) Hindus, 3 (76.60%) Buddhists, and 65 (68.42%) nonreligious people had STIs/HIV test experiences. There were 348 (61.59%) Muslims and 46 (63.01%) Hindus who believed that it was impossible for them to be infected with STIs/HIV, which accounted for the largest percentages. As for the willingness to undergo STIs/HIV testing in the future, the willingness of Muslims was relatively low and the willingness of Christians was relatively high.
Table 5 shows that a total of 50 (83.11%) Asians, 399 (60%) sub-Saharan Africans, 20 (45.45%) North Americans, 14 (60.87%) South Americans, 29 (72.50%) Europeans, and 12 (85.71%) North Africans had STIs/HIV test experiences. There were 3 (13.04%) South Americans who believed that they were extremely likely to be infected with STIs/HIV, and 11 (78.57%) North Africans believed that it was impossible for them to be infected with STIs/HIV, which accounted for the largest percentages. As for the willingness to undergo STIs/HIV testing in the future, the willingness of Asians was relatively low and the willingness of sub-Saharan Africans was relatively high.
**Religion and Geography Factors Associated With Risky Sexual Behaviors in International Immigrants**

The results of binary logistic regression modeling performed to identify factors significantly associated with risky sexual behaviors are shown in Table 6. In multivariate analyses, Muslim (adjusted odds ratio [AOR] 0.453, 95% CI 0.228 - 0.897), Hindu (AOR 0.280, 95% CI 0.082 - 0.961), and Buddhist (AOR 0.097, 95% CI 0.012 - 0.811) immigrants were less likely to report engaging in unprotected sexual behaviors. Moreover, Buddhist (AOR 0.292, 95% CI 0.086 - 0.990) were also less likely to have multiple sexual partners. With regard to geography, compared to Asians, South Americans (AOR 2.642, 95% CI 1.034 - 6.755), Europeans (AOR 2.310, 95% CI 1.022 - 5.221), and North Africans (AOR 3.524, 95% CI 1.104 - 11.248) had a higher probability of having multiple sexual partners. shows the multiplicative interaction between religion and geography in relation to risky sexual behaviors, indicating that there was no significant multiplicative interaction. Additionally, with regard to having multiple sexual behaviors, the additive interaction analysis indicated that the relative excess risk due to interaction was −0.731 (−4.957 to 3.495), the attributable proportion due to interaction was −0.526 (−3.732 to 2.680), and the synergy index 0.347 (0.002-63.644). Similarly, with regard to having unprotected sexual behaviors, the relative excess risk due to interaction was 0.197 (-3.320-3.715), the attributable proportion due to interaction was 0.116 (–1.899 to 2.131), and the synergy index was 1.390 (0.002-1041.066). Therefore there was no significant interaction between religion and geography in relation to risky sexual behaviors among international immigrants in this study (Table 7).

**Table 6.** Logistic regression results of the impact of religion and geography on risky sexual behaviors. The italicized *P* values are considered significant.

\(^a\)AOR: adjusted odds ratio.

\(^b\)Not applicable.
No sexual misconduct means abstaining from deception and killing, no stealing, no sexual misconduct, and no lying [35].

These precepts state the following: no harming (no sexual behaviors and multiple sexual behaviors than nonreligious participants (P < 0.05). In a previous study, African-American women reported that religious affiliation was associated with unprotected sex, and increased religiosity predicted a decrease of condomless sex [31]. Another prior study demonstrated that sexual standards among Muslims were reportedly paradoxical, with two opposing attitudes toward sex resulting in the back-and-forth swing in modern society; however, these standards have become increasingly restrictive now [32]. In a study conducted on men who have sex with men in China, Muslims were reportedly less likely to engage in unprotected sex, which aligns with the findings of our study [33]. The majority of the Muslims had STIs/HIV testing experiences, which was consistent with a prior study among Muslim Americans [34]. However, Muslims also had a low willingness to undergo STIs/HIV testing in the future. This may be because Muslims felt reassured after completing initial testing and believed that they were at low risk of contracting STIs/HIV, so their future willingness to undergo testing was relatively reduced. Notably, Buddhists were less likely to have unprotected sexual behaviors and multiple sexual behaviors than nonreligious people. Compared with other religions, Buddhism has less strict rules about sexual behaviors, but Buddhists are also taught to observe four ethical precepts that may limit their sexual behaviors. These precepts state the following: no harming (no killing), no stealing, no sexual misconduct, and no lying [35]. No sexual misconduct means abstaining from deception and betrayal within intimate or committed relationships. This precept aligns with the virtues of fidelity and purity of heart [36].

In this study, South Americans, Europeans, and North Africans were more likely to have multiple sexual partners and engage in unprotected sexual behaviors compared to Asians. The rate of engagement in unprotected sexual behaviors was highest in immigrants from South America, and the rate of having multiple sexual partners was also highest in immigrants from South America. In a study published in 2020, the prevalence of risky sexual behaviors among undergraduate students in Brazil was high [37]. The number of female sex workers is also high in South America, which may influence sexual attitudes, increasing rates of engagement in commercial sex with multiple partners and having unprotected sex [38,39]. Polygamy still exists in some South American and North African countries [40], and it may have influenced the sexual behaviors of people who migrate from these countries to other places, including acceptance of multiple sexual partners. Notably, global HIV data indicate that African regions had the highest number of people living with HIV in 2022 [41]. In 2022, the incidence rate of HIV in Southeast Asia was 6/100,000, compared to 57/100,000 in the African region, 20/100,000 in the European region, and 18/100,000 in the Americas [41]. In our study, compared with other geographical regions, immigrants from Asian regions had the lowest incidence of having multiple sexual partners and engaging in unprotected sex. This may be strongly influenced by Confucian culture, which compels a large number of Asians to maintain traditional conservative attitudes toward sexual behavior. In many Asian cultures, particularly Muslim communities, the supervision of female and male circumcision also limits the spread of STIs [42].

As a marginal group, immigrants have to experience cross-cultural adaptation. China is a nonreligious country; there may be few religious activities for religious international immigrants. Besides the differences in religious customs, they also face isolation and loneliness in the new living environment.
by the disruption of the social networks; the relatively poor living space; or the unfamiliarity with the language, the customs, and even the weather, which may result in their high rates of unethical sexual behaviors [43,44]. Moreover, China has a special cultural environment, such as the “condom culture” in terms of safe sex, which in the context of Chinese culture, can be considered as distrust of other parties and is often associated with “nightclubs,” commercial sexual behaviors, and stigmatization [12]. A previous study demonstrated that religious social capital was associated with higher levels of social support among international immigrants, and social support could reduce immigration stress effectively [45]. Additionally, another study in Nigeria [46] indicated that religion was beneficial to the quality of life of people living with HIV. Specifically, intrinsic religiosity, extrinsic religiosity, and positive religious coping had a positive correlation with psychological and physical health as well as the quality of life among people living with HIV. In such situations, religion is beneficial to health-promoting behaviors, as some religious communities are inclined to preach health education, which includes information delivered through faith ministers, religious leaders, and clergy. Furthermore, social support and encouragement from congregants are likely to foster acceptance of undergoing HIV testing [47]. Therefore, it may be a good way to organize religious activities in immigrant communities appropriately.

The reported rates of STIs/HIV testing experience and willingness to take these tests in the future were not high. This may be because many international immigrants are fearful of positive results or are reluctant to disclose private issues (eg, diagnosis of an STI) in a foreign country [48]. However, unawareness of HIV infection may result in severe consequences, contributing to the HIV/AIDS epidemic [49]. Additionally, international immigrants have proven to be risk groups for HIV [21]. Therefore, as an innovation, HIV self-testing should be promoted to increase the uptake and frequency of testing among international immigrants who are missed by existing services [50]. In addition, pre-exposure prophylaxis (PrEP) is widely recognized to reduce the risk of HIV acquisition among HIV-negative people; however, the awareness of PrEP among international immigrants is low [51]. A previous study indicated that language, cost, and medical system are the main barriers to acquiring HIV prevention, such as PrEP, when enhancing the reach of these services to international immigrants [52]. China is still developing the necessary legal regulations, implementation guidance, and standard operating procedures, which are needed for improving the coverage of PrEP. For instance, some researchers indicated that community-driven social media and web-based strategies are effective ways to promote PrEP use among Latino immigrant men [53]. Furthermore, sexual health education is still an effective and feasible way to enhance people’s awareness about the severe consequences of risky sexual behaviors. For example, health workshops could be held regularly in immigrant communities; carrying out STI/HIV-related knowledge contests with prizes may also have noticeable effects.

Limitations
First, the questionnaire was distributed via the internet, which entails a number of extensively previously described limitations, such as the accuracy of the results. However, it should be noted that web-based surveys also have advantages in numerous contexts, for example, avoidance of potential embarrassment during face-to-face surveys containing sex-related items. Second, it is possible that some international immigrants were compelled by social and cultural norms to hide their sexual behaviors. Third, given the very large numbers of international immigrants now relocating to China, the generalizability of the study results to the entire population may be limited. Fourth, the questionnaire was designed based on previous work and was amended according to our research participants and objectives. Thus, the validity of the questionnaire in the survey needs to be further tested.

Conclusions
Sex-related behaviors differ among international immigrants with different geographical regions of origin and religions. South Americans and nonreligious people were more likely to engage in risky sexual behaviors, such as having multiple partners and unprotected sexual behaviors. Given that international immigrants face a myriad of sexual health challenges, it is necessary to promote measures, including HIV self-testing, PrEP implementation, and targeted sexual health education to promote the physical and mental health of international immigrants in China.

Acknowledgments
We are grateful to all study participants for their participation. This work was supported in part by the National Natural Science Foundation of China (project number 71904171) and the Fundamental Research Funds for the Central Universities.

Data Availability
All of the main data have been included in the results. Additional materials with details may be obtained from the corresponding author upon reasonable request.

Authors’ Contributions
All authors were responsible for the structure of the manuscript. YZ conducted the data analysis and drafted the manuscript. JX contributed to the study’s conception and design, interpretation of the data, and critical revisions of the manuscript. FC contributed...
to the interpretation of the data and provided critical feedback on the manuscript. All authors approved the final version for submission.

Abstract

**Background:** As the life expectancy of individuals infected with HIV continues to increase, vigilant monitoring of non–AIDS-related events becomes imperative, particularly those pertaining to liver diseases. In comparison to the general population, patients infected with HIV experience a higher frequency of liver-related deaths. The CD4/CD8 ratio is emerging as a potential biomarker for non–AIDS-related events. However, few existing studies have been specially designed to explore the relationship between the CD4/CD8 ratio and specific types of non–AIDS-related events, notably liver damage.

**Objective:** This study aimed to investigate the potential association between the CD4/CD8 ratio and the development of liver damage in a sizable cohort of patients infected with HIV receiving antiretroviral treatment (ART). Additionally, the study sought to assess the effectiveness of 3 antiretroviral drugs in recovering the CD4/CD8 ratio and reducing the occurrence of liver damage in this population.

**Methods:** We conducted an observational cohort study among adults infected with HIV receiving ART from 2004 to 2020 in Guangxi, China. Propensity score matching, multivariable Cox proportional hazard, and Fine-Gray competing risk regression models were used to determine the relationship between the CD4/CD8 ratio recovered and liver damage.

**Results:** The incidence of liver damage was 20.12% among 2440 eligible individuals during a median follow-up period of 4 person-years. Patients whose CD4/CD8 ratio did not recover to 1.0 exhibited a higher incidence of liver damage compared to patients with a CD4/CD8 ratio recovered (adjusted hazard ratio 7.90, 95% CI 4.39-14.21; P<.001; subdistribution hazard ratio 6.80, 95% CI 3.83-12.11; P<.001), findings consistent with the propensity score matching analysis (adjusted hazard ratio 6.94, 95% CI 3.41-14.12; P<.001; subdistribution hazard ratio 5.67, 95% CI 2.74-11.73; P<.001). The Efavirenz-based regimen exhibited the shortest time for CD4/CD8 ratio recovery (median 71, IQR 49-88 months) and demonstrated a lower prevalence of liver damage (4.18/100 person-years).

**Conclusions:** Recovery of the CD4/CD8 ratio was associated with a decreased risk of liver damage in patients infected with HIV receiving ART, adding evidence for considering the CD4/CD8 ratio as a potential marker for identifying individuals at risk of non–AIDS-related diseases. An efavirenz-based regimen emerged as a recommended choice for recovering the CD4/CD8 ratio and mitigating the risk of liver damage.
Additionally, we assessed a potential link between 3 distinct cohort of patients infected with HIV, receiving ART. The aim of this study was to determine whether the CD4/CD8 ratio remains inadequately investigated [13].

Drugs class might lead to differing impacts on the CD4/CD8 ratio. Importantly, the CD4/CD8 ratio is routinely recorded and readily available in clinical practice. Therefore, it could be easily used as a predictor of non-AIDS-related illnesses, including liver damage and others, provided that more data are acquired to substantiate its applicability.

Owing to an insufficient frequency of occurrences in each category, this study was not originally designed to explore the association between the CD4/CD8 ratio and specific non-AIDS-defining events, notably liver damage [9,11,12]. Furthermore, previous studies have evaluated the effectiveness of various ART regimens within drug classes on the recovery and elevation of the CD4/CD8 ratio. However, findings concerning the potential benefit of the CD4/CD8 ratio exhibit inconsistency. Variations between the ART drugs within each class might lead to differing impacts on the CD4/CD8 ratio, and the relationship between liver damage and these effects remains inadequately investigated [13].

The aim of this study was to determine whether the CD4/CD8 ratio, a readily obtainable metric in most clinical settings and frequently evaluated in patients infected with HIV exhibited an association with the occurrence of liver damage within a large cohort of patients infected with HIV, receiving ART. Additionally, we assessed a potential link between 3 distinct antiviral medications and the prevalence of liver damage, along with their impact on the CD4/CD8 ratio.

### Methods

#### Participants and Study Setting

This was a retrospective cohort study. We collected the baseline and follow-up data from the National Free Antiretroviral Treatment Program database, a surveillance system that consistently records data on people living with HIV receiving free ART along with long-term follow-up care in China. We included all treatment-naïve people living with HIV aged 18 years or older who initiated therapy between November 15, 2004, and December 31, 2020, and were residents of Chongzuo City, Guangxi Province, China. Within the National Free Antiretroviral Treatment Program, routine monitoring of immunological parameters, including CD4+ and CD8+ cell counts, as well as other pertinent laboratory parameters and clinical treatment data such as bacterial-fungal infections and liver and kidney function, was performed.

#### Statistical Analysis

Quantitative data were presented as the median (IQR), whereas categorical variables were given as the frequencies. To mitigate any potential bias stemming from treatment selection, the CD4/CD8 ratio recovered and unrecovered groups underwent a 1:2 propensity score matching (PSM) process. Similarly, the lopinavir-based, efavirenz-based, and NPV-based groups were subjected to a 1:1:1 PSM procedure. Following the methods reported previously [14], PSM analysis was used to match specific sociodemographic characteristics (such as sex, marital status, HIV transmission route, age at diagnosis, age at ART initiation, and BMI) between the groups with a recovered and unrecovered CD4/CD8 ratio. A caliper of 0.05 was used to ensure the alignment of characteristic factors between the 2 groups. Subsequently, the standardized mean differences (SMDs) and chi-square test were then used to assess the efficacy of the PSM, with SMDs exceeding 10% indicating substantial differences. Similarly, a caliper of 0.00001 was established for the ART regimen groups.

Subsequently, we used Cox proportional hazard regression models to estimate the relationship between CD4/CD8 ratio recovery and the occurrence of liver damage. To determine whether CD4/CD8 ratio recovery is linked to a reduced risk of liver damage when competing risk of mortality is accounted for, we also used Fine-Gray competing risk regression models [15,16]. Using these same methodologies, we assessed the association between the ART regimen and the incidence of liver damage with the intention of enhancing clinical decision-making. A set of factors were selected as covariates: CD4/CD8 ratio recovery, ART regimens, sex, marital status, age at HIV diagnosis, age at ART initiation, HIV transmission route, WHO (World Health Organization) HIV disease stage at
baseline, BMI at baseline, CD4⁺ lymphocyte count at baseline, CD8⁺ lymphocyte count at baseline, CD4/CD8 ratio at baseline, cytomegalovirus (CMV) infection, aspartate aminotransferase (AST) at baseline, alanine aminotransferase (ALT) at baseline, and total bilirubin (TBIL) at baseline.

To visually represent the hazard ratio before and after PSM, a forest plot was generated. Additionally, as a sensitivity analysis to assess the potential for residual confounding, we calculated end point E-values [17]. Statistical significance was assessed at α=.05, and all analyses were 2-tailed. The statistical analyses were performed with R (version 4.1.0; R foundation for Statistical Computing) and SPSS Statistics (version 26.0; IBM Corp). The “MatchIt” R package (Noah Greifer) was used for PSM, while the “survival,” “cmprsk,” and “splines” R packages for Fine-Gray competing risk regression.

Ethical Considerations

This study was approved by the Human Research Ethics Committee of Guangxi Medical University (2019-SB-102), and it was carried out in accordance with the Helsinki Declaration. In this study site, when the patients first attended the HIV prevention department of Center of Disease Control and the HIV care clinic of the hospital, they were informed that their anonymized data could be used for research. As the data collection and extraction were anonymized, individual informed consent was not needed for this study. An informed consent waiver was approved by the institutional review board of Guangxi Medical University. Participants were compensated 50 RMB (US $7.14) or a free blood routine test for the first visit and each follow-up.

We identified liver damage as the primary end point during the follow-up period. This was delineated by the combined assessment of 3 liver function parameters: AST, ALT, and TBIL. We established reference values of AST=40 unit liter, ALT=40 unit liter, and TBIL=20 mol/L as the upper limits of normality (ULN) based on the division of AIDS toxicity guidelines. All values surpassing these thresholds were classified as abnormal and categorized into different grades of liver enzyme elevation (LEE) or total bilirubin elevation (TBE) as defined by the guidelines. Specifically, grade 1-IV LEE was defined as elevations ranging from 1-2.5, 2.5-5, 5-10, to more than 10 times the ULN, while grade 1-IV TBE was determined by elevations of 1-1.5, 1.5-2.5, 2.5-5, or more than 5 times the ULN. Participants with no LEE or TBE or only grade I LEE or TBE were categorized into the normal liver function group, while those with grade II, III, or IV LEE or TBE were classified into the liver damage group.

In addition to 2 nucleoside reverse transcriptase inhibitors, cART (combination antiretroviral treatment) was defined as a combination regimen that included a nonnucleoside reverse transcriptase inhibitor, protease inhibitor, or integrase strand transfer inhibitor. The ART regimens were categorized based on the primary medication used within the initial cART regimen. Specifically, these categories encompassed lopinavir from the protease inhibitor class and nevirapine and efavirenz from the nonnucleoside reverse transcriptase inhibitor class.

The baseline encompassed various clinical indices before the initiation of ART. Follow-up persisted until the earlier occurrence of the following events: liver damage, death, or the final clinical visit recorded at the end of the study.

The inclusion criteria for patients in this study were as follows: (1) having normal liver function parameters at baseline (including normal serum ALT, AST, and TBIL), (2) having at least 2 records of CD4/CD8 ratio, and (3) receiving combination ART regimens. Patients who met any of the following criteria were excluded from the study: (1) absence of baseline CD4⁺ or CD8⁺ lymphocyte count data, (2) absence of records for any of the 3 liver function markers (AST, ALT, or TBIL), (3) lack of normal liver function at baseline, (4) presence of only 1 CD4/CD8 ratio record, and (5) were treated with regimens other than cART.

The recovery of the CD4/CD8 ratio was defined as presence of 2 consecutive values ≥1.0 (with an interval between 2 consecutive records ranging from 180 days to less than 2 years) during the follow-up period [18]. Individuals meeting this criterion were defined as the recovered group, whereas those not meeting the criterion were grouped as the unrecovered group.

Results

We identified a total of 2440 patients with HIV who met the inclusion and exclusion criteria. The patient flow for inclusion in the analysis is presented in Figure 1. Among these eligible patients, the cumulative person-years of follow-up amounted to 9963, with a median of 4 (IQR 1-7) person-years. Within the cohort, 1516/2440 (62.13%) individuals were male, while 1616/2440 (66.23%) were married or cohabiting. The majority of patients were diagnosed with HIV (1043/2440, 42.75%) or initiated ART (1074/2440, 44.02%) at the age of 50 years or more. Heterosexual transmission accounted for 93.40% (2279/2440) of HIV acquisition, and 33.40% (815/2440) had progressed to WHO HIV clinical stage I disease at baseline. Regarding baseline characteristics, 53.12% (1296/2440) of patients had a normal BMI ranging from 18.5 to 23.9 kg/m². Furthermore, 51.19% (1249/2440) of patients exhibited a CD4⁺ lymphocyte count below 200 cells/μL, while 50.08% (1222/2440) of them had a CD8⁺ lymphocyte count ≤800 cells/μL. Notably, 68.89% (1681/2440) of patients displayed a CD4⁺/CD8⁺ ratio below 0.30 at baseline. Additionally, 0.70% (17/2440) of patients showed anti-CMV Immunoglobulin G antibodies (overall 17/2440, 0.70%; when only patients with an available CMV serology were considered: 17/2440, 0.70%; Table 1).

As illustrated in Table S1 in Multimedia Appendix 1, 9.96% (243/2440) of patients achieved CD4/CD8 ratio recovery when the cutoff point for CD4/CD8 ratio recovery was set at 1. To determine the most informative cutoff point, 3 distinct thresholds were tested. Fine-Gray competing risk regression analysis indicated that the highest subdistribution hazard ratio (sHR) was observed (sHR 6.80, 95% CI 3.83-12.11) when the cutoff point was set at 1.0. This value notably exceeded the sHR for a cutoff of 0.5 (sHR 5.93, 95% CI 4.63-7.58) and a cutoff of
1.2 (sHR 4.90, 95% CI 2.51-12.11). Consequently, a CD4/CD8 ratio recovery cutoff threshold of 1.0 was selected for subsequent analysis.

Tables S2 and S3 in Multimedia Appendix 1 showed the results of PSM, revealing that 480 patients with recovered CD4/CD8 ratios and 242 patients with unrecovered CD4/CD8 ratios were included. The matched participants from the 3 ART regimen groups were merged, resulting in a total of 501 patients (167 in the lopinavir-based group, 167 in the efavirenz-based group, and 167 in the nevirapine-based group). After matching, these demographic characteristics no longer exhibited statistically significant disparities across groups (SMDs<10% and P>.05).

Figure 2 shows the cumulative incidence curve, illustrating the unadjusted incidence of liver damage in both the recovered and unrecovered CD4/CD8 ratio groups. The Fine-Gray test revealed a substantially higher cumulative incidence of liver damage in individuals with a non-recovered CD4/CD8 ratio compared to those with a recovered ratio over the 16-year follow-up period (P<.001). Upon conducting multivariable analysis, both Cox proportional hazard regressions and Fine-Gray competing risk regressions (Figure 3) indicated that a nonrecovered CD4/CD8 ratio was associated with a heightened risk of liver damage both before and after matching (aHR 7.899, 95% CI 4.391-14.209; P<.001; sHR 6.803, 95% CI 3.831-12.107; P<.001) and after PSM (aHR 6.939, 95% CI 3.409-14.123; P<.001; sHR 6.123, 95% CI 2.962-12.659; P<.001). The aHR and sHR values for the other covariates are presented in Table S4 in Multimedia Appendix 1. Additionally, the E-value analysis revealed that an unmeasured confounding factor would need to exhibit a minimum association (aHR) of 6.17 (95% CI 2.55-9.79) with liver damage, considering the measured covariates, to challenge the observed outcome.

The CD4/CD8 ratio recovery rate exhibited no significant differences among the 3 ART treatment groups (χ²= 0.04; P=.98; v=2). Especially, the CD4/CD8 ratio recovery rate was 10.1% for the nevirapine-based group, 10% for the efavirenz-based group, and 9.9% for the lopinavir-based group (Table S5 in Multimedia Appendix 1). In addition, there was a notable disparity in the time required for CD4/CD8 ratio recovery (defined as the interval between cART initiation and the attainment of CD4/CD8 ratio recovery, measured in months) across the 3 ART regimen groups (P=.01). The nevirapine-based group had the longest duration for recovery (113 months, IQR 95-131 months), substantially surpassing the efavirenz-based (71 months, IQR 49-88 months) and lopinavir-based (77 months, IQR 59-91 months) groups (Figure 4).

Through the use of stratified analysis based on different ART regimens, the relationship between CD4/CD8 ratio recovery and liver damage was assessed across 3 distinct subgroups characterized by competing mortality risks. In the nevirapine-based regimen, it was evident that the cumulative incidence of liver damage was significantly higher in the CD4/CD8 ratio unrecovered group compared to the recovered group, both before (Figure 5C) and after PSM (Figure 5F). However, within the group administered lopinavir and efavirenz regimens, no notable discrepancy in liver damage incidence was observed after PSM (Figures 5A, 5D, and 5F). Notably, patients subjected to the nevirapine-based regimen and exhibiting an unrecovered CD4/CD8 ratio displayed the highest liver damage incidence rate (7/100 person-years), a notably elevated figure in comparison to CD4/CD8 ratio recovered patients (Table S6 in Multimedia Appendix 1).

As shown in Figure 6, after being modified for a specified group of factors through forward-selection, both the Cox proportional hazard time-to-event regressions and Fine-Gray competing risk regressions (Figure 6) indicated that the efavirenz-based regimen was associated with a notably reduced incidence of liver damage than the nevirapine-based regimen. This distinction held true both before (aHR 0.675, 95% CI 0.544-0.836; P<.001; sHR 0.658, 95% CI 0.532-0.814; P<.001) and after PSM (aHR 0.564, 95% CI 0.322-0.987; P=.045; sHR 0.573, 95% CI 0.332-0.987; P=.045).

Figure 1. Cohort enrollment criteria. ALT: alanine aminotransferase; ART: antiretroviral treatment; AST: aspartate aminotransferase; HBV: hepatitis B virus; HCV: hepatitis C virus; TBIL: total bilirubin.

Discussion

Principal Results

This study represents the first comprehensive large cohort study conducted in a real-world setting with long-term follow-up to examine the association between CD4/CD8 ratio recovery and the risk of liver damage among patients infected with HIV receiving ART. Our findings underscored the notable incidence of liver damage and its strong association with the unrecovered CD4/CD8 ratio. Furthermore, we observed that participants treated with an efavirenz-based regimen exhibited a diminished incidence of liver damage and an unrecovered CD4/CD8 ratio in comparison to those administered with the nevirapine-based regimen. Given that this study centered on individuals with HIV with initially normal liver function, with the end point defined as the occurrence of liver damage, these results bear significant implications for comprehending the interrelation between the CD4/CD8 ratio and non–AIDS-defining events in patients with HIV. Thus, this study contributes substantially to the body of research in this field.

Comparison With Previous Work

In this study, liver damage was observed in 20% (491/2440) of the participants, a prevalence in line with earlier studies that reported figures ranging from 12% to 27% [19,20]. However, it is noteworthy that the highest incidence of liver damage reported in this study was 48%, occurring within the initial 3 months following the commencement of cART. This rate is both higher and faster than what was observed in a previous study (35% at 9 months) [19]. Nearly half of the patients in this cohort were older adults, aligning with the prevalent demographic trend among patients in Guangxi province [21,22]. Indeed, the elevated incidence of liver damage can be attributed to the advanced age of the patient cohort. The higher incidence underscores the substantial burden of liver disease within these individuals and the early onset of liver function impairment upon initiating cART, accentuating the significance of the initial cART regimen.

CD4/CD8 ratio recovery exhibited a robust correlation with a notable reduction in the incidence of liver damage, a relationship confirmed by both Cox regression and PSM analysis, methodologies designed to mitigate bias stemming from potential confounding variables. Notably, the observed risk reduction in liver damage remained consistent across various ratio thresholds, even when accounting for the presence of competing mortality risks. Despite variations in analytic approaches and threshold values, these findings align with results reported by Mussini et al [9], which demonstrated that a diminished CD4/CD8 ratio following ART initial independently contributed to an escalated risk of severe non–AIDS-defining events.

Furthermore, a study conducted on individuals coinfected with the hepatitis C virus and HIV demonstrated a close correlation between liver damage, assessed through transaminase levels, and the CD4/CD8 ratio [23]. These findings align with other research that has established an association between a low CD4/CD8 ratio and markers of liver health, such as liver stiffness and fibrosis [24]. Additionally, this ratio has been linked to unfavorable outcomes in smaller, often single-center cohorts [7,25,26]. However, contrasting results have been reported. For instance, a Canadian cohort study, after adjusting for variables including age and HIV RNA levels, found the CD4/CD8 ratio did not offer additional short-term prognostic value for clinical outcomes [27]. A diminished or inverted CD4/CD8 ratio reflects sustained immunological activation and is associated with immunodiscordance and the persistent inflammation that is characteristic of HIV infection [25,28,29]. Besides HIV-induced hepatitis, drug-induced hepatotoxicity constitutes a significant cause of liver damage. A post hoc analysis of previous studies revealed that an efavirenz-based ART regimen exhibited a more substantial improvement in the CD4/CD8 ratio compared to other frequently used ART
regimens [30,31]. In this study, we further explored the relationship between the extent and duration of CD4/CD8 ratio recovery and the incidence of liver damage in the 3 main ART regimens. Our findings indicated that there were no significantly differences in the rates of CD4/CD8 ratio recovery at a cutoff of 1.0 across the three ART regimen groups. However, it is worth highlighting that the efavirenz-based regimen was associated with a significant shorter period until CD4/CD8 recovery compared to the nevirapine-based regimen. Notably, users of efavirenz and lopinavir exhibited a greater enhancement in the CD4/CD8 ratio than nevirapine users, a result consistent with findings from a different research cohort [32].

In addition, this study demonstrated a consistent correlation between CD4/CD8 ratio recovery and reduced liver damage in nevirapine-based regimen groups, as validated by PSM analysis. This conclusion is further supported by the observation that patients receiving nevirapine-based therapy exhibited the longest duration to achieve CD4/CD8 ratio recovery in this study. The outcomes of this study hold clinical significance, particularly within resource-limited settings, and underscore the need for careful consideration of CD4/CD8 ratio recovery in this population to mitigate the risk of liver damage. This recommendation holds particular weight given the lifelong duration of ART regimens, where drug toxicity assumes paramount importance.

Limitations
This research has several limitations that warrant consideration. First, as a retrospective clinical study, the presence of unmeasured confounding variables is a potential concern. Second, the assessment of antiretroviral drug adherence, a factor that could affect the CD4/CD8 ratio recovery, was not feasible within the scope of this study. Third, this study lacked control over the use of medications other than ART regimens, some of which could be associated with hepatotoxicity. Last, in absence of viral suppression data in our cohort precludes us from definitively ascertaining occurrences of virological failure. Despite these limitations, the strength of our research lies in its substantial patient enrollment and robust multivariate analysis. Notably, the application of E-value analysis underscores that a potent confounding variable would be required to reverse the observed findings. An additional advantage is the use of competing-risk analysis, which provides unbiased estimations of cumulative events by accounting for death as a competing event. The stringent baseline liver function inclusion criteria further contribute to the study’s strengths; however, it should be acknowledged that selection bias could be present, given that a portion of patients were excluded due to these rigorous criteria.

Conclusions
This study had clinical and public health significance and offered additional evidence that the recovery of the CD4/CD8 ratio was associated with a lower risk of liver damage compared to ratio inversion. Notably, patients with HIV treated with efavirenz-based and lopinavir-based regimens exhibited a more pronounced increase in the CD4/CD8 ratio and a lower incidence of liver damage in contrast to those receiving nevirapine-based regimens. These findings highlight the importance of ongoing monitoring of the CD4/CD8 ratio and prompt intervention in the event of ratio inversion, particularly for individuals under nevirapine-based ART regimens.

Acknowledgments
We thank all the researchers involved in this study and the staff of the Chongzuo Center for Disease Control and Prevention. This work was supported by the the National Key R&D Program of China (2022YFC2305001), Guangxi Scientific and Technological Key Project (Guike 2022AC23005 and Guike 2022JJA141110), Thousands of Young and Middle-aged Key Teachers Training Program in Guangxi Colleges and Universities (To Bingyu Liang), and the Guangxi Medical University Training Program for Distinguished Young Scholars (To Junjun Jiang).

Authors' Contributions
BL, HL, and LY conceived and designed the study. BL, RS, and YL analyzed the data and wrote the manuscript. AN, JH, FQ, YO, JC, ZW, JC, YY, and JQ were responsible for data collection. HL, LY, and LB further edited the manuscript and gave final approval. HL, LY, and LB contributed equally to the manuscript. All authors have critically reviewed the paper.

Abstract

Background: Public health surveillance data are critical to understanding the current state of the HIV and AIDS epidemics. Surveillance data provide significant insight into patterns within and progress toward achieving targets for each of the steps in the HIV care continuum. Such targets include those outlined in the National HIV/AIDS Strategy (NHAS) goals. If these data are disseminated, they can be used to prioritize certain steps in the continuum, geographic locations, and groups of people.

Objective: We sought to develop and report indicators of progress toward the NHAS goals for US cities and to characterize progress toward those goals with categorical metrics.

Methods: Health departments used standardized SAS code to calculate care continuum indicators from their HIV surveillance data to ensure comparability across jurisdictions. We report 2018 descriptive statistics for continuum steps (timely diagnosis, linkage to medical care, receipt of medical care, and HIV viral load suppression) for 36 US cities and their progress toward 2020 NHAS goals as of 2018. Indicators are reported categorically as met or surpassed the goal, within 25% of attaining the goal, or further than 25% from achieving the goal.

Results: Cities were closest to meeting NHAS goals for timely diagnosis compared to the goals for linkage to care, receipt of care, and viral load suppression, with all cities (n=36, 100%) within 25% of meeting the goal for timely diagnosis. Only 8% (n=3) of cities were >25% from achieving the goal for receipt of care, but 69% (n=25) of cities were >25% from achieving the goal for viral suppression.

Conclusions: Display of progress with graphical indicators enables communication of progress to stakeholders. AIDSVu analyses of HIV surveillance data facilitate cities’ ability to benchmark their progress against that of other cities with similar characteristics. By identifying peer cities (e.g., cities with analogous populations or similar NHAS goal concerns), the public display of indicators can promote dialogue between cities with comparable challenges and opportunities.

Keywords: HIV; epidemiology; surveillance; HIV care continuum; cities; HIV public health; HIV prevention; diagnosis; HIV late diagnosis

Introduction

Public health surveillance data are foundational in the understanding of the current state of the HIV and AIDS epidemics [1]. Surveillance data provide significant insight into patterns within and progress toward achieving targets for each of the steps in the HIV care continuum—here, defined as timely diagnosis of HIV infection, linkage to HIV medical care, receipt
of HIV medical care, and HIV viral load suppression—for geographic areas and populations [2]. Dissemination of these data can be used to categorize certain steps in the continuum, geographic locations, and groups of people.

AIDSVu was created in 2009 as part of a cooperative private-public-academic partnership between Emory University’s Rollins School of Public Health, Gilead Sciences, Inc, and the Center for AIDS Research at Emory University [3]. AIDSVu aims to provide policy makers, health departments, and others who have a stake in health with an instrument to educate the public, monitor progress and trends, and judiciously advocate for resources and plan programs. Here, we report, for the first time, descriptive statistics for 36 US cities’ status for each of the HIV care continuum steps and their progress toward achieving 2020 National HIV/AIDS Strategy (NHAS) goals based on AIDSVu data [4]. We describe a standardized method to compare HIV care continuum data at the city, regional, and national levels.

Methods

Data Collection

We obtained the data used in this analysis through a data request in the spring of 2020 sent to AIDSVu-participating health departments for continuum indicators for people with HIV aged 13 years and older from the enhanced HIV/AIDS reporting system. The request was sent to health departments who had submitted data to AIDSVu in the past or who expressed interest in participating. A total of 36 cities provided stratified data without identifiers related to timely HIV diagnosis, linkage to HIV care, receipt of HIV care, and HIV viral suppression. Data provided on the AIDSVu website are regularly updated and city participation varies by year; these analyses use only the data as they were available for 2018.

In this study, we defined cities as single cities, single or multiple counties that included the named city, or metropolitan statistical areas (MSAs) that included the named city. Use of common SAS code to calculate indicators enabled comparability of indicators across jurisdictions. Data stratifications for display (ie, by age, sex, and race or ethnicity) were chosen by the jurisdictions. For stratification purposes, age was defined as age at initial diagnosis for timely diagnosis and linkage to care; age for the other HIV continuum measures was age as of the end of 2018.

Although AIDSVu HIV care continuum indicator definitions were guided by a process that involved the Centers for Disease Control and Prevention (CDC), the counts and percentages for each of the 4 HIV care continuum indicators were defined slightly differently from those of the CDC (see the AIDSVu website for more information) [3,5]. Timely HIV diagnoses were assessed among persons aged 13 years and older with new HIV diagnoses within the 5-year period from 2014 through 2018. An HIV diagnosis was considered timely if the person did not receive an AIDS diagnosis within 3 months of their initial HIV diagnosis. Timely diagnosis represented the inverse of the traditional late diagnosis continuum measure. Linkage to care was defined as having a CD4 lymphocyte or HIV viral load test within 1 month of diagnosis among those at least 13 years of age with a new HIV diagnosis in the 5-year period from 2014 to 2018. The numerator for the receipt of care definition included individuals who were 13 years of age or older and had been diagnosed with HIV by the end of 2017 and were alive throughout 2018 with ≥1 CD4 lymphocyte or HIV viral load test within 2018. The denominator included those living with HIV in 2018 (excluding those newly diagnosed in 2018). Those diagnosed with HIV by the end of 2017 and living with HIV throughout 2018 with an HIV viral load <200 copies/mL for their most recent HIV viral load test within 2018 were determined to be virally suppressed.

Data Analysis

Descriptive analyses were conducted for data as of 2018 from 36 cities using SAS (version 9.4, SAS Institute). Cities were categorized by US Census region (ie, Midwest, 2 cities; Northeast, 9 cities; South, 21 cities; and West, 4 cities). The national HIV case counts and percentages for timely diagnosis, receipt of care, and viral suppression were obtained from the CDC’s HIV Surveillance Report for 2018 [6]. We compared indicators reported by the cities with NHAS-designated HIV care continuum benchmarks proposed to be achieved by 2020 [4]. There is currently an updated set of goals through 2025 [7]; however, because our data are from 2018, we compared the data to 2020 goals. Given that there is not an NHAS indicator for timely diagnosis, we used the goal for the indicator called “Knowledge of HIV+ Status,” which was 90% (note: “Knowledge of HIV+ Status” is not tied to a particular time period of receipt of diagnosis) [4]. The NHAS linkage to care goal was to have 85% of persons with a new HIV diagnosis linked to HIV medical care within 1 month of diagnosis. This goal was applied to our linkage to care indicator. The NHAS retention in care goal of 85% was adapted for our receipt of care indicator, and the NHAS viral suppression goal of 80% was used for our viral suppression indicator.

The cities’ progress toward each of the HIV care continuum goals was assessed by determining the relative percentage difference from each goal. For example, the NHAS goal for linkage to care was 85% and the percentage of people in Atlanta with newly diagnosed HIV linked to an HIV care provider was 69% (n=5321). To calculate Atlanta’s progress, we subtracted 0.69 from 0.85, divided the resulting number by 0.69, and then multiplied it by 100 to say that Atlanta was within 25% of achieving the NHAS goal for linkage to care. We categorized city- and target-specific progress toward the goal as follows: met or surpassed the goal, within 25% of attaining the goal, or further than 25% from achieving the goal. We applied the same method to each of the priority populations for the individual cities’ progress tables. We defined priority populations as sex, race or ethnicity, and age groups. Finally, we categorized age as the following: 13-24, 25-44, 45-59, and 60 years of age and older. We calculated the percentage of cities that were at least within 25% of meeting each indicator goal within priority populations.

Ethical Considerations

As this study used publicly available, secondary, deidentified data (numbers were aggregated to the city level or beyond),
ethical evaluation via institutional review board review was not warranted.

Results

All Cities’ HIV Care Continuum Indicators

Within our 36 cities, 447,371 people were living with HIV as of 2018, with 82,827 people newly diagnosed with HIV during the 5-year period from 2014 to 2018. In 2018 alone, 15,767 people were newly diagnosed with HIV. Table 1 displays the numerators and percentages for HIV care continuum indicators at the national (except for linkage to care), regional, and city levels. More than half (n=22, 61%) of AIDSVu cities had a higher percentage for timely diagnosis than the national percentage for timely diagnosis. For receipt of care, more than half of the cities (n=24) had higher percentages than the percentage for the national average (n=661,816, 75.7%). Compared to the national percentage for viral suppression (n=565,195, 64.7%), 10 cities had higher percentages. City-to-city comparisons were made with the understanding that cities were broadly defined at the city, single county, multicounty, or MSA level.
Table 1. HIV care continuum indicator numerators and percentages by AIDSVu city with categorization by progress toward 2020 National HIV/AIDS Strategy goals, 36 US cities, as of 2018.

Cities’ Progress Toward the HIV Care Continuum Goals

Overall, cities were closest to meeting the 2020 goals for timely diagnosis and receipt of care and struggled the most with meeting the goal for viral suppression (Table 1). The 2020 NHAS goal specified that at least 85% of people with newly diagnosed HIV should be linked to care. At the end of 2018, most of the 34 cities that provided data for linkage to care (n=20, 59%) were within 25% of the goal; 1 city (Seattle) surpassed the goal. All but 3 of the 36 cities were at least within 25% from meeting the receipt of care goal. For viral suppression, most cities (n=25, 69%) were not within 25% of the goal, and no cities met or surpassed the goal. Table S1 in Multimedia Appendix 1 contains a color-coded version of Table 1, with red, yellow, and green colors indicating categories of progress toward each of the HIV care continuum indicators’ NHAS goals.

Cities’ Progress Toward the HIV Care Continuum Goals by Priority Populations

Table 2 displays the percentage of AIDSVu cities that were within 25% of meeting, had met, or had surpassed the NHAS goal for each HIV care continuum indicator within sex, race or ethnicity, and age groups. Overall, receipt of care was the indicator that had the highest percentage of cities that were at least within 25% of meeting the goal for select demographic groups, 97% (n=35) of cities met, surpassed, or were close to meeting the goal for females, Black people, and 13 to 24-year-olds. Viral suppression was the indicator for which most group-specific city proportions were not close to meeting the NHAS goal. Within the races and ethnicities group, the White population had the highest percentage of cities that were close to meeting, had met, or surpassed the goal for the viral suppression indicator. Only 1 demographic group—13 to 24-year-olds—had all 36 cities at least within 25% of meeting the goal for timely diagnosis. Compared to other race and ethnicity groups, the Black population had the highest percentage of cities that were close to meeting, had met, or surpassed the timely diagnosis and receipt of care goals (n=35, 97% for both). The greatest variation in percentages within a demographic category across all indicators was found for age groups. Compared to the younger age groups, older age groups had substantially lower percentages of cities whose residents had timely knowledge of their HIV+ status; however, the opposite trend was seen for the linkage to care and viral suppression indicators across age groups. Across the race and ethnicity categories, the greatest variation in percentages of cities close to meeting or having met or surpassed the NHAS goals was seen for viral suppression.
Table 2. Percentage of AIDSVu cities that were at least within 25% of achieving each National HIV/AIDS Strategy HIV care continuum indicator goal by sex, race or ethnicity, and age, as of 2018.

*aOnly 34 AIDSVu cities are represented in the percentages. Denver and Providence did not provide data for linkage to care.*

**Discussion**

**Principal Findings**

The HIV care continuum can be a useful public health tool to characterize the state of the HIV epidemic in defined areas. Much of the progress along the continuum is framed in the context of national goals, but all public health is local, and national goals will not be achieved unless they are consistently met in the cities with the largest HIV epidemics. Cities have a strong understanding of their community’s perceptions of HIV and the needs of those affected by and infected with HIV, which can be used to tailor and focus efforts. For example, in 2016 New York City clinical providers and community-based organizations created the PlaySure Network [8]. This network is dedicated to making HIV-related services such as testing, treatment, and pre-exposure prophylaxis available to all New Yorkers [8].

Here, we expand the geographic level of analysis of the HIV care continuum beyond the county-level data disseminated by the CDC [9]. A total of 27 of the 36 cities included here are located within Ending the HIV Epidemic jurisdictions [10]. The 36 cities in this analysis illustrate progress in meeting national goals overall and for particular race or ethnicity, sex, and age groups [11]. Understanding this level of patterns of inequities in access to and maintained engagement in HIV care can inform local public health action needed to improve the HIV care continuum.

Many cities publish their own surveillance reports, but different cities may use different methods to calculate key indicators. To date, a consistently derived set of indicators that surpasses the depth of the county level for at least some cities has not been available. Similarly, examining NHAS goals at the local level has a great impact. All cities were within 25% of meeting the timely diagnosis goal, but varied in how close they were to achieving the linkage to care and receipt of care goals, with 38% (n=13) of cities >25% from meeting the linkage to care goal and only 1 city that met or surpassed the linkage to care goal. Viral suppression posed the greatest challenge for cities, with only 31% (n=11) of cities falling within 25% of meeting the NHAS goal and none meeting or surpassing the goal. Among cities, there were substantial differences in meeting linkage to care and viral suppression goals among racial or ethnic groups. Finally, a higher percentage of cities were close to or met or surpassed the NHAS goals for younger populations (13 to 24 and 25 to 44-year-olds) compared to older ones (45 to 59-year-olds and those aged 60 or older) for timely diagnosis; in contrast, compared to all other age groups, the highest percentage of cities (58%, n=21) that were close to or met or surpassed the goal for viral suppression was for the oldest population (60 years of age or older). The former may reflect older people’s perception of a lower risk of HIV acquisition, while the latter may signal that younger people are less likely to stay engaged in care [12]. Additionally, younger people are unlikely to be diagnosed 8 years or more after their infection (the estimated duration of infection associated with late diagnosis) because their infection most likely happened between ages 15 and 25 years.

Among the 36 cities, there were none that achieved or surpassed the timely diagnosis NHAS goal for 2020. Thus, there is room for improvement in diagnosing people with HIV in a timely manner for cities overall. The CDC recommends that everyone aged 13 to 64 years be screened for HIV once in their lifetime, with those with certain risk factors tested annually [13]. Routine testing for those at high risk of acquiring HIV can make substantial inroads to increasing the number of timely diagnoses, but it will not allow cities to reach 100% of all those at risk of acquiring HIV. Anyone can contract HIV, so even for cities that are close to meeting the timely diagnosis goal, the last few who are not diagnosed in a timely manner are the hardest to reach.
The ability of providers and patients to assess risks for HIV may not be optimal. Some studies suggest that older people are more likely to be diagnosed with advanced HIV, and women—as well as older people—have a higher likelihood of being diagnosed with HIV in a hospital [12,14]. This finding may reflect low perceived risk among these demographic groups, leading to less testing as a part of routine care. Additionally, fear of stigma may also play a role in individuals not requesting or being offered testing at younger ages or outside of hospital settings. Offering HIV tests as part of routine primary care may therefore help increase the number of timely diagnoses overall.

Young people, who are often healthy, may not feel compelled to regularly engage with the health care system, so cities should focus on installing and making low-cost HIV testing services available at more accessible locations such as retail pharmacies and at home (eg, self-test kits) [15]. CDC recently announced a multiyear program to distribute HIV self-test kits directly to people who request them; this program will include direct marketing to populations with increased risks for HIV [16]. Cities will be able to incorporate referrals to the program into local prevention programming. The idea of distributing self-test kits by mail may be more acceptable after the national experience with government distribution of COVID-19 self-test kits [17].

Local, structural, and social factors can play a significant role in the ability of people with HIV to be linked to care. When there is no formal system to foster tight-knit communication between public health facilities, HIV testing sites, and HIV providers, it can be difficult to effectively link people newly diagnosed with HIV to care. Shortages of local providers who can treat people with HIV may lead to long wait times for appointments, potentially interfering with initiation of care [18-20]. It is also important to consider the local communities’ general attitudes toward HIV as they may discourage people from showing up at facilities that others know may be associated with treatment for HIV [19]. Implementation of the following has been found to promote successful linkage to care: patient navigators, mental health services, care coordination, staff training, and reduced time to provider appointments [18].

Our data highlight the importance of stratifying the HIV care continuum by demographic populations. Priority populations may differ across cities and existing prevention and care interventions may not be designed for the priority population of interest, thus requiring adaptations of the intervention. One study that constructed a dynamic HIV transmission model incorporated information regarding HIV micro epidemics within 6 differing US cities and evidence-based interventions to determine what cost-effective combination of approaches resulted in the most health benefit [21]. The researchers found that approaches needed to be tailored to each of the cities because they each had varying levels of high-risk, vulnerable populations for which some interventions worked better than others [21]. Using consistent methods of deriving HIV care continuum indicators can enable cities to discover commonalities, such as similar high-risk populations, that may promote discussions of best practices more easily.

**Limitations of the General Field**

In this report, we presented the proportion of timely diagnoses among people diagnosed with HIV in 36 cities from 2014 to 2018. However, late diagnosis (the inverse of timely diagnosis) has been found to be flawed and thus, late diagnosis and timely diagnosis indicators should be used with caution because they are affected by both HIV incidence and testing [22-24]. We recommend CDC dropping these indicators and developing a new one to monitor HIV diagnosis, for example, the probability of diagnosis within 1 year of infection [25]. The timely and late diagnosis definitions are also imperfect in that they may not accurately account for those who rapidly progress to AIDS despite having tested negative for HIV within the prior year or 2.

Intermittent access to care can be difficult to isolate from the receipt of care definition because the receipt of care definition relies on testing alone. Using the CDC definition for receipt of care means that people who seek care but do not receive either test for whatever reason will be excluded.

**Limitations of the Study**

Our study has several limitations. It only included data from people who were diagnosed. Thus, we do not provide insight into what populations of people are living with undiagnosed HIV. The lack of data on undiagnosed HIV means that our percentages for the 4 indicators underrepresent the true estimates. More work needs to be done to fully capture the entire population of people with HIV. Furthermore, to measure receipt of care and viral suppression, we used HIV case reporting data to estimate the denominator, that is, the number of people with HIV at the end of 2018. It has been shown that such a method can overestimate the number of people with HIV in a jurisdiction [26]. Therefore, we may have overestimated our denominator and underestimated receipt of care and viral suppression. However, because the same method was used across all 36 cities, the rankings of receipt of care and viral suppression by city and region were likely to be valid. It is recommended that HIV laboratory reporting data be used to estimate the number of people with HIV to counter the flaws with HIV case reporting data [26]. However, while this approach may lead to more accurate estimates in jurisdictions that have laws requiring full reporting of CD4 lymphocyte or viral load data, only 47 states and the District of Columbia had such laws as of December 2019 [6]. Among the 36 cities in our analysis, Newark and Philadelphia were in states that did not have such laws [6].

CITIES themselves decided whether they provided input for their city alone, the county that encompassed their city, multiple counties including the one with their city, or an MSA that included their city. Cities’ data reporting was not complete, including exclusions of cases missing a zip code and exclusions due to low case count at the zip code level and for specific cities (eg, linkage to care for Denver and Providence). Additionally, not all cities had the same capacity to deduplicate their data, contributing further to the potential inflation of denominators. Also, these data do not include categories for 2 groups of people who are known to be at increased risk for HIV acquisition—men who have sex with men and people who inject drugs. Furthermore, we did not have information on nativity.
These comparisons were made with the idea that our unit of analysis, a city, was broadly defined with cities themselves deciding how their jurisdiction was defined—whether that be at the city, single county, multicounty, or MSA level. Finally, we do not include data for all major cities across the United States, such as those in California which have their own reporting mechanisms. Therefore, we are not capturing the full spectrum of progress toward the HIV Care continuum goals in all major cities or the 4 regions across the United States.

**Public Health Implications**

National strategy goals cannot be achieved without first meeting these goals at the city level. Cities represent a fundamental unit for change, with cities knowing how to best reach and support the communities that dwell within their bounds. Cities have often been at the forefront of enacting fundamental policies—such as certain cities’ that make it their practice to provide pre-exposure prophylaxis at minimal cost—to prevent the transmission of HIV and improve the lives of those living with HIV. Similar to the SARS-CoV-2 vaccination for which about 67% of the US population had received at least 1 dose of the vaccine as of July 2021, with the remaining population being more difficult to vaccinate, it will also be difficult to reach the remaining people in the US population who have not received their diagnosis of HIV [27]. Advocating for primary care practices to offer HIV tests to general patient panels, rather than only high-risk patients, can facilitate timely diagnosis for all people at risk of acquiring HIV. Our data suggest that linkages to care present challenges to some cities. Cities can encourage their public health departments that may offer HIV testing to create strong ties and relationships with those that provide HIV treatment services so that there is minimal delay and a smooth transfer of patients to HIV providers. Most cities in our study seem to have some success in ensuring that people receive HIV care once they surpass the barrier of being linked to it in the first place. Our data suggest opportunities for improvement at the far end of the HIV care continuum, namely, viral suppression, which is the culmination of dedicated commitment and adequate and acceptable access to care. Those at highest risk for acquiring HIV may sometimes be some of the most vulnerable people in our cities who need the most resources to ensure that their local environment recognizes their needs and addresses them in a timely, steady, and supportive manner. With the nation’s renewed efforts to end the HIV epidemic, cities—especially high-prevalence ones—are receiving even more dedicated monies to combat this issue, making achieving national HIV care continuum goals more possible than ever before.

Abstract

Background: The burden of hepatitis B virus (HBV), hepatitis C virus (HCV), and syphilis coinfections remains disproportionately high among people living with HIV/AIDS. Hubei province is located in central China, where there are distinct regional characteristics of the distribution of people living with HIV/AIDS acquired via diverse transmission routes and the AIDS epidemic itself.

Objective: We aimed to estimate the magnitude of HBV, HCV, or syphilis coinfections among people living with HIV/AIDS with blood-borne transmission, which includes former paid blood donors, contaminated blood recipients, and intravenous drug users, as well as among people with sex-borne HIV transmission (including heterosexual people and men who have sex with men) and people with mother-to-child HIV transmission.

Methods: From January 2010 to December 2020, people living with HIV/AIDS were tested for hepatitis B surface antigen (HBsAg), HCV antibodies, and syphilis-specific antibodies. The positive patients were further tested for HBV markers, HBV DNA, and HCV RNA, and received a rapid plasma reagin circle card test. All people living with HIV/AIDS were first divided into transmission groups (blood, sex, and mother-to-child); then, people with blood-borne HIV transmission were divided into former paid blood donors, contaminated blood recipients, and intravenous drug users, while people with sex-borne HIV transmission were divided into heterosexual people and men who have sex with men.

Results: Among 6623 people living with HIV/AIDS, rates of chronic HCV infection were 80.3% (590/735) in former paid blood donors, 73.3% (247/337) in intravenous drug users, 57.1% (444/777) in contaminated blood recipients, 19.4% (21/108) in people with mother-to-child HIV transmission, 8.1% (240/2975) in heterosexual people, and 1.2% (21/1691) in men who have sex with men. Chronic HBV infection rates were similar among all people with blood-borne HIV transmission. However, compared to heterosexual people, the chronic HBV infection rate was greater in men who have sex with men (213/1691, 12.6% vs 308/2975, 10.4%; \( \chi^2 = 5.469; P = .02 \)), although HBV exposure was less common (827/1691, 48.9% vs 1662/2975, 55.9%; \( \chi^2 = 20.982; P < .001 \)). Interestingly, the combination of HBsAg and hepatitis B e antigen (HBeAg) was found in 11 patients with sex-borne HIV transmission, but in 0 people with blood-borne HIV transmission (11/196, 5.6% vs 0/521, 0%; \( \chi^2 = 29.695, P < .001 \)). In people with sex-borne HIV transmission, the proportions of patients with a syphilis titer \( \geq 1:16 \) and neurosyphilis were 8.6% (105/1227) and 7.8% (37/473), respectively, whereas these values were 0 in people with blood-borne HIV transmission.
Conclusions: In people living with HIV/AIDS, HCV transmission intensity was significantly associated with specific exposure modes of blood or sexual contact. The rate of chronic HBV infection among men who have sex with men was higher than in any other population. Attention should be paid to the high prevalence of neurosyphilis in people living with HIV/AIDS who contract HIV by sexual intercourse.

KEYWORDS
acquired immunodeficiency syndrome; AIDS; human immunodeficiency virus; HIV; hepatitis B virus; HBV; hepatitis C virus; HCV; syphilis

Introduction
According to a 2020 World Health Organization (WHO) report, 37.6 million people are infected with HIV worldwide [1]. Hepatitis B virus (HBV), hepatitis C virus (HCV), and syphilis infection are also all major public health problems worldwide. HBV, HCV, and syphilis are the 3 most common infections among people living with HIV/AIDS all over the world and share similar transmission routes [2,3]. The burden of HBV, HCV, and syphilis infection in people living with HIV/AIDS is even larger than in the general population. The ever-increasing burden of these infections has become a growing concern [4]. The prevalence of HBV, HCV, and syphilis coinfections in people living with HIV/AIDS is 8% to 12.2% [5-7], 33% to 80% [8,9], and 40.5% [10], respectively.

With the apparent efficiency of infectious illness prevention and control, as well as the recent introduction of direct-acting antiviral medicines, the WHO has proposed long-term worldwide prevention and control as the ultimate goal. A full assessment of HBV, HCV, and syphilis coinfection in people living with HIV/AIDS will aid in the development of a phased management plan that will contribute to the global eradication of hepatitis B disease by 2030 [11] and make HCV eradication a reality [12].

As the distribution of high-risk groups varies by country, so does the burden of HBV, HCV, and syphilis coinfection. Currently, the characteristics of the AIDS epidemic and the distribution of high-risk populations have changed. On the one hand, people who became infected with HIV as a result of nonroutine HIV screening of blood products still have HBV or HCV-related diseases; on the other hand, with the increasing transmission of AIDS among men who have sex with men, the pressure to control syphilis transmission differs from the blood transmission era of AIDS and heterosexual unprotected contact. Although HIV, HBV, HCV, and syphilis infections have been reported in a wide range of populations, including prisoners [13], blood donors [14], parturient women [15], and even inpatients [16], data on comparative infection rates among different populations in the same region remain scarce. A more extensive comparison of the prevalence and transmission intensity of coinfection with HBV, HCV, and syphilis among different risk groups will serve as the foundation for a comprehensive assessment of the disease burden in the HIV-positive community.

The Hubei provincial region includes populations of all high-risk HIV-infected groups and can be described as an appropriate place to examine the coinfection status of HBV, HCV, and syphilis in different populations of people living with HIV/AIDS in the same province. Hubei is located in central China. Poor rural farmers supplied plasma under unsanitary conditions in the 1990s, resulting in HIV infection among former paid blood donors and contaminated blood recipients [17-19]. Later, as a result of imported cases, an AIDS epidemic began to spread among intravenous drug users, heterosexual people, and men who have sex with men. As a result, the Hubei province AIDS epidemic has distinct geographical characteristics.

In this study, HIV-infected people were classified according to 3 classical sources of transmission: blood, sex, and mother-to-child transmission (MTCT); further subgroup analysis was performed in the blood-source and sex-source populations, with the goal of comparing differences in the disease prevention and control burden of HIV combined with HBV, HCV, and syphilis among various high-risk groups. This can not only maximize the allocation of comprehensive disease prevention and control expenditures in resource-rich locations, but it can also serve as a reference point for resource-limited places to achieve larger returns with a small investment, allowing for progress in reaching the final goal.

Methods

Study Population
From January 2010 to December 2020, a total of 6623 people living with HIV/AIDS were tested for hepatitis B surface antigen (HBsAg), HCV antibodies, and syphilis-specific antibodies at Zhongnan Hospital of Wuhan University. Patients who tested positive for HBsAg were also tested for HBV markers and HBV DNA. HCV RNA was investigated further in HCV antibody–positive patients, and the rapid plasma reagin circle card test was used in syphilis antibody–positive patients. First, all people living with HIV/AIDS were divided into 3 groups based on their HIV acquisition route: blood, intercourse, or MTCT. They were then redivided into former paid blood donors and contaminated blood recipients, and intravenous drug users in the blood-borne transmission group, and heterosexual people and men who have sex with men in the sex-borne transmission group. The inclusion criteria were (1) confirmed HIV infection and (2) a definite route of HIV acquisition. The exclusion criteria were (1) having 2 or more high-risk behaviors for HIV infection, (2) acute HBV infection, and (3) acute HCV infection.

Ethical Considerations
This study was a secondary analysis of a preexisting data set, and ethical review and approval were waived for this study by
the institutional review board of the work unit (Zhongnan Hospital of Wuhan University) of the first author (RY). Informed consent was obtained, and all the analyzed data were anonymous.

**Study Protocol**

Differences in HBV, HCV, and syphilis transmission intensity were analyzed in groups divided according to the 3 classical transmission routes of HIV acquisition: blood, sex, and MTCT. Then, in the blood-origin population, the participants were further divided into former paid blood donors, contaminated blood recipients, and intravenous drug users, whereas the sex-origin population was further divided into heterosexual people and men who have sex with men. Differences in HBV or HCV coinfection rates and characteristics of syphilis infection were compared in the different high-risk groups with the same HIV origin.

**Laboratory Testing**

Two rapid assays or joint detection modes were used to assess HIV status: enzyme immunoassay (EIA) and Western blotting. Anti-HCV, HBsAg, and *Treponema pallidum* antibody detection testing were done with a third-generation EIA (Shanghai Kehua Bio-Engineering). HBV markers, including HBsAg, hepatitis B surface antibody (anti-HBs), hepatitis B e antigen (HBeAg), hepatitis B e antibody (anti-HBe), and hepatitis B core antibody (anti-HBc), were examined with an enzyme-linked immunosorbent assay (ELISA). HCV RNA was tested using a polymerase chain reaction fluorescence detection kit (Shanghai Kehua Bio-Engineering) with a lower limit of detection of 20 copies/ml. The conventional rapid plasma reagin (RPR) circle card test, which uses cardiolipin antigen with a carbon particle to detect reagin, was used to determine the titer of syphilis. The experimental procedure and the analysis of results were performed according to the manufacturer’s instructions.

**Definitions**

Passive immunization is defined as the presence of anti-HBe and a vaccination history. Natural immunization is characterized as having a vaccine history and HBV markers in addition to anti-HBe, or not having a vaccination history but having HBV markers. Natural HBV exposure was defined as not having had a hepatitis B vaccine but having one or more HBV indicators or having received a hepatitis B vaccine and having one or more HBV markers except for anti-HBe.

As in a previous report [20], a reactive cerebrospinal fluid (CSF) venereal disease research laboratory test result, a CSF white blood cell count of >20 cells/l, or both were used to define neurosyphilis. Patients who had received penicillin previous to lumbar puncture or who had missing data, such as from a full skin examination or a complete neurological examination, were excluded from this study.

**Statistical Analysis**

Differences in characteristics across groups were compared using the Wilcoxon rank-sum test (2-group comparisons) and the Kruskal-Wallis rank test (≥3 group comparisons). The Pearson chi-square test was used to compare categorical variables across groups. A 2-tailed t test was applied to compare differences in measurement data. Statistical calculations were performed using SPSS (version 17.0; IBM Corp), with a P value <.05 considered significant.

**Results**

**Demographic Characteristics of People Living With HIV/AIDS**

This study investigated 6623 people living with HIV/AIDS from January 2010 to December 2020, of whom 71.27% (4720/6623) were male. Their average age was 37.6 (SD 12.3) years, and most (n=5838, 88.15%) were aged 18 to 55 years. Most (n=5805, 87.65%) of the individuals were receiving antiretroviral therapy (ART), and the average CD4+ T lymphocyte count was 226 (SD 86) cells/ul. The routes of HIV acquisition for all individuals are shown in Table 1. On the whole, the positive rates for HBsAg, anti-HCV, and antisyphilis antibodies were 10.92% (723/6623), 23.6% (1563/6623), and 21% (1391/6623), respectively.

Figures 1C, 1D, and 1E depict the overall positive rates of hepatitis B surface antigen (HBsAg), HCV, and syphilis, respectively.

**Coinfection Rates of HBV and HCV in Patients Who Acquired HIV via the 3 Routes Of Transmission**

According to the route of HIV acquisition, the 6623 patients were divided into those with blood-borne transmission (n=1849), MTCT (n=108), and sex-borne transmission (n=4666). The coinfection rates of HBV were 10.6% (196/1849), 5.56% (6/108), and 11.17% (521/4666), respectively. There was no significant difference in HBV coinfection rate among the 3 groups ($\chi^2=3.680; P=.16$). However, the coinfection rates of HCV in people with blood-borne transmission, MTCT, and sex-borne transmission were 69.28% (1281/1849), 19.44% (21/108), and 5.59% (261/4666), respectively. These HCV infection rates were significantly different among the 3 groups ($\chi^2=2980.043; P<.001$). People with blood-borne HIV transmission had a higher prevalence of HCV coinfection than people with MTCT (1281/1849, 69.28% vs 21/108, 19.44%; $\chi^2=113.812; P<.001$) and people with sex-borne HIV transmission.
transmission (1281/1849, 69.28% vs 261/4666, 5.59%; \( \chi^2_{1}=2973.003; P<.001 \)); people with MTCT had a higher prevalence of HCV coinfection than people with sex-borne transmission (21/108, 19.44% vs 261/4666, 5.59%; \( \chi^2_{1}=36.434; P<.001 \)).

### Coinfection Rates of HBV and HCV in Different Populations With Same Origin of HIV

According to differences in risk factors, 1849 people living with HIV/AIDS who acquired HIV by blood were further divided into former paid blood donors (n=735), contaminated blood recipients (n=777), and intravenous drug users (n=337). The coinfection rates of HBV were 9.9% (73/735), 10.2% (79/777), and 13.1% (44/337), respectively. There was no significant difference in the HBV coinfection rate among individuals who acquired HIV through blood transmission (\( \chi^2_{1}=2.645; P=.27 \)). However, HCV infection rates in former paid blood donors, intravenous drug users, and contaminated blood recipients were 80.3% (590/735), 73.3% (247/337) and 57.1% (444/777), respectively, indicating a statistically significant difference between the three groups (\( \chi^2_{1}=98.060, P<.001 \)). Former paid blood donors had a higher prevalence of HBV coinfection than intravenous drug users (590/735, 80.3% vs 247/337, 73.3%; \( \chi^2_{1}=6.574; P=.01 \)) and contaminated blood recipients (590/735, 80.3% vs 444/777, 57.14%; \( \chi^2_{1}=93.462; P<.001 \)), and intravenous drug users had a higher prevalence of HCV coinfection than contaminated blood recipients (247/337, 73.3% vs 444/777, 57.1%; \( \chi^2_{1}=26.032; P<.001 \)). Similarly, 4666 people living with HIV/AIDS who acquired HIV by sexual contact were further divided into heterosexual people (n=2975) and men who have sex with men (n=1691). The coinfection rates of HBV in men who have sex with men were greater than in heterosexual people (213/1691, 12.6% vs 308/2975, 10.35%; \( \chi^2_{1}=5.469; P=.02 \)), but the reverse was the case for HCV coinfection (21/1691, 1.24% vs 240/2975, 8.07%; \( \chi^2_{1}=95.113; P<.001 \)).

### HBV Exposure and Chronic HBV Coinfection Among Individuals Who Acquired HIV Through Sexual Intercourse

The coverage of active immunization against HBV infection in men who have sex with men was greater than in heterosexual people (534/1691, 31.58% vs 574/2975, 19.29%; \( \chi^2_{1}=89.860; P<.001 \)), and the reverse was the case for passive immunity (614/1691, 36.31% vs 1354/2975, 45.51%; \( \chi^2_{1}=37.440; P<.001 \)). Compared with heterosexual people, the natural HBV exposure rate was lower in men who have sex with men (827/1691, 48.91% vs 1354/2975, 55.87%; \( \chi^2_{1}=20.982; P<.001 \)), but the chronic infection rate following natural exposure to HBV was greater in men who have sex with men (213/827, 25.76% vs 308/1662, 18.53%; \( \chi^2_{1}=17.412; P<.001 \)). These results are shown in Table 2.

### Uncommon Combination of HBV Markers Among Chronic HBV Infections

In people with blood- or sex-borne HIV transmission, 196 and 521 people, respectively, were found to be coinfected with HBV in this study. Three uncommon combinations of HBV markers were detected in these chronic HBV infection patients: HBsAg and anti-HBe positivity; HBeAg and anti-HBs positivity; and only HBsAg and HBeAg positivity. Among those with blood-borne HIV transmission, 6 of 196 (3.1%) people with HIV/HBV coinfection had HBsAg and anti-HBe positivity, compared to 12 of 521 (2.3%) people with sex-borne HIV transmission. The rates of HBsAg and anti-HBe positivity showed no statistical difference between the people with blood-
or sex-borne HIV transmission (6/196, 3.1% vs 12/521, 2.3%; \( \chi^2 = 0.334; P = .56 \)). Similarly, 1 of 196 (0.5%) people with HIV/HBV coinfection among those with blood-borne HIV transmission had HBeAg and anti-HBs positivity, compared to 8 of 521 (1.5%) people with sex-borne HIV transmission. The rates of HBeAg and anti-HBs positivity showed no statistical difference between people with blood- or sex-borne HIV transmission (1/196, 0.5% vs 8/521, 1.5%; \( \chi^2 = 1.208; P = .27 \)).

It was interesting that when testing HBV markers, coinfection with only HBsAg/HBeAg positivity was found in 11 patients with HIV/HBV among people with sex-borne HIV transmission, while none of the people with blood-borne HIV transmission (11/196, 5.6% vs 0/521, 0%; \( \chi^2 = 29.695; P < .001 \)) had this coinfection. The clinical indicators related to HBV infection in these 11 patients are shown in Table 3.

### Table 3. Clinical indicators related to hepatitis B virus (HBV) infection among the 11 patients who were positive for only hepatitis B e antigen (HBeAg) and hepatitis B surface antigen (HBsAg).

Characteristics of Syphilis Infection Among HIV Blood-Borne And Sex-Borne Transmission Population

The positive rate of \( T pallidum \) antibodies in the sex-borne transmission group was greater than in the blood-borne transmission group (1227/4666, 26.3% vs 164/1849, 8.87%; \( \chi^2 = 239.499; P < .001 \)). Among those individuals who were positive for \( T pallidum \) antibodies, the proportion of patients who were negative for RPR in the sex-borne transmission group was lower than in the blood-borne transmission group (1127/1227, 61.45% vs 117/164, 71.34%; \( \chi^2 = 6.046; P = .01 \)). Similarly, among those who tested positive for RPR, the proportion of patients without symptoms was lower in the people with sex-borne transmission than in the people with blood-borne transmission (346/473, 73.15% vs 42/47, 89.36%; \( \chi^2 = 5.932; P = .02 \)). It was intriguing to note that high-titer syphilis infection and neurosyphilis only occurred in the people with sex-borne transmission. In people with sex-borne transmission, the proportion of patients with a syphilis titer \( \geq 1:16 \) and neurosyphilis were 8.56% (105/1227) and 7.82% (37/473), respectively, indicating a statistically significant difference between the sex- and blood-borne transmission groups (105/1227, 8.56% vs 0/164, 0%; \( \chi^2 = 15.180; P < .001 \) and 37/473, 7.82% vs 0/47, 0%; \( \chi^2 = 3.958; P = .047 \)). These results are shown in Table 4.
The frequency of HCV exposure or the amount of blood contact is higher in former paid blood donors, contaminated blood recipients, and intravenous drug users. The chronic HCV infection rate was found to be highest in former paid blood donors (80.27%), followed by contaminated blood recipients, and intravenous drug users (73.29%). The difference was related to the outbreak of HIV and HCV infection in the special historical period of this study. Therefore, the prevalence of HIV and HBV coinfection among adults in China was mainly acquired during the preschool period. Therefore, the prevalence of HIV and HBV coinfection in Hubei province shows obvious regional characteristics. This large-scale epidemiological survey used HBV markers (anti-HCV combined with HCV RNA and T. pallidum titer level) to investigate the prevalence of coinfections with HBV, HCV, or syphilis, as well as the different intensities of propagation in individuals with different risk behaviors but the same HIV transmission route.

The recognized transmission routes of HCV are blood transmission, sexual transmission, and MTCT. The 3 main routes of HCV infection demonstrated varying levels of transmission intensity, with blood transmission being the most intense, followed by MTCT and sexual transmission. In order to determine the characteristics of HCV transmission from a blood origin, the populations in this study were further divided into former paid blood donors, contaminated blood recipients, and intravenous drug users. We confirmed that HCV infection was significantly associated with the specific exposure mode of blood contact. The chronic HCV infection rate was found to be highest in former paid blood donors (80.27%), followed by intravenous drug users (73.29%), and contaminated blood recipients (57.14%). The chronic HCV infection rate in all these groups was greater than the prevalence of posttransfusion HCV infection among individuals with β-thalassemia [21] and blood donors in sub-Saharan Africa [22]. The difference was related to the outbreak of HIV and HCV infection in the special historical period of this study. The strong relationship between the frequency of HCV exposure or the amount of blood contact and the risk of HCV infection among former paid blood donors, contaminated blood recipients, and intravenous drug users was validated using population characteristics from a specific historical time. Although this viewpoint is conceptually evident and has long been acknowledged, obtaining specific and objective data is challenging. This study, however, provides evidence on exactly this problem.

Multiple sexual partners, mucosally traumatic intercourse, and bleeding during anal contact have been found to be common among men who have sex with men, which can raise the risk of HCV infection [23]. However, it was found that the HCV infection rate in men who have sex with men was lower than in people who acquired HIV through heterosexual contact (1.24% vs 8.07%). In this study, the male-to-male contact behavior that caused the spread of AIDS in this region was relatively late, and HCV coinfection in this community was relatively infrequent, so it did not result in the broad spread of HCV in men who have sex with men.

The prevalence of HBV infections is affected by multiple factors, including epidemic HBV in the birthplace, rates of HBV vaccination, and risk behaviors for HBV exposure. In the general population, chronic HBV infection was reported as 2.18% in China [24]. A previous study showed that people living with HIV/AIDS were 7 times more likely to have been infected with HBV [25]. However, the overall rate of chronic HBV infection in this study was 10.92%, which was much lower than the above inferred values. As is well known, China is a country with a moderate prevalence of HBV, and the majority of chronic HBV infections occur through vertical MTCT during the preschool period, which is different from European and American countries. Almost 95% of people infected with HBV can completely clear the infection when it is acquired during adulthood, and only 5% to 10% of people infected with HBV will develop a persistent infection. The regional characteristics of HBV prevalence may well account for the result that chronic HBV coinfection was not as high as HCV in this study. Interestingly, we found that men who have sex with men had a higher chronic HBV infection rate but a lower HBV exposure...
rate compared to people living with HIV/AIDS among the heterosexual population, implying that sexual behavior among men who have sex with men was closely related to the increase in the chronic HBV infection rate, providing another reason to strengthen disease safety education among men who have sex with men. Previous research found that men are 1.5 times more vulnerable to HBV than women, implying that gender is a factor influencing persistent HBV infection after HBV exposure [26]. In addition, another key aspect that may account for the greater HBV infection rate in men who have sex with men is exposure to HBV-contaminated blood during mucosally traumatic sex. Combining all these data shows that in places where vertical HBV transmission is a key epidemic component, both the intensity of transmission and the effect of HBV exposure on the prevalence of chronic HBV infection are substantially lower than for HCV.

In this study, among people who acquired HIV by either the blood route or by sexual contact, the combinations of HBsAg/anti-HBe and HBeAg/anti-HBs were detected, which could account for the transient coexisting phases of antigens and antibodies, the overlapping infection of different subtypes of HBV, or the deletion of genes in the S region or pre-S region of HBV. An interesting finding of this study was that an unusual pattern for HBV infection (the combination of only HBsAg/HBeAg antigens) was found only among people who acquired HIV by sexual contact, which might stimulate interest in further exploration of this phenomenon. In a previous study focused on HBV vaccination among people living with HIV/AIDS, it found that anti-HBe titers in a low CD4+ group were much lower than a high CD4+ group (low CD4+ group: 462 mIU/ml vs high CD4+ group: 8834 mIU/ml), which shows that an immunosuppressed state can affect the ability to produce protective anti-HBe [27]. Although immune deficiency is a possible cause, it still could not fully explain this unusual pattern. Further follow-up monitoring in these patients will be considered to explicitly reveal whether HBV-related antibodies appear after implementation of ART. This large-scale epidemiological study based on the comprehensive HBV marker test could provide a clue for further research into the mechanism of this unusual combination of HBV markers.

As a transfusion-transmissible infection, the prevalence of syphilis coinfection among people who acquired HIV from the blood route was 8.87% in this study, which is higher than in reports on the HIV-negative populations in Nigeria (4.2%) [28], Burkina Faso (3.96%) [29], Kenya (4.3%) [30], Pakistan (0.43%) [31], and India (0.43%) [32]. Nonuse of protection in sexual relations has already been identified as a risk factor. Except for differences in sociocultural practices, geographical location, and condom coverage, people living with HIV/AIDS may be more susceptible to T pallidum than HIV-negative people, which is a possible reason for the observed discrepancy in the magnitude of syphilis in the different studies. High T pallidum and neurosyphilis titers were found to be more common in people living with HIV acquired through sexual contact, implying that safe sex education is essential to reduce the risk of late syphilis; providing easily obtained information, education, and communication materials with pictures in HIV and sexually transmitted disease clinics, even in public places, is an important measure.

Overall, there were some highlights in this study. First, the transmission mode of AIDS in Hubei province has an obvious time node, which makes the regional characteristics of this study more prominent. Second, this study used syphilis antibody titers combined with related clinical symptoms and a complete marker test of HBV, in addition to HBsAg, to conduct a large-scale epidemiological investigation on the prevalence of syphilis and HBV infection, making the observational indicators of this study more comprehensive and superior. Third, another highlight is the integration into the study of subject grouping. For example, the people with blood-borne HIV transmission were further subdivided into intravenous drug users, contaminated blood recipients, and former paid blood donors. Similarly, the people with sex-borne HIV transmission were further subdivided into men who have sex with men and heterosexual people. These divisions deepened the understanding of the intensities of propagation in people with varying risk behaviors but the same HIV-borne transmission route.

However, we recognize that our study has some limitations. Given the cross-sectional nature of the study, we are unable to observe changes in HBV markers in those patients who had unusual patterns for HBV (the combination of only HBsAg/HBeAg antigens), but further follow-up observation will be conducted in the future. Also, due to the large sample sizes involved in epidemiological analyses, HCV RNA detection was only performed in patients positive for anti-HCV, which may miss some patients with detectable HCV RNA who are negative for anti-HCV. In addition, HBV DNA screening was only done for HBsAg-positive patients, not for all people living with HIV/AIDS, which could lead to underestimating the HBV infection rate due to the presence of occult HBV infections. Finally, the level of stratified heterogeneity is something that deserves attention and needs improvement. However, given the low frequency of false negative anti-HCV and occult HBV infections in this investigation and the large sample size, the aforesaid limitations should not have influenced the overall trend of the results.

**Conclusion**

HCV, HBV, and syphilis all have similar transmission routes; however, the varied routes do not carry the same weight in terms of disease prevalence. The risk intensity of HCV transmission by blood is substantially higher than that by sexual contact, and it is closely related to exposure frequency. In Hubei province, where vertical transmission of HBV is the primary route, the influence of adult HIV infection and high-risk behavior on HBV transmission is much lower than on HCV, and the range of chronic HBV infection prevalence in different high-risk groups is relatively limited. In people with sex-borne HIV transmission, high T pallidum and neurosyphilis titers are common. The data presented in this study provide a comprehensive picture of the prevalence of HBV, HCV, and syphilis in various populations with HIV risk behaviors, deepening our understanding that repeated exposure to unclean blood or sexual contact increases the risk of HCV and emphasizing the close relationship between neurosyphilis and repeated exposure.
As the distribution of HIV high-risk groups varies by country, so does the burden of HBV, HCV, and syphilis coinfection, and these precise comparative and analytical data serve as the foundation for future local policy creation. It is necessary to invest in preventive and control funds based on the regional distribution of people living with HIV/AIDS in order to optimize the returns.

Acknowledgments
We thank the patients, nurses, and physicians who provided care for the patients. We also thank the investigators at Zhongnan Hospital of Wuhan University. This study was supported by the National Natural Science Foundation of China (82003511) and Discipline and Platform Construction Project of the Center for AIDS Research of Wuhan University (PTPP2023002).

Data Availability
All data generated or used during this study are included in this published article.

Authors’ Contributions
RY, KZ, HH, LL, and LF collected the clinical data. XG and HK interpreted the results. RY and XY drafted the manuscript. YY and ML modified the final manuscript.

Abstract

Background: Limited studies have explored the impact of the Omicron variant on SARS-CoV-2 infection, hospitalization, and associated factors among people living with HIV, particularly in China. The adjustment of preventive policies since December 2022 in China presents an opportunity to evaluate the real-world factors influencing SARS-CoV-2 infection and related hospitalization among people living with HIV.

Objective: This study aimed to investigate SARS-CoV-2 infection, hospitalization rates, and associated factors among people living with HIV following the adjustment of preventive policies from December 2022 to February 2023 in southeastern China.

Methods: A cross-sectional telephone or web-based survey was conducted among people living with HIV in 5 cities in southeastern China from December 2022 to February 2023. Demographic information, SARS-CoV-2 infection and related hospitalization, and HIV-specific characteristics were collected from existing databases and special investigations. Multivariate logistic regression analyses were conducted to determine the associated factors for infection and hospitalization rates of SARS-CoV-2. Additionally, subgroup analyses were conducted for the association between vaccination and infection across different vaccination statuses and time since the last vaccination.

Results: Among people living with HIV with a COVID-19 testing history, the SARS-CoV-2 infection rate was 67.13% (95% CI 65.81%-68.13%), whereas the hospitalization rate was 0.71% (95% CI 0.46%-0.97%). Factors such as age, latest CD4 cell count, latest HIV viral load, and transmission route were found to be associated with SARS-CoV-2 infection, while age, cancer, latest CD4 cell count, and latest HIV viral load were associated with SARS-CoV-2 hospitalization. In terms of SARS-CoV-2 vaccination, compared to unvaccinated people living with HIV, there was a lower infection rate among those who had been vaccinated for <3 months in the booster vaccination group (adjusted odds ratio [aOR] 0.72, 95% CI 0.53-0.98; P=.04); and there was also a lower risk of hospitalization among people living with HIV who had received vaccination in the past 6-12 months (aOR 0.33, 95% CI 0.14-0.81; P=.02) and more than 12 months ago (aOR 0.22, 95% CI 0.07-0.72; P=.01).

Conclusions: After the ease of prevention and control measures in China, we observed a high SARS-CoV-2 infection rate but a low hospitalization rate. General risk factors, such as higher age and vaccination status, and HIV-related parameters, such as the latest CD4 cell count and HIV viral load, were associated with SARS-CoV-2 infection and hospitalization. A booster vaccination campaign for booster doses should be considered among people living with HIV in confronting possible COVID-19 epidemic emergencies in the near future.
Introduction

HIV/AIDS has remained a significant global public health threat despite being discovered over 40 years ago. Currently, there are 38 million people living with HIV worldwide, and in 2021 alone, 650,000 individuals died from HIV-related illnesses [1]. The situation regarding global HIV epidemic control has become more severe due to the emergence of the COVID-19 pandemic caused by SARS-CoV-2 [2,3]. It can be understood that the weakening of the immune system of patients with HIV/AIDS increases the possibility of severe outcomes from SARS-CoV-2 coinfection. However, there is limited data on the susceptibility and vaccine effectiveness of people living with HIV to SARS-CoV-2 infection and severe outcomes. As there is no cure for HIV and there is a chance of SARS-CoV-2 infection, coinfection continues to pose a problem [3-5].

Previous studies have suggested that older age and comorbidities such as hypertension, diabetes, and cardiovascular disease are risk factors for developing severe COVID-19 and are associated with high mortality rates [6]. However, the interaction of people living with HIV-specific factors, such as CD4 cell count, HIV viral load, and antiretroviral treatment (ART), with COVID-19 remains inclusive [3,6-8]. Moreover, most of these studies were conducted before the vaccination or during the epidemics of the Alpha and Delta variants. Limited studies have explored the impact of the Omicron variant, which exhibits increased transmissibility and immune escape abilities, on people living with HIV [9]. Furthermore, because of the strict prevention and control policies for COVID-19 in China, few studies concerning the SARS-CoV-2 infection and hospitalization among people living with HIV have been reported in the country.

Due to a unified, tightly coordinated COVID-19 vaccination campaign during the dynamic COVID-19 Zero period, partial and full vaccination coverage in China reached 91.5% and 89.3%, respectively [10,11]. In the context of this high vaccination coverage and the relatively weak virulence of the SARS-CoV-2 Omicron variant, the Chinese government relaxed COVID-19 prevention and control measures in December 2022. Notably, several studies reported a significant surge in cases between December 2022 and January 2023, with reported infection rates ranging from 40.9% to 92.3% in the general population [11-15]. However, there are currently no reports regarding SARS-CoV-2 infection and hospitalization among people living with HIV during this period. Moreover, although a few studies demonstrate the short-duration protection of the COVID-19 vaccine against infection in the general population [11,12,16,17], there was no study on the impact of the COVID-19 vaccine on infection and hospitalization of SARS-CoV-2 among people living with HIV in China. The substantial epidemic presents an opportunity to evaluate the real-world factors influencing the infection and hospitalization of SARS-CoV-2 among people living with HIV. Therefore, this study investigated the infection and hospitalization of SARS-CoV-2 and identified associated factors among people living with HIV from December 2022 to January 2023.

Methods

Study Population

Zhejiang Province is located in southeastern China and is known for its thriving economy and high population density. This province is home to over 65 million local residents spread across 11 metropolitan areas.

By the end of 2022, the total number of people living with HIV living in Zhejiang Province was 39,744. For our study, we selected 5 metropolitan areas in Zhejiang province as our study sites: Ningbo in the east, Quzhou in the west, Jiaxing in the north, Wenzhou in the south, and Shaoxing in the middle of the province (Figure 1). The total number of people living with HIV in the 5 cities was unbalanced, with Ningbo the highest (6096) and Quzhou the smallest (1346). As a result, the 5 selected cities accounted for 46% of all living cases of people living with HIV in the entire province.
Our target sample size was 10,000, which was estimated by experts. Center for Disease Control and Prevention (CDC) staff from the 5 cities downloaded the database from the HIV/AIDS case reporting information system, established by the Chinese CDC. Considering the work foundation of each city, we randomly selected 50% (5933/11,865) of people living with HIV from Wenzhou and Ningbo and 80% (5102/6378) from Quzhou, Jiaxing, and Shaoxing as potential participants (total number=11,035) to be investigated. The inclusion criteria for people living with HIV in the final analysis were as follows: (1) be aged ≥15 years; (2) currently live in the abovementioned 5 cities; and (3) agree to participate in the survey. Exclusion criteria mainly included people living with HIV who were not currently taking ART or who did not have results of CD4 cell count and HIV viral load.

Data Collection
To collect information regarding SARS-CoV-2 infection, admission status, and related symptoms, a questionnaire was designed by the Zhejiang Provincial CDC. The investigation was conducted by trained county CDC staff between January 16 and February 10, 2023. Uniform training was organized by the Zhejiang CDC and provided to investigators to ensure the quality of the investigation. The method of investigation was determined by the investigators. Ningbo staff conducted a web-based survey using Questionnaire Star (one of the most widely used commercial web-based survey platforms in China). Staff from 4 other cities conducted an investigation by telephone. During the investigation, we first inquired whether the participants had experienced any COVID-19–related symptoms since December 7, 2022. Subsequently, we asked if they had tested positive for the SARS-CoV-2 infection. If they responded with a “yes” or “no,” we further asked for the method of confirmation, specifically whether it was through an antigen test or nucleic acid test. For those who self-reported having SARS-CoV-2 infection, we asked for the confirmation date and whether they had been hospitalized after the infection. We further investigated the reasons for hospitalization for individuals admitted to the hospital.

Demographic information such as age, sex, and marital status was collected from the HIV/AIDS case reporting information system. Information related to ART, such as the initiation date, the latest CD4 cell count, viral load, and treatment regime, was obtained from the national HIV treatment subdatabase of Zhejiang province. Regarding the ART regime, we focused on the national free drugs that are widely used among people living with HIV in China, such as tenofovir (TDF), azidothymidine.
COVID-19 vaccine–related data, including vaccine type, vaccine dose, and last vaccination date, were obtained from the vaccination information system. In terms of vaccine brand and manufacturer, an inactivated vaccine was produced by Sinopharm CNBG Beijing, Sinopharm CNBG Wuhan and the Beijing-based Sinovac Biotech; a recombinant protein (Chinese hamster ovary [CHO] cell) vaccine was produced by Anhui Zhifei Longcom Biopharmaceutical Institute of Microbiology; and an adenovirus vector vaccine was used, referred to as Cansino Ad5-nCoV-S COVID-19 vaccine.

**Definition**

Due to the absence of COVID-19 test results for all participants at the time of investigation, we categorized the study participants into groups A, B, and C. Group A consisted of individuals with no history of COVID-19 testing but reported COVID-19–related symptoms. Among these participants, those who presented with symptoms such as fever or cough were classified as having SARS-CoV-2 infection, while those who did not exhibit such symptoms were categorized as noninfected. Group B comprised individuals who had undergone COVID-19 testing between December 7, 2022, and the investigation date. Infection status was determined based on the positive or negative results of nucleic acid or antigen tests. Group C encompassed all study participants, including groups A and B.

Hospitalizations that were unlikely to be attributed to COVID-19, such as cases involving non–COVID-19 infections or long-term hospitalizations, were excluded from the study.

According to the Technical Vaccination Recommendations for COVID-19 Vaccines in China and previous studies [16-18], vaccination status was categorized into 4 levels: (1) unvaccinated, which indicates no history of COVID-19 vaccination before the last SARS-CoV-2 exposure date; (2) partially vaccinated, which includes people who have received 1 dose of inactivated vaccine, received 2 doses of inactivated vaccine but received the second dose within 14 days before the last SARS-CoV-2 exposure date, received 2 doses of recombinant protein vaccine (3 doses are recommended for full primary vaccination), and received 1 dose of adenovirus vector vaccine, or 3 doses of recombinant protein vaccine but with the last dose within 14 days before the last SARS-CoV-2 exposure date; (3) full primary vaccination, which includes people who received either 2 doses of inactivated vaccine, 1 dose of adenovirus vector vaccine, or 3 doses of recombinant protein (CHO cell) vaccine with the last vaccination 14 days or more before the last SARS-CoV-2 exposure date and with no booster dose; 2 doses of inactivated vaccine with 1 booster dose of inactivated vaccine, adenovirus vector vaccine, or recombinant protein (CHO cell) vaccine within 7 days before the last SARS-CoV-2 exposure date; or 2 doses of adenovirus vector vaccine within 7 days before the last exposure date; (4) booster vaccinated, which includes people who received either 2 doses of Ad5-vector vaccine with the second dose 7 days or more before the last exposure date; or 2 doses of inactivated vaccine and 1 or 2 booster doses of inactivated vaccine, adenovirus vector vaccine, or recombinant protein vaccine 7 days or more before the last exposure date.

The time since the last vaccination was calculated as the interval between the date of the last vaccination dose and the date of the last SARS-CoV-2 exposure. The date of last SARS-CoV-2 exposure was defined as the date of the investigation if the participants had not self-reported SARS-CoV-2 infection; otherwise, it was the date of the positive result of self-tested SARS-CoV-2.

**Statistical Analysis**

The means (SDs) or medians (IQRs) were obtained for continuous variables. Categorical variables were analyzed by calculating characteristic percentages. To analyze the associated factors for SARS-CoV-2 infection, logistic regression analysis was performed among those with a history of SARS-CoV-2 test (group B). To identify risk factors for hospitalization, a multivariable logistic regression analysis was conducted among participants who had undergone SARS-CoV-2 testing and received a positive result. Univariate factors with a significance level of P < .10 and factors previously identified to be associated with COVID-19 infection were included in the full multivariable regression models. Additionally, to make the results more robust, we conducted a sensitivity analysis for the association between SARS-CoV-2 infection rate and vaccination among groups A and C. Data cleaning and organization were performed using Microsoft Excel 2016 software (Microsoft Corporation). Statistical analysis was conducted using R statistical software (version 4.1.2, R Project for Statistical Computing). A significance level of P < .05 was considered statistically significant in the final model.

**Ethics Statement**

The study was approved by the ethical review board of the Zhejiang Provincial CDC (IRB approval number: 2023-003-01). No risk was involved in participating in this study, and we protected the confidentiality of the participants. For those participants aged 18 years or younger, we sought parental consent and collected data from their parents.

**Results**

**Characteristics of the Study Participants**

In total, 9922 people living with HIV (group C) were included in the final analyses, with 3628 classified as group A and 6294 as group B. The response rate was 89.91% (9922/11,035) for the potential participants and 24.96% (9922/39,744) for all people living with HIV in the province. The median age of the participants was 46 years (IQR 22), of which 7996 (80.59%) were male. Among them, 6848 (69.02%) were registered residents of Zhejiang Province. The prevalence of chronic diseases among the participants was as follows: hypertension (930/9992, 9.37%), diabetes 395/9922, 3.98%), and cardiovascular diseases (103/9922, 1.04%). Heterosexual transmission accounted for a higher percentage (5825/9922, 58.71%) compared to homosexual transmission (4001/9922, 40.32%). The median latest CD4 count was 462 cells/µL (IQR 301), and the median ART duration was 5.38 years (IQR 4.65). Among the people living with HIV, 9274 (93.47%) had an HIV (AZT), lamivudine (3TC), efavirenz (EFV), and lopinavir and ritonavir (LPV/r).
viral load below 50 copies/mL. Regarding vaccination status, 1530 (15.42%) were unvaccinated, 455 (4.59%) had received their last vaccination less than 3 months ago, 237 (2.39%) had received their last vaccination between 3 and 5 months ago, 4707 (47.44%) had received their last vaccination between 6 and 11 months ago, and 2993 (30.17%) had received their last vaccination more than 12 months ago (Table 1). Among the entire study population, the proportion of individuals with partial vaccination, full primary vaccination, and booster vaccination was 2.59%, 15.32%, and 66.67%, respectively (Table 1).
Table 1. Characteristics of the study participants among people living with HIV in southeastern China from December 2022 to February 2023.

</tbody>
</table>
Among people living with HIV with a COVID-19 testing history, the SARS-CoV-2 infection rate was 66.97% (95% CI 65.81%-68.13%). The SARS-CoV-2 infection rate was significantly higher in the younger age group, those with single or divorced status, those with homosexual transmission routes, those with higher education levels, those with higher latest CD4 counts, those with lower latest HIV viral load, those not taking TDF, 3TC, and EFV, and those taking AZT, and those who had a long time since their last vaccination (Table 2). Multivariate logistic regression analysis revealed that age, education, transmission route, latest CD4 count, and latest HIV viral load were statistically associated with SARS-CoV-2 infection. Regarding vaccination, compared to those who had not received any vaccination, there was no statistically significant difference among those who received vaccination 4–6 months and 7-12 months since their last dose. However, there was a statistically significant association among those who had been vaccinated for 0-3 months (aOR 0.74, 95% CI 0.56-0.98) and more than 12 months (aOR 1.20, 95% CI 1.01-1.43; Table 2).

</table>
Among the 4215 confirmed COVID-19 cases, 30 individuals (0.71%, 95% CI 0.46%-0.97%) required hospitalization. The highest hospitalized rates were observed among individuals aged ≥60 years, those with illiteracy, married individuals, individuals with hypertension, diabetes, chronic kidney disease, or cancer, individuals with the latest CD4 count below 200

The tests for COVID-19 in Zhejiang Province from December 2022 to February 2023

Among the 4215 confirmed COVID-19 cases, 30 individuals (0.71%, 95% CI 0.46%-0.97%) required hospitalization. The highest hospitalized rates were observed among individuals aged ≥60 years, those with illiteracy, married individuals, individuals with hypertension, diabetes, chronic kidney disease, or cancer, individuals with the latest CD4 count below 200.
cells/μL, an HIV load greater than 1000 copies/mL, and those who had not received any vaccination (Table 3).

In the multivariate analysis, several factors, including age, cancer, latest CD4 count, latest HIV viral load, and time since the last vaccination, remained significantly associated with COVID-19 hospitalization. Compared to people living with HIV aged <30 years, those aged >60 years showed an increased risk of hospital admission (aOR 7.44, 95% CI 1.23-45.17). Hospital admission was also associated with having cancer (aOR 12.19, 95% CI 2.98-49.93). Furthermore, compared to individuals who had not received any vaccination, people living with HIV who had received vaccination in the past 6-12 months (aOR 0.33, 95% CI 0.14-0.81) and those who had received vaccination more than 12 months ago (aOR 0.22, 95% CI 0.07-0.72) had a lower risk of hospitalization (Table 3).

Sensitivity analyses were conducted among groups A and C to evaluate the robustness of our results. The SARS-CoV-2 infection rate was 67.03% (95% CI 65.50%-68.56%) and 66.99% (95% CI 66.07%-67.92%) in groups A and C, respectively. Moreover, as shown in Figures 3 and 4, there was a statistically significant association between SARS-CoV-2 infection and vaccination for those who were vaccinated <3 months in group A (aOR 0.65, 95% CI 0.45-0.93; Figure 3) and group C (aOR 0.72, 95% CI 0.58-0.90; Figure 4). Subgroup analysis showed that the association between vaccination and SARS-CoV-2 infection occurred at the booster vaccination while not in the full primary group (Figures 3 and 4).
Table 3. SARS-CoV-2 hospitalization and associated factors analysis among people living with HIV who had positive tests of COVID-19 in Zhejiang province from December 2022 to February 2023.

Figure 4. Association between vaccination and SARS-CoV-2 infection among group C in Zhejiang province from December 2022 to February 2023 (group C encompassed all study participants, including group A and group B. Group A definition: those who presented with symptoms such as fever or cough were classified as having SARS-CoV-2 infection, while those who did not exhibit such symptoms were categorized as noninfected. Group B comprised individuals who had undergone COVID-19 testing between December 7, 2022, and the investigation date. Infection status was determined based on the positive or negative results obtained from nucleic acid or antigen tests). aOR: adjusted odds ratio.

Discussion

Overview

The public health impact of the COVID-19 pandemic in the community continues. Previous studies have investigated the SARS-CoV-2 infection and hospitalization and their associated risk factors among people living with HIV [6,19,20]. However, most of these studies were conducted during the early stages of the pandemic or when the Delta variant was predominant. Furthermore, due to the limited number of infections resulting from implementing the Dynamic Zero policy, no studies regarding the Omicron variant have been reported in China. This study aimed to investigate SARS-CoV-2 infection and hospitalization among people living with HIV during the Omicron variant epidemic in China. The infection rate was 66.97% (4215/6294) among people living with HIV with a COVID-19 testing history, whereas the hospitalization rate was 0.71% (30/4215). Moreover, we found that general risk factors such as higher age, vaccination status, and HIV-related parameters such as latest CD4 count and HIV load were associated with SARS-CoV-2 infection and hospitalization, and these results will provide scientific information for future control and prevention of COVID-19 among people living with HIV.

The SARS-CoV-2 infection rate was 66.97% (4215/6294) in this study, which was lower than the rate reported by Fu et al [11] (82.4%), the rate estimated by modeling calculation conducted by Leung et al (92.3%) [14], and Bai et al (87.54%) [15], and higher than the rate investigated among children conducted by Su et al [12] (40.9%) in the general population after adjustment of the Zero-COVID policy. During the early pandemic, studies mostly demonstrated a lower or similar incidence of SARS-CoV-2 infection among people living with HIV when compared to those without HIV in the general population [4]. The lower infection rate among people living with HIV could be due to the following 2 reasons: first, many studies have indicated that COVID-19 has a great impact on people living with HIV, and thus they usually have greater social distancing [4,21]. Second, some researchers have argued that antiretroviral medication, specifically nucleoside or nucleotide reverse transcriptase inhibitors, may have contributed to a protective effect [8,22]. However, the lower rate can be attributed to other factors such as sample size, confounding biases, and geographical, social, and health care disparities, which should be concluded with caution and deserve further study.

We found that age, education, marital status, transmission route, latest CD4 cell count, and HIV viral load were statistically associated with SARS-CoV-2 infection. Younger adults had a higher risk of SARS-CoV-2 infection, potentially due to a higher force of infection in working age groups; this result was consistent with a study conducted among the general population in Shanghai [17] and people living with HIV in Lebanon [8]. In this study, being married or cohabiting was independently associated with infection, which could be related to intrafamily transmission. Furthermore, consistent with the study conducted by Kim and Jeong [23], we found that the higher the education
level, the higher the SARS-CoV-2 infection rate. Interestingly, people living with HIV with higher latest CD4 counts had a higher risk of infection, while those with higher HIV loads had a lower risk. This phenomenon may also contribute to illustrating the lower infection rate in people living with HIV in our study compared to studies in the general population. Nonetheless, the reasons for this phenomenon require further investigation. In addition, people living with HIV who contracted HIV from homosexual transmission had a higher risk of SARS-CoV-2 infection than those who contracted HIV from heterosexual transmission. This higher risk may be attributed to higher mobility and multiple sexual partners among men who have sex with men, which may increase their risk of infection [24-26].

According to a World Health Organization report, people living with HIV have a significantly higher risk of experiencing a severe or fatal COVID-19 infection [27]. Consistent with previous studies, we identified several factors associated with an increased risk of hospitalization among people living with HIV. These factors include older age, lower latest CD4 count, higher latest HIV viral load, and the presence of cancer [3,6,7,19,28]. Therefore, people living with HIV with these risk factors should be given priority care and protection.

In this study, we found 3TC had a protective effect against SARS-CoV-2 infection, and this protective effect was not shown in other commonly used drugs (TDF, EFV, AZT, and LPV/r). Previous studies have demonstrated that there was a molecular basis for the inhibition of the SARS-CoV-2 RNA-dependent RNA polymerase by these nucleotide analogs [29,30]. However, the effectiveness of antiretrovirals in preventing COVID-19 infection or severe illness among people living with HIV has yielded mixed results in different studies and trials [8,22,31]. Therefore, it is currently impossible to definitively conclude whether antiretrovirals can protect people from contracting COVID-19 or experiencing severe illness from the virus.

Data on the effectiveness of COVID-19 vaccines among people living with HIV in real-world studies remain limited, as they have not been adequately represented in initial vaccine effectiveness trials. In our study, we found that vaccination was associated with reduced SARS-CoV-2 infection within 3 months of the last vaccination. Our subgroup analyses further demonstrated that the protective effect only occurred in the booster vaccination participants. Our findings were consistent with the vaccine effectiveness of COVID-19 evaluated among the general population in China [11]. Furthermore, the significant effect of vaccination in reducing hospitalization in our study aligns with observations made in the general population and among people living with HIV in other studies [17,32]. Notably, the duration of protection against hospitalization varied and may be attributed to the small sample size of hospitalized cases. Since no studies specifically focused on vaccination efficacy against SARS-CoV-2 Omicron infection and hospitalization among the population of people living with HIV in the country, our study provided a scientific basis for the vaccination program among people living with HIV. Consequently, we highly recommend expanding vaccination coverage among people living with HIV when the epidemic reemerges since 15% (1530/9922) of people living with HIV in our study remained unvaccinated.

**Limitations**

This study had several limitations. Firstly, a causal relationship could not be established between the investigated factors and the infection or hospitalization of SARS-CoV-2 due to the cross-sectional nature of our study. Secondly, although we used random sampling at the beginning of participant selection, the inability to collect data from refusal would lead to selection bias. Our findings should be extrapolated with caution. Thirdly, diagnoses of conditions such as SARS-CoV-2 infection, hospitalization, and other chronic diseases such as diabetes, hypertension, and cardiovascular disease rely on self-reporting, which can be influenced by social desirability and reporting biases. Fourthly, other potential risk factors for infection, such as individual behaviors and close contact infections, which may impact infection, were not investigated. Finally, the number of hospitalizations was too small to conduct subgroup analyses and further estimations of the effectiveness of different vaccination strategies against hospitalization.

**Conclusions**

We conducted the first investigation of HIV/SARS-CoV-2 coinfection and hospitalization following the ease of the control policy in China. Our findings revealed a high prevalence of COVID-19 but a low hospitalization rate. Besides general characteristics such as age and vaccination status, we also found that people living with HIV–specific factors such as CD4 cell count and HIV viral load were associated with SARS-CoV-2 infection and hospitalization. These findings will add to the growing literature on SARS-CoV-2 and HIV coinfection and contribute to optimizing COVID-19 preventive strategies among people living with HIV. A booster vaccination campaign for booster doses should be considered among people living with HIV in confronting possible COVID-19 epidemic emergencies in the near future.

Abstract

Background: Sexual health influencers (SHIs) are individuals actively sharing sexual health information with their peers, and they play an important role in promoting HIV care services, including the secondary distribution of HIV self-testing (SD-HIVST). Previous studies used a 6-item empirical leadership scale to identify SHIs. However, this approach may be biased as it does not consider individuals’ social networks.

Objective: This study used a quasi-experimental study design to evaluate how well a newly developed machine learning (ML) model identifies SHIs in promoting SD-HIVST compared to SHIs identified by a scale whose validity had been tested before.
Methods: We recruited participants from BlueD, the largest social networking app for gay men in China. Based on their responses to the baseline survey, the ML model and scale were used to identify SHIs, respectively. This study consisted of 2 rounds, differing in the upper limit of the number of HIVST kits and peer-referral links that SHIs could order and distribute (first round ≤5 and second round ≤10). Consented SHIs could order multiple HIV self-testing (HIVST) kits and generate personalized peer-referral links through a web-based platform managed by a partnered gay-friendly community-based organization. SHIs were encouraged to share additional kits and peer-referral links with their social contacts (defined as “alters”). SHIs would receive US $3 incentives when their corresponding alters uploaded valid photographic testing results to the same platform. Our primary outcomes included (1) the number of alters who conducted HIVST in each group and (2) the number of newly tested alters who conducted HIVST in each. We used negative binomial regression to examine group differences during the first round (February-June 2021), the second round (June-November 2021), and the combined first and second rounds, respectively.

Results: In January 2021, a total of 1828 men who have sex with men (MSM) completed the survey. Overall, 393 SHIs (scale=195 and ML model=198) agreed to participate in SD-HIVST. Among them, 229 SHIs (scale=116 and ML model=113) ordered HIVST on the web. Compared with the scale group, SHIs in the ML model group motivated more alters to conduct HIVST (mean difference [MD] 0.88, 95% CI 0.02-2.22; adjusted incidence risk ratio [aIRR] 1.77, 95% CI 1.07-2.95) when we combined the first and second rounds. Although the mean number of newly tested alters was slightly higher in the ML model group than in the scale group, the group difference was insignificant (MD 0.35, 95% CI –0.17 to –0.99; aIRR 1.49, 95% CI 0.74-3.02).

Conclusions: Among Chinese MSM, SHIs identified by the ML model can motivate more individuals to conduct HIVST than those identified by the scale. Future research can focus on how to adapt the ML model to encourage newly tested individuals to conduct HIVST.

artificial intelligence; HIV testing; key opinion leaders; machine learning; men who have sex with men; self-testing

Introduction

Globally, gay, bisexual, and other men who have sex with men (GBMSM) exhibit a significantly higher median HIV prevalence of 7.5%, in contrast to the global median of 0.7% [1]. In China, GBMSM are also disproportionately affected by HIV, accounting for 25.5% of new HIV infections in 2018 (vs 6.1% in 2008) [2]. Despite the efforts in HIV control, the HIV testing coverage among Chinese GBMSM is still low. In 2019, the national HIV prevalence of GBMSM was 6.3%, yet only 56% knew their HIV status in China [3]. Enhancing people’s awareness of their own HIV status could accelerate the initiation of treatment. People living with HIV who start treatment earlier have a higher likelihood of improving their survival and can also prevent HIV transmission by maintaining an undetectable viral load status (undetectable=untransmittable) [4].

Preventing HIV by increasing HIV testing rates is a key pillar in reaching the first “95-95-95” target, proposed by UNAIDS (the Joint United Nations Programme on HIV/AIDS), that 95% of all individuals living with HIV will be aware of their HIV status by 2025 [5]. One of the innovative approaches to expanding HIV testing coverage is HIV self-testing (HIVST). Specifically, HIVST is an effective decentralized testing tool that allows persons to test in a comfortable and private setting and mitigates concerns about inadvertent disclosure and confidentiality protection associated with facility-based testing [6]. In addition, HIVST may present an opportunity to address barriers that GBMSM may encounter when seeking care in health care facilities [7]. These barriers include but are not limited to, lack of access to health care, fear of HIV-related stigma, perceived discrimination, lack of confidence in health services, and limited knowledge and awareness about HIV [6-9].

HIVST can be conducted with or without assistance in various settings to reach diverse populations [10,11]. Directly assisted HIVST involves in-person guidance from trained providers or peers, while unassisted HIVST relies solely on manufacturer instructions [12]. A systematic review and meta-analysis indicated that self-testers achieve HIVST results with reliability and accuracy similar to trained health care workers [13]. In light of this, secondary distribution of HIV self-testing (SD-HIVST) was conducted within the unassisted HIVST implementation strategy.

In 2023, the World Health Organization (WHO) recommends expanding the use of HIVST services; one of the recommendations is using individuals’ sexual and social networks to promote HIVST and increase testing coverage [14]. One promising model is the social network–based SD-HIVST. As an innovative social network method, SD-HIVST is promising to help reach naïve testers and increase HIVST uptake among men who have never tested before [15-17]. The strategy of SD-HIVST involves individuals (defined as “index”) obtaining multiple HIVST kits and distributing them face-to-face or through peer referral (PR) links on the web to members within their social networks (defined as “alters”) [15,16]. There is increasing evidence demonstrating the effectiveness of SD-HIVST in improving HIV testing coverage and case identification worldwide [15-20]. In China, Wu et al [15] adapted the SD-HIVST model into a social media–based existing HIVST service provided by a GBMSM-friendly community-led
organization. Wu et al [15] also included components to improve test accuracy and result return rates. Building on the progress of Wu et al [15], Zhou et al [16] conducted a randomized trial with a modified model by providing monetary incentives to GBMSM index participants who motivated alters to upload their results to the web-based system. The study concluded that SD-HIVST with economic incentives could effectively promote SD-HIVST and encourage newly tested receivers to test. Consequently, this adapted digital secondary distribution strategy was culturally appropriate in the Chinese setting, where GBMSM influencers hold a premise in HIVST distribution to their social contacts with limited access to self-testing [15,16].

Sexual health influencers (SHIs) are individuals with a strong influence on disseminating information about HIV and sexually transmitted infections (STIs) within their social networks [21-23]. Studies have shown that those at the center of their networks may influence their peers’ adoption of healthier behaviors [21,22]. It was also reported that SHIs are important for improving HIV care-related services. For example, a study has shown that GBMSM with strong influence tend to participate in more sexual health campaigns and use HIV and syphilis testing [21]. The social comparison theory states that SHIs might serve as role models for well-being and self-improvement within the GBMSM community, offering an ideal to which other GBMSM can strive [24].

Artificial intelligence (AI), particularly machine learning (ML), shows promise in identifying key influencers and excels in classifying key populations, including pinpointing individuals at higher HIV risk [25-28]. The conventional empirical scales (ES) used a 6-item leadership questionnaire and were previously used to identify GBMSM SHIs and examine their demographic and behavioral characteristics [29]. A limitation of the ES is that there may be bias in the perception of one’s influence or leadership, and it did not consider the social network of these individuals. Thus, more objective and reliable measurements are required [21]. The ML model exhibits better flexibility, whereby it can incorporate more variables and measure SHIs more comprehensively.

To overcome the challenges of the ES to identify SHIs and to tailor this for SD-HIVST, we developed and validated an ML model (ie, an artificial algorithm) to help identify GBMSM SHIs [28]. This trial aimed to compare the effectiveness of SD-HIVST initiated by SHIs identified through the ML model in promoting alters for testing among Chinese GBMSM compared to the ES method. The authors of this paper hypothesized that SHIs identified using the ML model would be more effective in motivating more alters to conduct HIVST in comparison to SHIs identified by the scale.

**Methods**

**Ethical Considerations**

We registered this trial on the Chinese Clinical Trial Registry website (ChiCTR2000039632). We obtained the institutional review board approval through the Dermatology Hospital of Southern Medical University (2019020[R3]). We obtained different electronic consents from study participants before they started the screening survey, ordered HIVST kits, and uploaded the HIVST results. We provided each participant with 20 RMB (US $3) in compensation through WeChat Pay (China’s most popular social networking app with a mobile payment function) for their time spent completing a survey. We only used participants’ identifiable information for compensation and to eliminate any duplicate entries. We used deidentified data to conduct the analysis.

**Study Setting and Recruitment**

We used a quasi-experimental study design. This study was a collaboration between the Social Entrepreneurship to Spur Health team, the Zhuhai Center for Disease Control and Prevention, and the Zhuhai Xutong Voluntary Services Center, a GBMSM community-based organization (CBO).

The study participants were recruited from 5 provinces in southern China, including Guangdong, Guangxi, Fujian, Hunan, and Jiangxi, by putting recruiting banner ads on BlueD, China’s largest gay social networking app. Interested GBMSM who clicked the banner would answer the presurvey questions to complete the eligibility check. Eligible individuals were then sent an online baseline survey (Figure 1).
Eligibility Criteria

Participants met the following eligibility criteria: (1) were assigned male sex at birth, (2) were aged 18 years or older, (3) self-reported ever having sex with men, and (4) were willing to engage in the SD-HIVST program.

Identifying Sexual Health Influencers

To reduce self-report bias, we excluded respondents (survey outliers) who answered with more than 20 sexual partners in the previous 3 months. We randomly assigned eligible individuals to 1 of 2 groups in a 1:1 ratio. Identified SHIs were eligible to engage in the SD-HIVST program. Index participants were SHI who agreed to participate in the study.

A 6-item scale was used to identify SHIs among GBMSM allocated to the ES. This scale was adapted from the one (Cronbach α = 0.937) used in our previous study to assess GBMSM’s ability to spread information about sexual health [30,31]. The self-reported scale comprises 6 inquiries designed to evaluate each participant’s involvement in disseminating information about HIV and STIs, both through web-based and offline channels, over the past 3 months. These six questions assess (1) the frequency of their discussions with others regarding HIV and STI, (2) the extent to which they shared information about HIV and STI with others, (3) the number of individuals they informed about HIV and STI, (4) other people’s willingness to seek additional information about HIV and STI from them, (5) whether they or others within their social network were the primary sources of information about HIV and STI, and (6) how often they have sought advice about HIV and STIs. Participants received a total response score ranging from 0 to 24 based on their answers to these questions. Subsequently, SHIs were ranked according to their total scores. More details can be found in the protocol [32].

For the ML model group, we used our developed model to identify SHIs. The model was trained using data from our earlier SD-HIVST program [33]. We used an ensemble approach that involved 4 distinct ML models: logistic regression, random forest, decision tree, and support vector machine. By combining these 4 ML models, we developed our novel ensemble ML model. To ensure the models’ robustness, we applied a 5-fold cross-validation technique and evaluated the average metrics for each model [28]. We gathered data on the selected predictors from the baseline survey and fed it into our already-trained ML model, considering variables selected from social network characteristics, HIV testing, kit application willingness, GBMSM behavior, etc [16].

Conducting SD-HIVST

Identified SHIs were invited to conduct SD-HIVST on a web-based private platform, which we developed and piloted [15,16]. Index participants accessed the platform by following CBO’s public account on WeChat. CBO posted HIV knowledge and HIVST-related information (eg, kit manufacturer, things to be considered before ordering HIVST kits, and the ordering process) on their WeChat platform. Participants could click the link and read testing-related and HIV-related information. They could also send direct messages to CBO staff based on their needs. In addition, participants could also message research team staff if they had any research-related concerns.

HIVST kits, each including a delivery-tracking code, a result-tracking code, and a user guide, were sent by postal mail to the address provided by the applicant. Testers submitted their results by uploading images to the platform, accessed through a QR code on the package. CBO staff confirmed the results by reviewing the submitted photos. Then, CBO staff would message the verified result to each tester and provide counseling based on the tester’s needs. If a tester had reactive results, the CBO staff would provide information and link them to a confirmation test.

There were 2 rounds of HIVST ordering, and identified SHIs were invited at each round. The first round was from February to June 2021, and the second round was from June to November 2021.

In the first round, index participants could request a maximum of 5 HIVST kits and acquire a unique PR link, allowing them to invite up to 5 alters to order 1 HIVST kit each. In the second round, we lifted the upper limit to 10 HIVST kits and allowed index participants to invite up to 10 alters through the unique PR link. We asked for a refundable deposit of 40 RMB (US $7) per kit at each request.

Index participants would receive 20 RMB (US $3) as incentives for each validated testing result of alters. Furthermore, all unique testers earned 20 RMB (US $3) after verifying their testing results.

Outcomes

We identified unique alters as individuals who received tests from index participants and reported results using unique cell phone numbers. If alters were tested twice, we kept their most up-to-date results. We further classified alters who self-reported having never tested for HIV before this research as unique newly tested alters.

Primary outcomes included (1) the number of unique alters motivated by index participants in each group and (2) the number of unique newly tested alters motivated by index participants in each group. They were assessed when HIVST testers completed the return survey. Secondary outcomes included (1) the number of testers tested with HIV-reactive results, (2) the number of unique alters motivated by index participants categorized in subgroups, and (3) the economic cost comparison between the ES and the ML model.

Sample Size Calculation

We calculated a sample size of 400 SHIs with 80% power, a 2-sided α =.05, and a 20% loss to follow-up. According to our preliminary study data, we assumed the mean difference (MD) was 1 between the 2 groups in unique alters motivation and 0.3 in newly tested alters motivation [32]. We conducted sample size estimation using PASS software (version 16.0; NCSS, LLC).

Missing Data and Sensitivity Analysis

No index participants dropped out of the study during the entire study period. In data analysis, we only included baseline survey
data related to index participants’ sociodemographics without using follow-up survey data, and the baseline data was complete without any missing data. When uploading test results, some alters might choose their role as “index participants” to skip answering the alters’ survey through which we collected whether they were newly tested. Since CBO staff worked closely with index participants, they verified the identity of each uploaded result and made a note in the database for reference researchers.

We conducted sensitivity analyses under two assumptions: (1) considering all individuals who skipped the survey as newly tested, and (2) considering all individuals who skipped the survey as not newly tested.

Statistical Methods
We used the Shapiro-Wilk method to test the data distribution of baseline characteristics of index participants and presented the mean (SD) for the primary outcomes of each group. We calculated MD between groups and used bootstrapping to estimate corresponding 95% CIs. We used negative binomial regression for primary outcome analyses and adjusted covariates, including age group, income, education, residence permit, marital status, sexual orientation, and residence. We performed the same regressions on subgroup analysis, whereby we classified index participants based on their age, sexual orientation, sexual orientation disclosure, residence permit, education, and province of residence. We believe negative binomial regression is more suitable than other methods for the following reasons: (1) the variance of the count number (ie, outcomes) is larger than the mean value (Table 1), thus assumptions of Poisson regression are not met; (2) we conducted tests for the presence of excess 0s in the data. The results indicated that there were no excess 0s, suggesting that the data was not a suitable fit for 0-inflated negative binomial regression.

We considered $P<.05$ as statistically significant and performed data analysis in RStudio (version 1.2.5033; Posit).

We used a microcosting method to assess the economic cost (ie, the cost of all resources needed to implement the testing models) from the perspective of a health provider. We kept track of the resources used throughout the experiment and classified cost items. We collected cost data (Table S1 in Multimedia Appendix 1) and analyzed costs. All expenses are expressed in 2021 US dollars using OANDA currency conversions (US $1=6.51 RMB). We conducted the cost analysis in Excel 2019 (Microsoft Corporation).

Results
Overview
We received 2150 recruitment surveys from January 7 to January 28, 2021. After excluding 5% outliers from 1922 respondents, we identified 1828 unique participants with verified contact information. We randomly assigned 1828 participants to each group (ML model=914 and ES=914). We further identified 465 SHIs in the ES and 465 SHIs in the ML model group. After being invited to participate in SD-HIVST, 393 identified SHIs (ES=195 and ML model=198) further confirmed their interests, and 229 index participants (ES=116 and ML model=113) initiated SD-HIVST and were included in this study. SD-HIVST was implemented from February 2021 to November 2021 (Figure 2).
**Figure 2.** Flowchart of the quasi-experimental study: secondary distribution of HIV self-testing kits among gay, bisexual, and other men who have sex with men (GBMSM) in China, from January to November 2021. SHI: sexual health influencer.

### Sociodemographic Characteristics

In total, 229 index participants ordered SD-HIVST, with 59.5% (116/195) in the ES and 57.1% (113/198) in the ML model ordering HIVST kits on the web.

The social demographic characteristics were similar between the 2 groups, except for education status (Table 1). Overall, the mean age of index participants was 27.58 (SD 7.75) years, 76% (175/229) of them obtained at least a college degree, 87.3% (200/229) were single, 72.9% (167/229) self-identified as gay, 68.6% (157/229) disclosed their sexual orientation to people who are not gay, and 91.7% (210/229) ever tested for HIV.
Table 1. Baseline characteristics of index participants (n=229) in China, stratified by the empirical scale (ES) group versus the machine learning (ML) model group, from February to November 2021. A 2-tailed t test was applied to compare ages between the ES and ML models. Chi-square tests were applied to test differences in categorical characteristics between the ES and ML models.

a A total of 59.5% (116/195) participants in the ES ordered HIV self-testing kits on the web.

b A total of 57.1% (113/198) participants in the ML model ordered HIV self-testing kits on the web.

c Index participants disclosed their sexual orientation to other people who were self-identified as not gay.
Marital status refers to heterosexual marriage.

In the past 3 months refers to October 2020 to January 2021.

**Application (First Round)**

Overall, 224 index participants ordered HIVST kits through the platform. In the ES, 113 index participants ordered 244 kits and referred to 21 PR links. We received 227 results, with a return rate of 85.7% (227/265), among which 72 results were from 72 unique alters.

In the ML model, 111 index participants ordered 267 kits and referred 41 PR links to alters. We received 261 results, with a return rate of 84.7% (261/308), among which 129 results were from 127 unique alters.

A total of 84.1% (95/113) index participants in the ES completed the 3-month follow-up survey, while 86.5% (96/111) index participants in the ML model completed the survey.

**Application (Second Round)**

In the second round, 85 index participants ordered kits through the platform. A total of 46 index participants in the ES ordered 127 kits and referred to 31 PR links. We received 133 results, with a return rate of 84.2% (133/158), among which 34 results were from 30 unique alters.

In the ML model, 39 index participants ordered 132 kits and referred 32 PR links to alters. We received 129 results, with a return rate of 78.6% (129/164), among which 79 results were from 72 unique alters.

A total of 87% (40/46) index participants in the ES and 87% (34/39) participants in the ML model completed the 3-month follow-up survey.

**Unique Alter Motivation Results**

Table 2 presents the primary outcome results for 229 index participants in the 6-month study period on the effect of motivating unique alters and newly tested alters. We estimated a total effect from 2 rounds, with separate effects for the first and second rounds.

Overall, index participants in the ML model motivated an average of 1.76 (199/113, SD 3.97) unique alters to conduct HIVST compared with 0.88 (102/116, SD 1.84) in the ES, with an MD of 0.88 (95% CI 0.02-2.22). Index participants in the ML model were more likely to motivate unique alters than those in the ES (adjusted incidence rate ratio [aIRR] 1.77, 95% CI 1.07-2.95).
Table 2. The effectiveness in motivating alters and newly tested alters to conduct HIV self-testing (HIVST), comparing index participants in the empirical scale (ES) group to those in the machine learning (ML) model group in China, February to November 2021. We kept the unique index participants when analyzing the outcomes of the first and second rounds. Therefore, the number of overall index participants is not equal to the sum of the absolute number of 2 rounds of index participants.

<sup>a</sup>MD: mean difference.

<sup>b</sup>aIRR: adjusted incidence rate ratio. A negative binomial model was used to calculate the incidence rate ratio (IRR). aIRR was adjusted for age (<30 and ≥30 years), income, education, marital status (referring to heterosexual marriage), sexual orientation, and residence.

<sup>c</sup>P<.05.

<sup>d</sup>The Hauck-Donner effect occurred, causing the estimated coefficients to be in extreme situations.

**Newly Tested Alters Motivation Results**
Throughout 2 rounds, index participants in the ML model averagely motivated 0.73 (82/113) unique newly tested alters, compared with 0.38 (44/116) in the ES. The performance of index participants in the ML model was slightly better than that in the ES (MD 0.35, 95% CI —0.17 to 0.99), but the difference between these 2 groups was not statistically significant. (Table 2.) We identified 4 alters who chose their role as index participants. Our sensitivity analysis results showed a similar pattern.

**Subgroup Analysis Results**
Table 3 reveals subgroup analysis results. Index participants in the ML model who were aged 30 years or younger, not gay, or residents of Guangdong were more likely to motivate unique alters to conduct HIVST than those who were in the ES.
Table 3. The effectiveness in motivating alters to conduct HIV self-testing (HIVST), comparing index participants in the empirical scale (ES) group to those in the machine learning (ML) model group, stratified by their baseline demographics in China, from February to November 2021.

\(^a\)aIRR: adjusted incidence rate ratio. A negative binomial model was used to calculate the incidence rate ratio (IRR). aIRRs were adjusted for age, income, education, marital status, sexual orientation, and residence.

\(^b\)P<0.05.

\(^c\)The Hauck-Donner effect occurred, causing the estimated coefficients to be in an extreme situation.

\(^d\)Others include bisexual and unsure.

\(^e\)Index participants disclosed their sexual orientation to other people who were self-identified as not gay.

**HIVST Reactive Results**

Among 14 testers who were newly tested HIV reactive, 6 were index participants (3 in the ES and 3 in the ML model), and 8 were alters (4 in the ES and 4 in the ML model). CBO staff followed up with all testers with reactive results.

**Cost Analysis**

The total economic cost of implementing the SD-HIVST was US $6547.12 for the ES and US $6767.19 for the ML model. When comparing the ML model and ES approaches, the ML model is more effective in encouraging participants to get tested for HIV, but it is not cost-saving. The incremental cost to gain an additional tested participant is US $2.27, and for a newly tested participant, the incremental cost is US $5.79 (Table 4).
Table 4. Cost analysis evaluating the effectiveness in motivating alters and newly tested alters to conduct HIV self-testing (HIVST), comparing index participants in the empirical scale (ES) group to those in the machine learning (ML) model group, from February to November 2021.

**Discussion**

**Overview**

We conducted a quasi-experimental study among Chinese MSM and found that, overall, SHIs identified by the ML model can influence more individuals through their social network to conduct HIVST than SHIs identified by the conventional scale, highlighting the potential of artificial AI to enhance the efficiency of testing approaches. Building on the evidence that monetary incentives and peer referral can amplify the effect of SD-HIVST, this study extends the literature by comparing the effectiveness of the ES and a ML model in identifying SHIs for secondary distribution and reporting results on the total number of unique alters and newly tested alters motivated by the identified SHIs [15,16]. In addition, we acknowledged the important role that community engagement plays in promoting HIV testing among GBMSM. Identifying SHIs to implement community-led interventions could expand HIV testing services. As influential community members, SHIs build on their potential to support their peers in improving health awareness and behaviors, thereby engaging more individuals from their social networks and facilitating HIVST uptake.

**Principal Findings**

The ML model was more effective than the ES in engaging unique alters for HIVST during SD-HIVST. This is aligned with the results of a previous study using an interactive deep learning approach to identify HIV influencers; that is, not only ML models can detect HIV-related digital social influencers, but also ML models show higher accuracy in identification [34]. Despite studies showing that SHIs and noninfluencers can promote HIV testing within their social networks, the groups they can reach differ, particularly alters of SHIs who sought out more casual sexual partners, which increased their risk of HIV infection [22,23]. In light of this, it is promising to integrate them into the current SD-HIVST programs to facilitate HIV testing uptake and case identification further. Both the ML model and the ES revealed modest differences in the motivation of newly tested alters. The results of the ML model were statistically insignificant in promoting first-time testing compared to the ES; this may be due to the power of the study. However, in terms of implementation, SHIs identified by the ML model motivated a larger number of newly tested alters and promoted first-time testing coverage. Previous studies have demonstrated that first-time testing among GBMSM is associated with sociodemographic and other factors such as the number of sexual partners, condomless sex, and STI infection history [30,31]. Further refinement of the interventions may be warranted to reach more newly tested alters.

**Comparison to Previous Work**

Evidence-based HIV prevention strategies can be significantly enhanced through interdisciplinary collaboration between communities and academia [33]. At the community level, our research was rooted in strong partnerships between the academic and community sectors. We closely worked with the local gay-led CBO to evaluate the interventions designed for specific populations, ensuring a collaborative and informed approach to this study. A review paper demonstrated that AI, exemplified by Van Heerden et al [36] mobile app using natural language processing and Brown et al [37] partner notification model with unconditional logistic regression, shows promise in enhancing HIV counseling, testing, and partner notification strategies [33,36,37]. Our research extends the existing literature on the application of AI in HIV testing, specifically concentrating on identifying SHIs and expanding the effectiveness of the current SD-HIVST program.

Additionally, several studies have been done on the feasibility and acceptability of digital interventions, and further strategies to accelerate digital interventions for HIV prevention are needed [38,39]. ML as a data science approach has sparked significant research interest in developing digital health interventions [33,40]. The strength of our ML model lies in both accuracy and flexibility. In building the ML model, more specific variables were incorporated and weighted differently to define SHIs, such as the number of copies of HIVST wanted, the intention to deliver HIVST, and the willingness to obtain PR links [41]. Further, the absence of the data sets from the previous study for the ES or social network-based simulation optimization...
models renders them less accurate than the ML model in identifying SHIs during SD-HIVST [42].

**Strengths and Limitations**

This study also has several limitations. First, this study is quasi-experimental, which may be subject to selection bias. Only half of the identified SHIs agreed to participate, and only one-quarter initiated the HIV self-test kit application process. However, the social demographic characteristics were comparable between the 2 study arms. Second, the ML model did not outperform the ES in promoting newly tested alters. The main reason for this could be the selection of parameters when building the ML model that primarily motivates unique alters. Future research regarding motivating the newly tested alters requires additional consideration of the selection of variables and the weight given to them during modeling. Finally, compared to our previous studies, this study reported a relatively lower result return rate among the testers, mainly due to a much lower deposit, which reduces the “sunk cost” for the testers so that they are less inclined to return the results [15,16]. A higher deposit fee may be advisable for similar programs to ensure a higher rate of returns. However, our sensitivity analysis indicated that the impact of these nonreturns has a minimum impact on this study results.

**Future Directions**

As for implications, this study demonstrated that interventions led and delivered by CBO could facilitate participation. The local GBMSM-friendly CBO undertook the health service delivery in this study, including the construction and maintenance of the HIVST kit ordering platform, HIVST kit distribution, counseling, results interpretation, and linkage to care services. This was consistent with a systematic review that community engagement interventions are beneficial for marginalized populations in increasing health behaviors, health outcomes, participant self-efficacy, and perceived social support [43]. Particularly in COVID-19, our innovative digital health intervention can guarantee access to health services while saving costs. This ML model method of identifying SHIs may also apply to other regions and other interventions, as it has good extensibility and flexibility. Depending on the interventions (including but not limited to SD-HIVST), we can build the ML model based on different selected associated variables.

**Conclusion**

Identifying SHIs can enhance the effectiveness of social network–based intervention among GBMSM. We found that SHIs identified by the ML model can motivate more individuals to conduct HIVST than those identified by the ES in SD-HIVST programs among Chinese GBMSM. This study innovatively adopted data science techniques to develop the ML model for identifying SHIs and delivering interventions in collaboration with community-based organizations. This strategy can be adapted and implemented to improve HIV care services.

Abstract

Background: Numerous studies in South Africa have reported low HIV viral load (VL) suppression and high attrition rates within the pediatric HIV treatment program.

Objective: Using routine laboratory data, we evaluated HIV VL monitoring, including mobility and overdue VL (OVL) testing, within 5 priority districts in South Africa.

Methods: We performed a retrospective descriptive analysis of National Health Laboratory Service (NHLS) data for children and adolescents aged 1-15 years having undergone HIV VL testing between May 1, 2019, and April 30, 2020, from 152 facilities within the City of Johannesburg, City of Tshwane, eThekwini, uMgungundlovu, and Zululand. HIV VL test–level data were deduplicated to patient-level data using the NHLS CDW (Corporate Data Warehouse) probabilistic record-linking algorithm and then further manually deduplicated. An OVL was defined as no subsequent VL determined within 18 months of the last test. Variables associated with the last VL test, including age, sex, VL findings, district type, and facility type, are described. A multivariate logistic regression analysis was performed to identify variables associated with an OVL test.

Results: Among 21,338 children and adolescents aged 1-15 years who had an HIV VL test, 72.70% (n=15,512) had a follow-up VL test within 18 months. Furthermore, 13.33% (n=2194) of them were followed up at a different facility, of whom 3.79% (n=624) were in a different district and 1.71% (n=281) were in a different province. Among patients with a VL of $\geq 1000$ RNA copies/mL of plasma, the median time to subsequent testing was 6 (IQR 4-10) months. The younger the age of the patient, the greater the proportion with an OVL, ranging from a peak of 52% among 1-year-olds to a trough of 21% among 14-year-olds. On multivariate analysis, 2 consecutive HIV VL findings of $\geq 1000$ RNA copies/mL of plasma were associated with an increased adjusted odds ratio (AOR) of having an OVL (AOR 2.07, 95% CI 1.71-2.51). Conversely, patients examined at a hospital (AOR 0.86, 95% CI 0.77-0.96), those with $\geq 2$ previous tests (AOR 0.78, 95% CI 0.70-0.86), those examined in a rural district (AOR 0.63, 95% CI 0.54-0.73), and older age groups of 5-9 years (AOR 0.56, 95% CI 0.47-0.65) and 10-14 years (AOR 0.51, 95% CI 0.44-0.59) compared to 1-4 years were associated with a significantly decreased odds of having an OVL test.

Conclusions: Considerable attrition occurs within South Africa’s pediatric HIV treatment program, with over one-fourth of children having an OVL test 18 months subsequent to their previous test. In particular, younger children and those with virological...
failure were found to be at increased risk of having an OVL test. Improved HIV VL monitoring is essential for improving outcomes within South Africa’s pediatric antiretroviral treatment program.

**Introduction**

South Africa has an estimated 8 million people living with HIV [1]. Although the national Prevention of Mother to Child Transmission program, launched in earnest in 2004, has reduced the vertical transmission rate to approximately 3%, there remain around 280,000 children and adolescents nationwide aged <15 years living with HIV. Furthermore, pediatric and adolescent populations living with HIV have far worse clinical outcomes than older age groups [2]. Modeling studies from South Africa estimate that while the proportion of the total population living with HIV who are diagnosed, those accessing antiretroviral therapy (ART), and those with viral suppression (<1000 RNA copies/mL of plasma [hereinafter “copies/mL”]) is 94%, 69%, and 63%, respectively, for pediatric populations, these proportions are considerably lower at 82%, 57%, and 39%, respectively [1]. Partly in response to the disparity between pediatric and adult treatment outcomes, the UNAIDS (Joint United Nations Programme on HIV/AIDS) launched the Global Alliance to End AIDS in Children by 2030 program, with South Africa officially having launched its chapter in 2023 [3].

Poor pediatric linkage to care, high attrition rates, and high mortality rates have been described from a number of cohort studies across the country [4-6]. Such studies support the identification of variables associated with attrition—this is considered an important step toward improving care. Virological nonsuppression has been identified as one such key risk factor for subsequent program loss from both improving care and rural cohorts [7]. However, as variables associated with attrition may vary among regions and are likely to be influenced by a myriad of socioeconomic and political factors, additional mechanisms are urgently needed to not only identify children at risk of disengaging with care but also support the challenging process of re-engagement. Effective use of routine laboratory data offers opportunities toward this end.

The National Health Laboratory Service (NHLS) is the only clinical laboratory service provider within South Africa’s public health sector. As such, the NHLS Data Warehouses can potentially be leveraged for cost-effective disease surveillance and near–real-time reporting, with the advantage of not being restricted to facility-based monitoring as is the case with the national electronic patient monitoring system, TIER.Net. The ability of laboratory data to support the ready disaggregation of population-level data to provide a more nuanced understanding of program outcomes has been demonstrated for the pediatric HIV program, with younger children found to have markedly lower viral suppression rates than older children, and male patients being less likely to be suppressed than female patients across all age groups [8]. Furthermore, reporting of patient-identifying consolidated exceptions, both at district and facility levels, as indicated in the Results for Action reports of the National Institute for Communicable Diseases (NICD), a division of the NHLS, enables the timely identification of children in need of urgent follow-up based on HIV diagnostic and monitoring findings [9]. However, the potential for routine laboratory data for evaluating pediatric attrition in near real time, thereby supporting retention in care, has not previously been described.

In the following analysis, we aimed to evaluate HIV viral load (VL) monitoring within the pediatric HIV program by reporting on patient mobility and overdue VL (OVL) testing within 5 high-burden health districts in South Africa.

**Methods**

**Study Design**

This study is a retrospective descriptive analysis of routine laboratory data from South Africa’s public health sector, spanning a 4-year period. Data for children and adolescents aged <15 years living with HIV, who had undergone HIV VL testing between May 1, 2019, and April 30, 2020, from 152 facilities within 5 districts, were extracted from the NICD Data Warehouse. Test-level data were deduplicated to patient-level data by 2 sequential methods. The first one involved assigning a unique patient identifier (UPI) to all results by using a probabilistic record-linking algorithm, referred to in the text as the NHLS CDW (Corporate Date Warehouse) unique identifier (hereinafter referred to as the “CDW algorithm”), which links HIV tests performed nationally within the NHLS. This algorithm has been validated within the adult HIV program, with a reported sensitivity of 84% and incorrectly matching 0.3% of results [10]. Second, records were manually deduplicated by 4 data experts, according to a set of agreed upon rules listed in Multimedia Appendix 1 and referred to in the text as the manual deduplication UPI. Manual deduplication linked HIV tests for each patient within the 152 facilities only. Prior and subsequent tests were linked using both the CDW algorithm and manual deduplication identifiers. Prior tests from October 1, 2017, were linked to the cohort to describe the number of previous tests and number of previous high HIV VL (≥1000 copies/mL) results. Subsequent tests for an 18-month period up to October 31, 2021, were linked to the cohort to describe follow-up testing. An OVL test was defined as no subsequent VL test within 18 months of the last VL test, irrespective of the last HIV VL result. An 18-month period was informed by national ART guidelines, which recommend that all patients undergo HIV VL monitoring at least once every 12 months. While other similar analyses
have used a 24-month period [11,12], an 18-month period (ie, considering a 6-month grace period) was deemed sufficient and supported the inclusion of data up until April 2020 at the time of analysis. Due to known limitations with linking infant tests using demographic data [13], analysis of OVL tests was restricted to children and adolescents aged 1-15 years.

Setting and Laboratory Testing Methods

HIV viral load routine laboratory data were analyzed from 5 high-HIV-burden districts in South Africa considered by the National Department of Health as having the largest pediatric treatment gaps in the country, as determined from modeling data: City of Johannesburg and City of Tshwane in Gauteng Province, and eThekwini, uMgungundlovu, and Zululand in KwaZulu-Natal Province [14]. Data were restricted to patients who had undergone HIV VL testing at one of 152 designated facilities that have additional pediatric HIV support from District Support Partner organizations, representing 30% of all facilities and approximately two-thirds of all HIV VL testing performed for children and adolescents aged <15 years within these districts.

HIV VL monitoring is routinely recommended 6 months after ART initiation, with repeat testing performed at 12 months and 12-monthly thereafter if viral suppression is detected. The cutoff that defines suppression was revised in the 2019 national guidelines from <1000 copies/mL to ≤50 copies/mL, with patients with an suppressed VL requiring repeat testing at 3 months after a thorough assessment and management of the cause of an elevated VL [15].

Within the NHLS, HIV VL testing is performed using plasma samples at centralized laboratories using either the Cobas HIV-1 Test (Roche Diagnostics) or the Abbott RealTime HIV-1 assay (Abbott Molecular, Inc).

Statistical Analysis

Variables associated with the last HIV VL finding per patient, tested between May 1, 2019, and April 30, 2020, are reported; these include age group (<1, 1-4, 5-9, or 10-14 years), sex (male, female, or unknown), VL test result (≤50, 50-999, or ≥1000 copies/mL), district type (metropolitan districts classified as urban versus nonmetropolitan districts classified as rural), and facility type (hospital versus primary health care facility). The number of patients according to each deduplication step is described by comparing the number and percentage decrease of patients reported through manual deduplication of UPIs and deduplication performed using the CDW algorithm per variable. The proportion of people with an OVL was evaluated for both the CDW algorithm, these corresponded to 24,398 patients, while the manually deduplicated UPIs corresponded to 22,978 patients, representing a deficit of 5.82% (n=1420). This deficit was associated with considerable variation among variables except for sex and facility type (Figure 1). Facilities in the urban districts had a greater deficit in the number of participants (n=1144) than those in rural districts (n=276); however, this represented a smaller deficit in the proportion of people (5.7% vs 6.3%, respectively; Figure 1A). In terms of age, the 1–4-year age group had the highest percentage of deduplication at 6.4% (n=217), while the ≤1-year age group had the lowest proportion of deduplication at 4.0% (n=68; Figure 1B). There was considerable variation in deduplication among HIV VL result categories: those with a VL of ≤50 copies/mL decreasing by 2.7% (n=376), those with a VL of 50-999 copies/mL decreasing by 7.6% (n=390), and those with a VL of ≥1000 copies/mL decreasing by 11.8% (n=654; Figure 1C). In terms of sex and facility type, the variation was minimal, with a 5.9% (n=733) reduction among females and a 5.8% (n=647) reduction among males (Figure 1D), and a 6.0% (n=806) reduction for clinics compared with a 5.6% (n=614) reduction for hospitals (Figure 1E). In terms of the number of linked previous tests, there was a marked decrease in number of patients with a single HIV VL test and those with no prior high (≥1000 copies/mL) HIV VL finding (Figures 1F and 1G).

Differences were also observed in the number and proportion of patients with an OVL test after manual deduplication when compared with the CDW algorithm. According to the CDW algorithm, 22,690 children and adolescents aged 1-15 years had undergone an HIV VL test between May 2019 and April 2020 within the 152 designated facilities, of whom 9685 (42.68%) had an OVL test. After manual deduplication, 21,338 children and adolescents were identified, of whom 5826 (27.3%) had an OVL test, representing a reduction of 39.85% (n=3859) of patients considered to have an OVL test.

Ethical Considerations

The National Institute for Communicable Diseases has ethics approval for communicable disease surveillance and analysis of routine laboratory data by the Human Research Ethics Committee of the University of the Witwatersrand (M160667; M210752), with the requirement for informed consent having been waived. All analysis with patient-identifiable data was performed on a secure password-protected server located on the NHLS campus.

Results

Data Deduplication

A total of 29,822 HIV VL tests, registered among children and adolescents aged <15 years, were carried out between May 2019 and April 2020 at 152 facilities. According to the CDW algorithm, these corresponded to 24,398 patients, while the manually deduplicated UPIs corresponded to 22,978 patients, representing a deficit of 5.82% (n=1420). This deficit was associated with considerable variation among variables except for sex and facility type (Figure 1). Facilities in the urban districts had a greater deficit in the number of participants (n=1144) than those in rural districts (n=276); however, this represented a smaller deficit in the proportion of people (5.7% vs 6.3%, respectively; Figure 1A). In terms of age, the 1–4-year age group had the highest percentage of deduplication at 6.4% (n=217), while the ≤1-year age group had the lowest proportion of deduplication at 4.0% (n=68; Figure 1B). There was considerable variation in deduplication among HIV VL result categories: those with a VL of ≤50 copies/mL decreasing by 2.7% (n=376), those with a VL of 50-999 copies/mL decreasing by 7.6% (n=390), and those with a VL of ≥1000 copies/mL decreasing by 11.8% (n=654; Figure 1C). In terms of sex and facility type, the variation was minimal, with a 5.9% (n=733) reduction among females and a 5.8% (n=647) reduction among males (Figure 1D), and a 6.0% (n=806) reduction for clinics compared with a 5.6% (n=614) reduction for hospitals (Figure 1E). In terms of the number of linked previous tests, there was a marked decrease in number of patients with a single HIV VL test and those with no prior high (≥1000 copies/mL) HIV VL finding (Figures 1F and 1G).

Differences were also observed in the number and proportion of patients with an OVL test after manual deduplication when compared with the CDW algorithm. According to the CDW algorithm, 22,690 children and adolescents aged 1-15 years had undergone an HIV VL test between May 2019 and April 2020 within the 152 designated facilities, of whom 9685 (42.68%) had an OVL test. After manual deduplication, 21,338 children and adolescents were identified, of whom 5826 (27.3%) had an OVL test, representing a reduction of 39.85% (n=3859) of patients considered to have an OVL test.
Figure 1. Number and percentage deduplication of test-level to patient-level data using 2 unique patient identifiers (UPIs) among children and adolescents aged <15 years with an HIV viral load (VL) test between May 2019 and April 2020 from the City of Johannesburg, City of Tshwane, eThekwini, uMgungundlovu, and Zululand by (A) district, (B) age group, (C) VL test result, (D) sex, (E) facility type, (F) number of previous linked tests, and (G) number of previous linked high VL (>999 RNA copies/mL of blood) findings. CDW: Corporate Data Warehouse; cps/ml: RNA copies/mL of blood.

Follow-Up HIV VL Testing and Movement Across Facilities

Among the manually deduplicated data set of 21,338 children and adolescents aged 1-15 years who had undergone an HIV VL test between May 2019 and April 2020, a total of 54,160 tests were registered at 771 different facilities. Considering the results of the first test registered with each patient, 11,889 (55.7%) had a VL of <50 copies/mL, 4416 (20.7%) had a VL of 50-999 copies/mL, and 5033 (23.6%) had a VL of ≥1000 copies/mL. In terms of location, 17,341 (81.3%) tests were first registered in an urban district and 3997 (18.7%) were registered in a rural district. At the time of the first test, there were 3303 (15.5%) patients aged 1-4 years, 6126 (28.7%) patients aged 5-9 years, and 11,909 (55.8%) patients aged 10-14 years.

Of the 21,338 children and adolescents, 77.16% (n=16,465) of them had undergone a follow-up VL test, of whom 72.70% (n=15,512) had undergone a follow-up HIV VL test within 18 months and 4.47% (n=953) had a follow-up test after 18 months. Overall, 14,363 (87.2%) patients were followed up at the same facility, 1963 (11.9%) were followed up at 2 facilities, 120 (0.7%) were followed up at 3 facilities, 10 (0.01%) were followed up at 4 facilities, and 8 (0.01%) were followed up at 5 facilities. In total, 2102 (12.8%) patients were followed up at a different facility, of whom 604 (3.7%) were in a different district and 270 (1.6%) were in a different province. The median time to subsequent testing varied by VL result (Figure 2). For those with a VL of <50 copies/mL (n=9944), the median time of subsequent testing was 12.1 (IQR 11.1-13.1) months. For those with a VL finding of 50-999 copies/mL (n=3505), the median time to subsequent testing was 11.2 (IQR 7.2-12.8) months, and for those with a VL finding of ≥1000 copies/mL (n=3016), the median time to subsequent testing was 6.5 (IQR 4.2-10.3) months. For those with a single VL finding of ≥1000 copies/mL (n=1056), the median follow-up time was 7.1 (IQR 4.7-11.4) months, whereas for those with a repeat VL of ≥1000 copies/mL
(n=1960), the median follow-up time was 6.1 (IQR 4.0-9.6) months. The change in the national guidelines in 2019, whereby the threshold for viral suppression was revised from <1000 to copies/mL to <50 copies/mL, was associated with a biphasic pattern of time to follow-up among patients with a finding between 50 and 999 copies/mL.

Urban districts had a greater number and proportion of people (n=5077, 29.17%) with an OVL test than rural districts (n=749, 19.05%; Figure 3A). In terms of age, the 1-4-year age group had the highest proportion of OVL tests at 42.98% (n=1372), while the 10-14-year age group had the lowest at 23.83% (Figure 3B). However, given the number of patients, this age category also had the highest number of people with an OVL test (n=2882). In terms of HIV VL test results, 25.57% (n=3209) of patients with a VL of <50 copies/mL and 25.83% (n=1150) of those with a VL of 50-999 copies/mL had an OVL test, while those with a VL of ≥1000 copies/mL accounted for the greatest proportion of OVL tests, at 33.83% (n=1467; Figure 3C). In terms of sex, a slightly higher proportion of females (n=3052, 28.45%) had an OVL test than males (n=2614, 26.06%; Figure 3D). Furthermore, a slightly higher proportion of people who underwent VL testing at a clinic had an OVL (n=3419, 28.51%) than those who underwent testing at a hospital (n=2407, 25.76%; Figure 3E).

In terms of the number of linked previous tests, the largest proportion of people with an OVL test was observed among patients with no linked prior tests (n=3126, 64.39%; Figure 3F). Not only did having at least one prior linked VL test considerably reduce the proportion of people with an OVL test, but also this proportion generally decreased as the number of previous linked tests increased. This ranged from a peak of 21.96% (n=1217) for those with one prior VL test to a trough of 6.64% (n=16) for those with 6 prior tests. This pattern was replicated in the number of previous high VL findings (>999 copies/mL; Figure 3G).

**Figure 2.** Time to follow-up HIV viral load (VL) testing (in months) by VL findings, with medians reported per result category based on manual deduplication of unique patient identifiers among children and adolescents aged 1-15 years having undergone an HIV VL test between May 2019 and April 2020 from the City of Johannesburg, City of Tshwane, eThekwini, uMgungundlovu, and Zululand. cps/ml: RNA copies/mL of blood.
Figure 3. Number and percentage deduplication of test-level to patient-level data after manual deduplication for overdue viral load (VL) tests among children and adolescents aged 1-15 years having undergone an HIV viral load test between May 2019 and April 2020 from the City of Johannesburg, City of Tshwane, uMgungundlovu, and Zululand by (A) district, (B) age, (C) VL findings, (D) sex, (E) facility type, (F) number of previous linked tests, and (G) number of previous linked high HIV VL (>999 RNA copies/mL of blood) findings. cps/ml: RNA copies/mL of blood.

OVL Tests by Age and Outcome
As the age of the patient increased, the proportion of patients having an OVL test decreased, ranging from a peak of 52% among 1-year-olds to a trough of 21% among 14-year-olds (Figure 4A). This trend was observed across HIV VL result categories, with a higher proportion of OVL tests among patients with a VL of ≥1000 copies/mL (Figure 4B). Because of differences in population size among the age groups, the absolute number of patients with an OVL test varied, with high numbers of patients in the older age range having an OVL test (Figure 4A).
Figure 4. Number and percentage of people per age group (in years) with an overdue HIV viral load (VL) test among children and adolescents aged 1-15 years having undergone an HIV VL test between May 2019 and April 2020 from the City of Johannesburg, City of Tshwane, eThekwini, uMgungundlovu, and Zululand (A) overall and (B) by HIV VL findings. OVL: overdue viral load.

Variables Associated With an OVL Test

Multivariate logistic regression analysis was performed to determine variables associated with an OVL test. Only patients with 2 or more HIV VL tests were included in the model to control for limitations associated with deduplication of the test-level data (details of patients excluded from the model are provided in Multimedia Appendix 1). In total, 16,648 patients were included in the model, of whom 1554 (9.33%) had an OVL test and 15,094 (90.67%) had a follow-up VL test within 18 months of their last VL test. The 7 categorical variables included in the model, owing to their associated univariate Pearson chi-square test $P$ value of <.15, were age, current VL finding, any single high VL ($\geq 1000$ copies/mL excluding current results), 2 consecutively determined high VLs, number of previous tests, district type, and facility type (Table 1).

The Hosmer-Lemeshow goodness-of-fit $P$ value for the model was .90. On multivariate analysis, 2 consecutive (prior and current) HIV VL test results of $\geq 1000$ copies/mL were associated with a significantly increased odds of having an OVL test. Conversely, the odds of having an OVL test were significantly low among patients examined at a hospital (rather than a clinic), those with $\geq 2$ previous tests (compared to those with <2 tests), those with a history of a prior high HIV VL finding (excluding the current findings), those examined in a rural district, and those with an older age. A current VL finding of $\geq 1000$ copies/mL was associated with increased odds but was not significant in the final model (Figure 5 and Table 2).

Discussion

Principal Results

In this analysis, which included over 20,000 children and adolescents living with HIV who are aged 1-15 years from 5 districts in South Africa, we found that over one-fourth of individuals had no repeat HIV VL test within 18 months from their previous test, suggesting considerable attrition within the pediatric population. Furthermore, among patients who underwent follow-up testing, delays in repeat testing were found among those with an elevated VL of >1000 copies/mL, similar to delays described for adult cohorts in South Africa [16]. As viraemia is associated with both patient morbidity and the emergence of drug-resistant HIV strains, these findings highlight the need to improve VL monitoring and quality of care among children and adolescents within the ART program.

Individual variables associated with an OVL test included patients of a younger age, having more recently initiated ART (as determined by <2 prior HIV VL tests), having a repeatedly high HIV VL of >1000 copies/mL, being tested in an urban district rather than a rural district, and being tested at a clinic rather than a hospital. Factors accounting for higher rates of OVL in urban districts and clinics require further investigation but may be related to shifting patient populations (due to migration to or use of multiple clinics in urban areas) and access to multidisciplinary teams, respectively. Importantly, a consecutive high HIV VL finding of >1000 copies/mL was found to be a key risk factor for having an OVL test, whereas a single high VL result was protective, suggesting that patients initially identified with viraemia are successfully returned to care but if they remain unsuppressed (ie, have virological failure) they are at a high risk of subsequently disengaging with care.

Among those children and adolescent patients who had undergone additional VL testing, a fair amount of mobility was observed. In total, 13.33% of patients were followed up at a different facility, 3.79% were followed up in a different district, and 1.71% were followed up in a different province. As the time to follow-up for this analysis was restricted to only 18-30 months per patient, it is likely a far higher proportion of mobility can be expected over the course of a child’s treatment history. This highlights limitations with South Africa’s TIER.Net HIV treatment database, which uses facility-level monitoring and hence necessarily underestimates retention of HIV care [17-19]. Furthermore, the extent to which children who have initiated ART in South Africa cross national borders and resume HIV care outside of their countries has yet to be described, as well as the number of deaths among this cohort (on account of restricted access to the national death register).

One of the notable findings of this analysis was the impact that additional manual deduplication of an already automated deduplicated data set had on programmatic outcomes. As South Africa has yet to effectively implement a national UPI, automated record linking algorithms are applied to laboratory data in an attempt to deduplicate test-level data sets to represent patient-level data. However, our findings suggest that without additional manual deduplication, analysis of public health laboratory data using the NHLS CDW algorithm would have
overestimated the proportion of patients aged 1-15 years with an OVL by at least 40% (even though the data set was reduced by only an additional 6% after manual deduplication). This highlights the need to incorporate a national health UPI within the health system, including the laboratory information system and NHLS Data Warehouses, to effectively monitor the ART program.

Limitations
A number of important limitations need to be considered regarding these findings. The NHLS CDW data set was manually deduplicated at the facility level (for the 152 facilities evaluated in this analysis) without the opportunity to compare findings against a gold-standard data set. Although we report that 13% of patients with a repeat HIV VL test were followed up at a different facility, this is likely an underestimation on account of the reduced ability to accurately merge the test results of patients who were examined at multiple facilities. This may have been a contributing factor to the reason why the urban regions were associated with a higher rate of OVL testing, if patients examined in the urban areas are more likely to be followed up at multiple facilities within or even outside of the district. Additionally, patients may be retained in care but not have repeat HIV VL tests in accordance with the guidelines, for instance, on account of challenges with accessing pediatric phlebotomy services [20]; hence, the OVL testing rate may overestimate program attrition. This is likely to have been further exacerbated during the course of the COVID-19 pandemic, which impacted maternal and child access to HIV services [21]. As the multivariate analysis evaluating variables associated with OVL testing was restricted to patients with ≥2 VL tests (to ensure goodness-of-fit of the model by increasing the likelihood that if additional testing was performed, it would be linked via the deduplication methodology), this may have also influenced the findings by not including patients who were only followed-up for a single HIV VL test and hence disengaged with care soon after ART initiation. Lastly, as our analysis was restricted to 30% of facilities within 5 of the 52 national districts, the results may not be nationally representative, especially considering that the districts included in this study are known to have a high pediatric HIV disease burden.

Conclusions
In summary, linking population clinical data with laboratory data in a legal manner, which protects individuals’ rights, has the potential to improve patient outcomes for multiple health programs. A functional UPI for health care would enable improved longitudinal surveillance of children and adolescents living with HIV by using routine laboratory data for accurate, timely identification of patients who need to be returned to care, including infants. In the interim, 1-4-year-olds and those with a sustained VL of ≥1000 copies/mL should be managed as especially high risk for loss to follow-up.

Acknowledgments
The authors gratefully acknowledge the National Health Laboratory Services for access to laboratory data and Dr Trevor Graham Bell, principal health data analyst at the National Institute for Communicable Diseases, for assistance with data extraction and processing. The authors also wish to thank Mr Dumsani Mlotshwa, Dr Tanya Murray, and Dr Faith Moyo for their assistance with manual deduplication of facility patient lists. This work was partly funded by the ELMA Foundation. The funders played no role in the design of the study, data collection and analysis, or in the production of this manuscript.

Data Availability
The data sets analyzed in this study are not publicly available because they contain information that could compromise participant privacy, including patient first and last names, gender, locations, and tests conducted. Please contact the South African National Health Laboratory Service [22] for data requests.

Authors’ Contributions
GGS and AHM conceptualized the study, and LR analyzed the data. All authors contributed to the interpretation of the data. AHM played a major role in drafting the manuscript, and all the authors read and approved the final manuscript.

Abstract

Background: Men who have sex with men (MSM) constitute a significant population of patients infected with HIV. In recent years, several efforts have been made to promote HIV testing among MSM in China.

Objective: This study aimed to assess HIV testing coverage and factors associated with first-time HIV testing among MSM to provide a scientific basis for achieving the goal of diagnosing 95% of patients infected with HIV by 2030.

Methods: This cross-sectional study was conducted between July 2023 and December 2023. MSM were recruited from the “Sunshine Test,” an internet platform that uses location-based services to offer free HIV testing services to MSM by visiting the WeChat official account in Zhejiang Province, China. Participants were required to complete a questionnaire on their demographic characteristics, sexual behaviors, substance use, and HIV testing history. A logistic regression model was used to analyze first-time HIV testing and its associated factors.

Results: A total of 7629 MSM participated in the study, with 87.1% (6647) having undergone HIV testing before and 12.9% (982) undergoing HIV testing for the first time. Multivariate logistic regression analysis revealed that first-time HIV testing was associated with younger age (adjusted odds ratio [aOR] 2.55, 95% CI 1.91-3.42), lower education (aOR 1.39, 95% CI 1.03-1.88), student status (aOR 1.35, 95% CI 1.04-1.75), low income (aOR 1.55, 95% CI 1.16-2.08), insertive anal sex role (aOR 1.28, 95% CI 1.05-1.56), bisexuality (aOR 1.69, 95% CI 1.40-2.03), fewer sex partners (aOR 1.44, 95% CI 1.13-1.83), use of rush poppers (aOR 2.06, 95% CI 1.70-2.49), unknown HIV status of sex partners (aOR 1.40, 95% CI 1.17-1.69), lack of awareness of HIV pre-exposure prophylaxis (aOR 1.39, 95% CI 1.03-1.88), and offline HIV testing uptake (aOR 2.08, 95% CI 1.80-2.41).

Conclusions: A notable 12.9% (982/7629) of MSM had never undergone HIV testing before this large internet survey. We recommend enhancing HIV intervention and testing through internet-based platforms and gay apps to promote testing among MSM and achieve the target of diagnosing 95% of patients infected with HIV by 2030.

(JMIR Public Health Surveill 2024;10:e56906) doi:10.2196/56906
Introduction

Men who have sex with men (MSM) constitute a significant demographic of patients infected with HIV in China. Due to widespread unprotected sexual behaviors, engagement with multiple sexual partners, and the use of recreational agents, HIV prevalence among MSM remains notably high [1]. The overall national prevalence of HIV among MSM in China from 2001 to 2018 was estimated to be 5.7% [2]. In China, the annual number of newly diagnosed HIV infections through homosexual transmission has increased from 2.5% in 2006 to 25.6% in 2022 [3]. The Joint United Nations Program on HIV/AIDS (UNAIDS) proposed a 95-95-95 target by 2030 [4]. The overall aim of the target was to achieve diagnosis of 95% of patients infected with HIV, 95% of diagnosed patients treated, and 95% of treated patients having achieved viral suppression to reduce HIV transmission, and ultimately end the HIV epidemic worldwide.

In China, with the implementation of the “Four Frees and One Care” policy and lifelong follow-up care, achieving the second and third 95% targets is feasible. In 2022, a total of 92.8% of patients diagnosed with HIV received antiretroviral therapy, and 97% of treated patients achieved viral suppression (defined as HIV viral load <1000 copies/mL) in China [3]. The national estimate is that the proportion of patients infected with HIV was diagnosed at only 84% in 2022, and achieving a 95% diagnosis target for patients infected with HIV may be a huge challenge in China by 2030.

The “HIV testing as prevention” strategy stands as an effective approach to mitigate HIV transmission by encouraging early diagnosis of patients infected with the disease and linking them to antiretroviral therapy, thus reducing disease transmission [5,6]. There are 3 main HIV testing strategies among MSM in China. The first strategy is scaling up testing, expanding HIV testing coverage, and increasing testing frequency to prevent a substantial number of new HIV infections among MSM [7,8]. The second strategy is regular testing, which is a key prevention strategy for identifying and treating HIV infections among MSM [9,10]. The third strategy is HIV self-testing [11], which recommends self-testing as an innovative strategy and an additional testing approach to attain the UNAIDS targets to end HIV by 2030. With the implementation of the HIV testing strategy, annual HIV testing among MSM has reached nearly 600,000 in China [3], and an increasing number of MSM have received HIV interventions and are undergoing testing. To achieve the 95% diagnosis target for patients infected with HIV, promoting HIV testing among MSM is very important.

Previous studies found that younger individuals and students had lower HIV testing rates [9,12,13]. A higher HIV testing rate was observed in the developed country compared with the developing country. A meta-analysis study from the United States stated that only 15% of the MSM reported having first-time HIV testing [9], while the first-time HIV testing rate was 50.5% in Brazil [14] and 30.6% in Malaysia [15]. The first-time HIV testing rate in China was similar to other developing countries. A study showed that 30.1% and 29.4% of MSM underwent first-time HIV testing in Tianjin and Zhuhai, China, respectively [16]. A study on a large Chinese gay social media platform showed that 19.5% of MSM had never been tested for HIV [17]. An internet-distributed HIV self-testing study revealed that 16.6% of MSM had never been tested for HIV [18]. Some factors that have been associated with first-time HIV testing include Han ethnicity, HIV status, and income [19]. With the increasing popularity of the internet and smartphone usage in China, the internet penetration rate was expected to reach 76.4% in 2023 [20]. MSM who sought potential sexual partners from traditional places such as bars, parks, and baths, gradually transferred to internet-based dating apps, such as Blued app (BlueCity Group; a large gay Chinese social media platform). Consequently, the prevalence of gay app use among MSM has rapidly increased from 12.5% in 2015 to 52.6% in 2017 [21], suggesting that most MSM rely on gay apps to find sexual partners [22], internet-based HIV interventions and testing [23], as well as gay apps [24], are considered simple ways of promoting HIV testing among MSM in China and increasing awareness of HIV status [25].

Zhejiang Province is located in eastern China, with an economically developed and prosperous internet economy. There are many companies that do e-commerce internet-based platforms, such as the Alibaba Group which was founded in Zhejiang Province and has had an HIV prevalence of 8% among MSM since 2008 [1]. Also, more than 40% of the annually newly diagnosed patients infected with HIV were MSM. Based on the developed internet economy, Zhejiang Province relies on the internet to conduct HIV intervention and testing among MSM, including internet-based consulting and mailing HIV testing kits for self-testing and using internet-based technology could increase the HIV self-testing rate among MSM [26]. Approximately 62,000 HIV testing cases occurred among MSM in Zhejiang Province in 2022, accounting for 10.6% of the national proportion [3], with over 70% of HIV testing in the province relying on the internet. Internet surveys offer broader coverage of the MSM population, rendering them more representative [27]. Identifying patients infected with HIV from the internet is key to diagnosing 95% of the infections by 2030. Therefore, this study aimed to assess HIV testing coverage based on a large internet survey and determine the factors associated with first-time HIV testing uptake among MSM in Zhejiang Province, China.

Methods

Sampling

A cross-sectional study based on a large internet survey was conducted between July 2023 and December 2023, targeting the MSM population.

Study Participants

MSM participants were recruited based on inclusion criteria, which are (1) a minimum age of 16 years, (2) reported having sex with men in the past year, and (3) living in Zhejiang Province.

Participant Recruitment and Data Collection

Sunshine Coast Public Welfare, a social organization, uses the internet to provide HIV interventions and testing services for the MSM population. The organization comprises 13 full-time social workers, 22 part-time social workers, and over 400

https://publichealth.jmir.org/2024/1/e56906
registered volunteers. Sunshine Coastal Public Welfare has established a digital HIV prevention service using location-based services. MSM populations in Zhejiang Province can apply for free HIV testing services by visiting the WeChat (Tencent Holdings Ltd, a very popular communication software in China) official account, “Sunshine Test.” Two options are available for MSM to access HIV testing services. First, they can opt to have the testing reagent mailed to them through courier and perform self-testing after receiving the reagent. Alternatively, they can choose offline services, where volunteers in their neighborhood provide HIV testing services, or they can visit nearby voluntary counseling and testing sites for MSM. During the study period, MSM had repeated HIV testing (more than 2 times); only the first testing record was retained in the study.

**Questionnaires**

MSM who are applying for HIV testing services through “Sunshine Test” (a website by visiting WeChat in China) are required to complete a routine surveillance questionnaire. The questionnaire consists of 20 questions focusing on demographic characteristics such as age, marital status, education level, and sexual behavior characteristics such as sexual roles, number of sexual partners, whether to use rush poppers, sexual history, pre-exposure prophylaxis (PrEP), post-exposure prophylaxis (PEP), and HIV testing history. All questionnaires were completed on the “Sunshine Test.” MSM can apply for testing services after completing the questionnaire and being screened by a social worker or volunteer.

**Statistical Analysis**

For descriptive analyses, categorical variables are presented as frequencies and proportions, while continuous variables are presented as medians and IQRs or means and SDs. The significance of the difference in the general demographic characteristics was tested by a chi-square test. Factors from the univariate analysis with \( P<0.10 \) or those previously shown to be associated with the differences in sociodemographic characteristics among first-time HIV testing were included in multivariate logistic regression models, and adjusted odd ratios (aORs) were calculated along with corresponding 95% CIs. The statistical significance level was \( P\leq0.05 \) and \( \beta=1 \). Statistical analyses were performed using SPSS (version 19.0; IBM Corp.).

**Ethical Considerations**

This study was approved by the Zhejiang Provincial Center for Disease Control and Prevention (2022-011-01). All participants provided written informed consent before the completion of the survey. Participants received free HIV testing and health counseling, and all study procedures were conducted in accordance with the approved guidelines and regulations.

**Results**

A total of 7629 MSM participated in the study (Figure 1), with an average age of 29.0 (SD 8.5) years. Among them, 78.6% (5997/7629) were single, 50.7% (3869/7629) had a bachelor’s degree or higher, 16.4% (1254/7629) were students, and 49.1% (2985/7629) had a monthly income of less than US $700. The majority of 78.2% (5964/7629) had only male sexual partners, while 33.3% (2543/7629) had more than 2 sex partners in the past 3 months. Additionally, 31.2% (2380/7629) reported using rush poppers during sexual activity and 45.2% (3451/7629) were aware of their sex partner’s HIV status. The awareness rates of PrEP and PEP were 76.2% (5816/7629) and 78.1% (5960/7629), respectively. Furthermore, 54.8% (4183/7629) had HIV testing through mail reagent self-testing.

Of the 7629 participants, 12.9% (982/7629) underwent HIV testing for the first time. Factors associated with a high proportion of first-time HIV testing included being younger than 20 years old (30.9%, 133/430), having high school and below education (16.2%, 299/1851), being a student (21.6%, 271/1254), having a low monthly income (21.4%, 282/1320), identifying as bisexual (18.2%, 303/1665), having a small number of sex partners in the past 3 months (17.5%, 224/1277), frequently using rush poppers (18.5%, 198/1068), being unaware of their sex partners’ HIV status (18.6%, 275/1477), lacking awareness of HIV PrEP (18.9%, 342/1813), undergoing offline HIV testing (17.8%, 614/3446), and being HIV positive (24.4%, 20/82). The chi-square test showed that all factors except marital status, sex role, and history of sexually transmitted infections were associated with a high proportion of first-time HIV testing (Table 1).

Multivariate logistic regression analysis revealed that first-time HIV testing was associated with being younger than 20 years old (aOR 2.55, 95% CI 1.91-3.42), having attained high school education or lower (aOR 1.39, 95% CI 1.03-1.88), being a student (aOR 1.35, 95% CI 1.04-1.75), having a monthly income of less than US $330 (aOR 1.55, 95% CI 1.16-2.08), insertive anal sex role (aOR 1.28, 95% CI 1.05-1.56), identifying as bisexual (aOR 1.69, 95% CI 1.40-2.03), having a low number of sex partners in the past 3 months (aOR 1.44, 95% CI 1.13-1.83), frequently using rush poppers in the past 3 months (aOR 2.06, 95% CI 1.70-2.49), being unaware of their sex partners’ HIV status (aOR 1.40, 95% CI 1.17-1.69), lacking awareness of HIV PrEP (aOR 1.39, 95% CI 1.03-1.88), and undergoing offline HIV testing (aOR 2.08, 95% CI 1.80-2.41; Table 2).
Figure 1. A cross-sectional study based on a large internet survey by visiting the official account of WeChat (a very popular communication software in China), “Sunshine Test.” A total of 7629 MSM participated in the study between July and December 2023 in Zhejiang Province, China. MSM: men who have sex with men.

The “Sunshine Test” recruited 9568 MSM from July to December 2023

Excluded (n=1939)
• HIV testing ≥2 times

First testing record of 7629 MSM was retained

45.2% (3446) through offline testing
54.8% (4183) through mail reagent self-testing

Total 7629 in the analysis
12.9% (982) underwent first-time HIV testing

### Discussion

**Principal Findings**

This study described HIV testing coverage based on a large internet survey and the factors associated with first-time HIV testing uptake among MSM in Zhejiang Province, China. Based on data from 7629 participants, we found that 87.1% (6647/7629) of MSM had undergone HIV testing, and 12.9% (982/7629) had never been tested before the survey. This 87.1% HIV testing coverage marks a significant increase from the 55.9% reported a decade ago (2013-2014) in Zhejiang Province [28]. Comparative analysis revealed that the HIV testing rate of 87.1% aligned with the 85% reported in a US meta-analysis...
study [9], surpassing rates found in Tianjin [16] and Zhuhai (70.6%) [19], as well as an internet-based study based on gay apps (80.5%) [17]. These findings underscore the need for continued efforts to expand HIV testing and increase testing coverage among MSM to achieve the target of diagnosing 95% of patients infected with HIV by 2030.

Consistent with previous studies, we found that younger individuals and students had lower HIV testing rates [9,12,13]. In China, nearly 3000 patients infected with HIV are diagnosed annually, more than 80% of whom are MSM [3]. An internet-based study found that younger MSM were probably deterred from seeking testing due to apprehension about health care or local office settings [13]. HIV molecular transmission clusters found students and nonstudents with HIV infections in the same transmission clusters [29]. However, the nonstudent MSM had an HIV prevalence of nearly 8%. Accordingly, a lack of awareness of the HIV epidemic in students among MSM may result in a low HIV testing rate. The internet and smartphones are essential tools for the student population, and a previous study showed that HIV intervention and testing through internet-based platforms or gay apps could increase HIV testing among younger MSM [24,30,31]. We suggest that strengthening awareness of the HIV epidemic among students and enhancing HIV testing education through internet-based platforms or gay apps will increase the HIV testing proportion of MSM students.

We found that participants with fewer sexual partners had low HIV testing rates. A study in China showed that individuals with 2 or more sexual partners were more likely to undergo HIV testing [32]. MSM with multiple sexual partners usually exhibit high-risk behaviors that prompt them to undergo HIV testing. Similarly, MSM who often used rush poppers had a higher HIV testing rate. Rush poppers are widely popular among MSM and have become the main substance type used during sexual activities [33]. Rush poppers prolong sexual activity and increase the rate of unprotected sex, thereby increasing their risk of HIV infection. Studies have shown that people who use rush poppers have more unprotected, casual sex, and increased HIV testing rates [9,34].

Moreover, we found that being unaware of a partner’s HIV status was associated with lower HIV testing rates. Serostatus disclosure strategies can reduce the risk of HIV infection and promote regular HIV testing which has been gradually promoted among MSM in China in recent years [35]. The serostatus disclosure strategy refers to knowing each other’s HIV status before any sexual activity. The strategy encourages using HIV status to decide whether to have sex or not. If both partners have the same HIV infection status, do not use condoms; and if the HIV infection status is inconsistent, use condoms [36]. Our study also showed that those who knew their sexual partners’ HIV status had a higher HIV testing rate. Therefore, it is recommended to continue implementing this strategy among MSM to increase HIV testing rates.

Participants who were aware of PrEP had higher rates of HIV testing. HIV PrEP and PEP are biological interventions that prevent HIV transmission, providing effective prevention opportunities for MSM at a high risk of HIV exposure, and can effectively reduce HIV infection and transmission [37]. In China, PEP guidelines were released by the National Center for Communicable Diseases Control in 2020. PEP has been widely promoted among MSM after 3 years of promotion. However, PrEP has only been piloted in some cities, and there was no national guideline for PrEP [3]. Therefore, in the results of this study, only those who had an awareness of PEP had a higher rate of HIV testing. Several studies have shown that unprotected sex and sexually transmitted infections continue to increase among MSM who have used PrEP drugs [38]. Previous studies have also shown that the PrEP project effectively promoted HIV testing among MSM [39], and greater odds of PrEP awareness were associated with HIV testing [40].

This study had some limitations. First, the study recruited MSM who used web-based apps for HIV testing, 88.5% (6753/7629) of whom were younger than 40 years. It did not capture a few MSM who came from traditional places such as bars and baths, especially those who were older than 50 years. Previous studies have shown that this population has a higher HIV infection rate and a lower HIV testing rate [32]. Therefore, the results of this study apply only to MSM who rely on the internet for HIV testing. Second, participants who opted for HIV self-testing through mailed reagents may introduce bias, as the feedback on true HIV-positive results could be limited. Finally, the use of routine surveillance questionnaires may not capture all factors associated with HIV testing as identified in previous studies.

Conclusions
A significant finding from the large internet survey was that 12.9% (982/7629) of MSM had never undergone HIV testing before the study. We suggest enhancing HIV intervention and testing through internet-based platforms and gay apps to promote HIV testing among MSM. Future studies could explore strategies to increase HIV testing rates among underrepresented demographics, such as older MSM and those who do not rely on web-based testing services, ultimately helping to meet the target of diagnosing 95% of patients infected with HIV by 2030.

Acknowledgments
We express our gratitude to the participants and Sunshine Coast Public Welfare for their contributions to the study. The study was funded by a grant from the Health Science and Technology Project in Zhejiang Province Social (2023KY632 and 2021RC048).

Factors Associated With Surveillance Testing in Individuals With COVID-19 Symptoms During the Last Leg of the Pandemic: Multivariable Regression Analysis

Abstract

Background: Rural underserved areas facing health disparities have unequal access to health resources. By the third and fourth waves of SARS-CoV-2 infections in the United States, COVID-19 testing had reduced, with more reliance on home testing, and those seeking testing were mostly symptomatic.

Objective: This study identifies factors associated with COVID-19 testing among individuals who were symptomatic versus asymptomatic seen at a Rapid Acceleration of Diagnostics for Underserved Populations phase 2 (RADx-UP2) testing site in West Virginia.

Methods: Demographic, clinical, and behavioral factors were collected via survey from tested individuals. Logistic regression was used to identify factors associated with the presence of individuals who were symptomatic seen at testing sites. Global tests for spatial autocorrelation were conducted to examine clustering in the proportion of symptomatic to total individuals tested by zip code. Bivariate maps were created to display geographic distributions between higher proportions of tested individuals who were symptomatic and social determinants of health.

Results: Among predictors, the presence of a physical (adjusted odds ratio [aOR] 1.85, 95% CI 1.3-2.65) or mental (aOR 1.53, 95% CI 0.96-2.48) comorbid condition, challenges related to a place to stay/live (aOR 307.13, 95% CI 1.46-10,6372), no community socioeconomic distress (aOR 0.99, 95% CI 0.98-1.00), no challenges in getting needed medicine (aOR 0.01, 95% CI 0.00-0.82) or transportation (aOR 0.23, 95% CI 0.05-0.64), an interaction between community socioeconomic distress and not getting needed medicine (aOR 1.06, 95% CI 1.00-1.13), and having no community socioeconomic distress while not facing challenges related to a place to stay/live (aOR 0.93, 95% CI 0.87-0.99) were statistically associated with an individual being symptomatic at the first test visit.

Conclusions: This study addresses critical limitations to the current COVID-19 testing literature, which almost exclusively uses population-level disease screening data to inform public health responses.

Introduction

Pandemic Spread

The SARS-CoV-2 pandemic has had several waves of infection driven by the introduction and spread of multiple variants. In the United States, the first case of COVID-19 appeared in January 2020 [1]. The Alpha variant, first introduced in December 2020, comprised the second wave of the COVID-19 pandemic, occurring at the same time as vaccination campaigns were being rolled out in many states [2]. This was a critical
moment in the SARS-CoV-2 timeline, as Alpha was the first variant of concern with adapted mutations, increasing the risk of person-to-person transmission [3]. The pattern of spread and speed of the third and fourth waves involving Omicron variants (BA1-3 and BA4-5) were wider reaching and faster than previous variants [4]. Unfortunately, this was problematic with reduced testing efforts making it more difficult to monitor SARS-CoV-2 infections in populations [5].

Health Disparities

Urban US areas experienced the greatest burden of cases early in the epidemic with West Virginia, a largely rural state, being the last state to identify a confirmed case of COVID-19 in late January 2020. This is problematic as 50% of rural residents are at high risk of serious illness and hospitalization if they contract SARS-CoV-2 [6]. In West Virginia, the Alpha variant cases peaked in April 2021, 4 months after its initial detection in the United States and after vaccination campaigns were already underway, with subsequent peaks in October 2021 for the Delta variant and February 2022 for the first Omicron peak. Due to unequal access to health resources, the impacts of the disease vary throughout the state, particularly in southwest West Virginia where there are already health disparities [7].

Prior Work

By August 2020, testing in the United States had peaked at around 1 million tests per day, at which point COVID-19 had become the third leading cause of death [1]. COVID-19 testing data have been used in machine learning models and spatial epidemiological studies to help identify disparities in testing and outcomes for COVID-19, and guide public health policies [8-10]. Previous studies have analyzed socioeconomic status, race, comorbidities, mental health, and substance abuse effects to identify disparities and seasonal impacts [7,9-14]. Furthermore, other epidemic models have been tested using COVID-19 data to help forecast future SARS-CoV-2 waves and look at the impact of testing itself [11,12]. However, previous research was conducted during times with high-to moderate community testing, when data more accurately reflected the general population’s risk of disease and allowed for standard epidemiological models of study [1,13-15]. The pandemic is now in a phase where those seeking testing are largely symptomatic. Lower testing and increasing reliance on home testing for COVID-19 have created a situation in which traditional epidemiological measures are suboptimal [16].

Study Objectives

Subsequent waves of SARS-CoV-2 infection are now monitored with varying surveillance efforts, which have dwindled from the population to the community level as the focus shifted away from testing to preventing severe infection and health care strain [5]. This situation has resulted in a heightened reliance on testing data from people who are symptomatic and seek out testing. Currently, few studies have examined the demographics, clinical factors, or barriers to testing among people who are symptomatic and seeking COVID-19 testing [15,17]. As such, the objectives of this study were to identify factors that increased the prevalence of individuals who were symptomatic at testing locations and assess whether there was spatial autocorrelation among the rate of tested people who were symptomatic and their residential zip code. Spatial autocorrelation, or clustering of tested people who were symptomatic, was assessed to better understand if geographic differences in hospital or doctor referrals potentially biased the number of people who were symptomatic who visited testing locations [18,19]. The results address current literature gaps concerning which factors are associated with test seeking and have the potential to inform public health policy to ensure COVID-19 testing services remain available to vulnerable populations living in the rural United States.

Methods

Data Source and Management

This cross-sectional study utilized questionnaire data collected for phase 2 of the Rapid Acceleration of Diagnostics for Underserved Populations program (RADx-UP2). Detailed information on RADx-UP2, including program aims and research projects, has been described elsewhere [20]. Briefly, RADx-UP is a multisite National Institutes of Health–funded project, developed to disseminate testing resources within communities of varying social or economic vulnerability [21]. All sites are required to include common data elements (CDEs) in their data collection instruments to harmonize data across states [21]. Project CDEs include an individual’s address, demographics, clinical comorbidities, signs and symptoms at the time of testing, behavioral data, and more [21]. For the West Virginia site, data were collected using ArcGIS Survey 123 (Esri) at testing events. The benefits of using syndromic surveillance for public health programming and response have been described in previous public health research elsewhere [16,22-24].

Ethical Considerations

Approval for this study was given by the West Virginia University Institutional Review Board (protocol 2202534378A001). Informed consent was requested on the survey used for data collection in the form of an opt-out question. All included data has been deidentified for analysis and publication. Site-level incentives were developed in conjunction with community partners that assisted in hosting testing events. As such, these incentives varied by site and community and consisted of monthly raffles for all who participated in a survey during that month for each testing site, with prizes including technology, tickets to sporting events, and outdoor items. Other incentives included t-shirts and plastic reusable cups for participation.

Inclusion Criteria

The study inclusion criteria were any individual tested at a West Virginia RADx-UP2 testing site from May 2022 until November 2022. Testing sites included pharmacies, hospitals, and homeless shelters in underserved areas throughout the state manned by RADx-UP2 staff as well as at testing events such as Solutions Oriented Addiction Response (SOAR) meetings and other community-sponsored events. Individuals seeking COVID-19 testing paid for by RADx-UP funding and consented to have their information collected. For this study, the analytic sample

https://publichealth.jmir.org/2024/1/e52762
was limited to information collected at each individual’s first test, including the individual’s demographics, signs and symptoms, history of chronic disease, receipt of two vaccine doses, and challenges or motivators to seek care. The study outcome was the odds of an individual who was symptomatic (vs asymptomatic) being seen at the time of first testing. Individuals who were symptomatic presented with one of the following at the time of testing: fever or chills, cough, shortness of breath or difficulty breathing, lack of energy or general tired feeling, muscle or body aches, headache, new loss of taste or smell, sore throat/congestion or runny nose, feeling sick to your stomach or vomiting/diarrhea, abdominal pain, or skin rash.

**Predictor Covariates**

Predictor covariates in the analysis included age categories (<18, 19 – 29, 30 – 39, 40 – 49, 50 – 59, and ≥60 years), race, sex at birth, whether a person is an essential worker, whether a person is fully vaccinated (eg, received two doses of Moderna/Pfizer or one dose of Johnson & Johnson), presence/absence of physical or mental health conditions (yes/no), six challenges to health (yes/no), specific barriers to testing (yes/no), and a measure of economic distress based on the individual’s zip code of residence to adjust for nonrandom community-level effects. Physical health conditions, mental health conditions, and barriers to testing were combined into their groupings due to the small sample size of the individual and missingness in the subgroups. Physical health conditions included immunocompromised condition, autoimmune disease, hypertension, diabetes, chronic kidney disease, cancer diagnosis or treatment within the past 12 months, cardiovascular disease, asthma, chronic obstructive pulmonary disease, other chronic lung disease, and sickle cell anemia. Mental health conditions included depression, alcohol or substance use disorder, intravenous drug use, and other mental health disorders. The six challenges to health included access to mental/physical health care, having a place to stay/live, getting enough food to eat, having clean water to drink, getting the medicine needed, and having transportation from one place to another. Barriers to testing included protected time off to visit a testing site; out-of-pocket costs for test; out-of-pocket costs for transportation, childcare, or time off work to get tested; knowledge of where testing is done in their community; pain or discomfort from the test or saliva collection; and concern about others handling their personal data. All predictor covariates, except for the economic distress score, were collected as CDEs required for all funded RADx-UP2 projects [21]. The zip code–level Distressed Communities Index (DCI) was linked to survey data by individual zip code of residence to adjust for nonrandom selection of underserved communities for testing. The DCI is a measurement of community economic disparities that consists of seven measures obtained from the US Census Bureau’s American Community Survey: no high school diploma, housing vacancy rate, adults not working, poverty rate, median income ratio, changes in employment, and changes in establishments. This was critical as RADx-UP2 nonrandomly selects communities for testing based on whether they are underserved. DCI was a continuous variable, where higher numbers indicated more distress [25]. This index of socioeconomic deprivation has been utilized in previous social epidemiology literature to characterize health disparities [26,27].

**Statistical Analysis**

Data were analyzed by multivariable logistic regression to evaluate the association between the odds of an individual being symptomatic at the time of the first test and each of the predictors. Interaction effects between the six challenges to health and the DCI were also included in the multivariable logistic regression model, and backward selection with Akaike information criterion was used to ensure the best covariates model was used adjusting for age, gender, and race after selection. Statistical significance was evaluated using adjusted odds ratios (aORs) and corresponding 95% CIs at an α level of .05. Tests for global spatial autocorrelation (clustering) of individuals who were symptomatic were conducted using a global Moran I value. Statistical spatial dependence was evaluated using the tests’ computed z score and P value [28]. All data management and regression analyses were conducted in R (The R Foundation for Statistical Computing). Spatial analysis and thematic maps displaying zip code–level relationships between the rate of people who were symptomatic per 10 individuals tested and the distressed communities score were created in ArcGIS Pro 2.9.2 (Esri).

**Results**

**Data Source and Management**

Of the 2103 testing questionnaires completed between May 7 and November 14, 2022, 1423 unique individuals were identified as having self-reported as being symptomatic at the time of their first test (Table 1). In the overall sample, 24.5% (n=348) were 60 years or older, 85.5% (n=1217) were White, and 51.7% (n=735) were female. The majority of individuals were vaccinated (n=975, 68.5%), did not report any physical (n=773, 54.3%) or mental (n=1120, 78.7%) health conditions, and did not have any of the six challenges to health: access to health care (n=1155, 81.2%), place to stay/live (n=1162, 81.7%), enough food to eat (n=1198, 84.2%), clean water to drink (n=1228, 86.3%), getting needed medication (n=1163, 81.7%), and having transportation (n=1165, 81.9%). Among individuals who were symptomatic, 26.6% (n=219) were 60 years or older, 87.1% (n=717) were White, and 55.8% (n=459) were female. Similar to the overall sample, the majority of individuals who were symptomatic were vaccinated (n=581, 70.6%), did not report any physical (n=418, 50.8%) or mental (n=656, 79.7%) health issues, and did not have any of the six challenges to health: access to health care (n=736, 89.4%), place to stay/live (n=746, 90.6%), enough food to eat (n=759, 92.2%), clean water to drink (n=773, 93.9%), getting needed medication (n=741, 90%), and having transportation (n=747, 90.8%).
### Table
Demographics and clinical characteristics of individuals tested for SARS-CoV-2 during phase 2 of the Rapid Acceleration of Diagnostics for Underserved Populations program. The program took place between May 7 and November 14, 2022, and tested 1423 unique individuals who self-reported as being symptomatic at the time of their first test.

**Statistical Analysis**

In the parsimonious model, backward selection with Akaike information criterion dropped the following variables: essential worker, vaccinated, and access to health care. Among persons at the time of first testing, all age groups, races, sex at birth, barriers to testing, enough food to eat, clean water to drink, and the DCI and clean water to drink interaction were not statistically associated with the odds of seeing an individual who was symptomatic at a testing location (all P values >.05). Individuals with a physical health condition and challenges related to a place to stay/live were statistically more likely to seek testing while being symptomatic, and mental health condition and the DCI and clean water to drink interaction were moderately so. Those reporting physical health conditions were 53% more likely to have reported being symptomatic (aOR 1.53, 95% CI 0.96-2.48), and those living in a high DCI zip code while also not getting needed medicine were 6% more likely to have reported being symptomatic (aOR 1.06, 95% CI 1.00-1.13). Individuals with a challenge getting needed medicine and transportation as well as the DCI and challenges in having a place to stay/live interaction were statistically less likely to seek testing while symptomatic, and living in a high DCI zip code was moderately so. Participants who had challenges in getting needed medication were 99% less likely to report being symptomatic (aOR 0.01, 95% CI 0.00-0.82). Those who had challenges with transportation were 77% less likely to report being symptomatic (aOR 0.23, 95% CI 0.05-0.64). Those living in a high DCI zip code and facing challenges of having a place to stay/live were 7% less likely to report being symptomatic (aOR 0.93, 95% CI 0.87-0.99), and those living in a high DCI zip code were 1% less likely to seek testing as a symptomatic individual (aOR 0.99, 95% CI 0.98-1.00). Complete results for the logistic regression are displayed in Table 2.
Table. Adjusted odds ratios and corresponding 95% CIs for logistic regression models. Full discussion of results can be found in the Results: Statistical Analysis section. The parsimonious model was derived using backward selection from the original model. A full description of the procedure can be found in the Methods: Statistical Analysis section.

Geospatial Analysis

A bivariate map of the zip code–level rate of individuals who were symptomatic per 10 individuals seeking COVID-19 testing and the DCI is displayed in Figure 1. Visually, there appear to be overlapping trends in the DCI and rate of people who are symptomatic per 10 people served at testing locations in the southern and northern regions of West Virginia. In particular, southern West Virginia had more zip codes where the rate of tested people who were symptomatic was low and the DCI was low, indicating fewer people who were symptomatic from non-distressed communities when compared to the rest of the state. There was only 1 zip code in the northern region of West Virginia that followed this trend. However, both regions had zip codes where the rate of tested people who were symptomatic per 10 individuals was high and the DCI score was high, indicating a high number of people who were symptomatic coming from distressed communities. In the southern region, there were many zip codes with a high DCI score but a low rate of people who were symptomatic. This visual observation supports findings from the logistic regression that the DCI was statistically associated with a lower rate of tested people who were symptomatic, particularly for persons in southern West Virginia. When assessing spatial autocorrelation, global Moran I did not detect any statistically significant clustering in the rate of people who were symptomatic per 10 individuals tested throughout the RADx-UP study area. Statistically significant clustering was evaluated incrementally across distance thresholds of varying diameters (smallest: 357 km, Moran I=0.002, P=.63; largest: 784 km, Moran I=0.001, P=.06) without indication of statistical significance.
Discussion

Principal Results

This study identified several factors associated with test seeking among individuals who were symptomatic at RADx-UP2 COVID-19 testing locations. Our study found that individuals with a physical or mental health condition, those facing a challenge in having a place to stay/live, or those with the interaction of living in a high DCI zip code while also not getting needed medicine were more likely to appear at a testing location with symptoms. Additionally, individuals from less distressed communities, who were able to access needed medicine or transportation, and those with the interaction of living in a high DCI zip code and facing challenges in having a place to stay/live were less likely to be symptomatic at the time of their testing. Importantly, we found no statistically significant geographic pattern in the rate of people who were symptomatic per 10 individuals tested. This could suggest that differences observed for persons less likely to be symptomatic by a higher DCI were not due to geographic contexts, such as urban or rural, and perhaps more related to social determinants of health such as facing a challenge in having a place to stay/live within the individual’s zip code of residence. Importantly, these findings address a gap in the existing literature, particularly among studies that utilize recent testing data within epidemiological investigations by looking at underserved areas.
and the reasoning behind individuals seeking testing [15,17]. Recent testing data reflect a shift toward symptomatic populations who are more likely to struggle with a stable living situation and experience multiple physical or mental health conditions. This is an important consideration, as new information from this study provides an idea of the extent to which the generalizability of testing data is restricted to vulnerable populations or those separate from the general population.

Physical and Mental Health Conditions
Physical and mental health conditions were found to be associated with individuals presenting with symptoms for COVID-19 testing. Physical health conditions, such as autoimmune disease, hypertension, diabetes, chronic kidney disease, and cardiovascular disease, can cause impediments to the immune system and leave individuals more susceptible to severe illnesses, including COVID-19 [29,30]. These individuals may be more willing to seek out testing when they become symptomatic due to their increased risk of serious illness [4,15,27,29,30]. Altogether these individuals would be more likely to be symptomatic when reporting to testing facilities, whether due to the increased risk of the physical conditions themselves or as a preventative measure taken by the individuals. Additionally, mental health conditions, such as alcohol and substance use, can also increase an individual’s susceptibility to infection from and exposure to COVID-19 [22,31,32]. Mental health conditions can lead to impediments in the immune system, which make an individual more susceptible to COVID-19 and increase situations of greater exposure to COVID-19 [22,31,32]. This is particularly relevant to individuals experiencing homelessness, who are a vulnerable population at high risk for mental health conditions and must undergo COVID-19 testing to gain entrance to shelters [11,15,31-33].

Challenges to Health and Economic Distress
Those individuals who have challenges in having a place to stay/live and those with the interaction of DCI and getting needed medication were more likely to be symptomatic at the time of testing. These socioeconomic issues could be associated with these individuals being more vulnerable to exposures, leading to more chances of respiratory disease spread due to related aspects such as homelessness or not being able to afford health care such as medication. It was found that individuals who reported challenges in getting needed medicine or transportation, those who lived in distressed communities, and those with the interaction of living in a distressed community while having challenges in having a place to stay/live were less likely to be symptomatic at the time of testing. These associations with not having issues of getting needed medicine or transportation challenges to health could indicate there are fewer travel/access obstacles to the health of an individual as well as fewer people experiencing homelessness in these socioeconomic groups. This could indicate that individuals who are not impeded by these socioeconomic drivers are more likely to seek testing when becoming symptomatic. Coinciding with having no challenges to health, living in higher areas of greater economic distress was associated with lower odds of being symptomatic (Figure 1: pink areas). These findings are interesting because these components measure socioeconomic challenges at both the individual and community levels. These findings give insight into the behaviors of underserved communities that exist across West Virginia when compared to previous studies that look at population-level data and collection methods that would otherwise limit these underserved communities [15,17].

Limitations
This study has several limitations. First, data for the study comes from questionnaires that are self-reported by the individuals. Due to recall bias or social desirability bias, individuals may be misclassified according to symptomatic status or the presence of a potential predictor [34,35]. Next, many of these symptoms that individuals reported could also be present in the transmission of other pathogens [36]. However, we believe that this did not impact the validity of the study, as the goal was to better understand which factors were associated with the use of testing services in any individual who was symptomatic. Third, individuals who were symptomatic faced challenges to health, such as getting to a testing site or not knowing about available testing, and may not have sought testing. Fourth, the sample size does not indicate confirmed COVID-19 cases—only those who were symptomatic and seeking COVID-19 testing. Finally, the study population is only a subset of the total underserved areas of West Virginia, and some study variables had small sample representation or missing data.

Conclusions
Overall, this study of symptomatic factors associated with COVID-19 testing in West Virginia emphasized the urgent need to better understand barriers to testing. Despite limitations, this research addresses gaps in the current COVID-19 testing research. This is especially important in underserved areas experiencing disparities, such as the southwestern part of West Virginia (Figure 1). Critical to future public health policy creation is determining why individuals who are symptomatic in high-distress areas are less likely to seek free COVID-19 testing. While factors such as a lack of transportation are possible, there may be other reasons such as belief in the presence of ongoing SARS-CoV-2 transmission or belief in effective prevention (eg, vaccines or quarantine) or treatment.

Abstract

Background: The COVID-19 pandemic has underscored the significance of adopting healthy lifestyles to mitigate the risk of severe outcomes and long-term consequences.

Objective: This study focuses on assessing the prevalence and clustering of 5 unhealthy lifestyle behaviors among Vietnamese adults after recovering from COVID-19, with a specific emphasis on sex differences.

Methods: The cross-sectional data of 5890 survivors of COVID-19 in Vietnam were analyzed from December 2021 to October 2022. To examine the sex differences in 5 unhealthy lifestyle behaviors (smoking, drinking, unhealthy diet, physical inactivity, and sedentary behavior), the percentages were plotted along with their corresponding 95% CI for each behavior. Latent class analysis was used to identify 2 distinct classes of individuals based on the clustering of these behaviors: the “less unhealthy” group and the “more unhealthy” group. We examined the sociodemographic characteristics associated with each identified class and used logistic regression to investigate the factors related to the “more unhealthy” group.

Results: The majority of individuals (male participants: 2432/2447, 99.4% and female participants: 3411/3443, 99.1%) exhibited at least 1 unhealthy behavior, with male participants being more susceptible to multiple unhealthy behaviors. The male-to-female ratio for having a single behavior was 1.003, but it escalated to 25 for individuals displaying all 5 behaviors. Male participants demonstrated a higher prevalence of combining alcohol intake with sedentary behavior (949/2447, 38.8%) or an unhealthy diet (861/2447, 35.2%), whereas female participants tended to exhibit physical inactivity combined with sedentary behavior (375/3443, 39.9%) or an unhealthy diet (1260/3443, 36.6%). Married male participants had increased odds of falling into the “more unhealthy” group compared to their single counterparts (odds ratio [OR] 1.45, 95% CI 1.14-1.85), while female participants exhibited lower odds (OR 0.65, 95% CI 0.51-0.83). Female participants who are underweight showed a higher likelihood of belonging to the “more unhealthy” group (OR 1.11, 95% CI 0.89-1.39), but this was not observed among male participants (OR 0.6, 95% CI 0.41-0.89). In both sexes, older age, dependent employment, high education, and obesity were associated with higher odds of being in the “more unhealthy” group.

Conclusions: The study identified notable sex differences in unhealthy lifestyle behaviors among survivors of COVID-19. Male survivors are more likely to engage in unhealthy behaviors compared to female survivors. These findings emphasize the importance of tailored public health interventions targeting sex-specific unhealthy behaviors. Specifically, addressing unhealthy habits is crucial for promoting post–COVID-19 health and well-being.

Introduction

The COVID-19 pandemic has a significant impact on population health and causes widespread disruption globally [1]. Beyond the public health crisis, it has triggered substantial alternations in people’s lifestyles, including poorer nutrition intake, sedentary lifestyle due to prolonged lockdown, sleep disturbance, and mental health problems [2-4]. These unhealthy habits are associated with a higher risk of noncommunicable diseases (NCDs) [5-7] and greater vulnerability to SARS-CoV-2 infection, resulting in more severe COVID-19 outcomes [8-10].

In Vietnam, the COVID-19 control policies have exerted a considerable impact on people’s lifestyles [11]. The stringent isolation measures have resulted in significant changes in daily routines. For example, symptomatic patients underwent isolation for a minimum of 14 days in designated facilities such as medical camps or field hospitals, where living conditions were limited. This was followed by an additional 14 days of quarantaine at home after recovery [12]. These changes are particularly noticeable in alterations to diet and physical activities [13]. Even asymptomatic individuals with COVID-19 (those testing positive for SARS-CoV-2 without symptoms) quarantined for at least 14 days at home are susceptible to a sedentary lifestyle, primarily due to the limited physical activity options and dependence on provided foods [14]. Indeed, several publications have indicated that survivors of COVID-19 experience a wide range of health problems after recovery [15], and these problems are often linked to an individual’s lifestyle and health behaviors [16,17]. Additionally, studies have shown that unhealthy lifestyle behaviors tend to cluster, with individuals who engage in 1 unhealthy behavior being more likely to engage in others [18,19]. For example, the co-occurrence of a sedentary lifestyle with excessive substance use, alcohol consumption, and smoking can lead to worse health conditions [18-20], especially for survivors of COVID-19 who are already vulnerable. While several publications have examined the long-term mental and physical health of COVID-19 infection [21,22], there is limited evidence on the unhealthy lifestyles among survivors of COVID-19, that is, who are more likely to engage in these lifestyles. It would be of interest for policy makers to provide timely and targeted health promotion interventions to survivors of COVID-19 to avoid further complications of long-term COVID-19 health problems.

Several studies have found significant differences in the clustering of unhealthy lifestyle behaviors between sex [18,19,23-25]. For instance, one study in the United States...
investigated the sex differences in lifestyle behaviors among adults with diabetes between 1999 and 2018. The findings revealed that both male participants and female participants with diabetes displayed unhealthy lifestyle behaviors, but the specific behaviors differed by sex. Male patients with diabetes were more likely to smoke and engage in excessive drinking, whereas their counterparts were more likely to be physically inactive and have poor dietary habits [25]. In another study focusing on Indian adults, researchers explored that the prevalence of multiple unhealthy lifestyle behaviors is significant, with a higher tendency for male adults to exhibit the clustering of multiple factors compared to female ones [26].

In Vietnam, sex differences in lifestyle behaviors arise from societal expectations. Male participants often exhibit a higher tendency to participate in risky behavior influenced by socialization, whereas female participants benefit from their cautiousness and adherence to healthy behaviors and health education [27-29]. For instance, within Vietnamese tradition, smoking and drinking might be perceived as integral to the male gender role, serving to demonstrate masculinity and foster social connections [30]. In contrast, societal expectations generally discourage women from engaging in these behaviors, aligning with gender role norms.

Although previous research has extensively investigated various patterns of lifestyle behaviors, little is known about whether these patterns differ among adult survivors of COVID-19. Additionally, previous studies have examined the impact of sociodemographic characteristics such as race, ethnicity, culture, age, socioeconomic status, employment, and education on unhealthy behaviors [31-33]. However, a sex-specific analysis to understanding and measuring these behaviors is still lacking, except in studies conducted on adolescents [23,34]. Therefore, this study aims to use latent class analysis (LCA) to identify distinct patterns of unhealthy lifestyle behaviors, including cigarette smoking, alcohol consumption, unhealthy diet, physical inactivity, and sedentary behaviors, among survivors of COVID-19 after their recovery, focusing on sex differences. Furthermore, this study seeks to identify the factors associated with “more unhealthy” behaviors in this population.

**Methods**

**Study Settings**

Vietnam first confirmed the presence of the SARS-CoV-2 virus in January 2020, with initial cases being mostly from other countries. However, local transmission began to develop in February and March 2020. To curb the spread, the Vietnamese government implemented a zero-COVID-19 strategy throughout 2020, which involved contact tracing, mass testing, quarantining, and lockdowns. This approach was largely successful, but since April 2021, the country has been facing its largest outbreak yet. As a result, lockdowns have been implemented in one-third of provinces and cities, affecting roughly one-third of the population. The emergence of the Omicron variant in the first quarter of 2022 led to a sharp increase in infections, although Vietnam’s high vaccination rates resulted in fewer fatalities [35] (Figure 1).

Our study collection period spanned from December 1, 2021, to October 31, 2022. The research was carried out across 17 hospitals and health centers located in 9 provinces across the country. We included 5 provinces with 8 hospitals in the Northern region, 3 provinces with 3 health centers in the Central region, and 2 provinces with 6 hospitals and health centers in the Southern region (Multimedia Appendix 1).

**Figure 1.** COVID-19 situation in Vietnam from April 2021 to December 2022.
Study Design and Participants
This is a nationwide cross-sectional, web-based survey conducted from 2021 to 2022 in Vietnam. We enrolled Vietnamese adults (aged 18 years or older) who had been infected with SARS-CoV-2, which is confirmed by available positive test results for SARS-CoV-2 (either real-time polymerase chain reaction or rapid antigen test), and afterward recovered from the infection, which is confirmed by available negative test results for SARS-CoV-2 (either real-time polymerase chain reaction or rapid antigen test). Participants who did not consent, were nonpermanent residents of Vietnam, were unable to understand the survey questions, or had cognitive or mental health issues that may have affected their responses to the survey were excluded from the study (n=87).

Participants from 17 hospitals and COVID-19 health centers across 9 provinces representative of 3 geographical regions of Vietnam were purposively selected. We recruited 3450 participants in 4 Northern region provinces and cities, 1130 participants in 3 Central region provinces, and 1310 participants in 2 Southern region cities. In total, we collected data from 5890 participants. Details of the number of participants recruited per site of the 3 geographical regions can be found in Figure 2 and Multimedia Appendix 1.

Figure 2. Distribution of participants in the study.

Sample Size
A sample of 5890 participants provided sufficient data for inclusion in the analysis, representing 50.1% of the total 11,761 survivors of COVID-19 from 17 study sites and 0.05% of the total 10,607,166 survivors of COVID-19 in Vietnam until the end of data collection on October 31, 2022 [35].

Data Collection Procedures
The data were collected from December 1, 2021, to October 31, 2022. The survey form was prepared on Microsoft Forms (Microsoft Corp). Initially, we secured agreements to collaborate with 17 target sites for the research. Before data collection, senior researchers provided the enumerators, who were health care workers at each site, with an introduction to the data collection procedures. The enumerators reached out to survivors of COVID-19 through various contact channels (phone, smartphone app, and email) and distributed the survey link. The reminders were sent out to achieve the response rate. Data were collected, extracted, and coded for analysis anonymously.

Assessments and Measurements
LCA Indicators: Unhealthy Lifestyle Behaviors
Based on previous literature, we assessed 5 most common unhealthy lifestyle behaviors including the following binary indicators:

- Cigarette smoking: Participants were asked about their tobacco use status and were given 3 options: “currently smoking,” “used to smoke and stopped,” and “never smoke.” We coded the variable “cigarette smoking” as “nonsmokers” if participants answered “never smoke” or “used to smoke and stopped.” Participants who answered “currently smoking” were categorized as “smokers.”
- Alcohol consumption: We asked participants whether they had consumed at least 1 standard drink of alcoholic beverage in the past 30 days. The variable was binary coded as “yes” or “no.”
- Unhealthy diet: We used the 5-item healthy eating score to assess the healthy diet. The 5-item healthy eating score is comparable with the 2015 health eating index in assessing the overall diet quality [36] and has been validated and used in Vietnam [37]. Participants were asked to respond to 5
questions about their consumption frequency of fruits, vegetables, whole grains, dairy, and fish over the past 30 days using a 6-point scale ranging from 0=rarely or never to 5=3 or more times per day. The total score can range from 0 to 25, with a higher score indicating a healthier diet. We used a cut-off point as the median of 15 (IQR 13-17) to create a binary variable, with a score of less than 15 indicating the “unhealthy diet.”

• Physical inactivity: Physical activity is defined as any bodily movement that requires the contraction of skeletal muscles and increases energy expenditure above the resting metabolic rate [38]. In this study, we used the short version of the International Physical Activity Questionnaire to assess participants’ physical activity levels [39]. Participants who reported engaging in vigorous-intensity activity on 3 or more days per week, or moderate-intensity activity or walking for at least 30 minutes per day on 5 or more days, were considered to have met the criteria for being “physically active,” and the opposite was labeled “physically inactive.”

• Sedentary behaviors: Sedentary behaviors are defined as any activities that involve sitting or reclining and consume an energy expenditure equal to or below 1.5 metabolic equivalents. Sitting time is usually the main indicator used to quantify the time devoted to sedentary behaviors [40]. To assess sedentary behavior, we asked survivors of COVID-19 about the average number of hours they spent sitting for nonwork purposes (eg, watching television, playing computer games, using social media, or engaging in other sitting activities) on a typical day in the past 7 days. Participants who reported spending more than 2 hours per day on these activities were classified as having sedentary behavior [34].

**Clinical Parameters**

Participants were asked to report their height in meters and weight in kilograms. The self-reported weight is concordant with image-captured weight in web-based research [41]. The BMI was calculated by dividing their weight by the square of their height in meters. Participants were then classified as underweight (BMI<18.5 kg/m²), normal weight (18.5 kg/m²≤BMI<23 kg/m²), overweight (23 kg/m²≤BMI<25 kg/m²), or obese (BMI≥25 kg/m²) [42]. In addition, comorbid conditions other than COVID-19 were also assessed.

**Sociodemographic Characteristics**

Sociodemographic characteristics were also measured, including age (years), sex (male or female), marital status (single; married; or widow, divorced, or separated), education levels (illiterate or elementary, secondary or high school, vocational or college, or university or higher), employment status (dependent, independent, or unemployed), whether the participant was a health care worker (yes or no), and self-reported social status (low, middle, or high).

**Data Analysis**

Data were analyzed on Stata (version 17.0; StataCorp). First, we tabulated sociodemographic characteristics and nutritional status for the overall sample separately by sex and differentiated by Wilcoxon rank-sum tests, Pearson chi-square tests, and Fisher exact tests. Second, the prevalence and 95% CIs of 5 unhealthy lifestyle behaviors were calculated for male and female participants. The 95% CIs were calculated using the formula CI=proportion mean±1.96×SE of proportion mean [43]. We then used the UpSet diagrams to describe the combinations of these behaviors [44]. The UpSet diagrams can help display complex intersections of a lifestyle behaviors matrix, where the rows represent different sets of combinations and the columns represent the number of male and female participants who had these combinations.

LCA is a statistical method used to identify subgroups of individuals based on observed variables [45]. Previous studies have used LCA to identify subgroups with distinct patterns of lifestyle behaviors and explore the factors associated with these patterns [31,34]. We used the expectation-maximization algorithm of LCA with 30 iterations—a general optimization technique for deriving maximum likelihood estimates in the presence of latent variables from 5 indicators [46]. This algorithm alternated between the expectation step—imputing latent variables based on current parameter estimates, and the maximization step—updating parameters to maximize the likelihood of the observed data from these 5 indicators [46,47]. Our approach involved systematically testing a series of models with an increasing number of latent classes to pinpoint the most fitting model. We considered Akaike information criterion (AIC) and Bayesian information criterion (BIC) to choose the optimal number of classes. The class with the smallest AIC and BIC was considered a good fit [33].

We defined 2 distinct classes, namely, the “less unhealthy” group and the “more unhealthy” group. Within each latent group, we assessed the predicted probabilities for categorical indicators and assigned each participant to the group with the highest probability. The distribution of indicators and covariates was compared among each group membership, and logistic regression analysis was performed to estimate the association between covariates and being in the “more unhealthy” group, stratified by sex. The selection of covariates for this model was informed by our hypothesis of correlation, guided by the findings in the literature [4,16,18,19,23,25,29]. Odds ratio (OR) and 95% CIs were reported. Likelihood ratio tests were used to determine the effect of each variable in the models.

**Ethical Considerations**

This study was reviewed and approved by the institutional ethical review committee of Hanoi University of Public Health, Vietnam (IRB 400/2021/YTCC-HD3 and 45/2022/YTCC-HD3). Participants have consented their participation. Data were confidentially collected and analyzed. No compensation was provided for participation.

**Results**

**Participants’ Characteristics**

Table 1 provides a summary of participants’ characteristics, stratified by sex. Among 5890 survivors of COVID-19, the median age was 31 (IQR 23-40) years. More than half of them were female (n=3443, 58.5%), married (n=3402, 57.8%), and
had attained a university education or higher (n=3034, 51.5%). In total, 3475 (59%) participants were dependent workers, and 1928 (32.7%) were health care workers. Most participants belonged to the middle social status category (n=4822, 81.9%) and had no comorbidities other than COVID-19 (n=4177, 70.9%).

<sup>a</sup>P value from Wilcoxon rank-sum, Pearson chi-square, and Fisher exact test compared the distribution of covariates between male and female participants.

<sup>b</sup>N/A: not applicable.

There were significant differences in the distribution of all covariates between male and female participants except for comorbidities. A higher percentage of female participants were underweight (female: 576/3443, 16.7% vs male: 133/2447, 5.4%). In contrast, male participants had higher rates of overweight (male: 671/2447, 27.4% vs female: 372/3443, 10.8%) and obesity (male: 382/2447, 15.6% vs female: 183/3443, 5.3%) than female participants.

**Distribution of Unhealthy Lifestyle Behaviors**

Table 2 displays the proportion of unhealthy lifestyle behaviors in survivors of COVID-19, stratified by sex. Among both sexes,
sedentary behaviors were the most prevalent behavior (male: 1871/2447, 76.5% and female: 2629/3443, 76.4%), followed by unhealthy diet (male: 1508/2447, 61.6% and female: 2109/3443, 61.3%). The prevalence of smoking and drinking was significantly higher among male participants compared to their female counterparts (307/2447, 12.5% vs 12/3443, 0.3%; \( P < .001 \) and 1217/2447, 49.7% vs 816/3443, 23.7%; \( P < .001 \), respectively). Conversely, the proportion of physical inactivity among female participants was higher than among male participants (female: 1928/3443, 56% vs male: 988/2447, 40.4%; \( P < .001 \).

</table>

\(^a\) \( P \) value from Pearson chi-square and Fisher exact test compared the distribution of covariates between male and female participants.

Table 3 illustrates the distribution of co-occurring unhealthy lifestyle behaviors among male and female participants. Almost all survivors of COVID-19 had participated in 1 behavior (male: 2432/2447, 99.4% and female: 3411/3443, 99.1%). In all categories, there was a higher prevalence of male participants than female participants who had 2 (male: 1918/2447, 78.4% vs female: 2551/3443, 74.1%), 3 (male: 1091/2447, 44.6% vs female: 1243/3443, 36.1%), 4 (male: 331/2447, 13.5% vs female: 282/3443, 8.2%), and all 5 (male 61/2447, 2.5% vs female: 3/3443, 0.1%) behaviors. The absolute and relative differences between the prevalence of male and female participants also increased as the number of behaviors increased. The ratio of male to female participants participating in 1 behavior was 1.003. This ratio increased gradually with a higher number of behaviors and surged to 25 at 5 unhealthy behaviors.

Figure 3 illustrates different combinations of unhealthy behaviors, stratified by sex. The most frequent combination observed in 1123 (45.9%) of 2447 male participants and 1584 (46%) of 3443 female participants was sedentary behavior and unhealthy diet. Male participants showed a high prevalence of combining alcohol consumption with sedentary behaviors (949/2447, 38.8%) and an unhealthy diet (861/2447, 35.2%), followed by the combination of all 3 abovementioned behaviors (663/2447, 27.1%). On the other hand, female participants tended to combine physical inactivity with sedentary behavior (1305/3443, 37.9%) or an unhealthy diet (1260/3443, 36.6%), as well as all 3 behaviors (885/3443, 25.7%).

\(^a\)P value from Pearson chi-square and Fisher exact test compared the distribution of covariates between male and female participants.

Figure 3. UpSet diagrams for different combinations of unhealthy lifestyle behaviors of participants, stratified by sex. This figure does not illustrate the combination with a prevalence of less than 5% in both sexes. The table underneath depicts the co-occurrence of unhealthy lifestyle behavior combination, where the rows represent different sets of combinations and the columns represent the number of male and female participants who had these combinations.

The Cluster of Unhealthy Lifestyle Behaviors

Table 4 reports the model fit indices of LCA models from 2 to 6 classes fitting to 5 behavior indicators. The 2-class model has the lowest AIC and BIC. In addition, the 2-class model is easier to interpret than the other models. Therefore, we proceed with the 2-class model.

*AIC: Akaike information criterion.*

*BIC: Bayesian information criterion.*

Table 5 presents the 2-class membership, distributed among the prevalence of 5 unhealthy lifestyle behaviors and stratified by sex. The 2 classes were labeled based on the distribution of each behavior in each class. The “less unhealthy” group included 64.7% (3810/5890) of total participants, and among them, there were 48.4% (1184/2447) of male participants and 76.3% (2626/3443) of female participants. Sedentary behavior was the most common behavior exhibited in both male and female participants in this group (887/1184, 74.9% and 1954/2626, 74.4%, respectively), followed by an unhealthy diet and physical inactivity. None of the participants in this membership had participated in 4 or 5 behaviors, and none of them reported any alcohol consumption. More than 43% of both male (521/1184, 43.8%) and female (1143/2626, 43.5%) “less unhealthy” participants engaged in 2 behaviors.

Table 5. Distribution of unhealthy lifestyle behaviors among survivors of COVID-19 by 2-class memberships.

</tr>
</tbody>
</table>

The “more unhealthy” group included 35.3% (2080/5890) of total participants, and among them, there were 51.6% (1263/2447) of male participants and 23.8% (819/3443) of female participants. The most prevalent behavior practiced in both male and female participants was alcohol consumption (1217/1263, 96.4% and 816/819, 99.9%, respectively), followed by sedentary behaviors (984/1263, 77.9% and 675/819, 82.6%, respectively). Male participants in the “more unhealthy” group exhibited a significantly higher prevalence of cigarette smoking compared to their female counterparts (288/1263, 22.8% vs 9/819, 1.1%, respectively). There were 599 (47.4%) of 1263 male participants and 359 (43.9%) of 819 female participants in this group who participated in 3 unhealthy behaviors. Approximately 5% (61/1263) of male participants engaged in all 5 behaviors, while this proportion was 0.4% (3/819) among female participants in the same class.

Table 6 displays the distribution of covariates by class membership. There were significant differences in the distribution of all covariates between “less unhealthy” and “more unhealthy” groups. Nearly half (1010/2080, 48.6%) of the participants in the “more unhealthy” group were single, 60.7% (1263/2080) of them were male, 67.3% (1400/2080) of them had at least a university education, and 71.9% (1495/2080) of “more unhealthy” participants were dependent workers. Regarding “less unhealthy” group, nearly 69% (2626/3810) of the participants were female, and 62.4% (2377/3810) of them were married. More than half (314/2080, 52%) of “less unhealthy” participants were dependent workers, and 42.9% (1364/3810) of them had at least a university education. The prevalence of obesity was almost 3 times higher in the “more unhealthy” group compared to the “less unhealthy” group (314/2080, 15.1% vs 251/3810, 6.6%, respectively).

Table 6. Distribution of covariates by class membership.

The prevalence of obesity was almost 3 times higher in the “more unhealthy” group compared to the “less unhealthy” group (314/2080, 15.1% vs 251/3810, 6.6%, respectively).

Factors Related to the More Unhealthy Group

Table 7 presents multivariable logistics regression to examine the association between covariates and being in the “more unhealthy” group among male and female participants. In both sexes, younger individuals had lower odds of being in the “more unhealthy” group (male: P=.001; OR 0.99, 95% CI 0.98-0.99 and female: P<.001; OR 0.98, 95% CI 0.97-0.99). Marital status showed a significant association with the “more unhealthy” group in both models. Married male participants had higher odds of being in the “more unhealthy” group compared to single ones (OR 1.45, 95% CI 1.14-1.85), while female participants exhibited lower odds (OR 0.65, 95% CI 0.51-0.83). Independent workers and unemployed participants had lower odds of being in the “more unhealthy” group compared to dependent workers of both sexes. In both models, higher educational levels were found to be associated with increased odds of belonging to the “more unhealthy” group.

\(^a\)OR: odds ratio.  
\(^b\)P value from likelihood ratio test.

Furthermore, individuals who are overweight or obese were more likely to fall into the “more unhealthy” category when compared to participants with a normal weight. Among male participants, the odds of being in the “more unhealthy” group slightly increased for overweight individuals who are overweight (OR 1.04, 95% CI 0.85-1.26), while significantly higher odds were found for individuals who are obese (OR 2.03, 95% CI 1.58-2.62). For female participants, both individuals who are overweight (OR 1.42, 95% CI 1.07-1.87) and obese (OR 1.73, 95% CI 1.21-2.47) had an increased likelihood of being in the “more unhealthy” group. Female participants who are underweight showed a higher likelihood of falling into the “more unhealthy” group (OR 1.11, 95% CI 0.89-1.39), but this was not the case for male participants (OR 0.6, 95% CI 0.41-0.89). Being a health care worker, level of social status, and having comorbidities did not show a statistically significant association with higher odds of being in the “more unhealthy” group.

### Discussion

#### Principal Findings

This national study examines the prevalence and clustering patterns of 5 unhealthy lifestyle behaviors among survivors of COVID-19 in Vietnam. This study provides a distinct pattern of unhealthy behaviors exhibited by male and female individuals after their COVID-19 recovery. We found that sedentary behaviors and unhealthy diets are common unhealthy behaviors in both sexes. While physical inactivity was more commonly practiced among female participants, male participants tended to engage in smoking and alcohol consumption. Nearly all participants had engaged in at least 1 unhealthy behavior, and male participants had a higher likelihood of engaging in multiple behaviors than female participants. Male participants also tended to practice alcohol intake with others such as sedentary behaviors and unhealthy diet, whereas female participants engaged in physical inactivity with sedentary behaviors and unhealthy diet.

Two unhealthy behavior classes were identified using LCA, with the “more unhealthy” group featured by a greater...
proportion of male participants. Certain common factors associated with this group were observed in both male and female participants, including older age, dependent employment, high educational levels, and obesity. However, sex-specific differences were found. For male participants, being married was an additional factor linked to a higher likelihood of being in the “more unhealthy” group. On the other hand, for female participants, being single and underweight were additional factors associated with this group.

**Prevalence of Unhealthy Lifestyle Behaviors by Sex**

The most prevalent unhealthy behaviors among survivors of COVID-19 were sedentary behaviors and unhealthy diets, which is consistent with findings from other studies among students and younger adults [23,34,48]. While there were significant differences between the percentage of male and female participants engaged in almost all behaviors, there were no significant differences between the prevalence of unhealthy diet and sedentary behavior in male and female participants in our sample. Our findings are in line with those from a study conducted among 1058 first-year students in Greece in 2016, which also found no significant differences in the prevalence of sedentary behavior (defined by screen time of more than 2 hours) and fruit and vegetable intake between male and female participants [23]. Since the study collected data when several provinces and cities were under lockdown across Vietnam, one explanation for the absence of these significant sex differences in terms of sedentary behavior and an unhealthy diet could be that both sexes were impacted similarly in this period. The lockdown might have caused significant changes in daily routines and lifestyles for the whole population, such as reduced physical activity, increased sedentary behavior, and changes in dietary patterns. Similar changes were observed in previous studies that took place during the cordon sanitaire period globally [49-51]. These changes can then exacerbate the prevalence of both sexes engaging in unhealthy behaviors. Indeed, there was a considerable increase in snacking and meal numbers or in unfavorable food choices and dietary habits during the COVID-19 lockdown reported in 2020, and there were no significant differences in sex participation rate as well [52].

Our evidence highlights the significant sex disparities in cigarette smoking and alcohol consumption among survivors of COVID-19, skewing higher in male participants. This observation aligns with prior research, where male participants tend to engage in more hazardous behaviors than female participants [53-56]. Male participants were also more likely to combine alcohol consumption with other factors such as sedentary lifestyles and unhealthy diets. With nearly 30% (683/2447) of male participants in our sample with chronic conditions, the high prevalence of co-occurring unhealthy behaviors coupled with the possible long-term effect of COVID-19 infection might increase the risk of NCDs in this population [57]. The observed sex differences in cigarette smoking and alcohol consumption in this study might be explained by a range of social, cultural, and economic factors. Vietnamese tradition perceived smoking and drinking as a part of the male gender role, used to display masculinity and establish social connections [30], while women are generally not discouraged to engage in these behaviors due to gender role expectations. Following such a drastic health event such as a cancer diagnosis or in our case—COVID-19 infection, lifestyle behaviors might also differ between sexes [58]. While women are more likely to adhere to health education and healthy behaviors after diagnosis, men are less likely to change their behaviors [28]. In addition, possible stress and anxiety induced by both the infection and the pandemic might cause men to smoke or drink more as a coping mechanism [59]. To address this gap, targeted interventions for male survivors of COVID-19 are recommended. These interventions may include a health education program for health problems following COVID-19 infection focused on the consequences associated with smoking and alcohol intake or a health promotion campaign highlighting the double-burden aspects of long COVID-19 symptoms and unhealthy behaviors.

**Clustering of Multiple Unhealthy Lifestyle Behaviors by Sex**

We highlighted significant differences in the number and combination of lifestyle-compromising behaviors between male and female participants. Surprisingly, the prevalence of male participants engaging in 4 or 5 unhealthy lifestyle behaviors simultaneously was nearly twice and 25 times higher compared to female participants. These findings are consistent with evidence from the adult population in India, which suggests that more adult male participants tend to exhibit the clustering of multiple NCD risk factors than female participants [26]. However, these findings contradict previous research indicating that female participants tend to engage in multiple unhealthy behaviors more frequently than male participants [23,34]. For example, in a study involving 3495 adolescents in Vietnam, it was found that the prevalence of practicing 2 unhealthy behaviors was similar between male and female participants. However, there was a sex discrepancy in the co-occurrence of 3 factors (male: 27.3% and female: 31.5%) and 4 factors (male: 13.7% and female: 15.1%) [34]. Similarly, a study conducted with 1058 first-year students in Greece found that the co-occurrence of 4 unhealthy factors was twice as high in female participants compared to male participants (male: 2.9% and female: 5.2%) [23]. It is important to note that the percentages of co-occurring behaviors may vary across studies due to differences in the number and types of behaviors measured as well as the specific cut-off points used. This is particularly relevant in cases where clear guidelines are lacking [32,60].

Among survivors of COVID-19 in Vietnam, we identified 2 distinct behavior patterns: “less unhealthy” and “more unhealthy” groups. These groups differed significantly in various factors. In the “less unhealthy” group, which represented around 65% (3810/5890) of the sample, a sedentary lifestyle was most prevalent, and there were a higher proportion of female participants. Conversely, the “more unhealthy” group, constituting over one-third of the population, was predominantly male and exhibited higher rates of alcohol intake and sedentary behavior. Additionally, the 2 groups differed in the number of concurrent unhealthy lifestyle behaviors. None of the “less unhealthy” participants reported engaging in more than 3 unhealthy behaviors simultaneously, while over 70% (male: 930/1263, 73.6% and female: 642/819, 78.4%) of the “more unhealthy” ones reported 3 or more behaviors. These distinctions
were also reflected in the sex distribution. This finding is in line with a previous study documenting the clustering of health-related behaviors among Indian adults and US young adults [26], in which the authors also found a higher percentage of men grouped in the higher-risk cluster. Overall, the findings reaffirm that (1) there were distinct patterns of unhealthy lifestyle behaviors practiced by survivors of COVID-19, and (2) these patterns differ significantly by sex.

Our findings also indicate that several factors were associated with the “more unhealthy” pattern with sex-specific differences. In this study, male participants who were married displayed a higher likelihood of engaging in unhealthy behaviors compared to those who were single. This contradicts previous research conducted on healthy behaviors among young Korean adults [61] and survivors of cancer [62], which found that unmarried men or men without a partner were more likely to practice unhealthy behaviors compared to their married counterparts. Our evidence suggests that dependent workers, especially male participants, were more likely to engage in unhealthy behaviors. This aligns with previous research indicating that men in dependent jobs, particularly in Asian contexts, tend to participate in social gatherings at work that often involve smoking and drinking [63]. The drinking culture after work is a common practice in many Asian countries, including Vietnam [64], South Korea [65,66], and Japan [67]. On the other hand, self-employment was positively associated with healthier behaviors. This can be attributed to the flexibility self-employed individuals have in managing their work schedule, allowing them to allocate time for health promotion activities [68,69].

Additionally, we found that obesity was significantly associated with the “more unhealthy” group. This highlights the need to address the growing public health challenge of a higher prevalence of obese individuals, which has been exacerbated by the COVID-19 pandemic [70-73]. Given that our adults recovering from COVID-19 are already at risk of postrecovery complications, the engagement in unhealthy behaviors due to obesity conditions further places them in a vulnerable position. We strongly recommend targeted public health interventions and services for this population, focusing on promoting an active lifestyle and a balanced diet and discouraging unhealthy behaviors to regain and maintain their pre-COVID-19 infection health status.

Limitations and Strengths

This study has several limitations that should be acknowledged. First, the reliance on self-reported data for assessing lifestyle behaviors introduces the possibility of information bias. Participants may have underreported or overreported their engagement in certain behaviors. Second, the cross-sectional design of this study restricts our ability to establish causal relationships between lifestyle behaviors and different demographic factors. Third, the use of web-based surveys may have introduced selection bias, as only individuals who were contactable by phone were included in the sample, and the overall response rate was 50.1% (5890/11,761). It is important to consider the generalizability of our findings, as they may not apply to other vulnerable populations experiencing different chronic health impacts, given the variations in definitions, methodologies, and targeted populations in measuring lifestyle behaviors [32,60]. Fourth, the changes in lifestyle behaviors before and amid the pandemic were not investigated in this study. Fifth, we were unable to access data on Vietnamese societal and cultural dynamics to provide implications for the observed sex differences in lifestyle behaviors. Future research should address these limitations by using other empirical measures of unhealthy lifestyle behaviors and using longitudinal study designs to provide more robust evidence.

Despite certain limitations, this study possesses notable strengths. First, the data were derived from a large population-based cohort, enhancing the representativeness of our findings. Additionally, we used validated questionnaires to assess unhealthy lifestyle behaviors and associated factors, bolstering the generalizability of our study and facilitating comparisons with prior research. Moreover, this study contributes to the existing body of knowledge by shedding light on the distinct patterns of lifestyle behaviors observed among adults recovering from COVID-19, including sex differences, through the advanced application of LCA [55]. As survivors of COVID-19 constitute a growing population facing various health challenges, this study provides valuable insights into their sex-specific engagement in unhealthy behaviors. This, in turn, highlights the importance for public health agencies and policy makers to recognize the inadvertent detrimental impact of the COVID-19 pandemic, as well as the infection itself, on individuals’ lifestyle behaviors and overall health outcomes.

Conclusions

The study revealed distinct patterns of unhealthy lifestyle behaviors among survivors of COVID-19 in Vietnam, with sedentary lifestyles and unhealthy diets being the most prevalent. Notably, these patterns differed significantly between sexes, with male participants exhibiting higher unhealthy behaviors and engaging in a greater number of unhealthy behaviors compared to female counterparts. These findings have important implications for public health initiatives, highlighting the need for tailored educational interventions that address sex-specific lifestyle behaviors. Specifically, efforts should be made to reduce unhealthy tendencies, particularly among married male adults recovering from COVID-19 who are obese, to promote a healthy and active life after COVID-19.

Abstract

Background: Depression is often accompanied by changes in behavior, including dietary behaviors. The relationship between dietary behaviors and depression has been widely studied, yet previous research has relied on self-reported data which is subject to recall bias. Electronic device–based behavioral monitoring offers the potential for objective, real-time data collection of a large amount of continuous, long-term behavior data in naturalistic settings.

Objective: The study aims to characterize digital dietary behaviors in depression, and to determine whether these behaviors could be used to detect depression.

Methods: A total of 3310 students (2222 healthy controls [HCs], 916 with mild depression, and 172 with moderate-severe depression) were recruited for the study of their dietary behaviors via electronic records over a 1-month period, and depression severity was assessed in the middle of the month. The differences in dietary behaviors across the HCs, mild depression, and moderate-severe depression were determined by ANCOVA (analyses of covariance) with age, gender, BMI, and educational level as covariates. Multivariate logistic regression analyses were used to examine the association between dietary behaviors and depression severity. Support vector machine analysis was used to determine whether changes in dietary behaviors could detect mild and moderate-severe depression.

Results: The study found that individuals with moderate-severe depression had more irregular eating patterns, more fluctuated feeding times, spent more money on dinner, less diverse food choices, as well as eating breakfast less frequently, and preferred to eat only lunch and dinner, compared with HCs. Moderate-severe depression was found to be negatively associated with the daily 3 regular meals pattern (breakfast-lunch-dinner pattern; OR 0.467, 95% CI 0.239-0.912), and mild depression was positively associated with daily lunch and dinner pattern (OR 1.460, 95% CI 1.016-2.100). These changes in digital dietary behaviors were able to detect mild and moderate-severe depression (accuracy=0.53, precision=0.60), with better accuracy for detecting moderate-severe depression (accuracy=0.67, precision=0.64).
Conclusions: This is the first study to develop a profile of changes in digital dietary behaviors in individuals with depression using real-world behavioral monitoring. The results suggest that digital markers may be a promising approach for detecting depression.

Introduction

The mental health of students has become the forefront of concerns, particularly since the onset of the COVID-19 pandemic. Approximately 45% of college students in China reported experiencing mental health issues during the outbreak [1]. Depression screening typically involves self-reported data, but there is a lack of objective markers to promptly identify individuals experiencing depression. Early identification and intervention are crucial for mitigating the impact of depression during critical periods for the academic and occupational functioning of students [2].

Appetite disturbance or changes in dietary behaviors are common symptoms of depression and may serve as objective indicators of the condition in a large population [3]. Dietary behavior can exert an influence on mental health through a variety of pathways, including circadian rhythms, oxidative stress, and the gut microbiota [4]. Based on the time of meals, intervals between meals, daily eating window, and food intake of the day, dietary behavior patterns can be categorized into morningness, intermediate, and eveningness chronotypes [5]. Eveningness chronotype commonly exhibits a higher tendency to skip breakfast, eat dinner later, and allocate a greater proportion of their daily food intake to later hours of the day [6]. Prior research has additionally demonstrated that the eveningness chronotype, coupled with social jetlag, constitutes a risk factor for depression [7,8]. Besides, individuals with more pronounced fluctuations in their eating windows often display heightened emotional vulnerability [9]. However, previous studies of diet relied on retrospective questionnaires or interviews, which may fail to accurately reflect real-world behavior [10]. Additionally, these methods typically assess only 1 aspect of dietary behavior, such as diet quality or eating habits [8,11,12]. To fully understand dietary behaviors, it is necessary to use multiple scales to assess multiple dimensions, such as diet quality, emotional eating, and chronotype of eating habits. However, using multiple scales can lead to participants taking too long to complete the questionnaire, reducing its validity. Furthermore, understanding daily behavior features requires repeated behavioral monitoring over an extended period, while retrospective reports from a single point in time may not accurately reflect true behavior [13].

The use of electronic platforms for behavioral monitoring allows for real-time assessment of human behavior and can trigger an alert if measured behavior deviates from healthy norms [14,15]. Additionally, these platforms enable the collection of large amounts of high-frequency, high-dimensional continuous data, which can be used to identify typical multidimensional behavior features over an extended period based on naturalistic situations [16,17]. The growing body of literature leveraging behavioral monitoring for depression prediction has gained traction, spurred by the profound shifts in lifestyle behavior patterns, especially during the COVID-19 pandemic [18-20]. Nonetheless, predominant inquiries have predominantly concentrated on probing the correlation between physical activity, social network engagement, and mental well-being facilitated through mobile devices [21-23]. However, an evident void persists in comprehensively exploring the nexus between the surveillance of dietary behavior patterns and depression. On university campuses, meals are often paid for using electronic transactions linked to a student account, providing the opportunity to collect digital dietary behavior data. In this study, real-world monitoring was used to track dietary behavior for a month, and data on time, expenditure, and location patterns were collected.

To the best of our knowledge, this is the first study to use electronic device–based behavioral monitoring instead of retrospective self-reported data to examine the digital dietary behaviors of individuals with depression compared with controls, and to investigate the relationship between these behaviors and depression. It is common for depression to occur alongside other symptoms, but the relationship between digital dietary behaviors and these comorbid symptoms of depression remains underexplored. Therefore, we also aim to determine whether these comorbid symptoms are associated with dietary behaviors and to clarify the role these symptoms play in the relationship between changes in dietary behavior and depression. The final data analysis will involve using digital dietary behavior features to detect depression.

Methods

Recruitment of Participants

A total of 3678 medical students from Xinxiang Medical University willingly engaged in this study, responding to the institution’s mental health survey notification. As part of this engagement, they underwent a cross-sectional mental status survey from October 6 to 12, 2020. Concurrently, during the survey, these participants also consented to furnish records of their eating behaviors for the period spanning from October 1 to 31, 2020. These records were sourced from electronic transactions linked to their respective student accounts. All participants completed questionnaires via WeChat (Tencent Corp) and signed web-based informed consent.

Web-Based Measurements

Basic sociodemographic characteristics, such as gender, age, BMI, and educational level, were collected using the WeChat
official account platform. All participants also completed the following psychological assessments: the Patient Health Questionnaire-9 (PHQ-9), the Generalized Anxiety Disorder Questionnaire-7 (GAD-7), the Perceived Stress Scale-14 (PSS-14), and the Insomnia Severity Index (ISI). All the details of these psychological assessments can be found in Multimedia Appendix 1.

**Study Participants and Inclusion Criteria**

Based on the outcomes of the psychological survey, the inclusion criteria for the mild depression group, the moderate-severe depression group, and the healthy control (HC) group, as well as the exclusion criteria, were defined as follows. Inclusion criteria were established as follows: individuals in the mild depression group had PHQ-9 scores between 5 and 9, while those in the moderate-severe depression group had PHQ-9 scores of 10 or higher. The HC group had PHQ-9 scores below 5, GAD-7 scores below 5, PSS-14 scores below 29, and ISI scores below 8. Exclusion criteria for all participants included PHQ-9 scores below 5 and any of the following conditions: GAD-7 scores of 5 or higher, PSS-14 scores of 29 or higher, or ISI scores of 8 or higher. The participant inclusion process for this study is depicted in Figure 1 (Step 1).

**Ethical Considerations**

Prior to their involvement in the study, all participants provided their informed consent through a formally endorsed consent form. The study was approved by the Biomedical Ethics Committee of Xinxiang Medical University (XYLL-2020235).

**Dietary Data Collection**

During the COVID-19 pandemic in China, students were required to stay on campus, resulting in most students eating at the campus cafeterias on a daily basis. These meals are often paid for using electronic transactions linked to a student’s account, and there are 3 cafeterias at the school. The dietary data preprocess can be found in Multimedia Appendix 1. Previous studies have shown that diet time, or chronotype, is related to circadian rhythms and mood [5], and location and periodicity of meals are related to depression symptoms [24]. Therefore, we evaluated 6 dietary behavior features, including time, location, expenditure, daily dietary items and frequency of meals, and all-day dietary behavior patterns, to objectively assess dietary behaviors in relation to depression in this study (Figure 1, Step 2).

**Calculation of Dietary Features**

**Time Patterns**

To determine the number of daily meals, we counted the number of records starting from the first recorded meal. Dietary behaviors within 2 hours of this initial record were part of a single meal, which could be further divided into up to 1, 2, or 3 meals per day: breakfast, lunch, and dinner. In addition, based on the cafeteria’s hours of operation, the 3 meals are divided into time slots as follows: breakfast from 6:30 AM to 8:30 AM, lunch from 11 AM to 1 PM, and dinner from 5:30 PM to 7:30 PM. If there were multiple electronic transactions within a single meal, we used the timestamp of the first transaction as the time of the meal for analysis.

**Time Intervals Between Meals**

We used the times of breakfast, lunch, and dinner calculated from the time patterns to determine the time intervals between each pair of meals: breakfast and lunch, lunch and dinner, and breakfast and dinner.

**Expenditure on Meals**

After dividing meals into breakfast, lunch, and dinner based on the time patterns, we calculated the total cost for each meal by...
summing up multiple electronic transactions for a single meal. Expenditure on a single meal may indicate an individual’s appetite as it reflects the amount of food purchased.

**Location Patterns**

To determine location patterns of dietary behavior, we calculated the frequency of visits to each cafeteria by counting total number of cafeterias visited in October and calculated the frequency of the student’s visits to the cafeteria for breakfast, lunch, and dinner using the following formula:

\[ \text{Frequency} = \frac{\text{Number of visits}}{\text{Total number of days}} \]

**Daily Dietary Diversity and Frequency of Meals**

The average number of different foods consumed per day in October was calculated as a measure of food diversity. The frequency of breakfast, lunch, and dinner in the month was also calculated as a measure of dietary habits. These measures were used to understand the dietary behaviors of participants in the study.

**All-Day Dietary Behavior Patterns**

People may have regular or irregular dietary behavior patterns, such as consistently or selectively eating breakfast, lunch, and dinner. There are 7 possible dietary behavior patterns: eating only breakfast, only lunch, only dinner, breakfast-lunch, lunch-dinner, and all 3 meals (breakfast-lunch-dinner pattern). All-day dietary behavior patterns are defined as the meals eaten by a participant on a given day. The frequency of a participant’s daily dietary behavior patterns can be calculated based on their dietary records for the entire month of October. To do this, the daily records are taken as a unit and the frequency of each dietary behavior pattern is calculated using the following formula:

\[ \text{Frequency} = \frac{\text{Number of days}}{\text{Total number of records}} \]

**Statistical Indices of Dietary Features**

Statistical indices were calculated for dietary features such as time patterns, intervals between meals, and expenditure on meals, including mean, median, median absolute deviation (MAD), and maximum and minimum values for the entire month of October. The study also separated weekday and weekend behavior by calculating dietary features separately for the 2 time periods. More information can be found in Table S1 in Multimedia Appendix 1.

**Statistical Analysis**

ANOVA and chi-square tests were used to analyze demographic and psychological characteristics. ANCOVA (analyses of covariance) was used to compare dietary behavior features among groups, with age, gender, BMI, and educational level as covariates. All variables in the 6 dietary features were transformed into Z-scores to give equal weight and minimize the impact of outliers in the study. Logistic regression analyses were used to examine associations between all-day dietary behavior patterns and depression severity (mild depression, and moderate-severe depression), as well as associations between other psychological symptoms in depression groups or all participants and all-day dietary behavior patterns, with age, gender, BMI, and educational level as covariates. The all-day dietary behavior patterns were categorized into tertiles: Rare (less than 1 SD), Normal (within 1 SD), and Always (more than 1 SD) in logistic regression analyses. Mediation analysis was performed using Model 4 with 1 independent variable (all-day dietary behavior patterns), 1 dependent variable (groups), and 1 moderator (other psychological symptoms) in the PROCESS. A bootstrapping procedure with 95% CIs was used to measure the moderating effect, with 5000 bootstrap samples. Age, gender, BMI, and educational level were included as covariates in the model. All analyses were conducted using SPSS (version 25.0; IBM Corp).

**Results**

**Demographic and Clinical Characteristics of Participants**

A total of 3310 students, consisting of 2222 HC, 916 mild depression, and 172 moderate-severe depression, met the inclusion criteria and were ultimately included in the study. And 368 students exhibited psychological symptoms, notably anxiety, insomnia, or abnormal stress, while concurrently not manifesting depressive symptoms. As a result, they were excluded from the study cohort. In the students with mild depression, the following rates were observed: 37.7% (n=345) with anxiety, 17.8% (n=163) with perceived abnormal stress, and 23.8% (n=218) with insomnia. In moderate-severe depressive students, the corresponding percentages were: 75% (n=129) with anxiety, 70.3% (n=121) with perceived abnormal stress, and 53.5% (n=92) with insomnia. The demographic and clinical characteristics of the participants can be found in Table 1.

Dietary Features Among HC, Mild Depression, and Moderate-Severe Depression

The ANCOVA analyses showed that there were significant differences between the groups in terms of time patterns, the intervals between meals, expenditure on meals, daily dietary diversity and frequency of meals, and all-day dietary behavior patterns (details in Table S2 in Multimedia Appendix 1). There was no significant difference in location patterns among the 3 groups.

In terms of time patterns, post hoc analyses showed that compared with mild depression and HC, moderate-severe depression had significantly increased MAD of lunchtime (P=.04 and P=.004, separately), latest lunchtime (P=.02 and P=.007, separately) and MAD of dinner time (P=.02 and P=.01, separately) on weekdays, and there was no significant difference between mild depression and HC (Figure 2A). In terms of time intervals between meals, post hoc analyses that compared mild depression and HC, moderate-severe depression had increased MAD (P=.001 and P<.001, separately) and maximum (P=.02 and P=.005, separately) time intervals between lunch and dinner on weekdays, respectively, but mild depression and HC had no significant difference with each other (Figure 2B). On weekends, post hoc analyses that compared with HC, mild depression had a significant decrease in the mean time interval between breakfast and lunch (P=.01), while mild depression and moderate-severe depression had significant decreases in the maximum time interval between breakfast and lunch (P=.02 and P=.03 separately; Figure 2B). The MAD of lunchtime on weekdays was higher in moderate-severe depression (18 minutes 58 seconds) than mild depression (17 minutes 38 seconds) and HC (17 minutes 5 seconds). Similarly, the MAD of dinner time on a weekday was higher in moderate-severe depression (26
minutes 11 seconds) than in mild depression (23 minutes 39 seconds) and HC (23 minutes 26 seconds). Additionally, the MAD time interval between lunch and dinner on weekdays was larger in moderate-severe depression (34 minutes 20 seconds) than in mild depression (29 minutes 25 seconds) and HC (29 minutes 23 seconds; Table S2 in Multimedia Appendix 1).

These findings indicate a temporally erratic lunch and dinner dietary pattern in moderate-severe depression.

Figure 2. Alternations of dietary pattern features in mild depression and moderate-severe depression. a: $P < .05$; b: $P < .01$; c: $P < .001$; and d: significance at $P < .05$, after false discovery rate correction. The values of dietary pattern features in the graph were transformed into Z-scores. Bre: breakfast; Din: dinner; HC: healthy control; Lun: lunch; MAD: median absolute deviation; Max: maximum; MED: median; Min: minimum.

In terms of expenditure on meals, compared with HC, both students with mild and moderate-severe depression had significant increases in the mean ($P = .02$ and $P = .02$, separately) and median ($P = .002$ and $P = .006$, separately) of dinner expenditure on weekdays (Figure 2C). However, there was no significant difference between mild depression and moderate-severe depression. On weekends, the mild depressive students had a significant increase in the minimum lunch expenditure compared with HC ($P = .03$) and moderate-severe depression ($P = .01$), but HC and moderate-severe depression had no significant difference from each other (Figure 2C).

In terms of daily dietary diversity, post hoc analyses that moderate-severe depression had significant decreases compared with mild depression and HC both on weekdays ($P = .02$ and $P = .01$, separately) and weekends ($P = .03$ and $P = .01$, separately). However, there was no significant difference between mild depression and HC. We also found that compared with HC, moderate-severe depression had a significant reduction in breakfast frequency on weekdays ($P = .02$) and weekends ($P = .005$). Additionally, compared with mild depression, moderate-severe depression had a significant reduction in breakfast frequency on weekends ($P = .05$). However, there was no significant difference between mild depression and HC in breakfast frequency on weekdays and weekends (Figure 2D).

Finally, in terms of all-day dietary behavior patterns, compared with HC and mild depression, moderate-severe depression had a reduction in the breakfast-lunch-dinner pattern on weekdays ($P = .001$ and $P = .002$, separately) and enrichment in the lunch-dinner pattern on weekdays ($P = .005$ and $P = .03$ separately; Figure 2E). However, there was no significant difference between HC and mild depression. On weekends, we observed that moderate-severe depression had an enrichment in the lunch-dinner pattern compared with HC ($P = .008$; Figure 2E).

Associations Between All-Day Dietary Behavior Patterns and Depression

To gain a deeper understanding of the relationship between comprehensive indicators of all-day dietary behavior patterns and depression severity. Using multiple logistic regression, we analyzed the associations between alterations in all-day dietary behavior patterns and depression severity in Figures 3A and 3B. After adjusting for age, gender, BMI, and educational level, we found that the Normal and Always lunch-dinner patterns on weekdays were positively associated with mild depression (Exp(B), 95% CI 1.360, 1.050-1.761; 1.460, 1.016-2.100; respectively), and the Always breakfast-lunch-dinner pattern on weekdays was negatively associated with moderate-severe depression (Exp(B), 95% CI 0.467, 0.239-0.912). The comparison of tertile levels of these all-day dietary behavior patterns among 3 groups can be found in Table S3 in Multimedia Appendix 1, and the percent of tertile levels of these all-day dietary behavior patterns can be found in Multimedia Appendix Figure S1.
Figure 3. (A,B) Associations between all-day dietary behavior patterns and depression. (C) Associations between Bre-Lun-Din patterns on weekdays and comorbidity of depression and anxiety in individuals. (D) Associations between Bre-Lun-Din patterns on weekday and anxiety in individuals. (E) The mediating role of anxiety between groups (HC, mild depression, and moderate-severe depression) and Bre-Lun-Din patterns. a: $P<.05$, b: $P<.01$, and c: $P<.001$. AOR: adjusted odds ratio; Bre: breakfast; Din: dinner; HC: healthy control; Lun: lunch.

Associations Between All-Day Dietary Behavior Patterns and Other Clinical Symptoms

Our findings revealed a positive correlation between anxiety and adherence to the consistent always breakfast-lunch-dinner pattern on weekdays among individuals with depression as well as all participants (Figures 3C and 3D). However, no significant associations were discovered between other all-day dietary patterns and other clinical symptoms (Table S4 in Multimedia Appendix 1). In the mediation model, anxiety served as a mediator ($R^2=0.570$, $P<.001$). A bootstrapped 95% CI confirmed that the indirect effect of groups (HC, mild depression, and moderate-severe depression) had an impact of 0.042 that was produced by anxiety as a mediator on breakfast-lunch-dinner pattern (Figure 3E).

The Detection of Dietary Patterns for Depression

Our results showed that alterations in dietary behaviors of depression had an accuracy of 0.53, $F_1$-score of 0.52, precision of 0.60, recall of 0.62, and an area under curve of 0.59 for detecting mild depression and moderate-severe depression. For detecting moderate-severe depression specifically, the accuracy was 0.67, $F_1$-score was 0.60, precision was 0.64, recall was 0.65, and area under curve was 0.69 (Table 2).

Discussion

Principal Results

This study is the first to investigate digital dietary patterns of individuals with mild and moderate-severe depression using electronic device–based monitoring. The results indicate that individuals with moderate-severe depression exhibit more irregular eating time patterns, greater fluctuations in their feeding window, higher expenditure on dinner, lower food diversity, and a decreased frequency of consuming breakfast, as well as more irregular lunch-dinner patterns and less regular breakfast-lunch-dinner patterns compared with HC. The study also found that maintaining a regular breakfast-lunch-dinner pattern is negatively associated with moderate-severe depression, and maintaining an irregular lunch-dinner pattern is positively associated with mild depression. Additionally, the presence of anxiety is positively associated with the breakfast-lunch-dinner pattern, and the severity of anxiety has an indirect effect on the relationship between depression and the breakfast-lunch-dinner pattern. Importantly, the study suggests that digital dietary features can be used to detect depression, particularly moderate-severe depression, indicating that quantified digital behavior could be a promising approach to the detection of depression.

Comparison With Prior Work in Dietary Behavior of Depression

We found that individuals with moderate-severe depression exhibited a reduction in dietary diversity, a decreased frequency of consuming breakfast, and irregular timing for lunch and dinner. The loss of interest in pleasurable activities, including eating, is a core symptom of depression, which may explain the decreased dietary diversity in individuals with moderate-severe depression. The findings of decreased breakfast frequency in moderate-severe depression align with previous research, which has identified a significant association between skipped or infrequent breakfast and an increased risk for depression [25,26]. The frequency of lunch and dinner did not significantly contribute to depression [26,27]. This discrepancy may be attributed to the fact that individuals with depression tend to have worse moods in the morning, which may negatively impact their appetite for breakfast. Considering these findings, it is important to consider the specific meal that is skipped when implementing dietary interventions to prevent depression. The study found that individuals with mild and moderate-severe depression exhibited significant fluctuations in the timing of lunch and dinner, as well as an irregular time interval between these meals. These findings align with previous research that has identified the importance of the feeding window on mental health [28,29], with irregular eating time patterns being associated with an increased risk of mental health distress [30]. Additionally, this study is the first to investigate the expenditure on 3 meals in individuals with depression, which provides insight into their food intake and appetite for each meal. The results indicate that individuals with mild and moderate-severe depression spent more money on dinner, which is consistent with the observation that individuals with major depressive disorder tend to have higher food intake during dinner compared with breakfast and lunch [31]. Notably, this study is the first to report that depression is associated with a preference for higher expenditure on dinner, while also being accompanied by a low frequency of breakfast.

This study is the first to objectively quantify all-day dietary behavior patterns by integrating time patterns, frequency of meals, and other parameters, and it revealed that moderate-severe depression is associated with an increase in lunch-dinner patterns and a decrease in breakfast-lunch-dinner patterns. Previous research has demonstrated that consuming breakfast, lunch, and dinner every day can reduce the prevalence of first-onset depression in a 5-year follow-up [32]. The lunch-dinner pattern is associated with eating later in the day and a meta-analysis has indicated that depressed patients are more inclined to spend on food later in the day, a phenomenon known as eveningness chronotype [33]. The relationship between eveningness chronotype and depressive symptoms aligns with pre-existing theories of chronobiology, which suggest that circadian dysfunction can have adverse effects on psychological well-being [34,35]. Eveningness chronotype is associated with a higher likelihood of regularly skipping or postponing breakfast [36] and it is well recognized that eating breakfast plays an important role in lowering blood cortisol levels and disturbances in glucose metabolism, which may affect serotonin levels [37].

Prior research in the dietary patterns field, whether dietary nutrition, dietary frequency, or dietary chronotype studies, predominantly relied on questionnaires [38,39]. The use of electronic behavioral monitoring for evaluating dietary behavioral patterns is still in its nascent technological phase. The self-monitoring is a prevalent method for assessing electronic dietary behaviors in the study of mental health [40,41]. This approach predominantly entails participants proactively documenting their daily dietary intake using an electronic device, often an app. However, it is important to acknowledge that excessive self-recording of behaviors could potentially lead to fatigue and monotony. While a frequency ranging from 2 to 3 times per week proved to be acceptable and reasonable [42], it once again hinders the inherent issue of recall bias that was previously encountered. Moreover, the field of wearable device-based monitoring for tracking dietary behavior has witnessed notable advancements [43,44]. However, its application in the field of psychiatry remains unexplored to date. The study marks the pioneering use of objective electronic device–based monitoring, unveiling anomalous eating patterns among individuals with depression.

The Associations Between Dietary Behavioral Patterns and Depression

The study found that maintaining a lunch-dinner pattern was positively associated with mild depression. Furthermore, maintaining a breakfast-lunch-dinner pattern was negatively associated with moderate-severe depression. These findings align with previous research that has identified eating breakfast as a health-promoting behavior [45] and a positive association between skipping breakfast and depressive symptoms [46]. Additionally, it highlights the importance of meal substitution for regular eating patterns as a positive association with
emotional disorders [47]. Overall, these findings suggest that maintaining a regular dietary pattern can be considered a dietary strategy for depression prevention.

Furthermore, the study found that anxiety is positively associated with the breakfast-lunch-dinner pattern. We can infer from the result that individuals with anxiety tend to choose to regularly eat 3 meals in their daily life and that depression with increasing anxiety may lead to an increase in the breakfast-lunch-dinner eating behavior. Literature has also indicated that individuals with anxiety tend to engage in more overeating situations [48] and have a positive association between anxiety symptoms and emotional and external eating [49]. However, the study also indicates that those with depression tend to intake more in dinner and then postpone or skip breakfast the next day. The study also found that anxiety could mediate the relationship between depression and breakfast-lunch-dinner pattern, which indicates that students with anxiety tend to maintain a regular breakfast-lunch-dinner pattern rather than postponing or skipping breakfast. This highlights the need for careful consideration when implementing dietary interventions for the comorbidity of depression and anxiety.

The Potential Value of Digital Dietary Behaviors in Depression

This study is the first to use digital dietary behaviors based on real-world behavioral monitoring to detect mild depression and moderate-severe depression. The results indicate that digital dietary behaviors could distinguish between moderate-severe depression and HC. Depression is a disorder characterized by brain-based dysfunction that is expressed through behavioral changes. The diagnosis of depression traditionally relies on structured interviews or questionnaires, which are based on retrospective self-reports and the threshold scores of questionnaires. These methods can be prone to bias and subjectivity. The use of digital markers of continuous daily behavioral monitoring as an objective indicator to detect depression represents a promising supplementary approach [13].

In this study, students’ dietary behaviors were analyzed over a period of 1 month to draw a profile of dietary patterns in depression. This is the first exploration of the relationship between digital dietary behaviors and depression, and the use of digital dietary behaviors to detect depression. Another thing to watch out for is that the results indicate that a deep learning model of dietary behaviors from digital devices holds more accurate detection of moderate-severe depression than mild depression. This is likely due to the observation that moderate-severe depression presents more erratic dietary behaviors than mild depression and HCs. Overall, this study highlights the potential of digital dietary features as a promising manner in the detection of depression, particularly moderate-severe depression.

Limitations

There are several limitations in this study that should be acknowledged. First, the measurement of depression severity in this study was based on self-reported data, future studies should consider clinician-based rating scales to reduce bias. Additionally, this study used a cross-sectional survey of depression, which does not capture changes in symptomology over time. A longitudinal psychological survey combined with continuous daily behavioral monitoring could provide further insight into dietary progression markers related to the severity of depressive symptoms over time. Finally, the study did not assess daily dietary structure and nutrient intake.

Conclusions

This study represents a pioneering endeavor in objectively characterizing the digital dietary behaviors of individuals experiencing depression, using real-world monitoring as opposed to self-reported retrospective data. Our findings indicate that students with depression experience disruptions in various aspects, including time patterns, the intervals between meals, expenditure on meals, daily dietary diversity and frequency of meals, and all-day dietary behavior patterns. Notably, individuals with moderate-severe depression showcase greater irregularities in eating time patterns, fluctuated feeding windows, decreased food diversity, higher expenditure on dinner, and a preference for consuming only lunch and dinner. Furthermore, maintaining a regular breakfast-lunch-dinner eating pattern exhibits a negative correlation with moderate-severe depression. Keeping a lunch-dinner pattern is positively associated with mild depression. This research not only fills a critical gap in the existing academic literature but also sheds light on the promising potential of digital dietary behaviors as objective makers to the detection of depression, particularly moderate-severe depression.

Abstract

Background: The risk factors for oropharyngeal gonorrhea have not been examined in sex workers despite the increasing prevalence of gonorrhea infection.

Objective: This study aims to determine the risk factors for oropharyngeal gonorrhea in female and gender-diverse sex workers (including cisgender and transgender women, nonbinary and gender fluid sex workers, and those with a different identity) and examine kissing, oral sex, and mouthwash practices with clients.

Methods: This mixed methods case-control study was conducted from 2018 to 2020 at 2 sexual health clinics in Melbourne, Victoria, and Sydney, New South Wales, Australia. We recruited 83 sex workers diagnosed with oropharyngeal gonorrhea (cases) and 581 sex workers without (controls). Semistructured interviews with 19 sex workers from Melbourne were conducted.

Results: In the case-control study, the median age of 664 sex workers was 30 (IQR 25-36) years. Almost 30% of sex workers (192/664, 28.9%) reported performing condomless fellatio on clients. Performing condomless fellatio with clients was the only behavior associated with oropharyngeal gonorrhea (adjusted odds ratio 3.6, 95% CI 1.7-7.6; P=.001). Most participants (521/664, 78.5%) used mouthwash frequently. In the qualitative study, almost all sex workers reported kissing clients due to demand and generally reported following clients’ lead with regard to kissing style and duration. However, they used condoms for fellatio because they considered it a risky practice for contracting sexually transmitted infections, unlike cunnilingus without a dental dam.
**Conclusions:** Our study shows that condomless fellatio is a risk factor for oropharyngeal gonorrhea among sex workers despite most sex workers using condoms with their clients for fellatio. Novel interventions, particularly targeting the oropharynx, will be required for oropharyngeal gonorrhea prevention.

**Introduction**

**Background**
There has been an increase in gonorrhea incidence in several countries over the past decade [1-3], which is of particular concern given increasing antimicrobial resistance (AMR) [4,5]. The oropharynx has been implicated in Neisseria gonorrhoeae transmission, possibly through saliva exchanged during oral sex practices and tongue kissing [6-9]. The oropharynx is considered a crucial site for AMR given difficulties in treating oropharyngeal gonorrhea and the increased propensity for N gonorrhoeae to develop resistance in the oropharynx compared to other anatomical sites [4,10,11]. Sex workers have been identified as an important priority population that bears a disproportionate burden of gonorrhea worldwide, yet data on the prevalence of oropharyngeal gonorrhea in this population are sparse [12]. Therefore, there is an urgent need for research into the risk factors for oropharyngeal gonorrhea, particularly among sex workers, given its importance in AMR [13]. In 2017, an Australian study of female sex workers attending a sexual health clinic in Melbourne, Victoria, Australia, found that female sex workers had a higher prevalence of oropharyngeal gonorrhea (2%) than of genital gonorrhea (1%) [14]. That study also found that oropharyngeal infection was often independent of genital infection [14]. A retrospective study of 42 Australian sexual health clinics showed a 200% increase in oropharyngeal gonorrhea among female sex workers from 2009 to 2015 [15]. Among gay, bisexual, and other men who have sex with men, a case-control study found that oropharyngeal gonorrhea was associated with the number of kissing and receptive fellatio casual sex partners in the preceding 3 months [9]. Due to the overlapping nature of tongue kissing and oral sex practices, it was not possible to undertake an adjusted analysis to determine the risk for any one practice in isolation for the transmission of oropharyngeal gonorrhea [9]. To our knowledge, there has been no similar case-control study conducted to identify risk factors for oropharyngeal gonorrhea in sex workers.

A 2018 study of 180 female sex workers attending a sexual health clinic in Melbourne found that 149 (83.7%) tongue kissed and 175 (97.2%) performed fellatio on at least one male client in an average working week [16]. In addition to the lack of data on risk factors for oropharyngeal gonorrhea among sex workers, there is a lack of qualitative data exploring how sex workers decide whether to engage in tongue kissing and oral sex practices (ie, cunnilingus and fellatio) with male clients. There has been considerable research indicating an increased demand by male clients of female sex workers for the “girlfriend experience,” wherein sex workers and clients engage in sexual practices typical of those in intimate, noncommercial relationships (eg, kissing and cunnilingus) [17,18]. Research on the girlfriend experience tends to focus on the male clients who seek this interaction rather than on the sex workers who provide the service, with no studies exploring the decision to provide these services. A Finnish qualitative study (2008) explored sexual pleasure among female sex workers, a factor very rarely considered in the literature [19]. The study found that, while sex work sometimes required mental distancing or disengagement from the work, which decreases sexual pleasure, the work may empower women by giving them control over the sexual experience and enhancing their own pleasure. No study to our knowledge has explored which factors, including pleasure, may influence the decision of sex workers to engage in kissing and oral sex practices with clients.

Since the mid-2010s, the role of mouthwash has been and continues to be investigated as a novel intervention for gonorrhea prevention in at-risk populations such as men who have sex with men [20-23]. Using mouthwash as a means for harm reduction has been previously recommended for sex workers to reduce sexually transmitted infections (STIs) [24], and a Melbourne-based study has shown that 83% of female sex workers reported using mouthwash daily or weekly [16]. However, it is unclear why sex workers used mouthwash, be it driven by hygiene or a desire to reduce STI transmission, though recent research has shown that Listerine use does not reduce reinfection with gonorrhea [22,23]. In the event that recommendations are made incorporating mouthwash into an STI prevention strategy for sex workers, it would be beneficial to better understand what is driving mouthwash use among sex workers.

**Objectives**
The primary aim of this study was to identify the risk factors for oropharyngeal gonorrhea among sex workers (including female and nonbinary sex workers) using a case-control study design. The secondary aim was to explore why sex workers engage in tongue kissing and oral sex and use mouthwash using a qualitative approach.

**Methods**

**Study Design**
The Health Research in Sex Workers (HERS) study was a mixed methods study comprising an unmatched case-control study and semistructured interviews (Multimedia Appendix 1). Topics from the quantitative data were expanded on and explored in more detail in the semistructured interviews. The interviews were conducted simultaneously with the case-control survey and sought to clarify how and why sex workers may engage in oral sex practices involving saliva with clients.

https://publichealth.jmir.org/2024/1/e46845
Study Setting

The HERS case-control study was conducted at two sexual health clinics in Australia: (1) Melbourne Sexual Health Centre (MSHC) in Melbourne, Victoria; and (2) the Thai and Chinese clinics at Sydney Sexual Health Centre (SSHC) in Sydney, New South Wales (NSW). Participants were recruited for the case-control study at MSHC from November 2018 to March 2020 and at SSHC from November 2018 to December 2019. Both recruitment sites are large public sexual health clinics providing free sexual health services in inner urban settings. Sex work in Australia varies in legality by jurisdiction [25]. At the time of writing (January 2022), sex work was regulated by the Sex Work Act 1994 in Victoria [26], which included the criminalization of all sexual activities that include oral, vaginal, or anal penetration without a condom. In the state of NSW, sex work is decriminalized, there is no legislation criminalizing condomless sex, and risk is managed through Work Health and Safety legislation. High rates of condom use among female sex workers with male clients in both states have previously been reported, including >90% and >78% consistent use for vaginal sex and fellatio in an average working week, respectively [16-27,29].

During the study period, sex workers were required by law to receive mandatory HIV and STI testing every 3 months in Victoria [30]. There is no mandatory HIV and STI testing in NSW; rather, STI testing frequency recommendations are based on individual risk as per the Australian STI Management Guidelines [31].

Participants for the qualitative study were recruited from the MSHC from March 2019 to January 2020. Participants were unable to be recruited from the SSHC due to practical constraints as the interview team was based in Melbourne.

Female sex workers (cisgender and transgender) and sex workers who selected a different identity who were assigned male at birth, were aged ≥18 years, attended either clinic during the study period, and were working in the sex industry at the time of consultation were eligible for the HERS case-control study, and those English-speaking sex workers who attended the MSHC were also eligible for the semistructured interviews.

Case-Control Study

Participants

Sex workers attending the MSHC and SSHC for STI screening had a clinician-collected oropharyngeal swab to test for N gonorrhoeae. Cases were defined as sex workers with a positive oropharyngeal swab for gonorrhea, and controls were sex workers who had a negative oropharyngeal swab for gonorrhea.

Recruitment

Eligible and interested sex workers attending the MSHC or the Thai and Chinese clinics at the SSHC were given a paper-based questionnaire with a prelabeled study ID by the recruiting clinicians (Multimedia Appendix 2). In addition, sex workers attending either clinic for treatment of oropharyngeal gonorrhea were approached by a research nurse if they had not already completed the questionnaire and asked if they would like to participate in the study. In this way, cases were purposively recruited.

Data Collection

The questionnaire was designed by the study investigators with feedback sought from organizations that provide services for sex workers (Resourcing Health & Education [RhED] and the Sex Workers Outreach Project [SWOP], both services for sex workers in Victoria and NSW, respectively). The questionnaire was offered in English, Thai, and Chinese at both recruitment sites (translated by a professional translation company but checked for readability by bilingual clinicians). Participants’ unique patient identifier was recorded on a separate log with the corresponding questionnaire study ID. This log was collected daily by the research staff. Consent was implied by questionnaires being returned completed. No payment was given to participants for returning the questionnaire.

The HERS case-control quantitative questionnaire collected data on demographic characteristics (eg, age, sex, country of birth, length of time in Australia, and languages spoken at home), mouthwash practices, location of sex work, sex practices performed with male clients in an average working week, and sex practices with noncommercial male sexual partners in the previous 7 days. Sex practices with female partners were not ascertained given that most clients are male and the risk of gonorrhea among women who have sex with women is lower than among those who have sex with men [32]. Sex practices included tongue kissing, oral sex (fellatio with and without ejaculation and cunnilingus), vaginal sex, anal sex, sex involving toys, and using saliva (either theirs or a partner’s) as lubricant during sex (vaginal sex, anal sex, and sex involving toys).

Gonorrhea was diagnosed using nucleic acid amplification tests performed on the Aptima Combo 2 assay (Hologic) at the MSHC and the Roche cobas CT and NG assay (Roche Diagnostics) at the SSHC. The Aptima and Roche assays have similar sensitivity and specificity for oropharyngeal gonorrhea detection [33]. Returned questionnaires were linked (via the questionnaire study ID) to the patient identifier number recorded in the log by research staff to match their oropharyngeal gonorrhea test results with their questionnaire data.

Study Size

Sample size was calculated using OpenEpi [34] using the estimate that 25% of female sex workers have condomless fellatio [35], an assumed minimum risk factor prevalence of 25% in controls, and a minimum odds ratio (OR) of 2. It should be noted that our original aim was to conduct a 1:4 age-matched case-control study, which would have required 92 cases to 366 controls assuming the same parameters. However, due to the COVID-19 pandemic, recruitment had to be terminated before 92 cases were recruited given that all sex work was required by law to cease during the COVID-19 lockdown nationally (beginning March 25, 2020, in Australia) [36] and because sex practices with clients (and, thus, risk factors for oropharyngeal gonorrhea) might have changed during the pandemic after sex work resumed. For an unmatched case-control study with a ratio of 1:7 cases to controls, at 80% power and a .05 significance, there needed to be 83 cases to 579 controls. There were 83 cases...
and 581 controls recruited before the COVID-19 lockdown; thus, we were able to conduct an unmatched analysis with 80% power to detect a difference using a significance level of 5%.

This study was reported as per the Strengthening the Reporting of Observational Studies in Epidemiology 2008 guidelines for case-control studies.

**Statistical Methods**

Descriptive statistics were used to calculate the median age of participants. The median number of years in Australia for those born overseas was calculated, and participants were categorized as newly arrived or not based on whether they were in Australia for less than or equal to the median number of years or more than the median number of years. The median was calculated for the number of male clients seen in an average working week. The Mann-Whitney U test was used to compare the differences between continuous variables between cases and controls. A chi-square test was used to compare differences in the proportion of categorical variables, and those who declined to report were excluded from the chi-square analysis.

Univariable and multivariable unconditional logistic regression was conducted to identify (1) the factors associated with declining to report sexual practices and (2) the factors associated with oropharyngeal gonorrhea. There were some differences in patient characteristics between the MSHC and SSHC, so we adjusted for site of recruitment in the logistic regression. ORs and the corresponding 95% CIs were reported. Variables with \( P < .10 \) in the univariable analyses were included in the multivariable analyses. Given the different assays for gonorrhea detection used between the MSHC and SSHC, the site of recruitment was adjusted in the multivariable logistic regression for associations with oropharyngeal gonorrhea. All statistical analyses were conducted using Stata (version 14; StataCorp).

**Qualitative Study**

**Overview**

A qualitative descriptive approach was used for the qualitative study component. Qualitative description is a pragmatic rather than theory-driven approach that aims to provide a description of participants’ views and experiences rather than an interpretive, theory-driven analysis [37]. This approach is commonly used in health care when there are specific questions of clinical interest that the study seeks to answer [37].

**Participants**

Sex workers attending the MSHC who completed a HERS English-language version of the questionnaire for the case-control study were eligible for the semistructured interviews.

**Recruitment**

During the recruitment period, participants at the MSHC were shown an invitation at the end of the English-language version of the quantitative HERS questionnaire to participate in a one-on-one semistructured interview on the topics covered in the questionnaire. All participants who responded “yes” to taking part in the interviews were contacted via SMS text message (from the phone numbers listed on their medical records at the MSHC), and interviews were arranged either face-to-face or over the phone, according to participant preference, with those still wanting to participate. Written or verbal (if the interview was conducted over the phone) informed consent was obtained from participants after the study information was discussed with them.

**Data Collection**

The interview schedule was designed by the research team at the MSHC and then reviewed by the ACON Research Ethics Review Committee; the SWOP in NSW; and RhED, a service for sex workers in Victoria.

The interview schedule contained questions regarding sexual practices they performed at work that involved saliva exchange (either theirs or the clients’), as well as their use of mouthwash at work. The interview schedule was based on the case-control survey questions, allowing for further exploration and depth of understanding regarding oral sex practices that involve saliva (specifically, adding depth to the data in terms of the “what,” “how,” and “why” of these practices). Participants were given an Aus $50 (US $32.08) gift voucher after the completion of their interview (either in person or by mail in an unmarked envelope) to reimburse them for their time. All the interviews were audio recorded with the participants’ permission and transcribed verbatim. Transcripts were deidentified. Audio files and transcripts were stored on secure servers and will be destroyed after 7 years in line with Alfred Health ethics requirements.

Interviews were conducted in English by 1 of 2 researchers (TRP and KM), both of whom have experience with conducting interviews on sensitive sexual health issues. TRP sat in on the first 2 interviews conducted by KM, and the 2 researchers reviewed and discussed the interviews afterward to ensure consistency in the approach to them. TRP and KM met weekly to discuss the interviews, the interview schedule, and the developing themes. Upon completion of 12 interviews, the wider qualitative research team members (TRP, KM, and JB) met to discuss the data, the developing themes, and any further lines of questioning required. At this point, one question was added to the interview schedule to further explore a topic that some participants had touched on in the interviews. The new question concerned hypothetical willingness to change sexual practices at work if saliva was shown to transmit gonorrhea.

A total of 19 interviews had been completed when participant recruitment was interrupted by the COVID-19 pandemic. The research team met to discuss preliminary findings; it was decided that recruitment would not continue in late 2020 and 2021 due to the likely differing sex practices and risk perceptions with regard to COVID-19 as well as the ongoing COVID-19 lockdowns and restrictions causing continued disruptions in sex work and research in Australia.

According to Braun and Clarke [38], the concept of data saturation and its meaning and use depend on the purpose and goals of a study and the data analysis approach being used. While Braun and Clarke [38] argue that data saturation is not the best rationale for sample size, particularly when using a reflective thematic data analysis approach, when studies are...
conducted for largely pragmatic reasons and follow a fairly structured deductive approach to data analysis in which the data generated are relatively concrete, participants are largely recruited from a particular setting, coding largely relates to the broad topics or interview questions, and themes act largely as a summary of participants’ differing responses with little further interpretation regarding meaning, the concept of data saturation, or the point at which no “new” insights are provided, may be useful [38]. Given the deductive nature of the analysis and that the themes were largely guided by the research questions, the concept of data saturation was applied, with themes saturated among a broad sample with a range of ages, years working in the sex industry, and experiences in the context of brothel-based sex work in Melbourne. However, further insights into 2 particular groups of sex workers would have been beneficial, including those who worked outside of brothels or who were cases (diagnosed with oropharyngeal gonorrhea at the time of recruitment). For pragmatic reasons previously outlined (recruitment had to cease due to the COVID-19 pandemic), this was not possible.

**Data Analysis**

Data were analyzed using deductive thematic analysis, a “top down” approach wherein coding and analysis are largely informed by the ideas and concepts the researcher brings to the data rather than being created from the data themselves. In the case of this study, coding and themes were largely guided by the interview schedule questions and topics, which had been informed by literature in the field and the specific questions of clinical interest that the research team sought to answer [39]. Each transcript was initially read and coded by TRP. After all transcripts were coded, they were imported into NVivo (version 12; QSR International) for data management. The codes were grouped and labeled into preliminary themes before each transcript was read again, and the themes were further revised, refined, and compared for similarities and differences. A subset of transcripts was read and coded by JB and KM, after which all 3 researchers (TRP, JB, and KM) met to discuss and reach a final consensus on the themes. There were no major differences in interpretation evident.

This study is reported as per the RATS guidelines for qualitative research [40].

**Ethical Considerations**

This study was approved by the Alfred Hospital Ethics Committee, Melbourne, Victoria, Australia (project 596/17), and the South Eastern Sydney Local Health District (reference: 18/G/166). This study was also approved by the ACON Research Ethics Review Committee (reference number: 2018/17) with support from the SWOP NSW. This project was also reviewed by RhED, a service for sex workers in Victoria. As stated above, informed consent was given for the interviews and implied consent was considered by a returned completed questionnaire for the case-control study. Data presented is anonymous. Participants in the qualitative interviews were compensated Aus $50 (US $32.08). There was no compensation for participants in the case-control study.

**Results**

**Case-Control Study**

There were 386 surveys included from the MSHC, of which 23 (6%) were from cases and 363 (94%) were from controls. There were 278 surveys included from the SSHC, of which 60 (21.6%) were from cases and 218 (78.4%) were from controls (Multimedia Appendix 2). Thus, of the 664 surveys, the total number of cases was 83 (12.5%), and the total number of controls was 581 (87.5%). Of the 664 surveys included in the analysis, there were 542 (81.6%) that were returned with every section completed, 12 (1.8%) that were returned with every section except the demographics and mouthwash sections completed, and 110 (16.6%) that were returned with every section except the sex practice with clients and noncommercial partners sections completed. Being born in China or other countries aside from Thailand was associated with returning the survey with incomplete sections for sexual practices (Multimedia Appendix 3).

The median age of participants was 30 (IQR 25-36) years, and participants at the SSHC were older than those from the MSHC (median age 33 vs 28 y; \( P < .001 \); Table 1). Cases were older than controls (median age 32 vs 30 y; \( P = .01 \)).
Table 1. Risk factors for oropharyngeal gonorrhea among female sex workers recruited from 2 sexual health clinics in Australia (N=664).

</table>
There were 8.1% (54/664) transgender and gender-diverse participants. Most participants were born in Australia or New Zealand (230/664, 34.6%), followed by Thailand (166/664, 25%), China (156/664, 23.5%), and other countries (112/664, 16.9%). Overall, there were 39.2% (260/664) of participants who were newly arrived in Australia. For those cases who were born outside Australia, the median length of time in Australia was 2 (IQR 1-3) years compared to 3 (IQR 2-6) years for controls \((P=.002)\). There was no difference in the proportion of transgender and gender-diverse participants between the 2 sites (28/386, 7.3% from the MSHC vs 26/278, 9.4% from the SSHC; \(P=.33\)). Most participants from the SSHC were born in Thailand (147/278, 52.9%), China (120/278, 43.2%), or Taiwan (5/278, 1.8%); however, there were 2.2% (6/278) who were born in other countries. Most participants from the MSHC were born in Australia or New Zealand (228/386, 59.1%), followed by China (36/386, 9.3%), Thailand (21/386, 5.4%), India (7/386, 1.8%), and Malaysia (7/386, 1.8%). The remaining 22.5% (87/386) of participants from the MSHC were from 39 different countries. For those cases born outside Australia, the median length of time in Australia was 2 (IQR 1-3) years compared to 3 (IQR 2-6) years for controls \((P=.002)\). Most participants worked in only one type or venue of sex work; most worked at brothels only (336/664, 50.6%), followed by massage parlors (151/664, 22.7%) and private (72/664, 10.8%) and street-based sex work (1/664, 0.2%). There were 15.1% (100/664) of participants who worked in more than one type or venue of sex work, of which the most common combination was brothel and private sex work (56/100, 56%).

\(^a\) OR: odds ratio.  
\(^b\) aOR: adjusted odds ratio.  
\(^c\) MSHC: Melbourne Sexual Health Centre.  
\(^d\) Not applicable.  
\(^e\) SSHC: Sydney Sexual Health Centre.  
\(^f\) Variables with \(P\) values of <.10 in the univariable analyses were included in the multivariable analyses.  
\(^i\) Participants were asked to report any sex practices with male clients in an average working week.  
\(^j\) Includes 328 controls and 47 cases who did not have a noncommercial sex partner.  

Most participants worked in only one type or venue of sex work; most worked at brothels only (336/664, 50.6%), followed by massage parlors (151/664, 22.7%) and private (72/664, 10.8%) and street-based sex work (1/664, 0.2%). There were 15.1% (100/664) of participants who worked in more than one type or venue of sex work, of which the most common combination was brothel and private sex work (56/100, 56%).

Of the 578 participants who answered the question on number of male clients in an average working week, the median was 10 (IQR 6-20) clients; there was no significant difference in the number of clients between cases and controls \((P=.18; \text{Table 2})\). There were no significant differences in the proportion who performed fellatio on clients, received cunnilingus from clients, had vaginal or anal sex with clients, or had sex involving sex toys between cases and controls (Table 2). However, a significantly higher proportion of cases tongue kissed their clients (51/60, 85% vs 348/494, 70.4%; \(P=.02\)), performed condomless fellatio on clients (48/65, 74% vs 144/490, 29.4%; \(P<.001\)), and had condomless vaginal sex (17/60, 28% vs 78/470, 16.6%; \(P=.03\)) and condomless anal sex (10/18, 56% vs 56/183, 30.6%; \(P=.03\)) with clients in an average working week.
Table 2. Number of male clients seen in an average working week among female sex workers by cases with oropharyngeal gonorrhea and controls (N=664).

# Qualitative Findings

## Overview

In total, 9.5% (63/664) of sex workers indicated interest in participating in the interviews and were contacted by a research nurse at the MSHC. When contacted, of the 63 sex workers, 28 (44%) at the MSHC agreed to participate and scheduled a time for the interview; however, 9 (32%) did not attend their scheduled interview and could not be reached to reschedule. In total, 19 participants completed interviews before data collection was discontinued. The age of the 19 participants ranged from 18 to 44 years, with a median of 28 (IQR 24-31) years (Table 3). The duration of interviews ranged from 24 to 61 minutes, with a median of 41 minutes. One participant in the qualitative interviews was a case in the case-control group, whereas the rest were from the control group.
Table 3. Participant demographics for the qualitative interviews among female sex workers recruited from the Melbourne Sexual Health Centre (N=19).

The qualitative data were organized into six descriptive themes related to the kissing and oral sex practices and mouthwash use among sex workers (Textbox 1): (1) the “how” and “why” of kissing clients, (2) always covered—fellatio with clients, (3) not so risky—uncovered cunnilingus from clients, (4) clients’ saliva as lubricant is a “no go,” (5) pleasure with clients—a “perk” or not part of the job, and (6) mouthwash use with clients—a freshener and germ killer.
Textbox 1. An overview of female sex worker practices—the what, the why, and the how from semistructured interviews with 19 female sex workers recruited from the Melbourne Sexual Health Centre.

**Kissing (theme 1: the “how” and “why” of kissing clients)**

- Very common in some form
- Sex worker initiated
  - Typically closed mouth or shallow
  - To improve relationship with regular clients
  - To facilitate a more intimate experience
  - Pressured by client demand and availability
- Client initiated
  - Often negotiated before encounter
  - Commanded higher premium

**Expectations for clients**

- Good oral hygiene
- Sobriety

**Performing oral sex (fellatio; theme 2: always covered—fellatio with clients)**

- Very common
- Condoms used always
  - Perceived as “high risk”
  - Reduce sexually transmitted infection (STI) risks
  - Legal requirements
  - Public health campaigns
- Client pressure
  - Financial incentive
  - Waiting until the encounter had begun

**Receiving cunnilingus (theme 3: not so risky—uncovered cunnilingus from clients)**

- Very common
- Dental dams never used
  - Perceived as “low” or “no risk”
  - Detracts from client experience
  - Difficult to use
  - Not common or industry standard
  - No public health campaigns

**Saliva as lubricant (theme 4: clients’ saliva as lubricant a “no go”)**

- Uncomfortable with client using saliva as lubricant
  - Perceived as “high risk”
  - Disgusted by the idea
  - Not as effective as actual lubricant
- May sometimes use their own saliva as lubricant
  - Not preferred over actual lubricant
The How and Why of Kissing Clients

All participants in the qualitative interviews (19/19, 100%) reported kissing at least some of their clients; however, the style of kissing varied from closed-mouth kissing (“pecks”) and shallow tongue kissing to deep tongue kissing. For most participants, whether they kissed clients depended on whether the client requested the service before the booking as it entails an additional cost, although there were a few participants who reported reserving kissing for regular clients, those they judged to have good oral hygiene (ie, clean teeth), or those not visibly intoxicated.

The style and duration of kissing was most often dictated by the client’s preference and initiation, with almost half of participants describing following the clients’ lead:

- Will use out of convenience

Pleasure with clients (theme 5: pleasure with clients—a “perk” or not part of the job)

- Does not influence which sex practices are engaged in
- Some feel that it is not possible to feel pleasure with clients
  - Compartmentalizing as “work” and not for enjoyment
  - Lack of emotional connection
- Pleasure infrequent but can impact kissing and cunnilingus
  - May kiss for longer or deeper
  - May allow client to kiss or perform cunnilingus despite not paying for the service
- More enjoyment over time
  - More confident and relaxed with clients

Using mouthwash (theme 6: mouthwash use with clients—a freshener and germ killer)

- Routinely used by some female sex workers
  - Freshen up before the booking
  - Kill any germs they may have picked up from the client after the booking
  - As a matter of routine to “clean the slate” before the next client
- Occasionally used by some female sex workers
  - When they feel their breath needs to be freshened up before a booking
  - After a booking if left with unclean feeling
- Some never use mouthwash at work
  - Believe it is bad for oral health
- Most prefer that clients use mouthwash before the booking
  - Freshen breath
  - Perception that it makes client less likely to transmit germs
  - Brothel provides mouthwash
  - Expectation that client uses mouthwash and showers before the booking

So, it’s because they’re paying for it, it’s how they’re wanting that to happen. I’ll generally—if I’m doing the instigation of the kissing, it will usually be more pecking than full tongue. But there will still be saliva on the lips and that sort of thing. Then it’s up to them how they want to take it further. I continue on the line that they’re taking things. [Participant 5; aged 30 years; less than a year in the sex industry; brothel based]

Other participants did not allow the client to dictate kissing style; instead, they reported efforts to avoid deep kissing with clients, such as kissing with closed teeth or telling the client to use less tongue. Some described general discomfort with deep kissing clients, including one who felt that it was too intimate for work:

I just find the sharing of that much saliva is a bit...too...it’s a bit too intimate for just my work...
While participants commonly stated that pay was the only factor in deciding to kiss a client or not, there were several who felt pressured to agree to kiss clients to compete with other sex workers for clients. However, a couple of participants felt that kissing clients enhanced the booking in terms of making the service feel more genuine as well as allowing them to engage with the client in a more natural way.

**Always Covered: Fellatio With Clients**

All participants (19/19, 100%) described performing oral sex (fellatio) on some clients, and all (19/19, 100%) reported always using condoms for this practice. Almost all participants reported that the main reason for using condoms during fellatio was for safety as they did not want to contract an STI in the throat, whereas almost half of participants reported using condoms due to the legal requirement. One participant shared the following:

> Because it’s the law and I want to be really safe. That’s not—if I—I’ve had many, many, many people try to get it without a condom, but I don’t know these people. I don’t know where they’ve been. I need that protection. [Participant 9; aged 18 years; less than a month in the sex industry; brothel based]

Many of these participants described seeing posters in their workplaces that caution against performing fellatio on clients without a condom. Some participants reported receiving pressure from clients to perform oral sex without a condom, most often after the booking had commenced and they were alone in the room. Several participants reported men offering to pay more for a “natural” (condomless) fellatio service, and while reportedly declining these requests, several also said that they knew of other sex workers in their workplaces who accept these offers for more pay.

**Not So Risky: Uncovered Cunnilingus From Clients**

All participants except one reported having some clients perform oral sex (cunnilingus) on them, and none reported using a dental dam for this practice. Reasons for not using a dental dam varied, but the common sentiment among participants was that cunnilingus did not seem to place them at as much risk of STIs compared to them performing condomless fellatio on clients:

> I’ve heard it’s [cunnilingus] more likely to affect them more than me. That’s what I’ve been told anyway. So it’s like their risk, not mine and I know I’m clean, because I get tested all the time. [Participant 6; aged 26 years; 6 years in the sex industry; massage parlor]

Other reasons for not using a dental dam revolved around the dental dam detracting from the experience for the client. Many participants described dental dams as being difficult to use and anticipated that enforcing clients to use one would deter them from booking services with them and, ultimately, lead to less bookings. Several participants commented that it was not industry standard to use dental dams and there were no posters warning sex workers to use them for oral sex like there were for condoms.

**Client’s Saliva as a Lubricant a “No Go”**

With few exceptions, almost all participants were uncomfortable having a client use their own saliva as lubricant for sex, though several described previously having clients spit on their hands and touch the participants’ genitals without asking first and before they could be stopped. Reasons for not being comfortable included a fear of contracting STIs from the client’s saliva, preferring actual lubricant over saliva in general as it is more effective, and being generally disgusted by the client’s saliva. One participant said the following:

> Um, it’s [client’s saliva] kind of gross I guess it’s kind of a bit sticky and not very, yeah, not very effective. [Participant 4; aged 21 years; less than a year in the sex industry; brothel based]

In general, most participants described preferring actual lubricant during sex for its effectiveness over using their own saliva as lubricant with clients. However, there were several participants who were comfortable using their own saliva on occasion. Among these participants, saliva was only used as lubricant because of the convenience, with most still preferring lubricant if it was on hand.

Participants were not explicitly asked to reflect on why they might be comfortable with a client performing cunnilingus on them without a dental dam but not having a client use their saliva as a lubricant for vaginal sex. However, several participants raised this of their own accord. For one participant, the reasoning for this was because the saliva used as a lubricant would go inside her body, whereas she imagined that the client’s saliva during cunnilingus is not necessarily “inserted” into her vagina.

**Pleasure With Clients: A “Perk” or Not Part of the Job**

Most participants felt that their pleasure in a booking would not influence their decision to engage in oral sex practices with clients but rather was seen as a fringe benefit:

> No, not really. If I’m enjoying it, then I’m enjoying it, and that’s just a lucky perk. I wouldn’t stray from my boundaries just because they’ve kind of sprung something on me or whatnot. My service is my service and I stick to it. [Participant 12; aged 26 years; 8 years in the sex industry; brothel based]

Of these participants who said that pleasure was not a factor in their decision to engage in oral sex practices with clients, several felt that actually feeling pleasure from sex work was not possible as they compartmentalized it as work rather than for enjoyment. Others felt that pleasure during sex work was not possible due to the lack of emotional connection:

> I find that I, um, even if I have like the best client in the world, I’m never gonna, like have a pleasurable experience at work, because you’re always just like, on your guard a little bit, and you’re, I’m at work, you know...like I’m like just totally zoned out (laughs) Like they don’t think that, but I’m like thinking about what I’m going to eat for dinner, and, just like whatever, and so...I’ll never be like “I-I really wanna do this thing, and like get pleasure out of this” that
will never happen...But, I will definitely make choices to avoid, like, things that I know I definitely don’t like. [Participant 2; aged 26 years; 2 years in the sex industry; brothel based]

However, there were several participants for whom their pleasure, while infrequent with clients, could influence the duration or style of sex practices with clients, most notably kissing and cunnilingus (but not condom use). These participants described kissing for longer or deeper if they were enjoying the service with the client and, in some cases, allowing the client to kiss or perform cunnilingus on them if they had not paid for the service or simply to perform cunnilingus on them for longer if it was enjoyable:

...like if it was someone where there was a lot of saliva and it wasn't really feeling very good, I probably would let them do that for a while and then I’d just sort of be like “oh, it’s your turn now.” But if I’m having a really good time and it’s feeling really great, I’m not going to interrupt, and stop that person from what they’re doing sooner, if it means that I might get to have a really great time or even reach climax. You just kind of go along with it a bit more when it’s like, a really good time. But not to the point where I would, you know, not to the point where I would have unprotected oral sex on them, or oral, or vaginal sex with me. [Participant 14; aged 32 years; 2 years in the sex industry; brothel based]

Among the participants who felt that their pleasure sometimes influenced their oral sexual practices with clients, all but one stated that sex work became more enjoyable over time after they became more confident in their work:

[I enjoy it more now] Because I’m more relaxed with my clients, I’m more confident and experienced and I like to connect with them. Whereas before, I was like I don’t want to get to know you, but now I pretty much make friends with all my clients, so it’s more enjoyable. [Participant 7; aged 24 years; 4 years in the sex industry; brothel based]

**Mouthwash Use With Clients: A Freshener and Germ Killer**

Almost half of the participants reported using mouthwash before and after clients at work as a matter of routine. The main reason for using mouthwash before a client was to freshen up their breath before the booking. The main reason for using mouthwash after a client was to kill any germs they might have gotten from the client during the booking, particularly germs that cause bad breath and the common cold; however, gonorrhea was also occasionally mentioned. The other reason was to “clean the slate” for the next client; using mouthwash helped them feel refreshed and ready to see the next client:

...when I use mouthwash and redo my make-up, it’s like okay, that client’s finished, done with, go out and I’m ready to present again for the next client. [Participant 9; aged 18 years; less than a month in the sex industry; brothel based]

The remaining half of participants used mouthwash less routinely and tended to use it before a booking if they felt that they needed to freshen their breath or after a client who was a smoker or had left a feeling of uncleanness in their mouth. There were only a few participants who never used mouthwash at work, and these participants did not believe mouthwash was good for their oral health.

Most participants preferred clients to use mouthwash before bookings so that they had fresher breath and were less likely to transmit germs. Generally, for these participants, the brothels provide mouthwash and disposable cups for clients to use, and the mouthwash is poured and waiting for them when they enter the room for the booking. In this way, the participant does not have to ask the client to use mouthwash directly, which several described they would feel too uncomfortable doing as it might be considered rude. However, several others reported that they did not hesitate to ask clients to use the mouthwash if they noticed that it had not been used or if their breath smelled.

One participant, the only participant in our interviews who was a case upon recruitment (had oropharyngeal gonorrhea), made clients use a “cocktail” of mouthwash she brought from home for a full minute that combined Betadine, an antibacterial sore throat gargle, with Cepacol, an antibacterial mouthwash, which she used before and after every client as well. This participant had been using this “cocktail” of mouthwash before every client for 2 months before she became infected with oropharyngeal gonorrhea. This participant did not have outside-of-work sexual partners and did not perform fellatio without a condom with clients, nor did she report any other oral sex practices (ie, rimming or spit play) aside from tongue kissing. She felt that her “cocktail” of mouthwash kept her safe from germs that cause colds and gave her the security to engage in “passionate” tongue kissing that she felt gave her a competitive edge over other sex workers:

Like, if I don’t kiss at all, even lips, they will feel like “oh, this girl, she’s terrible, I’m not coming back” Like how can I have a passionate moment if I don’t kiss, you know? I try to trick them, like, oh it’s a passionate kissing without opening my mouth, you know what I mean? But like, if I do kiss with tongue, they love it. Like, they fall in love, they will always come back, and they will tell their friends, so their friends will come. Like most of my regular clients, I get them because of that, that treatment, you know? But obviously I won’t do that to someone I don’t feel comfortable. But it does help me to make a lot of money, you know. Have a lot of clients, and regular clients. And you know what because I do the mouthwashing, I ask them to do, I put hand sanitizer in their hands, I mean I ask them to use, they have a perception that I am a very clean person as well, and they always feel safe with me as well, you know? [Participant 17; aged 33 years; 2 years in the sex industry; brothel based]
Discussion

Principal Findings

This mixed methods study identified risk factors for oropharyngeal gonorrhea among sex workers in Australia’s 2 most populous cities, and it provided some explanations for the factors and forces that underpin oral sex and mouthwash practices. Our findings show that performing condomless fellatio on clients is associated with oropharyngeal gonorrhea. Furthermore, sex workers frequently tongue kiss clients as previously reported [16,41], yet this practice was not a significant risk factor for oropharyngeal gonorrhea. From our interviews with sex workers in Melbourne, almost all reported kissing clients due to demand for “the girlfriend experience” and generally reported following the client’s lead with regard to kissing style and duration. However, they used condoms for fellatio, often citing that it is illegal not to in Victoria, and they considered condomless fellatio a risky practice for contracting STIs, unlike cunnilingus without a dental dam. Client saliva use as a lubricant was similarly often viewed as risky and “gross” even among those who engaged in cunnilingus with clients without a dental dam.

Our study showed high proportions of condom use among sex workers for fellatio with clients. Previous studies have reported that 79% [16] of female sex workers in Melbourne and 75% of female sex workers in Sydney used condoms for all fellatio activities with clients in an average working week [35] in the previous 3 months. It is possible that sex workers who are not attending sexual health clinics routinely may practice condomless fellatio more often with clients. One study from Sydney in 2017 examining advertisements for private sex work found that half of the female sex workers with web-based profiles were offering condomless fellatio (170/339, 50.2%) [42]; however, it is not clear how often these sex workers actually practice condomless fellatio in an average working week.

In our multivariable analysis, kissing was not a significant risk factor for oropharyngeal gonorrhea; however, it should be noted that the adjusted OR of having oropharyngeal gonorrhea was 1.5 (95% CI 0.7-3.5) among sex workers who tongue kissed male clients compared to those who did not tongue kiss male clients. The OR was >1 even though it was not statistically significant, suggesting that kissing could be a potential risk factor for oropharyngeal gonorrhea and may have some clinical and public health implications. The non–statistically significant result may be due to the limited sample size to have sufficient power to detect the difference as the study was ceased earlier due to the COVID-19 pandemic. Given the overlapping nature of sex practices, particularly kissing, this is a common issue when determining risk factors for oropharyngeal gonorrhea [9]. It is interesting to note that the one case who was interviewed for the qualitative study had only reported tongue kissing clients in the previous 2 weeks as a risk factor for oropharyngeal gonorrhea as she did not have condomless fellatio with clients or engage in other practices with clients that involved saliva and she had no noncommercial sexual partners. However, previous research has found kissing to be a risk factor for oropharyngeal gonorrhea among men who have sex with men, and performing fellatio was not [8]. This is likely due to differences in testing practices and risk perceptions among men who have sex with men compared to heterosexual men, who are more likely to be clients of the sex workers in our study.

There have been previous case reports and epidemiological studies suggesting that tongue kissing can transmit oropharyngeal gonorrhea [8,43,44]. It is also interesting that this participant was diligent about using and having her clients use a particular cocktail of mouthwash (Betadine and Cepacol) before each booking, and after the booking in her case, because she was afraid of catching a cold from a client and having to take time off work. While investigations are being made into the role of Listerine [22,23], no studies to our knowledge have investigated the role of antibacterial mouthwashes such as Betadine and Cepacol in the transmission of gonorrhea. It is possible that the mouthwash cocktail she was using with her clients altered her oral microbiome in an unfavorable way and increased her odds of contracting gonorrhea. A previous study examining the incidence of syphilis among 96 men who have sex with men in Indonesia (2019) found that using antibacterial mouthwash containing chlorhexidine increased the odds of syphilis acquisition, and it was similarly suggested that this could be due in part to changes in the oral microbiome [45]. An Australian clinical trial has shown that daily use of Listerine or Biotene for 12 weeks had no significant effect on the oral microbiome [46]; however, no study to our knowledge has examined the effect of Betadine and Cepacol used in combination on the oral microbiome. In any event, it is clear from our interviews that, for some sex workers, mouthwash use gives the feeling of protecting against bacteria and viruses and is thus used as a safety precaution (in addition to being widely used for hygiene purposes), therefore establishing that the role of mouthwash use with regard to gonorrhea prevention is important to inform best practice.

Our findings from the case-control study that frequent mouthwash use was not associated with oropharyngeal gonorrhea positivity are consistent with those of a previous study among men who have sex with men that found no association between using any mouthwash daily and oropharyngeal gonorrhea positivity [47]. The duration and method of using mouthwash (ie, rinsing or gargling) can vary between individuals, and it remains to be seen whether duration and method could influence the ability of mouthwash to reduce the amount of gonorrhea bacteria in the oropharynx. Among a study of at-risk populations for oropharyngeal gonorrhea, female sex workers used mouthwash for the shortest duration (median 14 seconds); however, this was not a significant difference [48]. Future recommendations with regard to mouthwash use in this population, should it be found to be beneficial for reducing gonorrhea transmission, should take into account duration and method of use.

Our results showed no significant difference between controls and cases in the number of clients on whom they performed fellatio. A previous case-control study among men who have sex with men in Melbourne (2018) found that the number of casual partners in the previous 3 months was an independent risk factor for oropharyngeal gonorrhea [9]. When limiting our
analysis to only those sex workers who reported performing fellatio on clients (excluding those who did not perform this activity in an average working week) during an average working week, cases had fewer clients with whom they engaged in fellatio (median 5 for cases; median 7 for controls; \( P = 0.01 \); data not shown in the Results section). It is possible that female sex workers who perform condomless fellatio on clients see fewer clients in an average working week given that they may make more money per client offering this service compared to only offering fellatio with a condom as some participants in the qualitative interviews reported being offered more money by clients to perform “natural” or condomless fellatio (though none of our participants reported accepting these offers, in part due to concerns over STI transmission). It is also possible that having fewer clients is part of a risk reduction strategy among female sex workers who perform condomless fellatio. Further research is required to investigate why female sex workers who offer condomless fellatio might perform fellatio on fewer clients than those who do not.

There was a higher proportion of cases who reported tongue kissing clients in an average working week compared to controls (51/60, 85% of cases tongue kissed clients in an average working week compared to 348/494, 70.4% of controls). In contrast to performing fellatio on clients, among those who said yes to kissing clients, there were no differences in the number of clients that cases tongue kissed in an average working week compared to controls. In our study, there were 60.1% (399/664) of female sex workers who answered yes to kissing clients in an average working week, which is lower than what a cross-sectional survey of female sex workers from the MSHC in 2018 found (83.7%) [16]. This could be in part due to recruitment for this study occurring at 2 sites and including a higher proportion of non-Australian female sex workers as the 2018 study showed that Asian language–speaking female sex workers were significantly less likely than English-speaking female sex workers to tongue kiss clients [16]. Female sex workers recruited from the SSHC and those born in China, Thailand, or other countries were less likely than those recruited at the MSHC and those from Australia or New Zealand to report tongue kissing (data not shown).

For some participants in our qualitative interviews, kissing and cunnilingus were the only sexual practices that might be influenced by how much pleasure the sex worker was experiencing during the booking, though pleasure impacting these behaviors was generally reported as a rare occurrence. These participants described kissing for longer or deeper if they were enjoying the booking. However, most of the participants in our study described experiencing pleasure at work as an infrequent or nonexistent occurrence. There has been limited research into pleasure for sex workers during sex work. A previous qualitative study of 9 female sex workers in Victoria explored this concept and reported that, for some women, sexual pleasure was possible with a client only after developing intimacy through seeing them multiple times; however, this study was exploratory and specifically recruited women who had positive experiences of sex work [49]. Further research could clarify the extent to which sex workers experience sexual pleasure at work and whether this impacts sexual practice.

The main limitation to this study is that most of the cases were recruited from one clinic (SSHCL) and epidemiology may vary due to environmental and spatial factors. There was also a noted delay in recruiting cases at MSHC compared to SSHCL, which could indicate a higher rate of declining to participate. One reason for this may be the varying laws regarding sex work in the state of Victoria versus NSW, whereby performing condomless oral sex was illegal in Victoria but not in NSW. This may have been a deterrent for taking part in this study as participants may not have felt comfortable reporting any sex practices that were illegal. Previous research has shown that regulated and criminalized sex work often discourages female sex workers to seek health care [50], so it could be that they are less likely to disclose their sex practices to clinicians, which would make it difficult to assess risk. Despite a slower recruitment of cases from the MSHC, among those sex workers who participated in the survey, participants from the MSHC were no more likely to decline to report sexual practices compared to those from the SSHC after adjusting for oropharyngeal gonorrhea diagnosis, age, and country of birth. Only being born in China or other countries aside from Thailand and New Zealand was associated with declining to report sex practices on the survey.

Another limitation of this study was that our convenience sampling may have created a bias toward those who attended sexual health clinics for HIV and STI screening (or presented with symptoms), and this may not be generalizable to the entire sex worker population, including those who did not attend a sexual health clinic. Most of our participants worked in brothels and massage parlors, and only 0.2% (1/664) participated in street-based sex work; thus, the findings may not be generalizable to those engaging in street-based sex work.

A final limitation of this study is that interviews for the qualitative component were only offered in Victoria due to the financial and logistic difficulties of the interviews being conducted only in English and by researchers based only at the MSHC. However, similar to all qualitative data, the qualitative component was not meant to be generalizable to the wider population of sex workers. Rather, this component of our study provided additional depth and understanding to the data collected in the quantitative component among Melbourne-based female sex workers. These interviews were also cut short due to the COVID-19 pandemic; however, sufficient meaning was generated from the data to answer the questions of clinical interest.

The availability of phone interviews in combination with face-to-face interviews can be considered a strength of our study as it allowed participants to freely disclose personal and sensitive information. We found that our interviews over the phone provided rich data that were comparable to, and in some cases deeper, than those from our face-to-face interviews. Allowing the option of phone interviews, particularly asking the participants to select a phone or face-to-face interview upon recruitment, likely encouraged a wider array of participants as it is possible that some participants who would have been uncomfortable with a face-to-face interview opted to share their experiences over the phone rather than declining to participate. Our findings in this case reflect those of other studies that have
shown no difference in data quality between phone interviews and face-to-face interviews [51,52].

Conclusions
Our study shows that condomless fellatio is a risk factor for oropharyngeal gonorrhea among sex workers despite most sex workers using condoms with their clients for fellatio. Novel interventions, particularly targeting the oropharynx, will be required for oropharyngeal gonorrhea prevention.

Acknowledgments
The authors acknowledge the contributions of the participants in the case-control and qualitative components of this study and thank them for their time and insights. The authors would like to acknowledge the Sex Workers Outreach Project and Resourcing Health & Education for their assistance in reviewing the case-control questionnaire and the qualitative interview schedule. They would also like to acknowledge Mark Chung for designing the study graphics, Sabrina Trumpour for assistance with data entry and transcription, Sandra Walker for her help in drafting the study questionnaire, and Jana Sisnowski for her help preparing the study documents for the Sydney Sexual Health Centre (SSHC). The authors would also like to acknowledge Maggie Ma and Birdie Thirapat at the SSHC and the clinicians at the SSHC and the Melbourne Sexual Health Centre for their help recruiting participants for the Health Research in Sex Workers study. EPFC and JJO are supported by an Australian National Health and Medical Research Council (NHMRC) Emerging Leadership Investigator Grant (GNT1172873 and GNT1193955, respectively). CKF is supported by an NHMRC Leadership Investigator Grant (GNT1172900). JEB is supported by an ARC Discovery Early Career Researcher Award grant (DE200100049). BD is supported by an NHMRC Practitioner Fellowship (GNT1154828).

Data Availability
The data sets generated during and analyzed during this study are not publicly available due to ethics requirements considering the confidential nature of patient data. Further information can be obtained by contacting the Alfred Hospital Ethics Committee, Melbourne, Victoria, Australia (project 596/17).

Authors' Contributions
TRP, CKF, AM, BD, RG, RV, DC, JEB, and EPFC were involved in study conceptualization and design. KM, RM, and RW were involved in study recruitment and management. TRP and KM conducted the interviews. TRP analyzed the data and wrote the first draft of the manuscript. JEB and EPFC provided supervision. All authors were involved in manuscript revision.

Conflicts of Interest
None declared.

Abstract

Background: Prepandemic sentinel surveillance focused on improved management of winter pressures, with influenza-like illness (ILI) being the key clinical indicator. The World Health Organization (WHO) global standards for influenza surveillance include monitoring acute respiratory infection (ARI) and ILI. The WHO’s mosaic framework recommends that the surveillance strategies of countries include the virological monitoring of respiratory viruses with pandemic potential such as influenza. The Oxford-Royal College of General Practitioner Research and Surveillance Centre (RSC) in collaboration with the UK Health Security Agency (UKHSA) has provided sentinel surveillance since 1967, including virology since 1993.

Objective: We aim to describe the RSC’s plans for sentinel surveillance in the 2023-2024 season and evaluate these plans against the WHO mosaic framework.
Methods: Our approach, which includes patient and public involvement, contributes to surveillance objectives across all 3 domains of the mosaic framework. We will generate an ARI phenotype to enable reporting of this indicator in addition to ILI. These data will support UKHSA’s sentinel surveillance, including vaccine effectiveness and burden of disease studies. The panel of virology tests analyzed in UKHSA’s reference laboratory will remain unchanged, with additional plans for point-of-care testing, pneumococcus testing, and asymptomatic screening. Our sampling framework for serological surveillance will provide greater representativeness and more samples from younger people. We will create a biomedical resource that enables linkage between clinical data held in the RSC and virology data, including sequencing data, held by the UKHSA. We describe the governance framework for the RSC.

Results: We are co-designing our communication about data sharing and sampling, contextualized by the mosaic framework, with national and general practice patient and public involvement groups. We present our ARI digital phenotype and the key data RSC network members are requested to include in computerized medical records. We will share data with the UKHSA to report vaccine effectiveness for COVID-19 and influenza, assess the disease burden of respiratory syncytial virus, and perform syndromic surveillance. Virological surveillance will include COVID-19, influenza, respiratory syncytial virus, and other common respiratory viruses. We plan to pilot point-of-care testing for group A streptococcus, urine tests for pneumococcus, and asymptomatic testing. We will integrate test requests and results with the laboratory-computerized medical record system. A biomedical resource will enable research linking clinical data to virology data. The legal basis for the RSC’s pseudonymized data extract is The Health Service (Control of Patient Information) Regulations 2002, and all nonsurveillance uses require research ethics approval.

Conclusions: The RSC extended its surveillance activities to meet more but not all of the mosaic framework’s objectives. We have introduced an ARI indicator. We seek to expand our surveillance scope and could do more around transmissibility and the benefits and risks of nonvaccine therapies.

Introduction

Prior to the COVID-19 pandemic, sentinel surveillance was orientated toward influenza and its associated winter pressures [1-6]. It has subsequently evolved to include a systematic collection of acute respiratory infections (ARIs) and a wider range of indicators. The World Health Organization (WHO) Global Influenza Surveillance and Response System (GISRS) was launched in 1952 to provide a global response to influenza and other respiratory infections [7,8]. The focus of the GISRS and other national surveillance networks is seasonal influenza monitoring and associated vaccination effectiveness studies [9,10], as well as pandemic preparedness [11,12]. Viral testing became an essential component, with serosurveillance introduced into some systems [13]. Prepandemic virological testing was largely carried out in the winter season with influenza-like illness (ILI) as the key clinical indicator of community influenza infection [14]. In addition to ILI, ARI started to be used by the European Centre for Disease Prevention and Control as a surveillance indicator [15,16]. The WHO 2013 global epidemiological standards for influenza surveillance proposed the use of severe ARI (SARI) as an indicator. SARI is defined as an incident ARI in a person admitted to a hospital [17,18]. The WHO mosaic framework suggests sentinel ILI, ARI, and SARI surveillance as the core approach for monitoring the epidemiological characteristics of respiratory viruses in interpandemic periods [16].

Subsequent to the COVID-19 pandemic, the WHO published its mosaic framework for respiratory disease surveillance [16,19]. It recommended that the surveillance strategies of countries include the virological monitoring of influenza, SARS-CoV-2, respiratory syncytial virus (RSV), and other viruses with pandemic potential. The mosaic has a broad framework and includes 14 surveillance objectives set out across three domains: (1) detection and assessment of respiratory viruses; (2) monitoring their epidemiological characteristics; and (3) informing on the use of health interventions [16,19].

The Royal College of General Practitioners (RCGP) has been collecting data about respiratory and other infections in England in its epidemic research center since 1957 [20]. This research center became rebranded as the RCGP Research and Surveillance Centre (RSC) and has been conducting sentinel surveillance since 1967 [21], in collaboration with the UK Health Security Agency (UKHSA) and its predecessor bodies. The RSC has included reference laboratory virology since the 1993-1994 season [22]. The network has grown to almost 2000 practices in England and Wales (31.6% of the active practices) with a contemporary extract of over 19 million patients (31.9% of the England and Wales population) in 2023 [23].

This protocol describes the Oxford-RCGP RSC’s plans for the 2023-2024 sentinel surveillance season and evaluates them against the WHO mosaic framework. The RSC will be offering all-year-round virology and sentinel surveillance of respiratory infections in collaboration with the UKHSA. Our extended surveillance includes the adoption of SARI as an important severity indicator, alongside ILI and other components of the WHO mosaic framework.

The objectives are as follows: (1) describe the planned patient and public involvement (PPI) with the RSC, with the aims of improving public understanding of the RSC’s program and co-designing changes to our sentinel surveillance; (2) develop
an ARI digital phenotype and contemporaneously report the incidence of ARI and SARI, including new severity indicators, using primary care data; (3) collect and share high-quality data to support vaccine effectiveness (VE) studies for COVID-19 and influenza vaccines in the coming season and enable the reporting of RSV’s disease burden; (4) ensure that the volume of virology and serology sampling from member practices following our sampling framework is sufficient to determine VE by vaccine type and has the minimum required clinical data recorded; (5) introduce technological developments by using general practitioner (GP) and laboratory links to support virology and serology sampling, establishing a messaging system to enable more representative sampling and targeted sampling when required, increasing point-of-care testing (POCT) capability, piloting virology sampling from asymptomatic individuals, and testing for pneumococcus infection; (6) create a biomedical resource that provides a unique longitudinal clinical resource and enables genomic surveillance by linking individual-level human phenotypes to the genomic sequences of viruses detected in those individuals; and (7) describe the legal basis and governance framework for conducting sentinel surveillance.

Methods

Comparison With the WHO Mosaic Framework

We describe our approach to sentinel surveillance in functional components. Many of these, such as PPI, span across all of the mosaic’s sentinel objectives. Others sit outside or beyond its scope, for example, bacterial causes of infection and information governance requirements. We conclude the results section with a table summarizing the surveillance objectives achieved and those to be delivered beyond its scope.

PPI Group

We will use 2 channels of PPI and engagement within the RSC. The first channel is with national PPI groups, the Health Data Research-UK and the RCGP Patient and Carer Participation Groups. Additional national patient representatives will be recruited from the People in Research portal of the National Institute for Health and Care Research [24] to ensure geographical representation across England. The second channel includes local patient participation groups of general practice members of the RSC network. Opportunities for patients to provide feedback will be communicated to all network practices in England.

We will invite patient representatives to participate in 2 meetings per year held with the UKHSA and Oxford-RCGP RSC. The meetings aim to raise awareness of surveillance, including its use of patient data, and to gain input on the RSC’s work, particularly on optimizing the acceptability of sampling and the feedback of results. PPI feedback will be used mainly to improve communication with patients, but may inform other areas of the surveillance. We will send a monthly newsletter covering topics and findings related to surveillance to increase transparency and patient engagement (Multimedia Appendix 1). We will use the cube framework to plan and evaluate PPI [25]. To improve transparency in reporting PPI and its impact, we will use a standard international guideline (GRIPP2 checklist) [26].

ARI Phenotype

A digital phenotype is a set of rules that allows the identification of cases, such as ILI or ARI, from the computerized medical record (CMR) [27]. At the RSC, we have a well-established digital phenotype for ILI. To bring our strategy in line with the most recent WHO recommendations, we are developing a new ARI phenotype for the coming season.

The phenotype is being built around Systematized Nomenclature of Medicine (SNOMED) Clinical Terms (CT) as this is the medical terminology mandated by the National Health Service (NHS) and used by all primary care providers [28]. The phenotype consists of code lists representing common conditions that make up the ARI concept. This allows the identification of ARI events coded by member practices in the CMR.

We plan to build on the ARI phenotype by characterizing the nature and severity of ARI events. We will do this by exploring primary care codes recorded in association with ARI and by linking the primary care data to secondary care records [29,30]. We differentiate ARI from SARI by checking whether ARI leads to hospitalization, as recorded in the CMR.

Our phenotype development uses the Phenotype Execution Modeling Architecture (PhEMA) toolkit [31]. The Health Level-7 Fast Healthcare Interoperability Resources (FHIR) is a global standard for passing health care data between systems [31] and is used by the NHS. The PhEMA comprises developing an ontological layer using clinical query language and then presenting a “code list” using the Health Level-7 FHIR value set format or as a SNOMED CT refset. For example, the SNOMED clinical term “Lower respiratory tract infection (disorder)” (SCTID: 5041700) has 10 child codes (also known as subtypes), which are all automatically included. If extra child codes are included, they will automatically be included in our definition, unlike the extensional process where “code lists” need frequent review [32]. We have a “Helper Tool” developed in-house to facilitate the selection of SNOMED CT (Figure 1).
Figure 1. Tool used to facilitate the intentional identification of Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) refsets. The lower figure demonstrates how SNOMED CT supertypes and subtypes are included or excluded using the Helper Tool.

High-Quality Data to Support Influenza and COVID-19 VE and Other Studies

We will collect and share high-quality data, such as primary care CMR and vaccine exposure data, to support VE studies for COVID-19 and influenza vaccines and enable the reporting of RSV’s disease burden in the coming season. We will focus on the data collection areas that need better data quality as follows: (1) Identifying and coding cases of ARI, SARI, and ILI as a problem title in CMRs, including whether these are first or new episodes [33]; (2) Consistent capturing of symptoms, signs, and any markers of severity upon the presentation of people with ARI; (3) Complete recording of vaccine exposure data, particularly for influenza and COVID-19 vaccines, but other vaccines, such as pneumococcus, may be relevant; (4) Complete recording of sociodemographic and comorbidity data; and (5) Recording of outcomes in both primary care and linked secondary care data sets. This is particularly important for people who have had virology sampling (see the next section) and practices that are incentivized through data quality payments.

We also need sufficient data (ie, sample size) to support UKHSA’s syndromic surveillance [34,35], our Weekly Return [36,37], and our Annual Report [38]. The Weekly Return and Annual Report will be in their 56th year of production. This will set out to make the network as nationally and regionally representative as possible by recruiting additional practices, particularly to improve virology sampling.

Virology and Serology Sampling and Testing

We collect serology samples from volunteer patients who are attending their practice for a routine blood sample appointment by asking them to contribute one more blood sample to the serology surveillance. Patients are invited through messages before their routine blood tests and are provided a link for further information about the serology surveillance. Verbal consent is taken from the patients before the sampling. We aim to collect 500 serology samples per month from each of the 3 age groups (younger than 18 years, 18 to 64 years, and 65 years or older) with representative sampling across the network. We plan to divide the younger than 18 years age group based on immunization age groups in the future to allow more granular information to be collected. Serology samples are batch processed in different labs depending on operational needs, for example, understanding vaccine waning in immunocompromised people.

We collect virology samples (nasal and pharyngeal swabs) all year round from patients who present ILI or ARI symptoms to general practices and meanwhile capture their symptom onset day. We aim to reach 1000 samples per week every week in the coming year. Virological samples collected in RSC surveillance practices are analyzed in UKHSA’s respiratory virus reference laboratory in Colindale, London. Practices code the results returned from the UKHSA according to SNOMED CT or Read Code (Multimedia Appendix 2), along with the date that the swab was taken. The test results are used for virological surveillance as well as test-negative case-control studies [39] that evaluate VE for influenza and COVID-19 vaccines.

The UKHSA tests for a panel of 8 viruses (Figure 2), including (1) SARS-CoV-2; (2) influenza (influenza A subtypes are differentiated based on their hemagglutinin [H] and neuraminidase [N] surface proteins; the 2 subtypes that are commonly in circulation are H1N1 and H3N2, though some influenza A cases are only reported as influenza A; influenza B is reported collectively, with close monitoring of circulating lineages); (3) RSV A and B; (4) human metapneumovirus (hMPV); (5) other seasonal coronaviruses (NL63, 229E, OC43, and HKU1), in addition to SARS-CoV-2; (6) adenovirus; (7) human rhinovirus; and (8) enterovirus.

To reach a sufficient volume of tests, the behavioral change we want primary care clinicians to achieve is conducting virology and serology sampling where possible and making CMR system entries of high data quality. We will use the behavioral change wheel, otherwise known as the COM-B model, to theorize behavioral change expected in clinicians. This suggests that for a behavioral change (B) to take place, an individual requires capability (C), opportunity (O), and motivation (M) [40]. We are using the COM-B model as a high-level theoretical frame to describe our interaction with practices rather than a formal experimental work.
New Technologies and Capabilities

We have an ambitious program of introducing new technologies and extending the scope of our surveillance. We are looking to introduce 3 new technologies in the coming year: (1) LabLinks, integrating our surveillance sampling with online pathology test requests carried out via primary care CMR systems; (2) creating a POCT-ready nested cohort within the RSC; and (3) introducing a messaging system that enables us to effectively target specific groups for sampling.

The 2 surveillance capabilities we are looking to introduce are (1) urinary antigen (UAG) tests that test for pneumococcus infection, and (2) collecting virology swabs from asymptomatic infections.

We will conduct a feasibility study of testing for *Streptococcus pneumoniae* infection using UAG. We would like to perform this study over 1 to 2 years, recruiting 2 practices from each NHS region, with ARI patients having both respiratory swabs and urine tests. We will also pilot asymptomatic testing for our panel of viral tests [41]. Running this within the RSC will enable linkage of virology results to medical records and the monitoring of household transmission as we can identify people in the same household [42-44]. The protocols for the feasibility and pilot studies will be published separately.

Creation of a Biomedical Resource

We will complete the work to create a unique biomedical resource that offers 2 unique opportunities for research. First, we will create a longitudinal database that runs back to the start of the RSC’s involvement in sentinel surveillance in 1967. Second, we will link clinical records and the virology results for all tests performed at UKHSA’s reference laboratory. This will create a resource to support the emerging discipline of genomic surveillance [45,46] by linking clinical phenotype, as defined in an individual’s CMR, at the individual level with details of the infecting virus, including its genome sequence. Summary results of the unique longitudinal data are presented.

Ethical Considerations

Pseudonymized primary care data and samples from general practices collected for surveillance purposes are processed under Regulation 3 of the Health Service (Control of Patient Information Regulations 2002) and annually renewed under Regulation 7 by UKHSA’s Caldicott Guardian [47]. Any further research or studies require their own ethical approval and approval of the Joint RSC Committee of the University of Oxford and RCGP.

There are data-sharing agreements in place with every GP practice within the network, where the purpose of data collection and the processing of activities are stated. We link primary care data collected via sentinel surveillance to secondary care data provided by NHS England via a bespoke data sharing agreement that is renewed annually. All the data controllers (UKHSA, RCGP, and University of Oxford) complete NHS England’s data security and protection toolkit to meet the performance standards set by the National Data Guardian [48].

Results

PPI Group

We presented the protocol to patient representatives in July 2023. Patient representatives proposed promoting self-testing for virology to help increase the uptake of sampling. They also suggested considering swabbing in different settings, including a pharmacy, as patients with respiratory illnesses may be more likely to visit a pharmacy rather than a GP.

The patient groups have suggested that the following themes and content should form part of our PPI communications: (1) information about how patient data are used in surveillance, (2) information about how sentinel surveillance fits in with pandemic preparedness, and (3) further personal areas of interest, for example, to better understand patterns in patients with post–COVID-19 condition. The PPI representatives expressed that some patients may have concerns about patient confidentiality and data use, which can be overcome by written dissemination and regular engagement.
Based on initial feedback, we have tailored our communication to focus on key areas of interest to the public. For example, we have delivered a presentation and discussion group to patients at a Midlands practice, which focused on how data are used for surveillance and how transparency can be improved. We have developed a poster designed for practice waiting rooms to promote awareness of the RSC. We consider patient feedback in training our surveillance practices (eg, we inform new practices that patients like to receive their swab results, which may enhance patients’ experience of care).

**ARI Phenotype**

To ensure that we identify and classify all relevant coded events in the CMR, the ARI phenotype will be hierarchical. The top level will represent the overall ARI concept. The middle level will include codes for upper respiratory tract infection (URTI), lower respiratory tract infection (LRTI), exacerbations of chronic lung disease, and ILI. The bottom level will include codes for lower-level syndromes, such as sinusitis, that are descendants of middle-level syndromes (Figure 3). We will recommend that RSC network member practices consider coding ARI-associated diseases and symptoms as the diagnosis when patients present with ARI symptoms.

We have also developed a recommended coding sequence for patients presenting with ARI to primary care. The overall ARI and ILI signals are important for respiratory surveillance; hence, we recommend considering ILI first, using the RSC’s ILI definition: ARI with measured or clinically plausible temperature ≥38 °C, cough, systemic upset, such as headache or myalgia, sudden onset, and absence of a more plausible diagnosis. Our current surveillance categories do not reliably capture exacerbations of chronic lung diseases, which are vulnerable to severe outcomes from infective exacerbations [49,50]. We are therefore asking practices to consider this next. We then ask the consulting clinician to consider LRTI and subsequently URTI (Figure 4).

We are also standardizing the recording of symptoms, signs, and any emergency management decisions made for ARI events, so we request RSC practices to record these in the CMR. We fully understand the pressures on consulting time, so we will be producing data entry forms that practices can use in the major brands of CMR systems to facilitate high-quality data entry. The key symptom data to be coded are as follows: (1) date of onset of symptoms; (2) presence of “absence of fever” because infections, particularly in older people, may not be associated with fever [51]; (3) sore throat symptoms; (4) cough or no cough, and if coughing, is it productive; (5) coryza and nasal symptoms; and (6) presence or absence of shortness of breath and wheezing. The signs we would like to see coded are as follows: (1) measured tympanic temperature; (2) peripheral oxygen saturation, where available; (3) pulse rate; (4) respiratory rate; (5) upper respiratory signs where present, including cervical and anterior cervical lymphadenopathy, and any tonsillar exudate or enlargement; and (6) lower respiratory signs, including wheezing or other physical signs.

**Figure 3.** Research and Surveillance Centre recommendations for classifying the etiology of respiratory symptoms or signs in people presenting to primary care. COPD: chronic obstructive pulmonary disease; ILI: influenza-like illness; LRTI: lower respiratory tract infection; SoB: shortness of breath; URTI: upper respiratory tract infection.
**High-Quality Data to Support VE and Other Studies**

To enhance data quality, RSC member practices will receive feedback about their recording of key sociodemographic variables, vaccine exposure, and risk groups. We also provide a dashboard to enable RSC practices to compare their rate of vaccination with the rest of the network (Figure 5).

Most of the relevant data in VE studies are recorded as part of standard care, but some are not recorded to a satisfactory standard. For example, some important sociodemographic data are not automatically recorded, including ethnicity, smoking status, and obesity. Vaccine exposure data should include brand and batch wherever possible, but these recordings are problematic for vaccinations outside general practices.

Risk groups and patient outcomes are also important for VE and other studies, and most of these data are recorded well as part of chronic disease management. We used these data to derive the Cambridge Multimorbidity Score, a single measure of multimorbidity for all adults, and the electronic frailty index (eFI). While the eFI can be used from the age of 50 years, we will use it in the coming season for people aged 65 years or older [52,53].

Our data are linked to national collection of hospital and death data, so we can report severe outcomes [54]. Our data are also linkable with the National Immunization Management System, which provides vaccination data for COVID-19 and influenza in England. These data will be used to estimate VE, with mid-season and end-of-season studies for influenza, an autumn VE study for COVID-19 vaccines, and a burden of disease study for RSV. These results will contribute to the Joint Committee on Vaccination and Immunization impact of vaccine policy, contribute to WHO reviews, and be published in peer-reviewed journals.

The protocol for our VE studies is included in Multimedia Appendix 3.
Virology and Serology Sampling and Testing

Ongoing recruitment and checking the representativeness of the network by region will ensure the RSC is representative. Maps of the distribution of virology and serology sampling practices and the entire network are included in Multimedia Appendix 4. We plan to increase the number of virology samples taken each week. The total so far for the 2022-2023 season is 11,001, with 878 as the highest number of virology swabs collected in week 51 of the year 2022. The median weekly total is 259 samples, with an interquartile range of 173 to 304 samples. These data have been and will be used to estimate VE for influenza and COVID-19 vaccines with a test-negative design, and can be used in the future to study the VE of RSV.

Applying COM-B, our practice liaison team will be working with practices to achieve higher rates of virology samples. We will be continuing our regular visits and weekly and monthly reports to practices, and the scope will be driven by our learning from visits about how best to change (increase) sampling behavior and from our PPI input (Multimedia Appendix 5). Our virology dashboard provides practices with a comparison of what viruses are circulating in their practices compared with nationally (Figure 6). This can support practices to review their antibiotic prescriptions and antiviral medication uptake, and support better antibiotic stewardship.

We will need to control numbers in subgroups to achieve better representativeness of our serology sampling in the coming year, and produce a dashboard that practices can use to monitor activity (Figure 7). We will implement a technology-driven or manual approach to ensure national representativeness by age band and region. We will also offer pediatric phlebotomy training to encourage sampling in young people and children (Multimedia Appendix 6). The scale of serology sampling will be determined according to season.
Figure 6. Circulating virology data taken from our observatory showing the percentage of positive samples by viral strain for Research and Surveillance Centre (RCS) general practitioners (GPs) combined and an example of an individual practice (2022-2023 season). hMPV: human metapneumovirus; RSV: respiratory syncytial virus.

Figure 7. Serology data taken from our observatory and dashboard showing the number of samples collected by age band for Research and Surveillance Centre general practitioners combined (2022-2023 season).

New Technologies and Capabilities
We plan to integrate LabLinks into the RSC. Currently, customized kits are provided to RSC practices for virology and serology sampling, and these kits are returned to UKHSA laboratories through the post. We plan instead to integrate RSC sampling with the electronic pathology test–requesting system currently integrated into primary care CMR systems. The details of the LabLinks program are described in Multimedia Appendix 7. Figure 8 provides an overview of the process.

We will create a POCT nested cohort of practices willing to participate in feasibility studies. The key area of interest is POCT for group A streptococcal infection because there was a higher peak in the incidence of group A streptococcal infection in late 2022 than in the previous 8 years (Figure 9). A protocol for using molecular POCT is included in Multimedia Appendix 8 [55-57].

We will test EMIS Recruit [58] as a messaging system to invite targeted risk groups (immunocompromised) or younger people who had a booked blood test to consider volunteering to provide an extra blood sample for serology. The messaging system runs through EMIS Recruit to detect patients in target groups that have a recent blood test request. A message is sent to the patients to invite them to participate in our serology sampling. We will also be asking practices whether there would be interest in pediatric phlebotomy training to increase the sample number in younger children.

We will recruit one or two virology sampling practices per region that volunteer to collect urinary samples for UAG testing to infer pneumococcal infection.

We will start with children under 5 years of age coming for vaccination. We may then move on to include people aged 40 to 74 years attending NHS health checks and people aged 40 years or older attending hypertension clinics in primary care.
**Figure 8.** Virological surveillance data workflow. Samples are taken in practice. They pass through the local pathology laboratory to the UK Health Security Agency (UKHSA) viral reference laboratory at Colindale. Virology results go back to the general practitioner (GP) and patient and also into the Research and Surveillance Centre (RSC) database. ICE: Integrated Clinical Environment; LIMS: Laboratory Information Management System.

**Figure 9.** Weekly incidence of scarlet fever or streptococcal sore throat presenting to the English primary care sentinel network practices from 2010 to 2023. The incidence in the last quarter of 2022 was higher than that seen in the previous 10 years.

**Creation of a Biomedical Resource**

The RSC has unique longitudinal data stretching back to 1967. Currently, we are progressing with the assembly of these data into a single quinquagenarian resource (**Figure 10**). We have curated ILI incidences between 1967 and 2022 as an example (**Figure 11**).
Legal Basis and Governance Framework for Conducting Sentinel Surveillance

Surveillance is authorized each year through a commissioning letter, authorized by the UKHSA, and sent out to all RSC sentinel network general practices. Privacy notices for individuals registered at a GP within the network are publicly available [59]. We request all member practices to share these with their registered patients.

Evaluation of RSC Surveillance Compared With the WHO Mosaic Framework

The RSC meets many of the surveillance objectives of the WHO mosaic framework but within the scope of its virology plus primary and secondary care data (Table 1).

In Domain I (detection and assessment of respiratory viruses), we have a comprehensive virology panel and a nationally representative primary care network. Our data are strong but could be stronger with respect to having detailed information about clinical presentation. Our household key and information about residential care provide only limited information about transmission [43], and piloting whether there is asymptomatic spread will provide additional evidence about the spread of the disease.

In Domain II (epidemiological characteristics of respiratory viruses), our data are strong. Our linked data set allows us to monitor severe outcomes and mortality. We do not have sufficient coverage of all high-risk settings and do not collect data from hospitals where nosocomial infection is common. We can readily identify community-recorded vulnerable populations, and we term these “risk groups” [60]. We do not directly measure whether health care systems are overwhelmed, but we do record community rates of illnesses compared with other years [61].

In Domain III (informing about health interventions), we are able to infer the impact of interventions, such as lockdowns and shielding, during the COVID-19 pandemic, and we can see from our data the impact of school closures [62,63]. We are strong...
in measuring vaccine uptake and effectiveness, and our data have been used for vaccine adverse events [60,64]. We only have limited abilities to assess the effectiveness of some antivirals and other therapeutics owing to their central administration, and our capabilities are greater where these are recorded in the GP CMR. We have the capability to assess diagnostic tests and will compare POCT with reference virology laboratory results [55,65]. NHS England ARI hubs are planned to join the network, and we plan to evaluate the impact of these networks. We do not provide candidate vaccine viruses.

The RSC has additional surveillance objectives (Table 2). PPI and bacterial surveillance are essential. We could have a role at the system level of exploring how POCT might have an impact on treatment selection and health outcomes. Additionally, we see compliance with information governance standards as essential and linkage between clinical and viral sequencing data as enabling genomic surveillance.

Discussion

Principal Findings

The RSC and UKHSA are providing the most comprehensive primary care respiratory infection surveillance in the United Kingdom. We have extended the number of surveillance approaches for the coming season, meeting more of the areas proposed in the WHO mosaic framework (Table 1) [19].

In Domain I (detection and assessment of respiratory viruses), we have a robust system that has run over decades. However, we have scope to improve the rapidity and reliability of our results by increasing our sampling numbers and data quality so we can better detect changes.

In Domain II (epidemiological characteristics), we also have a robust system. There is potential to integrate work about asymptomatic infection, do more to include high-risk settings in our system, and develop indicators of our health care system’s ability to cope.

Domain III (informing the use of health interventions) is an area where we provide some key data, but this could be strengthened. We are able to monitor the impact of nonmedical interventions like social distancing [62,63], but other data are also needed to extend our capability of informing health interventions. We do report vaccine coverage, though data about vaccine exposure where vaccines are not given in primary care are more limited. We have primary care data and can link to other data to monitor the effectiveness of antivirals and other therapies, but access to centrally held data sets can be slow. We are well placed to report VE and adverse events of interest following vaccination [37,54] rapidly when using primary care data but with a greater lead time when we need to link to secondary care data. We can measure the costs of medically attended conditions. However, including measures of health-related quality of life would extend our ability to assess the disease burden.

Finally, we propose additional objectives that might be added (see Table 2). Among these, we consider that PPI and addressing the burden of primary and secondary bacterial infections are the most important.

Comparison With Prior Work

The strength of the RSC’s sentinel surveillance has long been established, but it has now been greatly extended, with the network more than doubling in size during the pandemic [66]. Other countries adapted their surveillance during the COVID-19 pandemic, including setting patient sampling routes outside of primary care (Sweden, Netherlands, and Scotland), decentralizing reference testing laboratories (France, Portugal, Scotland, and Spain), and optimizing digital data collection (Sweden, Netherlands, England, Scotland, France, Portugal, and Spain) [67]. Most of these changes were temporary, but the changes in the RSC network, such as the expanded sentinel practices and the introduction of electronic links to laboratories, have remained and will be further developed.

Australia, Belgium, the Netherlands, and the United States have shown that GPs would like to use more POCT to help them diagnose acute conditions [68]. Currently, the Welsh government has introduced a pharmacy-led service to undertake a structured
clinical assessment using clinical prediction scores and POCT for cases of suspected strep A infection [69].

**Strengths and Limitations**

The strengths of our network are its size (just under a third of the English national population), the level of sampling, and the commitment to improving data quality. The network has shown adaptability through the COVID-19 pandemic and a strong partnership working with the UKHSAs. We also have collaborations with other European sentinel networks and international collaborations [67]. The United Kingdom has a registration-based system that is free at the point of care, which allows good population coverage and facilitates the presentation of population-based infection rates. A unique national ID, the NHS number, ensures that primary care data can be linked to hospital and death data, allowing severe outcomes to be reported.

The limitations of routine data are that they are recorded by busy clinicians often working under pressure, and thus, they can be incomplete. Despite our best efforts, there can be gaps in data quality [70]. It is inevitable that our data will not capture all cases, and disease etiology might not be precise. While primary care data can be reliably reported within 3 days in arrears, it is much slower to gain access to secondary care data and other data sets. The national policy is to move toward a smaller number of secure data environments, and the RSC may need to migrate into one of these [21]. NHS primary care is increasingly working at scale, with the NHS setting up ARI hubs to work across geographical areas. We are exploring recruiting ARI hubs into our network.

**Conclusions**

The RSC has grown and adapted through the pandemic. Our biggest areas of change will be the introduction of an ARI phenotype, using technology to reduce the barriers to virology sampling and hopefully increase the scale and representativeness of virology sampling. The challenges in implementing change and the requests for more consistent data recording risk discouraging practices from remaining part of the RSC. Overall, our plans for the coming season will deliver more of the WHO surveillance mosaic.

**Acknowledgments**

We thank participating Research and Surveillance Centre (RSC) member practices and their patients for sharing pseudonymized data for disease surveillance, quality improvement, research, and education. We also thank computer system suppliers in English primary care: EMIS, TPP, In Practice Systems, and Wellbeing (Magentus). The RSC’s respiratory disease surveillance work is funded by the UK Health Security Agency. The Wellcome Biomedical resource is funded by the Wellcome Trust (212763/Z/18/Z).

**Conflicts of Interest**

SdL has received funding through his university from Astra-Zeneca, Eli-Lilly, GSK, MSD, Novo Nordisk, Sanofi, Seqirus, and Takeda, and has been a member of advisory boards for Astra-Zeneca, Sanofi, and Seqirus. He is the Director of the Oxford-Royal College of General Practitioner Research and Surveillance Centre. MZ is the chair of the charitable organization International Society for Influenza and other Respiratory Viruses (ISIRV) (not remunerated) and a member of the UK Government Scientific Advisory Groups Scientific Advisory Group for Emergencies (SAGE), New and Emerging Respiratory Virus Threats Advisory Group (NERVTAG), and Joint Committee on Vaccination and Immunization (JCVI) (not remunerated). UH has received funding from Sanofi for vaccine-related workshops and has been a member of the advisory board for Janssen. All other authors declare no conflicts of interest.

Abstract

Background: Assessing HIV outcomes in key population prevention programs is a crucial component of the program cycle, as it facilitates improved planning and monitoring of anticipated results. The Joint United Nations Programme on HIV and AIDS recommends using simple, rapid methods to routinely measure granular and differentiated program outcomes for key populations. Following a program science approach, Partners for Health and Development in Africa, in partnership with the Nairobi County Government and the University of Manitoba, aims to conduct an outcome assessment using a novel, expanded polling booth survey (ePBS) method with female sex workers and men who have sex with men in Nairobi County, Kenya.

Objective: This study aims to (1) estimate the incidence and prevalence of HIV; (2) assess biomedical, behavioral, and structural outcomes; and (3) understand barriers contributing to gaps in access and use of available prevention and treatment services among female sex workers and men who have sex with men in Nairobi.

Methods: The novel ePBS approach employs complementary data collection methods, expanding upon the traditional polling booth survey (PBS) method by incorporating additional quantitative, qualitative, and biological data collection components and an improved sampling methodology. Quantitative methods will include (1) PBS, a group interview method in which individuals provide responses through a ballot box in an unlinked and anonymous way, and (2) a behavioral and biological survey (BBS), including a face-to-face individual interview and collection of linked biological samples. Qualitative methods will include focus group discussions. The ePBS study uses a 2-stage, population- and location-based random sampling approach involving the random selection of locations from which random participants are selected at a predetermined time on a randomly selected day. PBS data will be analyzed at the group level, and BBS data will be analyzed at an individual level. Qualitative data will be analyzed thematically.
Results: Data were collected from April to May 2023. The study has enrolled 759 female sex workers (response rate: 759/769, 98.6%) and 398 men who have sex with men (response rate: 398/420, 94.7%). Data cleaning and analyses are ongoing, with a focus on assessing gaps in program coverage and inequities in program outcomes.

Conclusions: The study will generate valuable HIV outcome data to inform program improvement and policy development for Nairobi County’s key population HIV prevention program. This study served as a pilot for the novel ePBS method, which combines PBS, BBS, and focus group discussions to enhance its programmatic utility. The ePBS method holds the potential to fill an acknowledged gap for a rapid, low-cost, and simple method to routinely measure HIV outcomes within programs and inform incremental program improvements through embedded learning processes.

female sex workers; men who have sex with men; Kenya; polling booth survey; program science; HIV prevention; outcome assessment

Introduction

Background

Kenya has made significant strides in its HIV response, evident by the continuous decline in HIV prevalence among adults aged 15 to 49 years within the general population. HIV prevalence has dropped from a peak of approximately 10% in the mid-1990s to 4.3% in 2021 [1]. An analysis of the HIV epidemic within Kenya [2] highlights substantial heterogeneity. HIV prevalence varies geographically, ranging from 20.1% in Homa Bay County to 0.2% in Mandera and Wajir counties. Notably, HIV prevalence in Kenya is also disproportionally high among female individuals (5.5%) than among male individuals (2.9%) [3]. Furthermore, compared to the general Kenyan population, HIV prevalence is significantly higher among key populations, namely, female sex workers at 29%, men who have sex with men at 18.9%, people who inject drugs at 18%, and transgender people at 40% [4,5]. This underscores the critical importance of properly scaled and tailored interventions to address the HIV epidemic within key populations in the country [4].

In 2020, a nationwide mapping and population size estimation exercise estimated that there were 197,096 female sex workers and 61,650 men who have sex with men living in Kenya (National AIDSSTI Control Programme, unpublished data, December 2020). Approximately 20% of key populations are concentrated in Nairobi County, the largest of the 47 counties in Kenya [6]. Findings from a 2017 national study underscore the high prevalence of HIV among female sex workers and men who have sex with men in Nairobi, with self-reported rates of 22% and 27%, respectively [7]. In the same study, 91% of female sex workers in Nairobi reported using condoms with their last client, while 81% of men who have sex with men reported condom use during last anal sex [7]. Furthermore, peer educators played a significant role in outreach efforts, with 88% of female sex workers and 76% of men who have sex with men reporting contact with a peer educator within the last 3 months. The majority (82%) of both groups had undergone HIV testing within the last 3 months, while 22% of female sex workers and 27% of men who have sex with men reported that they were living with HIV. However, only 65% of female sex workers and 68% of men who have sex with men living with HIV reported being enrolled in antiretroviral therapy programs. Notably, 56% of female sex workers and 18% of men who have sex with men reported experiencing incidents of police violence within the last 6 months, respectively [7].

HIV prevention programs for key populations in Nairobi County are implemented by several partner organizations, all of whom report to the county government and the National Key Population Program, led by the Kenyan Ministry of Health, on a monthly basis (National AIDS and STI Control Programme, unpublished data, September 2023). Having up-to-date, representative, and robust data on key populations is of paramount importance for effective planning, management, and monitoring of programs and interventions aimed at addressing their needs [8]. The most recent population-based behavioral survey conducted among key populations in Nairobi dates back to 2017 [7] and did not include biological data. The absence of recent biobehavioral data among key population groups limits the ability of both county and national programs to understand the current epidemiologic situation, assess the impact of investments in HIV prevention and treatment programs for key populations, and identify gaps in program coverage. The high cost and resource requirements for implementing nationally representative, population-based integrated biobehavioral surveillance surveys factor into the relative infrequency of their deployment [8]. The availability of methods that can efficiently collect timely data among key population groups at appropriate scale and relatively low cost across diverse contexts is extremely limited [9]. Striking a balance between the need for methodological rigor and practical, adaptable approaches that are accessible to countries with diverse income levels is a pressing requirement [10].

Objectives

Partners for Health and Development in Africa (PHDA), in collaboration with the University of Manitoba and the Nairobi County Government, aims to conduct an outcome assessment study using a novel, expanded polling booth survey (ePBS) method for data collection. This outcome assessment focuses on 2 key populations with whom PHDA works in Nairobi County, Kenya: female sex workers and men who have sex with men. The objectives of the study are to (1) estimate the incidence and prevalence of HIV; (2) assess biomedical (HIV testing, condom use, pre-exposure prophylaxis [PrEP] uptake, and HIV treatment), behavioral (knowledge and risk behavior), and structural outcomes (experiences of violence, stigma, and discrimination); and (3) gain a deeper understanding of barriers
that contribute to disparities in accessing and using HIV services among female sex workers and men who have sex with men in Nairobi County, Kenya. Importantly, this study will pilot the feasibility of the novel ePBS method to measure outcomes in key population programs, with the intention of disseminating the approach for scaling up in other key population programs within and outside Kenya.

Methods

Study Setting
Nairobi County is the largest of Kenya’s 47 counties by population and has a robust key population program. According to the latest mapping and population size estimation exercise, Nairobi County has the highest concentration of female sex workers (n=39,227) and men who have sex with men (n=15,271) living or working in the country, or both [6]. The county has identified 2032 locations, across its 12 subcounties, where female sex workers solicit clients and 369 locations where men who have sex with men meet their sexual partners [6]. Bars (without lodging) have the highest proportion of female sex workers and men who have sex with men among these locations [6]. Importantly, same-sex sexual practices are criminalized throughout Kenya, and in 2017, Nairobi County implemented a ban on all forms of sex work [11,12]. This has contributed to the elevated levels of violence, stigma, and discrimination experienced by female sex workers and men who have sex with men [7] within the county. There are currently 4 large implementing partners responsible for prevention programs for female sex workers and men who have sex with men in Nairobi, which are funded by the Global Fund to Fight AIDS, Tuberculosis, and Malaria and the US President’s Emergency Plan for AIDS Relief. Among these partners, PHDA implements the largest prevention program in Nairobi and Kenya, serving approximately 34,000 female sex workers and 14,000 men who have sex with men. PHDA reaches these groups across all 17 counties in Kenya through an extensive network of peer educators and 9 Sex Workers Outreach Program (SWOP) clinics. To implement this program, PHDA receives funding from the US President’s Emergency Plan for AIDS Relief and technical support from the University of Manitoba and the University of Maryland, Baltimore. Furthermore, this collaboration involves Nairobi County and the National AIDS and STI Control Programme (NASCOP) [13].

Program Science Approach
This study adopts a program science approach, which systematically applies scientific theory and empirical knowledge to answer critical programmatic questions that are generated by the program itself [14]. The approach seamlessly integrates the program cycle with research questions, strategically embedding iterative cycles of research and learning within a program, thus facilitating rapid uptake of knowledge and evidence into program operations. Furthermore, the program science approach generates embedded research agendas to address ongoing programmatic challenges [15]. In the context of this study, the research questions and study objectives have evolved from 2 primary programmatic concerns within the Nairobi County’s key population program. The first concern revolves around the absence of recent population-based data to assess program outcomes (biomedical, behavioral, and structural) pertinent to key populations in Nairobi County. The second concern is the lack of a low-cost, reliable, and easily reproducible method capable of routinely evaluating granular and differentiated program outcomes for key populations, assessing and identifying gaps in the program’s coverage, and making programmatic adjustments to address emerging challenges.

Program science emphasizes the importance of routinely identifying, quantifying, examining, and addressing gaps in program coverage, through tools, such as the effective program coverage framework, to reduce inequities in health outcomes and achieve population-level impact [16]. A program science approach underscores the importance of engaging affected communities [17] and actively works toward developing program and policy solutions to public health challenges [18]. As such, this study is conducted by PHDA in partnership with the community advisory board of the SWOP clinics and the Department of Public Health, Nairobi County.

Research Questions
The study sets out to answer four specific research questions.

1. What is the HIV incidence and prevalence among female sex workers and men who have sex with men in Nairobi, Kenya?
2. Has the program successfully met its targets related to biomedical, behavioral, and structural outcomes among female sex workers and men who have sex with men in Nairobi, Kenya?
3. What is the estimated program coverage of the prevention services among female sex workers and men who have sex with men in Nairobi, Kenya?
4. What are the key barriers experienced by female sex workers and men who have sex with men when accessing and using prevention services in Nairobi, Kenya?

Outcomes for Measurement
In total, 12 outcomes will be measured to address the study’s research questions (Textbox 1). Specifically, to address research questions 1 and 2, five biomedical outcomes, 2 behavioral outcomes, and 2 structural outcomes will be measured. For research questions 3 and 4, program coverage, availability coverage, contact coverage, and utilization coverage will be measured among both key population groups, following the definitions outlined in the program science–informed effective program coverage framework [16]. HIV prevalence and incidence at the population level will also be measured.
Measured HIV outcomes among female sex workers and men who have sex with men using an expanded polling booth survey in Nairobi County, Kenya, from April to May 2023.

### Themes and outcomes

#### Biomedical
- Prevalence of sexually transmitted infections (STIs) symptoms, diagnosis, and treatment
- Consistent condom use
- Routine HIV testing (and receipt of results)
- Linkage to and retention in HIV treatment and care
- HIV viral load suppression

#### Behavioral
- Self-reported HIV risk behaviors
- Knowledge of HIV

#### Structural
- Prevalence of gender-based violence
- Prevalence of stigma and discrimination

#### Program coverage
- Availability coverage
- Contact coverage
- Utilization coverage

### Study Timeline

The ePBS study was designed with a quick turnaround; all activities are expected to be completed within 9 months. The data collection phase was planned to span 30 consecutive days, followed by data cleaning and analyses. Results will be finalized for dissemination at the end of the 9-month period.

### Study Team

#### Composition

A total of 4 study teams were established to manage the implementation of ePBS, and each team concurrently collected data in 4 different locations daily. Each team consisted of 6 members including a prevention officer, a key population outreach worker (a member of either key population community), a clinical officer, an HIV and testing service (HTS) counselor, and 2 qualitative researchers (1 focus group discussion [FGD] facilitator and 1 notetaker). Peer educators working in the SWOP clinics supported the study teams in participant enrollment. All ePBS team members, except the qualitative researchers, were enrolled from PHDA-SWOP clinic staff. All 4 teams were supervised by senior members (site supervisors) of the PHDA-SWOP clinic team and representatives from the Nairobi County government.

#### Study Team Training

The study team underwent a comprehensive 5-day training. The first 3 days of training included classroom instruction, during which the study’s investigators introduced and facilitated training on (1) the conceptual and theoretical underpinnings of the study (ie, the program science approach and the effective program coverage framework) [16]; (2) the ePBS methodology; (3) data collection methods and tools; (4) logistics, implementation flow, and study procedures; and (5) data entry processes. Subsequently, 2 days were dedicated to field practice during which mock data collection exercises were conducted to enhance the skills of the study team and to provide opportunities for troubleshooting any anticipated challenges in the field. Importantly, all 5 days of ePBS training prioritized practical exercises to ensure that the study team felt confident and proficient, thereby ensuring consistency and quality in data collection.

### ePBS Method

The ePBS method is a rapid, cross-sectional study design using complementary quantitative and qualitative methods for data collection. The innovative approach expands upon the traditional polling booth survey (PBS) method [19] by incorporating additional qualitative, quantitative, and biological data collection methods and an improved population-based approach to random sampling. Within the ePBS method, quantitative methods include (1) PBS, a group interview method in which individuals provide anonymous and unlinked responses to survey questions through a ballot, which has been shown to reduce reporting and social desirability biases for sensitive questions about conventionally stigmatizing behaviors, experiences, and social circumstances [19,20] and (2) behavioral and biological survey (BBS), which includes a short face-to-face, individual interview linked to the collection of biological samples (blood and urine). Qualitative methods include FGD with a subset of ePBS participants to inquire about factors that contribute to gaps in
program coverage. Hence, the expansion of the traditional PBS by adding a BBS and FGD is referred to as ePBS.

Cross-sectional designs are commonly used for population-based surveys and to assess the prevalence of diseases in a population [21]. They are also useful for informing planning, monitoring, and evaluation of public health programs and interventions. In this study, we use quantitative methods to measure prevention program outputs and relevant outcomes among female sex workers and men who have sex with men participants, as outlined in research questions 1 to 3. We use qualitative methods to gain insight into the barriers affecting the accessibility and use of HIV services, as specified in research question 4.

**PBS Component**

**Overview**

The PBS method is a well-established group survey method comprising only binary questions, in which individuals provide responses to survey questions by placing a token corresponding with their answer into a ballot box [22]. Individual responses remain anonymous and unlinked, ensuring confidentiality. This anonymity has been shown to enhance participants’ trust in the confidentiality of the data collection process, thereby minimizing social desirability biases and lending itself to more accurate reporting on sensitive behavioral information [23]. Data generated through PBS have been found to be comparable to the findings from other studies that used different methodologies with the same populations [20].

**Sampling Procedure**

Potential participants are selected using a 2-stage, randomized, probability-based sampling procedure and organized into small homogenous groups by key population groups (ie, female sex workers and men who have sex with men) and typology of the location at which sex work and cruising take place (eg, bar, bar with lodges, street, and clubs). Each PBS session consists of 10 to 12 participants of the same key population group who congregate and solicit clients or cruise in the same locations. Given the group interview format, the number of survey questions is intentionally limited, and each question is short and simple to facilitate easy response [22]. The key population program in Kenya has previously used PBS, and participants from different key population groups have found it to be an acceptable approach [7].

**Implementation Procedure**

The PBS component of the ePBS study was led by prevention officers and outreach workers. Conducting PBS requires materials that are not typically considered for other survey methods. First, each participant in a PBS session must have 3 different colored ballot boxes associated with yes, no, and not applicable responses (typically green, red, and white, respectively) and a set of cards to use as tokens to be dropped into the ballot boxes. Cards should be clearly numbered in alignment with the number of survey questions. Each participant’s station also requires a polling booth carton to create a private space that is not visible to other participants in the PBS session (often a cardboard box with 1 open face pointed at the participant). The facilitator at each PBS session should be equipped with copies of the standardized data collection tool (survey) and reporting forms to tally and record responses to each question.

Peer educators from SWOP mobilized 10 to 12 potential participants and invited them to participate in a PBS session, each of which was conducted as follows:

- Participants invited to the PBS were provided with an individual polling booth carton at the study venue. The polling booths were separated by at least 1 m to ensure privacy and confidentiality for each participant and their responses.
- The facilitator welcomed the participants and explained the objective of the study, read out the consent format, provided time and space for questions, and sought informed consent from every participant.
- Each participant received 3 ballot boxes (green, red, and white) and a pack of cards, with each card numbered and stacked in a sequential order to correspond with the number of questions in the survey.
- The facilitator confirmed that each participant had the correct number of cards arranged in the proper order before proceeding with the questions.
- The facilitator provided a full explanation of the PBS procedure, including an example question and a practice response, to assure participants that their responses will remain anonymous and unlinked.
- In terms of responses, the facilitator explained the following:
  - If the response to the question is yes, the participant should put the card with the corresponding question number into the green box.
  - If the response to the question is no, the participant should put the card with the corresponding question number into the red box.
  - If the question does not apply to the participant, the participant should put the card with the corresponding question number into the white box.
  - If the person does not want to answer the question, the card with the corresponding question number should be kept outside the provided boxes.

- The facilitator read the survey questions, one at a time, making the exercise engaging and lively. They ensured that each question was clearly understood by all participants by (1) reading each question clearly, slowly, and loudly to ensure that each participant heard the question clearly; (2) reading out the questions in a language that is easily understood by participants; (3) repeating the question, if necessary; (4) using local terms and giving sufficient pause, taking care not to rush through the questions.
- After all the PBS questions had been administered, the facilitator (1) collected the cards separately for each of the boxes: green, red, and white and (2) tallied and recorded the number of responses from each card in each of the colored boxes into a standard reporting form.
- All data generated through the PBS process were entered into a tablet by the study team using a standardized database created specifically for the ePBS. The data collection was facilitated using SurveyCTO (Dobility, Inc), a secure and
scalable mobile data collection platform designed for researchers working in offline settings.

**BBS Component**

**Overview**
The BBS is an expansion to the standard PBS method and was led by the study teams’ clinical officers and HTS counselors.

**Table 1.** Biological samples collected from female sex workers and men who have sex with men during the biobehavioral survey in Nairobi, Kenya, from April to May 2023.

**Individual, Face-to-Face Structured Interviews**
Following the PBS, all participants who provided informed consent participated in a brief, face-to-face, structured interview with a clinical officer to gather limited demographic information, basic behavioral information related to HIV risk, and program access and service use data. These data will be linked, at the individual level, to biological samples (blood and urine), which were collected following the face-to-face interviews.

**Biological Samples**

**Urine Sample**
To protect the confidentiality of participants’ HIV status, urine samples were collected from all participants who provided informed consent to providing biological samples. However, only samples from those participants who had reported currently taking PrEP in the preceding face-to-face interview underwent testing using a rapid tenofovir assay developed and validated by the University of California, San Francisco in conjunction with Abbott Laboratories [24]. Depending on timing and the facilities available on-site, the samples were either tested for tenofovir at the study site or sent to the PHDA laboratory for processing the following day (Table 1).

**Blood Samples**
HTS counselors collected fingerprick blood samples from all participants who provided informed consent for on-site rapid HIV testing. Following Kenyan rapid testing algorithms, Determine HIV-1 or HIV-2 (Abbott Diagnostic Medical Co Ltd) was used as the initial screening assay. All reactive samples underwent confirmatory testing using First Response (Premier Medical Corp Ltd) rapid tests. Pre- and posttest counseling sessions were administered to all participants undergoing HIV rapid testing in accordance with the national guidelines [25].

In addition, clinical officers drew 5 mL venous blood samples from consenting participants who tested positive for HIV in the rapid test. Whole blood samples were transferred to the PHDA laboratory for further analyses, including HIV viral load and recency testing (Table 1). The HIV viral load analyses will be conducted using GeneXpert HIV-1 Viral Load Kits (Cepheid). HIV recency will be determined using the Asante HIV-1 Rapid Recency Assay (Sedia Biosciences Corporation). All laboratory-based tests will be carried out in accordance with the PHDA laboratory’s standard operating procedures and in adherence to the national guidelines [26].

**Biological Sample Management**
All specimens, both urine and blood, were affixed with preprinted standard codes along with the corresponding survey identification at the time of collection. Following collection, all biological samples were carefully placed in boxes at room temperature. These samples were transported to the PHDA laboratory using PHDA vehicles for processing and subsequent testing. The transfer of samples from study sites to the PHDA laboratory followed a protocol outlined by the PHDA laboratory’s standard operating procedures. Both urine and blood samples will be maintained at a temperature of −80°C for 5 years within the PHDA laboratory per standard operating procedures. This extended storage period ensures the availability of samples for the confirmation of any discrepant laboratory results that may arise over time. Stored specimens will not be linked to any personal identifiers and cannot be traced back to the individuals who provided them, preserving the confidentiality and privacy of the participants.

**FGD Component**
The FGD component of the ePBS study was led by the study teams’ qualitative researchers. For each key population group, participants were selected from every fifth PBS session and were engaged in the FGD after providing informed consent. Each FGD consisted of the same 10 to 12 participants who participated in the preceding PBS session. The FGDs were facilitated by trained qualitative researchers using an FGD guide. The discussions were conducted in either Kiswahili or Sheng, which is a local slang language predominantly spoken in urban areas of Kenya, particularly Nairobi. All FGDs were audio...
recorded and will be translated and transcribed verbatim for analysis.

**Participant Inclusion Criteria**

To be eligible for participation in this ePBS study, female sex workers had to be assigned female at birth, aged at least 18 years, and acknowledge having received money or gifts in exchange for sexual intercourse with an individual assigned male at birth at least once in the past 3 months. Eligible men who have sex with men had to be assigned male at birth, aged at least 18 years, and report at least 1 anal sex act (insertive or receptive) with another individual assigned male at birth in the past 3 months. To be eligible, all participants had to be capable and willing to provide written or verbal informed consent to participate in the 3 components of the ePBS study, self-identify as a sex worker or a man who has sex with other men, and report actively practicing sex work or cruising within Nairobi County.

**Target Sample Size Calculation**

To be representative of each key population group, the study’s sampling strategy was based on probability sampling techniques that provided an equal chance to all members of the study populations, meeting defined inclusion criteria, to be included in the study. The determination of an appropriate sample size for a single study domain is usually based on the following considerations: (1) the number of measurement units in the population, (2) the parameter of interest, and (3) the degree of confidence by which the parameter is estimated and the desired level of precision.

One objective of our study was to estimate the HIV prevalence and incidence among female sex workers and men who have sex with men in Nairobi County. As such, sampling parameters were set with the prevalence and sample size having 95% statistical confidence, with a desired precision of ±5% or –5%.

The sample size for PBS and BBS study was calculated using the following formula: 

\[ n = \frac{1.96^2 p(1-p)(DEFF))}{d^2} \]

Where \( p \) is HIV prevalence, \( DEFF \) is the design effect of the sampling approach, and \( d \) is the desired precision.

The finite population correction factor is then applied to the derived sample size using the following formula: 

\[ nf = \frac{n \times N}{(n + (n - 1))} \]

Where \( nf \) is the sample size adjusted for finite population correction, \( n \) is the sample size required, and \( N \) is the population size.

To calculate the sample size for this ePBS study, we used the most recent estimate of HIV prevalence among female sex workers (26%) and men who have sex with men (12%) in Nairobi, as reported in a 2017 study conducted by NASCOP [7]. The sample size calculation was adjusted to accommodate an anticipated nonresponse rate of 15%. The final target sample size, adjusted for population size and nonresponse, for female sex workers was \( n = 769 \) and for men who have sex with men was \( n = 420 \). Ideally, each PBS session comprises 10 to 12 participants; the total target sample sizes for female sex workers and men who have sex with men were divided by 12 to determine the total number of PBS sessions required for each key population group, that is, 64 PBS sessions with female sex workers and 35 sessions with men who have sex with men.

For each key population group, participants in every fifth PBS session were invited to participate in an FGD. In total, 20 FGDs were conducted with ePBS participants (female sex workers: \( n = 13 \), 65%; men who have sex with men: \( n = 7 \), 35%).

**Developing a Sampling Frame**

**Overview**

The study used a 2-stage, random sampling approach. In the first stage, random locations (ie, places where female sex workers solicit clients or engage in sex and where men who have sex with men cruise or engage in sex) were selected from a previously validated list. In the second stage, participants were randomly selected from the locations on a randomly selected day of the week.

**Stage 1 Sampling**

As a first step, the ePBS study team developed the sampling frame by validating lists of mapped locations in Nairobi County where female sex workers and men who have sex with men solicit clients, cruise, meet sexual partners, and engage in sexual activities. The sample frame was derived from a programmatic mapping exercise conducted in 2018 [6]. The lists were updated—that is, closed locations were removed and newly emerged locations were added—through a validation process facilitated by the study team members who are in regular, direct contact with key population members. Through this validation process, population size estimates for each location, the days and times when these locations are operational, and the days when the locations have the highest number of female sex workers or men who have sex with men were verified and revised, as needed, via a standardized approach.

The lists of validated locations (1 each for female sex workers and men who have sex with men) formed the sampling frames representing the universe of locations across Nairobi County. Key population members spending time within a given location tend to be more homogeneous, in terms of typology and risk behavior, than those in different locations [27]. As such, potential participants for each PBS session were randomly selected from a single location. During the first stage of sampling, 99 locations (equal to the number of PBS sessions planned for each group) were randomly selected such that 1 PBS session was conducted per selected location. The random selection of key population group–specific locations from which potential participants were identified was stratified by subcounty and location typology.

**Stage 2 Sampling**

In stage 2 of sampling, each of the 99 randomly selected locations was randomly allocated to an assigned week and day on which potential participants were enrolled from the location. For example, data collection for this ePBS study was projected to take 30 days; for each location, 1 week (ie, from weeks 1 to 4 of the study period) was randomly selected first, followed by the random selection of 1 specific day within that chosen week. This process determined the precise week and day that each selected location was designated for the study. Ultimately, 10 to 12 potential participants were randomly approached by...
community researchers at the location on the specified day and week and invited to take part in the study.

This 2-stage sampling approach ensured that participants were representative of the total population of the key population group by geography (subcounty) and location typology across days of the week, yielding a comprehensive and diverse sample of participants from communities of female sex workers and men who have sex with men in Nairobi County.

Study Procedure

The overall flow of the ePBS study procedure from participant identification and enrollment to PBS, BBS, and FGD (every fifth PBS session) is outlined in Figure 1. The duration to complete PBS and BBS was 120 minutes, including 10 minutes for initial screening and consent, 60 minutes for the PBS, 20 minutes for pretest counseling, and 30 minutes for BBS. For every fifth PBS group participating in an FGD, an additional 45 to 60 minutes was added to their total estimated participation time.

Figure 1. Expanded PBS study procedure flowchart used to collect data from female sex workers and men who have sex with men in Nairobi, Kenya, from April to May 2023. BBS: behavioral and biological survey; FGD: focus group discussion; PBS: polling booth survey; PrEP: pre-exposure prophylaxis; SWOP: Sex Workers Outreach Program.

Participant Enrollment and Data Collection Site Preparation

Potential participant enrollment occurred at selected locations on the allocated days of the week, according to the study’s sampling frame. Enrollment primarily occurred in the late afternoon or evening on the day of data collection to increase the likelihood of meeting a higher number of female sex workers or men who have sex with men in the location. Peer educators and outreach workers from the SWOP clinics facilitated the identification of potential participants within their own key population group. They were responsible for introducing potential participants to the study and assessing their eligibility. Any eligible individuals were provided with detailed information about ePBS. If eligible participants were interested in participating in the study, they were brought to the data collection site by peer educators and outreach workers. As much as possible, data collection occurred within the selected locations. Ahead of participant enrollment, the study team members scouted selected sites to identify suitable spaces for safe and confidential data collection. Team members were responsible for setting up stations for PBS and private, quiet locations for face-to-face structured interviews and biological sample collection. If the selected sites posed challenges (e.g., logistical or safety challenges) for data collection, prescouted alternate locations nearby were used instead.

Ethical Considerations

Informed Consent

At the data collection site, before ePBS data collection commenced, prevention officers, with the support of community researchers, guided participants through the informed consent process, ensuring that all participants understood and were comfortable with the information included in the consent form. Any questions from potential participants were addressed before commencing the study. Nonconsenting or unwilling participants were thanked for their time and excluded from the study. All eligible participants who provided written or verbal informed consent received a unique identifying code that was used for the BBS portion of the study.

Participant Compensation

Participants received compensation for their time and travel at a standard local rate of Ksh 500 (US $5). Those participating
in FGDs received an additional Ksh 500 (US $5) for their extra time.

**Safety**

Conducting research studies with key populations who are criminalized in Kenya requires careful consideration to ensure community safety. Before initiating data collection, extensive consultations with key population communities were conducted. The primary objectives of the study and the methodology were shared and explained during these consultations. Feedback obtained from the community was instrumental in shaping the study procedures to ensure the communities’ safety and comfort. Furthermore, a collaborative partnership with Nairobi County authorities was established to enhance the safety and protection of both the study teams and the key populations and participants. The study teams carried official identity cards and study approval letters to show that they were conducting an official study. The data collection took place in locations where female sex workers and men who have sex with men generally congregate and that were considered to be safe. Location managers were sensitized and informed about the study ahead of implementation. Study team members were trained in crisis management and were provided a protocol to follow in case of an emergency or a breach in safety for the study team or participants. A team of supervisors, including senior team members of PHDA and Nairobi County officials, visited the sites each day for supervision and support.

**Ethics Approvals**

The research study has received ethics approvals from Amref Health Africa Ethics and Scientific Review Committee, Kenya (Amref ESRC P1365/2022); Health Research Ethics Board, University of Manitoba, Canada (HS25883); National Commission for Science, Technology, and Innovation, Kenya (NACOSTI/P/23/24009); and Nairobi City County, County Health Research Ethics Committee (NCCG/HWN/REC/349).

**Privacy and Confidentiality**

All investigators have completed a web-based course on the protection of human participants in research and have obtained certificates. Furthermore, investigators and all study team members have signed data confidentiality agreements with PHDA, pledging to uphold the highest standards of data privacy and security.

During the informed consent process, female sex workers and men who have sex with men participating in the study were clearly informed of their right to withdraw from the study at any point if they so desired. This withdrawal did not affect their access to the services provided by SWOP clinics. The potential benefits and risks associated with participating in the study were thoroughly explained to the participants during the informed consent process.

**Study Instruments**

Standardized instruments adapted for female sex workers and men who have sex with men were used for the PBS and BBS. The FGD guide was standardized for all populations. All tools were available in English and Kiswahili.

**Data Entry and Management**

Each study team had 2 tablets that were preloaded with customized web-based survey software (SurveyCTO) and were used for data entry and management. Data collected during PBS sessions were first compiled in hard copy format using standardized reporting forms that were filled out by the prevention officer and community researchers after PBS responses were tallied. Reporting form tallies were then entered into tablets by the prevention officers on each study team. BBS data were directly entered into tablets using SurveyCTO. Data quality checks were automated within the web-based system. Data were uploaded securely to a central server at the end of each field day via a virtual private network (VPN).

Select biological samples collected were sent to the PHDA laboratory (Table 1). These laboratory data were managed using the Laboratory Information Management Software (LMIS), uploaded to a repository in CSV format, and merged with data collected through SurveyCTO by the study’s data manager.

The study team’s qualitative researchers were responsible for digitally audio recording FGDs and transcribing and translating (into English) the FGD data.

**Data Security**

Data were transmitted over an encrypted channel (HTTP secure), and personal identifiers were automatically encrypted at data entry. Access to central servers is restricted. Data will be stored in encrypted format for 5 years, following national data security protocols.

**Data Cleaning**

Daily data quality checks will be performed on PBS and BBS data collected through SurveyCTO, addressing discrepancies, missing data, and inconsistencies as they are identified. The study teams’ prevention officers and site supervisors will oversee the data cleaning and quality assurance procedures.

**Data Analysis**

Data from PBS and BBS will be analyzed at the group and individual levels, respectively. Descriptive statistics will be calculated, and univariate analyses will be conducted to measure previously specified outcomes (Textbox 1) and assess risk factors associated with HIV. Guided by the coverage cascade element of the effective program coverage framework [16], coverage gap analyses will be performed to identify and quantify gaps in availability coverage, contact coverage, and use coverage in relation to required coverage targets. Thematic analysis will be done for FGD data to capture recurring concepts and ideas related to barriers and facilitators to accessing, contacting, and using prevention services that emerged during discussions.

**Knowledge Translation and Dissemination**

The study’s findings and lessons on the feasibility and utility of ePBS as a data collection method will be shared through participation in the Nairobi County Key Population Technical Working Group and the National Key Population Technical Working Group led by the NASCOP. This working group comprises members representing implementing partners, key...
population community representatives, donors, and the Kenyan Ministry of Health officials. These stakeholders will have the opportunity to use the study’s findings to inform and strengthen programs and policies for key populations in Nairobi. In addition, the study results will be shared with the PHDA-SWOP Community Advisory Board and peer educators. These insights will support the development of strategies to enhance program effectiveness and improvement.

Research findings and methodological insights from implementing the novel ePBS study will be shared with academic communities in Kenya and globally through international conferences and peer-reviewed journal articles. PHDA is a part of an extensive, existing network of researchers in public health sciences, health policy, and basic and natural sciences who focus on HIV and sexually transmitted infections. Other scientific forums within the University of Manitoba will be leveraged to share the findings.

Results

The study enrolled 759 female sex workers (response rate: 759/769, 98.6%) and 398 men who have sex with men (response rate: 398/420, 94.7%) across 64 and 35 PBS sessions, respectively (Table 2).

In total, 758 (99.9%) female sex workers (1 participant refused participation in BBS) and 398 (100%) men who have sex with men participated in the face-to-face interview for the BBS, and all (n=1156) provided blood and urine samples for rapid tests. In total, 14.79% (171/1156) of participants (female sex workers: n=101, 59.1%; men who have sex with men: n=70, 40.9%) tested positive for HIV via rapid test. Among those testing positive, 93.6% (160/171) of participants (female sex workers: n=100, 62.5%; men who have sex with men: n=60, 37.5%) provided consent for venous blood sample collection. Three whole blood samples from female sex worker participants were discarded due to missing bar codes on the sample tubes. A total of 73 participants reported currently receiving PrEP in the BBS face-to-face interview (Table 2), and rapid urine tests were conducted on the samples from these participants (female sex workers: n=56, 77%; men who have sex with men: n=17, 23%).

Table 2. Expanded polling booth survey (ePBS) participant enrollment and data collection among female sex workers and men who have sex with men in Nairobi County, Kenya, from April to May 2023 (n=1157).

*aBBS: behavioral and biological survey.

A total of 20 FGDs were completed with female sex workers (n=14, 70%) and men who have sex with men (n=6, 30%).

Data cleaning and analysis are ongoing. Aggregate responses from each PBS session and individual data from BBS respondents have been entered into separate data modules in the data entry software. The data will then be exported to SPSS (version 28.0; IBM Corp) for analysis. Weights will be applied to data during analyses to account for the sampling design and to adjust for unequal selection probabilities. CIs will be calculated, and descriptive analyses of the PBS and BBS data will be performed separately to address the study objectives.

The FGD data will be simultaneously translated and transcribed into English by the qualitative study team. Qualitative notes taken during the FGDs will be incorporated into a final transcript to provide appropriate contexts and details where necessary. Thematic analysis will be used to systematically capture recurring concepts, ideas, and topics that emerged during the discussions.

Furthermore, we will use the effective program coverage framework [16] to assess gaps in availability coverage, contact coverage, and use coverage within the condom, PrEP, and antiretroviral therapy program components. Equity analyses will be conducted with program coverage data to assess inequalities in the coverage of each component intervention based on age, geography, and location typology.

Discussion

Overview

Joint United Nations Programme on HIV and AIDS encourages countries to annually measure outcomes using nimble, rapid, and low-cost methods [28]. Through this study, the novel ePBS method was implemented for the first time, which expands upon the traditional PBS method by integrating BBS and FGD modules with minimal requirements for additional resources. Furthermore, this innovative approach adopted robust sampling methods to ensure the representativeness required for a population-based survey, unlike the traditional PBS method, which uses program-based sampling approaches [7,23]. This approach included data gathered at the group level (PBS and FGD) and individual level (BBS), encompassing behavioral, biological, and structural aspects of a combination prevention approach, from a total sample of 1157 participants within a
30-day timeframe. This method significantly enhances the range of tools currently available to collect routine outcome data from HIV prevention programs. Importantly, the ePBS method empowered the research team to efficiently gather a rich data set comprising both quantitative and qualitative data for program optimization and expanded the understanding of local HIV epidemics among key populations. The inclusion of community researchers in the study team and the involvement of peer educators at the sampled locations fostered trust and instilled confidence among study participants, enhancing the study’s credibility, which is reflected in the study’s high response rate.

Program and Policy Implications

Notably, this study draws upon a program science approach using the effective program coverage framework to assess HIV program coverage [16,18] and outcomes among female sex workers and men who have sex with men in Nairobi County, Kenya. This embedded approach facilitates the emergence of research questions from programmatic needs and challenges, and findings contribute to defining program and policy priorities. The study questions were formulated by PHDA-SWOP in collaboration with the community advisory board and the Ministry of Health, Nairobi County, who are the primary beneficiaries of the study findings. Engaging stakeholders involved in implementing key population programs, advocating for their rights, developing policies, and being accountable for creating an enabling environment enhance their commitment to use the study’s findings [29].

The study will provide comprehensive data on biological, behavioral, and structural outcomes, as well as program coverage, within an HIV prevention program tailored for female sex workers and men who have sex with men in Nairobi County. In alignment with the Global AIDS Strategy 2021 to 2026, which includes a high-level target of ensuring that 95% of people at risk of HIV infection have access to and use effective combination prevention options, our study findings will serve as a critical measure of the outcomes of such a combination prevention program [30]. In resource-limited settings, the use of ePBS methods can serve as a pragmatic and affordable approach to assessing program outcomes. It allows for rapid data collection and accommodates the integration of qualitative data collection methods and individualized surveys with standard PBS. Critical to a program science approach, because this research is embedded within Nairobi County’s key population program, the results of this ePBS study can be seamlessly incorporated to refine the program strategy to improve coverage and outcomes. In addition, this embeddedness allowed for the ePBS study to be carried out by the program team, thereby minimizing expenses in comparison to traditional integrated biobehavioral surveillance surveys.

Limitations

It is important to acknowledge that this study has inherent limitations, primarily due to its cross-sectional design. The results of this study will be descriptive in nature and will not contribute to the understanding of causal relationships. In addition, the study relies upon several self-reported variables, which are always subject to recall and social desirability biases. Finally, this study, and the ePBS method generally, greatly benefit, in terms of scalability and implementation, from being embedded within an established HIV prevention program for key populations, which might not be feasible in all settings.

Conclusions

The ePBS method has the potential to meet the demand for a rapid, cost-effective, and practical approach to regularly measuring HIV outcomes in key population programs and generating insights for ongoing program improvement. The study gathered crucial data on HIV outcomes and piloted a new method called ePBS, which combines PBS, BBS, and FGDs to enhance its practicability. Our findings will help improve the HIV prevention program for key populations and develop policies in Nairobi County.

Acknowledgments

The authors would like to thank the Nairobi County HIV team including Jesca Omai, Vanessa Chelimo, Shillah Mwavua, Douglas Kibanda, Ann Wahome, Edwin Mwangi, Nicasio Ngaji, and Lilian Tuara, who supervised data collection and ensured that an enabling environment was created for conducting the study. The authors especially thank Ephantus Wachira, Jackline Achieng, Rachel Lishindu, and Hadija Abdullah from the Partners for Health and Development in Africa (PHDA)-Sex Workers Outreach Program (SWOP) outreach team for their contribution to developing the tools and data collection. Furthermore, the authors would like to appreciate the contributions to data collection from the SWOP team members: Reuben Nyuru, Dan Khaemba, Martin Mbuthia, David Ngata, Tali Lumbasi, Kennedy Ojwang, Chrispo Nyamweya, Mary Kung’u, Anderson Mafusa, Kenneth Munene, Caroline Muriuki, Bernard Juma, Irene Wanjiru, Rachael Lishindu, Celilia Mwangi, Monica Okumu, and Pollet Ong’ayo. The authors would like to thank Erastis Irungu and Peggy Obam for setting up the PHDA laboratory for the study. They would also like to thank Santosh Singh for setting up the database for the study. In addition, the authors would like to appreciate the contribution of Dr Collins Owek, Apollo Kamau, Tony Kariri, Betty Rugendo, Wycliff Kioko, Festus Muriuki, and Laisa Lumumba from PHDA for providing supervisory support to the data collection team. The authors would like to thank Siobhan Malone and Geoff Garnet from the Bill & Melinda Gates Foundation (BMGF) for their support in the expanded polling booth survey method. This publication is made possible by the support of BMGF (investment ID INV050927). The views expressed herein are those of the authors and do not necessarily reflect the official policy or position of BMGF.
Data Availability
The data sets generated and analyzed during this study will not be publicly available due to the sensitivity of the data collected—sex work and same-sex relationships are criminalized in Kenya—and a prevailing antagonistic environment against LGBTQI+ (lesbian, gay, bisexual, transgender, queer, intersex, and others) populations exists across the country. However, data can be made available from the corresponding author on reasonable request.

Authors' Contributions
PB, LMM, SI, JK, RWK, A Kinyua, HM, A Kiplagat, PA, SS, FE, MLB, and JB participated in the design of the study. PB, SI, LMM, MLB, and SS developed the quantitative tools. LMM developed the qualitative tool. SI conducted sample size calculations. JK, PB, SI, LMM, HM, RWK, A Kinyua, and A Kiplagat trained the study teams and supervised data collection. JKO and VNN supported in the training and were involved in data collection. JK supervised biological sample collection and laboratory tests. PB wrote the first draft of the manuscript with support from LMM and SI. All authors have read and approved the final manuscript.

Abstract

Background: Drug-induced suicide (DIS) is a severe adverse drug reaction (ADR). Although clinical trials have provided evidence on DIS, limited investigations have been performed on rare ADRs, such as suicide.

Objective: We aimed to systematically review case reports on DIS to provide evidence-based drug information.

Methods: We searched PubMed to obtain case reports regarding DIS published until July 2021. Cases resulting from drugs that are no longer used or are nonapproved, substance use, and suicidal intentions were excluded. The quality of each case report was assessed using the CASE (Case Reports) checklist. We extracted data regarding demographics, medication history, suicide symptoms, and symptom improvement and evaluated the causality of DIS using the Naranjo score. Furthermore, to identify the potential suicidal risk of the unknown drugs, we compared the results of the causality assessment with those of the approved drug labels.

Results: In 83 articles, we identified 152 cases involving 61 drugs. Antidepressants were reported as the most frequent causative drugs of DIS followed by immunostimulants. The causality assessment revealed 61 cases having possible, 89 cases having probable, and 2 cases having definite relationships with DIS. For approximately 85% of suspected drugs, the risk of suicidal ADRs was indicated on the approved label; however, the approved labels for 9 drugs, including lumacaftor/ivacaftor, doxycycline, clozapine, dextromethorphan, adalimumab, infliximab, piroxicam, paclitaxel, and formoterol, did not provide information about these risks.

Conclusions: We found several case reports involving drugs without suicide risk information on the drug label. Our findings might provide valuable insights into drugs that may cause suicidal ADRs.

Introduction

Suicide is a serious global public health problem. According to a 2019 report from the World Health Organization, more than 700,000 people die annually by suicide, implying that 1 person dies by suicide every 40 seconds [1]. Suicide results in fatal outcomes, enormous emotional distress for families, and a significant economic burden on society [2]. Therefore, much attention is required to reduce the burden of suicide. Suicide is associated with multiple factors, such as sex, age, history of suicide attempts, familial history of suicide, alcohol use, psychiatric disorders, and physical disorders. Among the identified risk factors, psychiatric and physical health disorders are the main controllable factors that prevent suicidal adverse drug reactions (ADRs). However, therapeutic drugs for these disorders have also been reported as a cause of suicide.

Psychiatric drugs, such as antidepressants, anxiolytic drugs, and antipsychotics, are representative drugs that have potential adverse effects, such as suicidal behavior. For instance, Stone et al [3] have conducted a meta-analysis involving 372 randomized controlled trials of antidepressants and reported that the odds ratio for suicidal behavior and ideation among patients aged younger than 25 years was 2.30 (95% CI 1.04-5.09). Moreover, several studies have demonstrated that some commonly prescribed drugs, such as hormonal contraceptives and beta-blockers, may induce suicidal ADRs [4,5]. According to a study by Qato et al [6], labels of 103 drugs indicated suicidal symptoms as side effects and the rate of administration of these drugs increased by approximately 1.09-1.35 folds from 2005-2006 to 2013-2014. Moreover, they revealed that patients who took these medicines had approximately 5.3% greater concurrent symptoms of these adverse events than those who did not.

Owing to the growing awareness regarding drug-induced suicide (DIS), several studies have investigated the association between specified drugs and suicide [7-15]. Most of these studies involved case-control and cohort study designs and disproportionality analysis of pharmacovigilance databases. However, investigating the overall suicidal risk of all available drugs is challenging. Furthermore, the databases used in observational studies may not fully account for detailed clinical presentations, symptoms, and all other relevant factors contributing to suicide risk, such as preexisting mental health conditions, social support, and family history. Therefore, more comprehensive research is necessary to fully understand the potential association between all available drugs and DIS, considering individual patient factors and drug interactions.

In pharmacovigilance, case reports are crucial in identifying new safety signals and alerting physicians regarding the potential rare ADRs [16]. Case reports provide detailed clinical presentations and increase awareness regarding drug safety, although they are limited in establishing causality evidence. Thus, this study aimed to conduct a systematic review of published case reports on DIS associated with all available drugs. We further assessed the causality of DIS in each case and compared it with drug labeling information to establish new safety signals of DIS.

Methods

Overview

We conducted a systematic review of case reports on DIS published until July 2021 according to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) reporting guidelines (Multimedia Appendix 1) [17]. The literature search was performed on PubMed based on a combination of the following keywords—“suicide” and “drugs”—using Medical Subject Headings and text words. Two independent authors validated the search strategy, using the detailed search terms presented in Textbox S1 in Multimedia Appendix 2. For drug keywords, we used the active ingredient and generic name of the drug to obtain as many case reports as possible. The active ingredients or generic names of drugs were searched on “DrugBank.” We limited the article type and language to case reports and English, respectively.

Study Selection

In this systematic review, we included case reports on suicidal behavior after administering the prescribed medications. We defined suicidal ideation and behavior as self-harm, suicidal ideation, and completed suicide. The exclusion criteria were (1) case reports on drugs that were no longer used or were nonapproved, (2) case reports on patients who took drugs for suicidal purposes, and (3) case reports without any mention of suicidal ADRs (eg, suicide genes). There were no restrictions on patient conditions, such as age, sex, psychiatric status, and outpatient or inpatient treatment.

Two authors with a background in pharmacology were independently involved in the process of article selection. They screened the titles and abstracts of all searched articles that met our eligibility criteria. If no consensus was reached between the 2 authors, a third independent author was solicited to make the final decision.

Data Extraction

We extracted data from relevant case reports regarding patient demographics (ie, age, sex, psychiatric status, and socioeconomic status), medication history (ie, ADR, drug dosing, time to event, concomitant medication, and laboratory test), symptoms, improvement in symptoms after dose reduction or drug discontinuation, and causality assessment results.

Data Synthesis and Analysis

For all cases of DIS, we summarized patients’ demographics, including age, sex, and underlying psychiatric status. The demographics of cases were presented as the frequencies and percentages. Age was categorized into 3 groups (<19, 19-59, and 60+ years). Data were presented according to the classes of suspected drugs involved in DIS cases. The drug classes were classified according to the anatomical therapeutic chemical (ATC) code [18]. The third level of the ATC (ie, the chemical, pharmacological, or therapeutic subgroup) was mainly used to categorize drugs; some drugs were classified based on the second level of the ATC (ie, the pharmacological or therapeutic subgroup). Detailed code classification is presented in Table S1 in Multimedia Appendix 2.
Furthermore, we assessed the probability of drug administration that leads to DIS using the Naranjo ADR score [19], which has been widely used as a tool for causality assessment in case reports. This scale included 10 simple and clarified questions, and the answer to each question is categorized into 3 options “Yes,” “No,” and “Unknown.” This scale can consider the missing values when evaluating the causality. The calculated score was classified into 4 levels, as follows: doubtful (≤0), possible (1-4), probable (5-8), and definite (≥9). As some questions in the original version of the Naranjo algorithm were not detailed enough to assess causality, we defined and used detailed criteria (see Multimedia Appendix 3). Although few articles had already included information regarding the Naranjo score as a causality assessment, we reevaluated this score for all articles. The quality of the selected reports was evaluated using the CARE (Case Reports) guidelines [20].

Investigation of Potential Drugs for DIS Risk

We compared the causality assessment results with corresponding label information to identify drugs with the potential risk of suicide. In this analysis, we used the average Naranjo score for each drug as a representative value of our causality assessment. We reviewed the label information for all suspected drugs using the Food and Drug Administration (FDA)-approved label and Micromedex and classified these drugs into 3 groups, as shown in Textbox 1 (high-, intermediate-, and low-level evidence). Drugs were considered “high-level evidence” if the label information indicated a direct expression of “suicide” (ie, suicide, suicide attempts, suicidal ideation, suicidal thoughts, suicidal behavior, suicidality, or suicide risk). Drugs were considered “intermediate-level evidence” if the label information did not directly indicate suicide but specified psychiatric disorders often associated with suicide-related symptoms (ie, depression, anxiety, delirium, hallucinations, and psychotic behavior). The remaining drugs were considered “low-level evidence.” In our case reports, if the suspected drugs associated with DIS were classified as low-level evidence according to the label information, we considered them as potentially unrecognized drugs for DIS.

Textbox 1. Current evidence levels for reported drugs associated with DIS based on the approved labeling information.

</thead>
<tbody>
<tr>
<td>High</td>
<td>Drugs with information that includes a direct expression of “suicide,” such as suicide, suicide attempts, suicidal ideation, suicidal thoughts, suicidal behavior, suicidality, and suicide risk.</td>
</tr>
<tr>
<td>Intermediate</td>
<td>Drugs with information regarding psychiatric disorders associated with suicide-related symptoms, such as depression, anxiety, delirium, hallucinations, and psychotic behavior.</td>
</tr>
<tr>
<td>Low</td>
<td>Drugs without any adverse drug reaction information for suicide and suicide-related symptoms.</td>
</tr>
</tbody>
</table>

Results

We identified 2877 articles from the PubMed database and removed 7 duplicated records. After reviewing the titles and abstracts of these articles for eligibility, we excluded 2778 articles that met the exclusion criteria. Overall, 9 of the remaining 92 articles were excluded because they did not contain full text (n=7) or had ineligible study designs (n=2). Finally, we selected 83 articles that involved 152 individual drug-suicide relationships (Figure 1). In total, there were 70, 65, and 17 cases of suicidal ideation, suicide attempts, and completed suicide, respectively. The studies had total scores ranging from 17/30 to 24/30 according to the CARE checklist (Multimedia Appendix 4).
In these case reports, 61 individual drugs were identified as drugs associated with DIS and were grouped into 31 classes. Table 1 summarizes the demographics and characteristics of DIS cases according to the class of the suspected drugs. There were 26 cases of DIS related to antidepressants, which was the most frequently reported drug class. For antidepressants, most patients were aged between 19 and 59 years (n=16) followed by the age group of 2-18 years (n=8). A psychiatric diagnosis was made in all patients, except for 1; and 6 patients had a history of suicide attempts. In 25 patients (with a mean age of 37.8 years), immunostimulants were identified as the causative drug for DIS. A total of 7 patients showed a personal or family history of psychiatric disorders or suicide attempts. Antiepileptics were identified as the causative drugs for DIS in 15 patients, of whom 8 had a history of psychiatric disorders. Furthermore, 8 patients associated with anabolic steroids were all male and aged between 19 and 59 years (mean age of 26.5 years). All 8 patients associated with psychostimulants were aged 2-18 years (mean age 10.3 years; range 9-13 years), which was the youngest among all the drug classes.

</table>

- Number of patients who were duplicated because the cases were associated with more than 2 individual drugs.
- The proportion was estimated as the proportion of reported cases within each drug classes.
- AI: anti-inflammatory.
- AR: antirheumatic.

Figure 2 and Table S2 in Multimedia Appendix 2 show the results of the causality assessment of all cases based on the Naranjo algorithm. The results revealed a definite causal association with DIS in 2 cases, probable association in 90 cases, and possible association in 61 cases. The 2 cases with definite causation of DIS were identified in cases associated with doxycycline (antibacterial) and perampanel (antiepileptics), respectively.
Table 2 shows the results of the comparative analysis between our results and the drug labels. The labels of 51 (85%) of 60 drugs contained information regarding the risk of suicidal ADRs. The high- and intermediate-level evidence groups included 33 and 18 drugs, respectively. However, the risk of suicidal ADRs was not indicated on the label of the 9 suspected drugs. Of these, 6 drugs had a “probable” causal relationship (lumacaftor/ivacaftor, doxycycline, piroxicam, clozapine, adalimumab, and paclitaxel), whereas the remaining 3 drugs had “possible” causality (infliximab, dextromethorphan, and formoterol).

Table 2. Comparative assessment of suspected drugs in suicidal adverse drug reactions between reviewed case reports and the approved labeling information.

</tbody>
</table>

\(^a\) In this analysis, we excluded anabolic androgenic steroids because they did not present the information of the involved agent.

\(^b\) Causality was evaluated for each drug based on the average Naranjo scores in the case reports for each drug.

\(^c\) Lumacaftor/ivacaftor, doxycycline, piroxicam, clozapine, adalimumab, and paclitaxel.

\(^d\) Infliximab, dextromethorphan, and formoterol.
The number of cases and the criteria and average score of Naranjo for 17 case reports implicating suspected drugs with low-level evidence on the approved labels were as follows, respectively: lumacaftor/ivacaftor (5 cases, probable 5); doxycycline (3 cases, probable 7.3); piroxicam (1 case, probable 5); clozapine (2 cases, probable 6); adalimumab (2 cases, probable 6.0); paclitaxel (1 case, probable 5.0); infliximab (1 case, possible 4); dextromethorphan (2 cases, possible 3.5); and formoterol (1 case, possible 3). Multimedia Appendix 5 [21-55] provides detailed information on the evidence of the Naranjo score of each case.

Discussion

Principal Findings

To the best of our knowledge, this is the first comprehensive systematic review of DIS based on published case reports. While several studies have reported on the suicide risk of drugs [7-15], most of them have concentrated on limited drugs for which risks have previously been reported. Therefore, our study aimed to bridge this gap by conducting a systematic review of case reports for all available drugs with suicidal risk, including those not previously known to have such a risk. We identified 61 drugs from 29 classes associated with DIS based on published case reports, of which 9 drugs showed a potential risk of suicide despite not being mentioned in their labels.

Most documented DIS cases involved drugs that already had a potential suicidal risk indicated on their labels. This tendency might result from an increased focus on drugs recognized for their potential risk of suicidal ADRs. For instance, antidepressants, the most frequently reported drugs related to suicidal ADRs, carry black box warnings of suicidal risk issued by the FDA. While some drug labels did not directly mention the risk of suicide, they indicated the potential psychiatric ADRs that can lead to suicidal behaviors. Propranolol labels present depression and hallucinations among its psychiatric side effects, which could contribute to triggering suicidal events. Recent studies using pharmacovigilance databases have also strengthened evidence regarding the suicidal risks associated with these drugs [11-15].

This systematic review has found 9 drugs—lumacaftor/ivacaftor, doxycycline, piroxicam, clozapine, paclitaxel, adalimumab, infliximab, dextromethorphan, and formoterol—that potentially carry suicidal risks not mentioned on the labels. Despite the absence of available data on labels, previous studies have investigated the potential for suicide or suicide-related behaviors associated with these drugs. However, the precise mechanism related to these suicidal risks remains still unclear. For instance, doxycycline, which exhibited the highest causality for suicidal ADRs in our study, might be related to heightened psychiatric adverse effects due to increased retinoid levels by CYP450 inhibitory effect [21]. In addition, other studies suggested changes in the gut microbiome composition after antibiotic use, leading to the incidence of psychiatric disorders, such as depression and schizophrenia [22-24]. A previous systematic review reported that several clinical trials reported the improvement of depressive, anxiety, and mood symptoms after probiotic treatment [25].

The suicide risk of piroxicam may be related to inhibiting cyclooxygenase activity involved in synthesizing prostaglandins [26,27]. However, there is a lack of direct information about changes in prostaglandin levels [28]. Paclitaxel may be attributed to glutamine depletion and neurotransmitter [29], even though a clear association with suicide is challenging due to the limited information on patients' posttreatment status [30]. Other drugs, tumor necrosis factor-α inhibitors [31-35], paclitaxel [29], dextromethorphan [36-38], formoterol [39], clozapine [40-43], and lumacaftor/ivacaftor [44-46] are not easy to explain the clear mechanism for the suicidal events. Despite these complexities, most cases involving these 9 drugs reported symptom improvement after drug discontinuation. Hence, the potential risk of suicide associated with these drugs cannot be disregarded, and further studies are a crucial for clear understanding of the potential suicidal risk of these drugs.

Limitations

This study also has certain limitations. First, as case reports are not experimental studies conducted with a placebo, the causal relationship between drugs and ADRs cannot be determined. Although we used the Naranjo algorithm to evaluate causality, other factors, such as the underlying psychiatric disorders and other drugs, could affect suicidal events. Therefore, our findings only provide some safety signals regarding which drugs may have a higher risk of suicide not identified in clinical trials [56]. Second, the number of cases for each drug is insufficient for generalizing the findings to the population level. Third, we used PubMed only and did not manually search other journals or sources of gray literature and restricted the inclusion of studies to those published in English. Therefore, our findings might not represent all published case reports. Nevertheless, we constructed a detailed search query using the term of all marketed drugs, which may minimize the impact of limitation. Furthermore, studies have demonstrated that excluding non-English studies might have little effect on the results [57,58].

Conclusions

Our systematic review of case reports identified a potential risk of suicide associated with several drugs. Most of the cases involved drugs with a documented suicide risk on the label, but 9 drugs were identified without such reporting. Although it is difficult to establish evidence of ADRs based on case reports alone, our findings highlighted the need to raise awareness of the potential for DIS beyond what is documented in drug labels. Therefore, further research exploring suicidal ADRs across various drugs is essential.

Abstract

Background: Handpumps are used by millions of people as their main source of water. Although handpumps represent only a basic form of water provision, there have been continuous efforts to improve the performance of these systems as they are likely to remain in use for many years to come. The introduction of a professional maintenance service in southern Kenya has shown an order of magnitude improvement in operational performance over community-based management, with 90% of handpump faults repaired within 3 days of being reported. One driver behind these efforts is the assumption that a more reliable water supply will lead to a reduction in water-related disease. However, it is not clear if operational improvements lead to health gains. Despite limited empirical evidence, some modeling studies suggest that even short periods of drinking contaminated water can lead to disproportionate negative health impacts.

Objective: The aim of this study was to assess whether the improvements in operational performance from the rapid professional maintenance of rural handpumps lead to improved household health outcomes.

Methods: From a sample of households using handpumps as their primary water source in Kwale County, Kenya, we measured the 2-week prevalence of World Health Organization–defined diarrhea in children, reported by the adult respondent for each household. We compared the rates before and after a period during which the households’ handpumps were being professionally maintained. We then conducted a cross-sectional analysis, fitting logistic regression models with reported diarrhea as the dependent variable and speed of repair as the independent exposure of interest, adjusting for household socioeconomic characteristics; dwelling construction; and Water, Sanitation, and Hygiene (WASH)-related factors. We fitted an additional model to examine select interactions between covariates.

Results: Reported diarrhea in children was lower in households whose pumps had been repaired within 24 hours (adjusted odds ratio 0.35, 95% CI 0.24-0.51). This effect was robust to the inclusion of multiple categories of covariates. No reduction was seen in households whose pump repairs took more than 24 hours. Analysis of interaction terms showed that certain interventions associated with improved WASH outcomes were only associated with reductions in diarrhea in conjunction with socioeconomic improvements.

Conclusions: Only pump repairs consistently made within 24 hours of failure led to a reduction in diarrhea in the children of families using handpumps. While the efficacy of reduction in diarrhea is substantial, the operational challenges of guaranteeing same-day repairs limits the effectiveness of even best-in-class pump maintenance. Maintenance regimes that cannot bring...
handpump downtimes close to zero will struggle to generate health benefits. Other factors that reduce diarrhea prevalence have limited effect in isolation, suggesting that WASH interventions will be more effective when undertaken as part of more holistic poverty-reduction efforts.

Introduction

In rural areas with no grid electricity or limited funds to run diesel generators, many communities depend upon handpumps to access shallow groundwater for their daily water needs. Groundwater, in contrast to surface water, is more likely to be available year-round and less likely to require treatment to be potable [1]. Despite efforts throughout the period of the Millennium Development Goals and now in response to Sustainable Development Goal (SDG) 6.1, “safely managed water for all,” millions of people will still be relying on water from handpumps beyond 2030. While “safely managed” water—as defined by the World Health Organization (WHO)/United Nations Children’s Fund (UNICEF) Joint Monitoring Programme (JMP) as the use of “an improved drinking water source which is located on premises, available when needed, and free of fecal and priority chemical contamination”—remains the goal for water services for all, the size of the task and difficulty in achieving this goal has been acknowledged through the JMP Service Ladder’s inclusion of an interim service level of “basic” water, the category that includes most handpumps [2].

There are many reasons for aspiring to the goal of safely managed water for all. One of the main drivers of this goal—and Water, Sanitation, and Hygiene (WASH) interventions more generally—has been the understanding that disease morbidity can be reduced through better water service provision [3]. Piped water to the home, the most usual conception of safely managed water, is associated with lower morbidity, in particular of diarrheal disease [4]. However, with 26% of the world’s population—and 73% in sub-Saharan Africa—still lacking safely managed water and the achievement of SDG 6.1 unlikely at current rates of progress [5], it is important to understand the health implications of having only a basic water supply, as these are at risk of contamination [6], which can lead to diarrheal disease [7].

The contribution of diarrheal disease to the worldwide disease burden is falling but remains substantial [8]. Diarrhea itself contributes to the burden of disease for individuals and consequently to the global burden of disease estimates. Diarrhea is the cause of 1.31 million deaths worldwide, with 303,045 of those being of children under 5 years of age in sub-Saharan Africa; for that same demographic, diarrhea also causes 27 million disability-adjusted life years (DALYs) [9], which corresponds to approximately one in every seven DALYs. Diarrhea interacts with nutrition, reducing nutrient absorption [10,11]; therefore, this figure may significantly underestimate the disease burden from diarrhea by up to 39% [12]. Again, this is especially egregious in children, as undernutrition can produce long-term, nonrecoverable negative impacts on physical and cognitive development [13-16], with associated long-term economic and welfare impacts and related policy implications [17,18].

Community-based management, the model by which local communities are responsible for the repair and maintenance of their pumps, became the default management model for rural water supply in the late 1970s, with mixed success [19-24], and an estimated one in four handpumps in sub-Saharan Africa are out of action today [25]. Since the 2000s, there has been increasing interest in professional management models more akin to how urban piped water systems are run, whether directly by governments or subcontracted to a water service provider [26-29]. More recent evidence indicates that communities do have a preference for private sector involvement in service provision over community management or direct government provision, but only if service performance is high [30-32].

We here present results obtained from a cross-sectional survey following the introduction of a professional handpump maintenance service in Kwale County in southern Kenya. The service was initially funded by a research program that was investigating whether the intervention of a rapid, professional repair service, supported by data measuring handpump use using sensors attached to the pumps [33], could result in repairing handpumps faster than had been the case under community-based management. The rapid repair service reduced average pump downtimes from approximately 1 month to a few days, an improvement that is valued by households and communities [34-37]. This study examined whether this improvement in service performance also led to health benefits. Although there is limited empirical evidence to inform service decisions, some studies suggest that even the shortest periods of drinking contaminated drinking water can lead to disproportionate negative health impacts [38,39], implying a threshold effect with a nonlinear relationship between quality of service and the health benefits of that service. Obtaining empirical evidence about this relationship would inform both local operational decisions and wider WASH policy, and in doing so shed light on the role of handpumps in meeting SDG 6.1.

We hypothesized that shorter pump downtimes resulting from the professional maintenance service would be associated with lower rates of child diarrhea. We examined this by combining data on pump failures and subsequent repairs, generated by the pump mechanics, with self-reported child diarrhea data from households that were surveyed before the repair service was introduced and after 18 months of the service. To overcome the
challenges associated with an observational study, we analyzed the data using two complementary techniques. The first technique compared child diarrhea prevalence (during a 2-week period) in the same households before and after the repair service was introduced to control for time-invariant household characteristics. The second approach involved a cross-sectional analysis comparing households reporting diarrhea with those not reporting diarrhea, adjusting for household characteristics gathered at the same time as the self-reported diarrhea data.

**Methods**

**Study Area**

This study took place in Kwale County, located on the southern coast of Kenya between Mombasa and the border with Tanzania. This region covers an area of around 8300 km$^2$ and has a population of 720,000 that is 82% rural, with the seventh-highest poverty rate among Kenya’s 47 counties. The study area was limited to the Msambweni and Matuga subcounties closer to the coast, covering an area of around 2200 km$^2$. The coastal climate has a bimodal rainfall pattern with an average annual precipitation of 1400 mm with significant interannual variability. Within the study area there is heterogeneity both in socioeconomic characteristics and physical geography. We simplified the study area into three geographical zones for the purposes of analysis (see Figure 1) [36]. In the area in and around the urban center of Ukunda, the population density is higher and there are more alternative sources of water available during handpump breakdowns. There is also easier access to medical facilities in this area. Inland, where shallow wells are supplemented by deeper boreholes drawing water from sandstone, the population is less dense and livestock ownership is more common. Being more sparsely populated makes access to other sources of water more challenging; however, the deeper boreholes into the sandstone enable better source protection relative to shallow wells and improve the likelihood of a given handpump producing uncontaminated water. This is in contrast to the coastal strip where the population is still rural but the density is higher. Alternative nonsurface water sources in the form of other handpumps and shallow wells are relatively close by. However, this proximity of other sources, combined with the high population density and the fact that the wells in this area are mostly shallow and were hand-dug into the karstic coral, make source protection extremely difficult in this area.

Handpump Repair Service

The professional repair service was set up in Kwale as part of a project examining whether professional handpump maintenance, aided by better data on handpumps, could lead to reduced pump downtimes [33,40]. A waterpoint mapping exercise was undertaken in August 2013, recording the location and functionality of the handpumps in the study area, along with basic information about pump repair and management arrangements. A total of 626 pumps were found, with 351 identified as having been functional during the previous 12 months. We then set up an office in Msambweni, near the center of the study area, and recruited two experienced pump fundis (mechanics) and a manager. Two hundred handpumps were offered a free maintenance service, which corresponded to all of the functioning handpumps in a smaller geographical area across Msambweni and Matuga subcounties. The service started in February 2014 and continued until the end of 2015.

We provided the mechanics with motorbikes, tools, and a stock of spare parts to be able to quickly respond to handpump failures and complete most repairs during a single visit to the pump.

Figure 2. Timeline of activities that generated data used in this study.

The survey questionnaire included questions on household makeup and demographics; socioeconomic status, including key consumption and wealth indicators; basic self-reported health indicators for each household member; water use, collection, and storage; and waterpoint institutional arrangements, payment policies, and behavior. These questions were asked of one respondent for each household. For this study, we used the presence or absence of diarrhea reported for children in the household in the 2 weeks prior to the survey as the primary outcome measure; the other items were considered as covariates in the analysis. The only variable used from the 2013 survey was self-reported diarrhea in the 2 weeks prior to the survey.

A second household survey was conducted in March, April, and May of 2015. This was a repeat of the first survey, the aim being to see what had changed for the communities in the study area during the time of the project, specifically in relation to the pump repair service. The two surveys were matched: 59% were matched by household and respondent, 30% were matched by household but not respondent, and the remaining 11% represent cases where a different family/household was living in the dwelling. All the socioeconomic data used in this study were from the 2015 survey as these data represented the households’ situation during the time they were receiving the free repair service. At the time of this survey, the maintenance service had been operational for at least 12 months.

When repairs required more labor, such as removing rising mains, the communities provided pro-bono support to the mechanics. Toward the end of 2015, we spun the repair service out from the research program, establishing it as an independent locally owned entity, named FundiFix. At this point, communities were given the opportunity to continue receiving the maintenance service through paying a heavily subsidized monthly fee [41].

Data Sources

The study timeline is schematically summarized in Figure 2. Building on the mapping exercise completed in August 2013, a more extensive household survey was conducted in October and November 2013. A total of 2508 households who had access to a functioning handpump were surveyed, randomly selected from those using each of the 351 functional handpumps identified during the earlier waterpoint mapping exercise. Household selection was made by the enumerator team leader, selecting a direction and distance from the pump for each enumerator based on a throw of a six-sided die. A mean of 7.1 households were interviewed per handpump.

The two mechanics and their manager who were providing the handpump maintenance service kept detailed records of repairs undertaken, the most significant details being when the breakdown was first identified, when they attended, and when the repair was completed. These records yielded the time and duration of pump outages. Over the whole period, 599 repairs were completed on 169 pumps. The time between a breakdown being reported and repaired varied due to factors such as the complexity of the required repair, the geographical remoteness of the pump, and other logistical or operational constraints. The majority of repairs (90%) were completed within 3 days of a breakdown—the stated target of the service—and 44% were repaired within 24 hours of the fault being reported.

Blinding and Concealment

Efforts were made to ensure blinding and concealment when collecting the data. The enumerators were blinded to the intervention as, other than being aware that the mechanics were operating in the area as part of another University of Oxford–funded research project, they had no knowledge of which pumps had been repaired. While the households were certain not blinded to whether or not they had had a repair, it would not have been readily apparent to participants that the questions about their household members’ health were to be linked to the repairs, because the health questions were part of a large questionnaire and questions about the pump were intentionally asked in a later section of the survey than the health questions.
Mirroring the enumerators, the mechanics had very little knowledge of the household surveys. They were aware that the first household survey had taken place and that the second was occurring, and that it was broadly connected to their work, but they were not in any way involved in the survey. Treatment allocation—in this case, pump repair by the mechanics—could not be entirely randomized given that chance and other factors, measurable or otherwise, will have led to pump breakdown; however, the mechanics’ responses to reported breakdowns were unpredictable and not influenced by the enumerators or research team.

Inclusion Criteria
A total of 1451 households used pumps that were offered the free repair service. Out of these, 294 were excluded as our mechanics had not made a repair to their handpumps during the trial period. A further 182 were excluded as it was reported during the household survey that the reference handpump was not their primary water source. Finally, 135 were excluded as there were no children reported in the household, leaving a sample of 840 households served by 139 pumps. These pumps received 412 repairs, of which 41% were repaired within 1 day and 39% more within 2 days. The longest repair time was 11 days. In the self-controlled analysis, an additional 89 households were excluded because the families living in the dwelling had changed between the two surveys.

Statistical Analysis
Using the data from the second household survey, we first performed bivariate analysis to test the relationship between speed of pump repairs and self-reported diarrhea. We then used the household-matched data from the first survey to compare the period prevalence of diarrhea reported in 2013 against repair performance measured in 2015. This was to determine whether any relationship between the outcome and exposure was due to time-invariant characteristics of the household that were somehow correlated to the speed of repairs and not due to the repair service itself.

We then performed a cross-sectional analysis, fitting multivariable logistic regression models of self-reported diarrhea using the data from the 2015 household survey to adjust for covariates that have been shown to affect diarrhea period prevalence in the WASH-related literature. We fitted a series of multivariable regression models that iteratively adjust for an additional thematic block of covariates: (1) socioeconomic factors, (2) dwelling factors, and (3) WASH factors (see the Results for detailed factors). Additionally, we fitted a model with interaction terms to further explore results of the first three models, which was also guided by the WASH-related literature. Standard errors were adjusted for clustering using the three geographical zones to control for potentially unobserved/unquantified factors that are hypothesized to be correlated among households within each zone [42]. Because multiple households typically share a handpump, the handpump was another potential analytical unit for the clustering of standard errors between households. As a robustness check, we performed an additional analysis that clustered errors by pump instead of geographical zone.

All statistical analyses were undertaken with Stata version 14.2 (StataCorp, College Station, TX, USA).

Ethical Considerations
This research was conducted with permission from Kenya’s National Council for Science and Technology and with ethics approval from the University of Oxford’s Central University Research Ethics Committee (CUREC reference: SOGE C1 13-125). Informed consent was given by all research participants, all of whom were aged 18 years or over.

Results

Unadjusted Analysis
Bivariate logistic regression models did not provide evidence of any association between households reporting diarrhea and the number of repairs performed on their respective handpumps or the time elapsed since the most recent repair. However, this analysis did reveal an association between the speed of repairs (or pump downtime) and reported diarrhea (Table 1). Pumps consistently repaired within 24 hours upon a breakdown, irrespective of the number of repairs, were associated with a lower reported diarrhea rate. This effect disappeared when analyzed against longer repair times (Table 2).

The analysis comparing the same exposure of rapid repairs in 2015 but with the outcome of self-reported disease from the same household in 2013 (ie, when the repair service could not have had any influence) showed no effect. This suggests that the disease reduction was not due to unobserved time-invariant household characteristics that were somehow correlated with the speed of repairs. Rates of reported diarrhea were comparable between the two surveys: 8.2% in 2013 (dry season) and 9.8% in 2015 (wet season).

Cross-Sectional Analysis

The cross-sectional analysis revealed possible predictors of reporting diarrhea. Table 3 shows the odds ratios for diarrhea against other household information gathered during the 2015 survey, along with summary statistics for those characteristics. The quality of dwelling construction was associated with lower reported diarrhea in children, as were having a female head of household and cultivating crops. Apparent risk factors were those related to higher household occupancy and having no regular income. The WASH-related factors of higher per-person water collection and having an improved toilet were apparently protective. Of note, 1.5 jerrycans of water were collected for each household member per day, corresponding to 30-35 liters per person, with few households treating water either by adding chlorine (eg, Waterguard) or by boiling.

Multivariable Analysis of Self-Reported Diarrhea

Table 4 presents the adjusted odd ratios (AORs) and 95% CIs of iterative mixed-effects multivariable logistic regression models of child diarrhea: model 1 begins with socioeconomic factors, model 2 introduces a block of dwelling-related factors, and then model 3 introduces a block of WASH-related factors. The protective effect of handpump repairs consistently made within 24 hours remained robust across all multivariable models.
Of the socioeconomic factors, having a female head of household (AOR 0.54, 95% CI 0.36-0.82; \( P =.004 \)) and growing crops (AOR 0.67, 95% CI 0.48-0.95; \( P =.02 \)) were associated with lower reported diarrhea across all models. Having no income (AOR 1.36, 95% CI 1.11-1.69; \( P =.003 \)) and being further from the market (AOR 1.10, 95% CI 1.07-1.13; \( P <.001 \)) were associated with higher odds of child diarrhea. Having more people in the household was also associated with reporting diarrhea (AOR 1.12, 95% CI 1.04-1.21; \( P =.003 \)), although this was possibly an artifact of aggregating all cases of child diarrhea in the household into a binary variable; nevertheless, an alternate analysis with the number of children in the household produced a similar result. Among the WASH-related factors, having an improved toilet was associated with lower diarrhea (AOR 0.61, 95% CI 0.44-0.84; \( P =.002 \)). The effect of the dwelling characteristics was less consistent across the three models. As a robustness check, we also refitted these models with errors clustered by pump, rather than by geographical zone, but we observed no substantive differences from the results presented in Table 4.

We built on the full model (model 3) by introducing interaction terms between the following pairs of covariates: having no income and growing crops, a female household head and the presence of soap, and having an improved floor and improved toilet. These interactions are presented in Table 5. Having no regular income and not growing crops was the largest risk factor for reporting diarrhea. Strikingly, if a household was growing crops, it had no additional odds of reporting diarrhea if it had no regular income. Conversely, the benefit of having soap in a household seemed only to accrue to households headed by a woman, in which case the odds of reporting diarrhea reduced substantially. Finally, having an improved floor substantially reduced the odds of reporting diarrhea in households with an improved toilet, but provided no added benefit to those without.

### Table 4. Mixed-effects logistic regression models of self-reported diarrhea, adjusted for blocks of covariates, using 2015 household survey data and handpump repair data from 2014 and 2015.

**Discussion**

**Principal Findings**

This study revealed an association between the speed of pump repairs and child diarrhea morbidity. Only households whose pumps were consistently repaired within 24 hours of a failure reported a significant reduction in child diarrhea. This finding is consistent with modeling work that suggests that even the briefest time without high-quality water can lead to disproportionate health impacts [38,39], but the microbiological pathway very likely does not fully explain the higher likelihood of self-reported illness for pumps that were repaired less rapidly. The lag time between pump failure and survey completion varied considerably, ranging from the day before the survey took place to pumps that were repaired when the maintenance service started over 1 year before the survey took place and had remained functional ever since. In these latter cases, direct microbiological causality between pump downtime and illness is unlikely.

In lieu of the presence of a consistent microbiological pathway, we would propose an additional behavioral explanation. If a household has higher confidence in the reliability of their pump, knowing that mechanical failures will be consistently fixed within 24 hours, they may be less likely to immediately fall back on using lower-quality alternative water sources as they might in the case of an extended pump downtime. If households experience any variability in the speed of pump repairs, then they are more likely to collect, store, and use water from less wholesome alternative sources. These are unlikely to be discarded once the pump is fixed, because there was a time or financial cost in acquiring them, thus raising the potential for ongoing waterborne disease exposure.

In addition to providing evidence that only rapidly repaired handpumps lead to a reduction in child diarrhea, this study highlights other factors that contribute to diarrheal disease in rural households reliant on basic water services. Striking, but unsurprising, are the socioeconomic effects, consistent with the WASH literature: the poorer you are, the more likely you are to experience water insecurity and consequently an increased burden of water-related diseases. Growing crops mitigated the impact of having no income; however, we do not have sufficient information from this study to attribute this to the nutritional benefit of growing food or because it generated occasional income or barter opportunities, either being plausible.

Individual components of traditional WASH interventions and programs did not seem to provide a beneficial health effect when considered in isolation. Our use of interaction terms (Table 5) suggested that soap being available and observed at a home was
only associated with a reduction in diarrhea in households headed by women, suggesting that hygiene behaviors in children may be better taught or enforced in households headed by women than by men. Similarly, the benefits of having an improved toilet were magnified by having an improved floor (ie, one made of cement or concrete). Such floors are easier to clean, reducing the likelihood of having human and animal feces present in homes. These empirical data are consistent with conceptual models that articulate a nonlinear relationship between the reduction in fecal contamination and consequent reduction in diarrhea [43,44].

The adaptation strategy of collecting and drinking more unsafe water in response to pump unreliability increases the risk of water-related illnesses. However, this strategy is one that households will rationally stick to unless there is compelling and enduring evidence that it is not necessary. This is consistent with studies on household preferences for rapid pump maintenance [31,34], and was supported anecdotally by conversations with people who were receiving the free repair service. However, even the well-resourced maintenance service linked to this study only fixed 15% of pumps within 24 hours every time they broke down. Acknowledging the possible selection bias in this study, community-managed handpumps are even less likely to be consistently repaired within 24 hours. This is not to discount the many other benefits from reducing pump downtimes, it is simply that health cannot be assumed to be one of them.

From an operational perspective, any pump maintenance service that reduces downtimes by an order of magnitude would be viewed as excellent in the rural water sector or even a best-in-class option. This study demonstrated an association between consistent, rapid handpump repairs and reduced child diarrhea reported in the households that use these pumps, suggesting that such a high level of service may also lead to better health outcomes. Any WASH intervention that achieves a reduction in diarrhea of over 50% would certainly be viewed as a success. If professionalizing handpump operations and maintenance to minimize pump downtimes can yield the health impacts demonstrated in this small study, can it have a substantial impact on the burden of disease?

Only the pumps with the lowest downtimes were associated with this level of health benefit. The 60% reduction in diarrhea was only the best possible outcome for a best-in-class service. The households using handpumps that had received very rapid repair corresponded to only the 15% of pumps where all repairs were completed within 24 hours. An efficacy of 60% translated into an effectiveness in reducing diarrhea morbidity of less than 10% for all the households receiving the repair service. To produce a health benefit, continuity of service must be maintained with near-zero downtime. This level of service is extremely difficult for professional service providers to maintain, and there is scant evidence that community maintenance can consistently achieve these performance levels [24,25,45,46]. FundiFix now operates a hybrid system of reactive and preventative maintenance to maintain pump uptime. Work is underway to use the sensors on the handpumps to monitor the pumps’ condition and predict failures with the aim of eliminating pump downtime altogether [40,47].

Limitations
This study’s primary outcome variable was self-reported diarrhea, with enumerators trained to ask the question according to the WHO definition. Self-reporting is known to have limitations, and diarrhea is a crude proxy for water-related diseases [48,49]. The use of self-reported diarrhea in this study does not in itself call into question the primary finding that consistently rapid repairs are paramount to the delivery of health benefits, but it does mean that caution should be used in interpreting the effect size measured here. As the cross-sectional element of the study was based around one survey, the primary outcome variable was measured at times that varied with respect to the primary exposure. This had advantages for blinding and concealment, but limits the ability to attribute any observed effect to a specific breakdown event. We can only speculate on the extent to which the mechanism for the observed effect is directly biological or behavioral.

Household matching between the two surveys was undertaken rigorously, with unmatched households excluded from analysis where appropriate. The two surveys were 18 months apart and the household characteristics were not necessarily identical during each survey wave. Household composition may have changed with births, deaths, or others joining or leaving the household; household water budgets may also have changed as members transitioned from child to adult roles, or from being breastfed to directly consuming food and water, and other factors.

The exclusion criteria used for this study necessarily restricted the survey to households confirmed to have used pumps that had received repairs from the free maintenance service. The average downtime for handpumps across the study area prior to the trial was 27 days. It is plausible that the communities that chose not to engage with the repair service were those with better repair arrangements and performance prior to the study, introducing a possible selection bias. In addition, the method of household selection was likely to have created a bias toward households living closer to the pump (the average distance from a dwelling to its reference handpump was 136 meters and the maximum was 739 meters). These issues do not affect the internal validity of the study but may reduce external validity and the wider inferences that can be made.

Most of these limitations were the result of using an observational study design, which was linked to establishing the local pump maintenance provider. While the findings may be less widely generalizable, opportunistic operational studies linked to local WASH programs—whether by governments, private operators, or development agencies—have certain benefits. Here, the findings are directly informing the service provider’s operational management of handpumps in this area. By operating within existing and ongoing local programs in this way, findings from such studies can feed directly into local decision-making, and are thus more likely to have an immediate and sustainable impact on local health outcomes [50]. In this case, these findings—already shared with the maintenance service provider—have underscored the importance of reducing pump downtimes to a minimum.
Conclusions

Implicit in the JMP’s definition of “basic water” is the assumption that improved sources of water are of higher quality than unimproved sources and would therefore be associated with the health benefits of lower diarrheal disease morbidity. Our findings suggest that handpumps may only produce health benefits if service delivery can achieve the highest levels of performance, a level of performance difficult to maintain even under ideal operational circumstances. These findings provide empirical support to prior modeling of the relationship among water service reliability, water quality, and health, which suggests that even short periods of supply intermittency may have large adverse health impacts [38,39].

The required consistent reduction in downtimes needed is a challenge for even FundiFix, a well-resourced and tightly managed service provider that achieves higher uptimes than are typical in the sector. Our findings have implications beyond handpumps and are potentially relevant to other forms of basic water service. For these, the management arrangements are often limited, back-up sources are most likely from an unimproved source, and similar household choices will have to be made in response to an unreliable supply. This underscores the need to pursue on-premises, continuous supply.

These findings are also consistent with a rich literature linking water-related diseases to poverty. We found that socioeconomic factors were more closely linked to household disease than some classic WASH factors, which taken in isolation did not reduce the incidence of child diarrhea. This implies that WASH interventions will be more effective when integrated into wider anti-poverty and service delivery efforts, rather than implemented in isolation. Both of these findings support the current direction of the WASH and Water Security research agenda, which considers the key role water plays in other fields such as education and nutrition, and emphasizes the wider systems of service delivery, governance, and rights of which WASH interventions are a part [51,52].

Abstract

Background: Online sexual experiences (OSEs) are becoming increasingly common in young adults, but existing papers have reported only on specific types of OSEs and have not shown the heterogeneous nature of the repertoire of OSEs. The use patterns of OSEs remain unclear, and the relationships of OSEs with sexual risk behaviors and behavioral health outcomes have not been evaluated.

Objective: This study aimed to examine the latent heterogeneity of OSEs in young adults and the associations with sexual risk behaviors and behavioral health outcomes.

Methods: The 2021 Youth Sexuality Study of the Hong Kong Family Planning Association phone interviewed a random sample of 1205 young adults in Hong Kong in 2022 (male sex: 613/1205, 50.9%; mean age 23.0 years, SD 2.86 years) on lifetime OSEs, demographic and family characteristics, Patient Health Questionnaire-4 (PHQ-4) scores, sex-related factors (sexual orientation, sex knowledge, and sexual risk behaviors), and behavioral health outcomes (sexually transmitted infections [STIs], drug use, and suicidal ideation) in the past year. Sample heterogeneity of OSEs was analyzed via latent class analysis with substantive checking of the class profiles. Structural equation modeling was used to examine the direct and indirect associations between the OSE class and behavioral health outcomes via sexual risk behaviors and PHQ-4 scores.

Results: The data supported 3 latent classes of OSEs with measurement invariance by sex. In this study, 33.1% (398/1205), 56.0% (675/1205), and 10.9% (132/1205) of the sample were in the abstinent class (minimal OSEs), normative class (occasional OSEs), and active class (substantive OSEs), respectively. Male participants showed a lower prevalence of the abstinent class (131/613, 21.4% versus 263/592, 44.4%) and a higher prevalence of the active class (104/613, 17.0% versus 28/592, 4.7%) than...
female participants. The normative class showed significantly higher sex knowledge than the other 2 classes. The active class was associated with male sex, nonheterosexual status, higher sex desire and PHQ-4 scores, and more sexual risk behaviors than the other 2 classes. Compared with the nonactive (abstent and normative) classes, the active class was indirectly associated with higher rates of STIs (absolute difference in percentage points ($\Delta$)=4.8%; $P=0.03$) and drug use ($\Delta$=7.6%; $P=0.001$) via sexual risk behaviors, and with higher rates of suicidal ideation ($\Delta$=2.5%; $P=0.007$) via PHQ-4 scores.

Conclusions: This study provided the first results on the 3 (abstent, normative, and active) latent classes of OSEs with distinct profiles in OSEs, demographic and family characteristics, PHQ-4 scores, sex-related factors, and behavioral health outcomes. The active class showed indirect associations with higher rates of STIs and drug use via sexual risk behaviors and higher rates of suicidal ideation via PHQ-4 scores than the other 2 classes. These results have implications for the formulation and evaluation of targeted interventions to help young adults.

Introduction
Digital technology has transformed the communication styles and lives of young generations who have grown up with the internet. During emerging adulthood, individuals experience intense developments in the physical, cognitive, and psychosocial domains [1], which include greater interactions with the social environment, self-identity development, and sexuality exploration [2]. Emerging adults typically establish their sexual identity and patterns of health and risk behaviors, which have health implications for later life. The internet and social media are essential for forming social relationships among these adults.

Popular culture in Western countries has embraced uncommitted sex, such as casual sexual relationships and experiences, among young adults [3]. Online sexual experiences (OSEs) involve a range of sex-related behaviors performed via the internet or social media, including accessing sexual information, exposure to graphic nudity, watching pornography, online dating, sexting, and naked chatting [4-6]. A study in Spain found a rising prevalence of sexting among high school students [7], and pornography use has been shown to be associated with sexually aggressive behaviors, such as sexual coercion, among American adults [8]. In the past few years, the COVID-19 pandemic has further increased OSEs as a result of decreased interpersonal physical intimacy due to social distancing measures [9].

In Chinese culture, sexuality is viewed more conservatively, and frequent parent-adolescent communication about sexuality has been shown to be associated with fewer sexual risk behaviors in young adults in mainland China [10]. However, a qualitative study found that family communication about sexuality was rare and implicit in mainland China [11]. A mixed-method study found that 87.3% of young adults in mainland China obtained sexual health information online [12]. In Hong Kong, a previous study found that one-tenth of young adults engaged in sexual risk behaviors [13]. Exposure to sexually explicit online materials was associated with subsequent psychological well-being and sexual permissive attitudes in Hong Kong adolescents [14]. Existing papers [4,7,8,12,14] only assessed specific subsets of OSEs, such as accessing sexual information, sexting, and watching pornography. The failure to acknowledge the diverse nature of OSEs implies that more research is necessary to investigate an inclusive list of OSEs.

Latent class analysis (LCA) is a statistical method that identifies latent classes based on respondents’ responses and elucidates diverse profiles of behavioral indicators [15]. Instead of using aggregated item averages, LCA can model the complexity and individual differences of OSEs. A literature search on Web of Science using the keywords of (“sexual experience*” OR “sexual behavior*” OR “sexual activit*” [title]) AND latent class [title]) on April 6, 2023, found only 2 studies that explored OSEs using LCA, with small sample sizes (N=269-322) and analyses limited to female adolescents. These studies found 4 latent classes of OSEs, which were associated with sexual health and substance use [16,17]. However, they did not include young adults or males. A recent LCA study investigated sexual behavior indicators among youth in mainland China [18], but no existing papers have examined the latent heterogeneity of OSEs in young adults.

Given the importance of online sexual behaviors in health sciences [19], it is necessary to better understand the prevalence and profiles of OSEs among young adults. Multiple sex partners and unsafe sex have been shown to be associated with alcohol and tobacco use in Chinese youth [18] and American young adults [20], with sexual risk behaviors mediating sexual health outcomes [21,22]. However, no papers have examined the direct and indirect relationships between OSEs and behavioral health outcomes, namely, sexually transmitted infections (STIs), drug use, and suicidal ideation, via sexual risk behaviors and mental health. This study had the following 3 objectives: (1) to investigate the prevalence and heterogeneity of OSEs in young adults in Hong Kong; (2) to validate the derived OSE classes and analyze their associations with external variables, including demographic, family, psychological, and sex-related characteristics; and (3) to examine the direct and indirect relationships between OSE classes and behavioral health outcomes via sexual risk behaviors and mental health.
Methods

Study Design and Research Procedures

The data for this study originated from the 2021 Youth Sexuality Study (YSS) of the Hong Kong Family Planning Association, which was conducted every 5 years to examine sexual health and behaviors, and the psychosocial health of young adults. The sampling methods are described in the 2021 YSS survey report [23]. The survey was delayed due to the COVID-19 pandemic and was conducted via mobile phone from March to June 2022. The inclusion criteria were as follows: living in Hong Kong, age 18 to 27 years, and ability to understand spoken Cantonese or Putonghua. The survey was conducted by Social Policy Research Limited, a well-known third-party survey agency in Hong Kong. This agency has conducted a number of surveys on similar sensitive topics, such as organ donation, COVID-19 health-related risks, and fertility decisions, among various stakeholders in the general public. The agency has ample experience in undertaking studies of a similar nature with considerable expertise in survey planning and implementation, and data security. A total of 22,000 phone numbers were randomly generated, and a computer-assisted telephone interviewing system was used to contact potential respondents on weekdays from 6:30 PM to 10:30 PM.

The purpose and confidentiality of the survey were clearly explained to all potential participants, and voluntary participants provided oral informed consent. After excluding 1909 invalid telephone numbers and 17,253 numbers without target respondents, 2838 participants were eligible for the study. Some of the eligible participants did not take part in the phone interviews because they were too busy and could not make another survey appointment. In total, 1205 phone interviews were completed, with a response rate of 42.5%. Trained interviewers who were fluent in Cantonese and Putonghua conducted the interviews in around 20 minutes and provided emotional support information at the end. The survey did not collect personal identifying information and used anonymous questionnaires to encourage honest answers to sensitive questions, such as OSEs, sexual orientation, and sexual risk behaviors. The phone interviews were conducted in a private and secure setting. The interviewers used nonjudgmental and nonthreatening language to help participants feel comfortable and safe. Half of the interviews underwent quality checks by independent checkers, and 93.8% (563/600) of the sampled cases were successfully verified.

Measures

The study questionnaire was designed by the 2021 YSS Task Force based on previous YSS questionnaires. It included questions on OSEs, demographic and family characteristics, mental health, sex-related factors, and behavioral health outcomes. It was field tested in the second half of 2021 and underwent minor revisions based on feedback from respondents and interviewers.

OSEs were assessed using 11 binary questions (yes/no) on lifetime experiences of online sex-related behaviors (Multimedia Appendix 1). The first 5 items were from the 2016 YSS, and the latter 6 were new items added to the 2021 YSS based on recent literature [7,24]. The 11 items referred to 3 types of OSEs [25]: nonarousal, solitary arousal, and partnered arousal. These items had good reliability (Cronbach α=.83) and satisfactory item-total correlations (r=0.40-0.62; P<.001) in the present sample.

Demographic characteristics assessed in the questionnaire included sex, age, education level, student status (versus working), and place of birth (Hong Kong or other places). Family characteristics included marital status (married versus single) and perceived family satisfaction via a single item “Are you happy with your family life?” on a 5-point Likert scale ranging from 1 (“very unhappy”) to 5 (“very happy”). Participants also reported the number of hours spent per week on social media.

The Patient Health Questionnaire-4 (PHQ-4) measured 4 anxiety and depression symptoms experienced by the participants over the past 2 weeks. The items were rated on a 4-point Likert scale ranging from 0 (“not at all”) to 3 (“nearly every day”), and the composite PHQ-4 score ranged from 0 to 12. The PHQ-4 has been validated as a brief assessment of psychological distress in Hong Kong young adults [26] and had good reliability (α=.86) in the present sample. Participants were asked about the perceived negative impact of COVID-19 on mental health on a 5-point Likert scale ranging from 1 (“much better”) to 5 (“much poorer”).

Questions on sex-related factors included sexual orientation (heterosexual=0 and nonheterosexual=1); sex desire (“How strong is your desire to have sex with others?” on a 5-point Likert scale ranging from 1 “[not at all]” to 5 “[very strong]”); and 12 knowledge statements on sex-related behaviors, HIV, and AIDS (response options of “true” or “false,” or “don’t know”). Each correct answer scored 1 point, and higher total scores (range: 0-12) indicated better sexual knowledge. The questionnaire assessed lifetime experiences of 5 sexual risk behaviors: sexually harassed others, sexual coercion (insisted on having sex while ignoring a partner’s wish), compensated dating with sex, unsafe sex without contraception, and multiple sex partners. The items on sexual knowledge and sexual risk behaviors showed good reliability (α=.74-.83) in the present sample.

The study assessed 3 behavioral health outcomes, namely, STIs, drug use, and suicidal ideation, of the participants in the past year. Drug use referred to the use of various psychotropic substances such as ketamine, ecstasy, cocaine, and heroin.

Statistical Analysis

The variables were summarized using descriptive statistics, and the reliabilities of OSEs, PHQ-4 scores, sexual knowledge, and sexual risk behaviors were assessed via Cronbach α coefficients. Sampling weights were calculated based on 2021 population census data stratified by sex, place of birth, and age group to correct for the imbalance in the sample. Weighted analyses were used for all subsequent analyses unless otherwise stated. Missing data were handled using full information maximum likelihood under the missing-at-random assumption [27]. LCA was used to identify latent classes based on the 11 OSE items among young adults. LCA models with 1 to 5 classes were estimated
using the robust maximum likelihood estimator in Mplus 8.6 [28]. Model fit was evaluated using the Bayesian information criterion (BIC), with lower values indicating better fit. The Lo-Mendell-Rubin (LMR) likelihood ratio test [29] compared the fit of the k-class LCA model to the alternative k-1 class model, with a small P-value of <.01 favoring the former. Model classification quality was assessed using entropy and average latent class probabilities, with high values (>0.90) indicating adequate classification.

The heterogeneity of the OSEs in the sample was described via prevalence and conditional item probabilities of latent classes, with probabilities above 0.40 considered substantial. LCA models were estimated separately for males and females to test the stability of the latent class structure by sex. Measurement invariance was evaluated by comparing the BIC of the LCA models with and without equality constraints on the OSE item thresholds. Latent classes were checked against demographic and family characteristics, mental health, sex-related factors, and behavioral health outcomes. Class differences were estimated using the Bolck, Croon, and Hagenaars (BCH) procedure [30], with post-hoc comparisons using Sidak correction. Sidak correction controlled the family-wise error rate with slightly higher power than the Bonferroni correction method. Multinomial logistic regression with a 3-step approach used demographic and family characteristics and sex-related factors as predictors of latent class membership, with the strengths of associations estimated by adjusted odds ratios (ORs).

We used a structural equation model (SEM) to investigate the associations among OSE latent classes, sexual risk behaviors, PHQ-4 scores, and behavioral health outcomes. The most likely OSE class membership was the primary independent variable; sexual risk behaviors and PHQ-4 scores were latent mediators; and STIs, drug use, and suicidal ideation were binary outcomes. Model fit was evaluated by the following criteria on fit indices: root mean square error of approximation (RMSEA) ≤0.06, comparative fit index (CFI) ≥0.95, and standardized root mean square residual (SRMR) ≤0.06. The SEM estimated standardized regression coefficients for direct (β) and indirect effects (αβ) of the OSE latent class on behavioral health outcomes via the mediators. The SEM included covariates, namely, sex, age, place of birth, education level, student status, marital status, family satisfaction, sexual orientation, sexual knowledge, COVID-19 mental impact, and time spent on social media. The direct and indirect effects were estimated using bootstrapping with 10,000 bootstrap draws. Statistical significance was determined by 95% CIs not including zero for the direct and indirect effects, and 95% CIs not including one for the ORs.

**Ethical Considerations**

The study received ethical approval from the Human Research Ethics Committee of the University of Hong Kong (reference number: EA200333). All participants provided oral informed consent after the survey’s purpose was explained, with anonymity, confidentiality, and voluntary participation emphasized. The privacy of personal information was protected throughout the study via anonymous data collection, and confidentiality was preserved to ask participants to provide honest answers. Eligible participation in this survey was voluntary and was not compensated. The authors assert that all procedures contributing to this work comply with the ethical standards of the relevant national and institutional committees on human experimentation and with the Helsinki Declaration of 1975, as revised in 2008.

**Results**

**Sample Characteristics**

Table 1 shows that among 1205 participants (613 males and 592 females), the average age was 23.0 (SD 2.86) years. The majority of them were born in Hong Kong, working, single, and heterosexual. They had good sexual knowledge (mean 10.1, SD 2.19) and spent a mean of 2.94 (SD 2.04) hours per day on social media. The prevalence of sexual risk behaviors and behavioral health outcomes ranged from 3.2% (38/1205) to 12.3% (148/1205) and from 1.7% (20/1205) to 6.5% (78/1205), respectively. As shown in Multimedia Appendix 1, more than half (616/1205, 51.1% to 801/1205, 66.5%) of the participants were exposed to pornographic content, accessed sexual content, and discussed sex with others online or on social media. Naked chatting online, sending pornographic messages online, and having sex with people acquainted with online or on social media had the lowest prevalence (77/1205, 6.4% to 134/1205, 11.1%). Male participants showed higher prevalence of all 11 OSEs ($\chi^2 = 20.6-55.7; P < .001$) than female participants.

\(^a\)Higher scores indicate better family satisfaction, more negative COVID-19 mental impact, and higher levels of psychological distress, sex desire, and sexual knowledge.

\(^b\)PHQ-4: Patient Health Questionnaire-4.

**Latent Class Models**

Multimedia Appendix 2 shows a decreasing trend in the BIC from 1-class to 5-class LCA models in the whole sample and in males and females separately, with substantial decreases in the BIC from 1-class to 3-class models. The LMR likelihood ratio tests did not show significant improvement (\(P=.10-.38\)) in model fit for the 4-class model over the 3-class model. These findings supported the 3-class LCA model with good entropy and average latent class probabilities. Multimedia Appendices 3 and 4 show the class prevalence and conditional item probabilities of the 3-class LCA model in males and females, respectively. The multiple-group LCA model with sex-invariant item thresholds showed a substantially lower BIC (12,792 versus 12,925) than the noninvariant LCA model, supporting measurement invariance of the latent class structure across sex.
As shown in Table 2, the abstinent class comprised 33.1% (398/1205) of participants and had the lowest conditional item probabilities (1/398, 0.3% to 46/398, 11.5%) of all OSEs. The normative class, comprising 56.0% (675/1205) of participants, accessed sexual content and pornographic content online or on social media, discussed sex with others on social media, and sought pornographic content online actively. This class did not show substantial prevalence (<40%) in the remaining 7 items. The active class, comprising 10.9% (132/1205) of participants, had the highest conditional item probabilities (65/132, 49.5% to 132/132, 100%) of all OSEs. The prevalences of the normative and active classes were higher among males (378/613, 61.6% and 104/613, 17.0%, respectively) than among females (301/592, 50.9% and 28/592, 4.7%, respectively).

</table>

\(^a\)Items are presented in descending order for the crude unweighted probabilities. The item numbers indicate the order in the questionnaire.

\(^b\)Substantial conditional item probabilities that are greater than 0.40 for the latent classes.

**Comparison of Profiles Across the Latent Classes**

As shown in Table 3, females had a significantly lower prevalence of the normative and active classes than the abstinent class. No significant differences ($\chi^2=2.17-4.68\; P=.10-.34$) were found in age, place of birth, education level, student status, and marital status. Compared with the abstinent class, the normative class had significantly higher sex desire and PHQ-4 scores, while the active class had significantly lower family satisfaction and spent more time on social media, and both the normative and active classes had a significantly more negative COVID-19 mental impact and higher rates of suicidal ideation. The normative class had significantly higher sexual knowledge and lower unsafe sex rates than the other 2 classes. The active class had significantly higher sex desire and PHQ-4 scores and higher rates of nonheterosexual orientation, other sexual risk behaviors, STIs, and drug use than the other 2 classes. For instance, young adults in the active class had significantly higher rates of sexually harassed others, sexual coercion, compensated dating with sex, and multiple sex partners than those in the normative class or abstinent class.

$^{a,b,c}$Significant post-hoc differences among the 3 latent classes (c < b < a).

$^d$Higher scores indicate better family satisfaction, more negative COVID-19 mental impact, and higher levels of psychological distress, sexual knowledge, and sex desire.

$^e$PHQ-4: Patient Health Questionnaire-4.

Age, place of birth, education level, current student, and marital status were not significantly associated ($P=.13–.98$) with the latent class membership (Table 4). Females had low odds of the active class (OR 0.19, 95% CI 0.09-0.38; $P<.001$) compared with the other 2 classes. Higher COVID-19 mental impact (OR per score 1.54, 95% CI 1.23-1.89; $P<.001$) was associated with high odds of the normative class compared with the abstinent class. Family satisfaction was associated with low odds of the active class (OR per score 0.67-0.68; $P=0.03–.049$) compared with the other 2 classes, while nonheterosexual orientation (OR 3.36-6.82; $P<0.001$) and daily hours spent on social media (OR 1.13-1.19; $P=.01–.04$) were associated with high odds of the active class compared with the other 2 classes. Sexual knowledge was associated with high odds of the normative class compared with the other 2 classes (OR 1.16-1.29; $P=.001–.006$).

*a*OR: odds ratio.

*b*For continuous independent variables, ORs are per score. Higher scores indicate better family satisfaction, more negative COVID-19 mental impact, and higher levels of psychological distress, sexual knowledge, and sex desire.

**Associations Between the Active Class and Behavioral Health Outcomes**

Considering the higher rates of behavioral health outcomes in the active class than in the nonactive classes, the SEM was used to examine the effects of the active class on the behavioral health outcomes. The SEM fitted the data approximately well (RMSEA=0.026, CFI=0.98, SRMR=0.056). Significant factor loadings were found for sexual risk behaviors and PHQ-4 scores. Male sex, being married, nonheterosexual orientation, and higher COVID-19 mental impact were associated (β=0.13-0.27; P=.001-0.02) with more sexual risk behaviors. Male sex, younger age, education level, being married, lower family satisfaction, nonheterosexual orientation, and higher COVID-19 mental impact were associated (β=0.09-0.28; P=.001-0.04) with higher PHQ-4 scores. COVID-19 mental impact was positively associated (β=0.18-0.27; P=.001-0.02) with STIs, drug use, and suicidal ideation.

Figure 1 shows the SEM results. The model covariates and residual correlations between sexual risk behaviors and PHQ-4 scores have not been shown for simplicity. Controlling for the model covariates, the active class was positively associated with sexual risk behaviors and PHQ-4 scores (β=0.13-0.34; P<.001). Sexual risk behaviors were positively associated with STIs and drug use (β=0.71-0.93; P<.001), and PHQ-4 scores were significantly positively associated with suicidal ideation (β=0.40; P<.001). The residual correlations among the 3 behavioral health outcomes were not statistically significant (r=-0.26 to 0.03; P=.35-.91). There was a positive residual correlation between sexual risk behaviors and PHQ-4 scores (r=0.28; P<.001). The active class did not have significant direct effects (β=-0.09 to 0.03; P=.41-.62) on behavioral health outcomes. However, the active class had positive indirect effects on STIs (β=0.31; P<.001) via sexual risk behaviors, drug use (β=0.24; P<.001) via sexual risk behaviors, and suicidal ideation (β=0.05; P<.001) via PHQ-4 scores. These results implied that sexual risk behaviors substantially mediated the effects of the active class on STIs and drug use, and PHQ-4 scores substantially mediated the effects of the active class on suicidal ideation. The model explained 48.8%, 52.7%, and 81.7% of the variances of suicidal ideation, drug use, and STIs, respectively. Compared with the nonactive classes, the active class was indirectly associated with higher prevalences of STIs (Δ [absolute difference in percentage points]=4.8%, 95% CI 0.5%-8.1%), drug use (Δ=7.6%, 95% CI 2.9%-11.8%), and suicidal ideation (Δ=2.5%, 95% CI 0.8%-4.3%).
Figure 1. Standardized coefficients in the structural equation model on the associations among the active class (N=132) compared with the nonactive (abstinent and normative) classes (N=1075) of online sexual experiences (OSEs), sexual risk behaviors, Patient Health Questionnaire-4 (PHQ-4) scores, sexually transmitted infections (STIs), drug use, and suicidal ideation. For simplicity of presentation, model covariates and residual correlations between sexual risk behaviors and PHQ-4 scores are not shown. Standard errors of the coefficients are shown in parenthesis. Factor loadings ($\lambda$) of the latent factors of sexual risk behaviors and PHQ-4 scores are shown with orange dotted arrows. The direct effects ($\beta$) of OSE class on STIs, drug use, and suicidal ideation are shown with pale green dashed arrows. The indirect effects of OSE class on STIs and drug use via sexual risk behaviors are highlighted with red solid arrows. The indirect effects of OSE class on suicidal ideation via PHQ-4 scores are highlighted with blue solid arrows. The residual correlations ($r$) among STIs, drug use, and suicidal ideation are shown with black dash-dotted arrows. Significant indirect effects (red and blue solid arrows) are highlighted in bold.

Discussion

Principal Findings

This is the first study to report results on the latent heterogeneity of OSEs in young adults. Young adults could be classified into the following 3 latent classes: abstinent class with minimal OSEs, normative class with occasional OSEs, and active class with substantive OSEs. The measurement invariance test results supported stability of the 3 classes across sex. The 3 derived OSE classes were validated with distinct profiles in demographic, family, psychological, and sex-related characteristics amid the COVID-19 pandemic in 2022. Moreover, the SEM found significant indirect associations between OSE classes and STIs, drug use, and suicidal ideation via sexual risk behaviors and mental health. In particular, sexual risk behaviors were found to mediate the relationships between OSE classes and STIs and drug use, and mental health was found to mediate the relationship between OSE classes and suicidal ideation.

Comparison With Prior Work

The normative class, comprising the majority of the sample, had mainly nonarousal and solitary arousal OSEs, indicating passive exposure of sex-related information and active pursuit of sex knowledge. This class showed higher sexual knowledge but not increased sexual risk behaviors compared with the other classes and could represent young adults who are curious about sexuality and explore pornographic content online. A cluster randomized controlled trial on internet-based sexuality education programs significantly improved the sexual knowledge of adolescents in mainland China [31]. Our 2021 YSS survey found that internet use was positively associated with sexual knowledge in Hong Kong adolescents amid the COVID-19 pandemic [32]. A national survey in Germany found greater perceived positive outcomes of OSEs (eg, better sexual well-being) than negative outcomes (eg, online dating scams and cyberbullying) in adults [33]. Our findings align with these results and suggest a beneficial relationship between implicit types of OSEs and better sexual knowledge in young adults.
The prevalence of our normative and active classes (66.9%) was similar to the prevalence of online sexual activities (68%) in a previous German study [33]. In our study, males showed a lower prevalence of the abstinent class and a much higher prevalence of the active class than females. This sex difference is consistent with the findings of a meta-analysis [34] on the higher prevalence of online sexual behaviors among young male adults and the literature on higher sensation-seeking and lower impulse control in males in early adulthood [35]. In our sample, there was a significantly higher sex desire (Cohen $d=0.71$; $P<.001$) in males than in females. A longitudinal study on British young adults found significant decreases in sex desire in females but not males during COVID-19 social lockdown restrictions compared with prelockdown levels [36]. Future studies should examine sex differences in OSEs across cultural contexts.

We found that the active class had higher PHQ-4 scores and more sexual risk behaviors than the nonactive classes. These findings agree with previous studies on the positive associations between sexting and depressive symptoms in American youth [4] and between pornography use and sexual risk behaviors in Chinese youth [18]. All of the 3 residual correlations among STIs, drug use, and suicidal ideation were not statistically significant in the SEM. This suggests that the behavioral health outcomes were relatively well explained by the OSE class and latent mediators such that there were no leftover associations among them. The active class was at risk of behavioral health outcomes via sexual risk behaviors and PHQ-4 scores, and our results suggest a mediating role for sexual risk behaviors in the relationship of the active class with STIs and drug use. We recently found a mediating role for PHQ-4 scores between meaning in life and suicidal ideation in Hong Kong young adults [26]. PHQ-4 could be a simple and useful tool in future studies on the relationship between OSEs and risk factors.

This study has several strengths. First, we developed 11 items to measure 3 types of OSEs in young adults [25]. The moderate item-total correlations indicated good reliability and adequate discriminant validity of the items. Second, LCA classified the participants from empirical data into distinct latent classes of OSEs while allowing for potential misclassification errors. The 3 latent classes were validated using the BCH procedure and a 3-step approach [30]. Third, the SEM offered more reliable results by accounting for measurement errors of the latent factors and estimated the direct and indirect effects of OSE classes on behavioral health outcomes.

Early prevention and intervention are necessary to reduce the health burdens on young adults and society. The active class, although the smallest group, had more nonheterosexual individuals, had a worse family relationship, and spent more time on social media than the nonactive classes. Recent studies [37,38] found higher rates of sexual and suicidal risks in nonheterosexual individuals among Canadian and American young adults. Future research can explore risk factors like HIV knowledge and sexual identity stigma in this group [39-41]. Our previous study found that lower family satisfaction was associated with more sexual risk behaviors in Hong Kong adolescents [42]. The COVID-19 pandemic has increased young adults’ social media use, and those with a poor family relationship may rely on the internet for sexual content and be exposed to pornographic content online. Greater internet exposure has been shown to be associated with sexual risk behaviors among young male adults in mainland China [43].

Limitations

Our study had several limitations. First, the cross-sectional design made it difficult to determine the directionality between OSE classes and other variables. Since both OSEs and sexual risk behaviors were measured over the lifetime, their relationships could be bidirectional with reciprocal effects from sexual risk behaviors to greater OSEs. Future longitudinal studies are needed to clarify the temporal relationships among OSEs, sexual risk behaviors, mental health, and behavioral health outcomes. Second, we did not assess the underlying causes for OSEs, and young adults could engage in OSEs for different purposes such as boredom regulation, sexual gratification, and sensation seeking. Further qualitative studies should elucidate and compare the associations and motives for OSEs in the normative and active classes. Third, we did not differentiate between active solicitation and passive exposure in some OSE items, which may have included unwanted or forced behaviors. Further studies should examine the relationships between unwanted OSEs and online sexual harassment. Fourth, our questionnaire did not consider potential confounding factors such as impulsivity, compulsivity, internet and gaming addictions, and peer influences. Future research could examine the comorbidity between problematic OSEs and other risk or protective factors via network analysis. Fifth, the 11 OSE items we developed were not previously validated. Future studies should develop a new scale on OSEs with reference to our items and evaluate the psychometric properties. Sixth, the response rate of the phone survey was only 42.5%, and over half of the eligible participants did not take part in the phone interviews. The relatively low response rate implied potential selection biases. Our study sample of 1205 interviewed people might differ from the 1633 noninterviewed people in terms of OSEs and sexual risk behaviors. It was plausible that young adults with active OSEs could opt out of the survey, which led to underreporting of OSEs and a reduction in the effect size. It is necessary to be cautious when generalizing the present results to the general population of young adults.

Conclusions and Implications

This study provides the first results on the 3 latent classes of OSEs (abstinent, normative, and active) with distinct profiles in demographic and family characteristics, mental health, sex-related factors, and behavioral health outcomes. The active class showed indirect associations with higher rates of STIs and drug use via sexual risk behaviors and higher rates of suicidal ideation via PHQ-4 scores than the nonactive classes. Our results have clinical implications for personalized interventions to help young adults with substantive OSEs.

In Hong Kong, school-based sex education primarily focuses on the biological aspects of sexual and reproductive health among young adults, and sex education could promote sexual knowledge and be protective against STIs [44]. Comprehensive sex education interventions in northwest China have been successful in increasing sexual knowledge and sexual
self-efficacy among adolescents [45]. Recent reviews [46-48] suggest that sex education programs should emphasize the social aspects of sexual health via positive youth development approaches and include up-to-date topics, such as internet pornography, safe use of social media, and caveats of OSEs, to promote media literacy. Social media platforms could be an effective means of delivering sex education programs, and a pilot randomized controlled trial [49] in the United States has shown feasibility in reducing sexual risk behaviors and drug use via mobile health apps among 50 young individuals. Future research is needed to test the cost-effectiveness of mobile health apps in promoting sex knowledge, enhancing self-efficacy for refusing risky OSEs, reducing sexual risk behaviors, and preventing STIs and drug use among young adults.

Acknowledgments
We would like to express our appreciation to Ms Joe Yiu and Mr Sun Chan for providing support for the Youth Sexuality Study and young adults for their participation in the survey. The work was supported by the Family Planning Association of Hong Kong and Department of Health of the Hong Kong SAR government.

Abstract

Background: Cough is a common symptom during and after COVID-19 infection; however, few studies have described the cough profiles of COVID-19.

Objective: The aim of this study was to investigate the prevalence, severity, and associated risk factors of severe and persistent cough in individuals with COVID-19 during the latest wave of the Omicron variant in China.

Methods: In this nationwide cross-sectional study, we collected information of the characteristics of cough from individuals with infection of the SARS-CoV-2 Omicron variant using an online questionnaire sent between December 31, 2022, and January 11, 2023.

Results: There were 11,718 (n=7978, 68.1% female) nonhospitalized responders, with a median age of 37 (IQR 30-47) years who responded at a median of 16 (IQR 12-20) days from infection onset to the time of the survey. Cough was the most common symptom, occurring in 91.7% of participants, followed by fever, fatigue, and nasal congestion (68.8%-87.4%). The median cough visual analog scale (VAS) score was 70 (IQR 50-80) mm. Being female (odds ratio [OR] 1.31, 95% CI 1.20-1.43), having a COVID-19 vaccination history (OR 1.71, 95% CI 1.37-2.12), current smoking (OR 0.48, 95% CI 0.41-0.58), chronic cough (OR 2.04, 95% CI 1.69-2.45), coronary heart disease (OR 1.71, 95% CI 1.17-2.52), asthma (OR 1.22, 95% CI 1.02-1.46), and gastroesophageal reflux disease (GERD) (OR 1.21, 95% CI 1.01-1.45) were independent factors for severe cough (VAS>70, 37.4%). Among all respondents, 35.0% indicated having a productive cough, which was associated with risk factors of being female (OR 1.44, 95% CI 1.31-1.57), having asthma (OR 1.84, 95% CI 1.52-2.22), chronic cough (OR 1.44, 95% CI 1.19-1.74), and GERD (OR 1.22, 95% CI 1.01-1.47). Persistent cough (>3 weeks) occurred in 13.0% of individuals, which was associated with the risk factors of having diabetes (OR 2.24, 95% CI 1.30-3.85), asthma (OR 1.70, 95% CI 1.11-2.62), and chronic cough (OR 1.97, 95% CI 1.32-2.94).

Conclusions: Cough is the most common symptom in nonhospitalized individuals with Omicron SARS-CoV-2 variant infection. Being female, having asthma, chronic cough, GERD, coronary heart disease, diabetes, and a COVID-19 vaccination history emerged as independent factors associated with severe cough, productive cough, and persistent cough.

KEYWORDS
COVID-19; Omicron variant; nonhospitalized; cough

Introduction

The SARS-CoV-2 virus has been spreading globally since 2019, causing over 664 million infections and 6.7 million deaths as of January 14, 2023 [1]. The epidemiology and clinical characteristics of COVID-19 have been widely studied; however, SARS-CoV-2 has continued to mutate from the dominant Alpha to Delta variants and now the Omicron variant and subvariants, and the clinical characteristics of COVID-19 also change according to the particular virus variant [2-4]. The Omicron variant has been the dominant variant in the fourth wave of the global COVID-19 pandemic having infected an estimated 300 million people worldwide as of January 2023. Since December 2022, infection with the Omicron variant has been spreading rapidly across China.

Omicron is recognized as being highly contagious with a high capability for immune escape [5,6]. Over half of patients are reported to have at least one symptom during the infection period, including fever, cough, sore throat, fatigue, dyspnea, headache, and body pain [2,7]. Among these symptoms, cough is one of the most common [8,9]. Experiencing a chronic cough is associated with a significant decrease in quality of life, with symptoms such as incontinence, chest pain, headache, and poor sleep [10]. Studies in the United Kingdom [3] and the United States [4] have shown that the prevalence of acute cough during Omicron infection ranges from approximately 67.4% to 78%. A study conducted in a mobile cabin hospital in Shanghai demonstrated that cough was present in 57.5% of 1139 patients [7]. In addition, nearly 2.4%-7.2% of patients still experience cough as a symptom 1-2 months after Omicron infection is resolved [8,9]. However, few studies have described the specific cough features such as its severity, pattern, and risk factors.

We hypothesized that certain risk factors might be related with severe cough, productive cough, and persistent cough after...
Omicron infection. Additionally, there has been no nationwide survey concerning the clinical characteristics of Omicron infection in China to date. Therefore, we investigated the prevalence, severity, and associated risk factors for cough in nonhospitalized individuals with Omicron infection during the latest COVID-19 wave (2022-2023) in China.

Methods

Study Design and Participants

A nationwide survey was conducted online by China Cough Coalition [11], which is an organization dedicated to promoting the regular diagnosis, management, and research on cough in China, and has been assessing the cough characteristics of the Omicron pandemic. From December 31, 2022, to January 11, 2023, we recruited individuals aged ≥18 years with positive nucleic acid or antigen detection of SARS-CoV-2 or highly suspected symptoms of COVID-19; individuals with mental illness or other conditions that might hinder their ability to complete the survey were excluded. Only nonhospitalized individuals were included in the study.

Data were collected using Wenjuanxing [12], an online questionnaire survey platform in China. Participants were asked to fill out the questionnaire by using their smartphone, and each device was restricted to submitting the questionnaire results only once. The questionnaires were mainly distributed by physicians of China Cough Coalition and the survey link was also available for the public. At the top of the questionnaire, the purpose and contents of the survey were briefly introduced and participants were required to read the informed consent and confirm that they voluntarily agreed to join this survey. Participants had full right to quit the study at any time during the survey.

Ethics Considerations

This study was approved by the Ethics Review Committees of the First Affiliated Hospital of Guangzhou Medical University (ES-2023-012-01). Although verbal consent was provided as described above, the requirement for written informed consent was waived by the institutional ethics board of the hospital. No financial compensation was offered to the subjects for their participation. All data were collected anonymously and promised to be used only in this study.

Questionnaire Items

A standardized and structured questionnaire was designed for this study. Prior to the distribution of the final version of the questionnaire, it was first tested in a pilot study (data not shown). The questionnaire consisted of 21 items, divided into the following six aspects (see Multimedia Appendix 1): (1) baseline data (age, sex, smoking history, vaccination history for COVID-19, and comorbidities); (2) detection of SARS-CoV-2 (date of the positive result of SARS-CoV-2 antigen/nucleic acid testing); (3) general and severe symptoms, including date of onset of COVID-19 symptoms (cough, fever, fatigue, myalgia/arthritis, nasal congestion, headache/dizziness, sore throat, runny nose, hyposmia/hypogeusia, chest tightness, diarrhea, postnasal drip, and conjunctivitis; see Multimedia Appendix 1 for the definition of “severe” symptoms); (4) cough characteristics, including the date of cough onset, cough pattern, type of sputum, duration of cough, timing of cough, and cough severity compared with previous common cold experience; (5) results of chest computed tomography/chest X-ray according to radiology reports if available; and (6) medication, including antipyretics, antibiotics, antiviral drugs, antitussives, nasal drugs, and traditional Chinese medicine. Cough severity was evaluated using a visual analog scale (VAS), with a range of 0-100 mm, where 0 indicates no cough and 100 indicates the worst cough imaginable [13]. Severe cough was defined as VAS > 70. Persistent cough was defined as a cough duration >3 weeks and chronic cough was defined as a cough duration >8 weeks.

Statistical Analysis

Categorical variables are presented as frequency (percentage), while continuous variables are expressed as mean (SD) or median (IQR). Statistical comparisons between groups were performed with unpaired Student t tests for normally distributed data, Mann-Whitney U tests for skewed data, and χ² tests or Fisher exact tests for proportional data. Multivariable logistic regression was performed to detect the risk factors for persistent cough adjusted by age, sex, and duration from infection to the survey, assessed according to estimates of adjusted odds ratios, 95% CIs, and P values [14]. The final model selection was determined according to the backward selection of all factors based on the Akaike information criterion. Statistical analysis was performed using R software (v 4.1.2).

Results

Demographic and General Information of Participants

A total of 12,227 questionnaires were recorded in 31 provinces across China. The number of questionnaires in different provinces is shown in Multimedia Appendix 2. We excluded 78 individuals with incorrect information and 431 hospitalized individuals. Therefore, data were analyzed from a total of 11,718 nonhospitalized individuals, including clinic attendees (15.4%) and individuals not diagnosed or treated in hospitals (84.6%).

The demographic characteristics of the individuals are shown in Table 1. Among the 11,718 individuals with a median age of 37.0 (IQR 30.0-47.0) years, 7978 (68.1%) were female. The median duration from Omicron infection to the survey was 16.0 (IQR 12.0-20.0) days. The majority of individuals were not current smokers and had no comorbidities. The most frequent comorbidities were chronic rhinitis/sinusitis, followed by hypertension, chronic urticaria/allergic dermatitis, and asthma.

Among the total sample, the most common symptoms were cough, followed by fever, fatigue, and nasal congestion. The most common severe symptoms included severe bone pain/myalgia, high fever, and severe nasal congestion (Table 2).
Table 1. Baseline characteristics of nonhospitalized participants with Omicron variant infection (N=11,718).

Cough Characteristics

Among the 10,741 respondents with cough, 44.0% (n=4724) presented with cough during both daytime and nighttime and 36.8% (n=3956) only had the cough during the daytime (Table 3). In terms of the cough pattern, 35.0% (n=3760) of individuals presented with a productive cough; white thick sputum and yellow purulent sputum were common.

Coughs were commonly initiated within 3 days, as reported by 6580 (61.3%) of the 10,741 individuals with cough. At entry to the survey, 38.2% (n=4103) of individuals still had cough, while 61.8% (n=6638) of individuals reported that their cough was relieved. Among the 2209 individuals with a duration from infection to the survey over 3 weeks, the cough was relieved within 1 week in 23.9% (n=528) of individuals, lasted for 1-3 weeks in 52.6% (n=1162) of individuals, developed into a subacute cough (3-8 weeks) in 12.7% (n=281) of individuals, and developed into a chronic cough (>8 weeks) in 0.3% (n=8) of individuals.

\(^a\)VAS: visual analog scale.
\(^b\)Proportions were calculated among patients with productive cough.

**Factors Associated With Severe, Productive, and Persistent Cough**

With a cut-off VAS score of 70, 4388 (37.4%) of the total 11,718 respondents were categorized in the severe cough group and 7330 (62.6%) were categorized in the nonsevere group. Compared with those in the nonsevere group, the group with severe cough had a higher proportion of female participants (\(P<.001\)), a younger age (\(P<.001\)), fewer current smokers (\(P<.001\)), more individuals who had been vaccinated for COVID-19 (\(P<.001\)), and higher proportions of individuals with gastroesophageal reflux disease (GERD) (\(P=.03\)) and chronic cough (\(P<.001\)) as comorbidities (Table 4).

With respect to the different patterns of cough, more female respondents presented with a productive cough than male respondents (\(P<.001\)). In addition, the group with a productive cough included higher proportions of individuals with COPD (\(P=.01\)), asthma (\(P<.001\)), chronic cough (\(P<.001\)), interstitial lung disease (\(P=.03\)), chronic rhinitis/sinusitis (\(P=.003\)), and GERD (\(P=.008\)) as comorbidities (Table 5).
The group with a persistent cough included higher proportions of individuals with their most recent vaccination injected longer than 6 months before ($P = .03$) and higher proportions of comorbidities, including asthma ($P = .005$), chronic cough ($P < .001$), chronic rhinitis/sinusitis ($P = .02$), and diabetes ($P = .002$) compared to the group with acute cough (Table 6). Multivariate analysis showed that being female; being younger; having received vaccination for COVID-19; having asthma, chronic cough, coronary heart disease, or GERD as comorbidities; and being a nonsmoker were independent factors associated with more severe cough (Figure 1A). Being female, of younger age, and having asthma, chronic cough, and GERD as comorbidities were independent factors for productive cough (Figure 1B). The most recent vaccination more than 6 months ago, and having asthma, chronic cough, and diabetes were independent factors for persistent cough (Figure 1C).

\(^a\)Acute cough: duration of cough ≤7 days and without cough at the time of this survey.  
\(^b\)Received an inactivated SARS-CoV-2 vaccine.  
\(^d\)Proportions were calculated only among patients with a COVID-19 vaccination history.  
\(^e\)GERD: gastroesophageal reflux disease.
Figure 1. Forest plot of risk factors for severe cough (VAS>70), productive cough, and persistent cough. (A) Adjusted odds ratios (ORs) of factors for severe cough (VAS>70) versus nonsevere cough (VAS≤70). (B) Adjusted ORs of risk factors for productive cough versus nonproductive cough. (C) Adjusted ORs of risk factors for persistent cough versus acute cough. Adjusted by age, sex, and duration from infection to survey. COPD: chronic obstructive pulmonary disease; GERD: gastroesophageal reflux disease; VAS: visual analog scale.

Discussion

To the best of our knowledge, this is the first study with a large sample size to investigate the characteristics of cough and associated factors in nonhospitalized individuals infected with the SARS-CoV-2 Omicron variant in China. In this study, the prevalence of cough was 92.6%, followed by fever, fatigue, myalgia/arthritis, nasal congestion, headache/dizziness, sore throat, and runny nose. Productive cough (35.0%) with white thick sputum or yellow purulent sputum was common, which developed into a persistent cough in a subset of the surveyed individuals. Female sex, being a current smoker, and having comorbidities (such as asthma, chronic cough, GERD, and/or diabetes) were factors associated with severe, productive, and persistent cough.

Early reports showed that the prevalence of cough during COVID-19 infection ranged from 44% to 72.5% [15], with a higher prevalence associated with Omicron variant infection than with Delta variant infection [4], although one survey from the United Kingdom [3] indicated that the prevalence of cough was similar between infections with the Omicron and Delta variants. In this study, the prevalence of cough was 92.6%, which was higher than that reported in previous studies [2-4,7], especially those based on data collected prior to emergence of the Omicron variant [16-18], suggesting that the prevalence of cough might be higher with the Omicron variant than with previous variants. In addition to cough, other symptoms such as fever, fatigue, myalgia, nasal congestion, and sore throat were also common, and over 60% of individuals reported having severe symptoms in our study.

With 15 amino acid substitutions in the receptor-binding domain, Omicron has been identified as being highly transmissible and possessing a remarkable capability of immune escape [19]. It has been reported that Omicron caused less damage to the lungs compared with Delta [20] and was more likely to target the upper airways [21]. The vagal sensory nerves play essential roles in regulating cough, which terminate primarily in the larynx, trachea, carina, and large intrapulmonary bronchi [22]. This may explain the greater prevalence of cough among patients with Omicron variant infection. The other possibility for the
higher proportion of cough and other symptoms identified in this study might be related to the reduced herd immunity against SARS-CoV-2. After the outbreak of COVID-19 in early 2020, a very strict prevention and control policy was implemented in China; thus, most people have not been exposed to COVID-19 in recent years [23]. In addition, the latest pandemic outbreak in China occurred during the winter, when viruses multiply more rapidly and spread more quickly on the one hand and the immune response of the airway is decreased on the other hand.

Previous studies have reported that compared to female patients, male patients with COVID-19 are at a higher risk of hospitalization, with worse outcomes and a higher mortality rate, independent of age [24]. In our study, all participants had mild-to-moderate disease and had not been hospitalized for COVID-19. We found that the female participants reported a higher proportion of cough and more severe cough. There was also a female predominance in the group reporting a chronic cough, which could be related to the heightened cough sensitivity among female patients [25]. This female preponderance in the chronic cough population and enhanced cough sensitivity may be explained by sex-related differences in the central processing of cough sensation [26]. However, further studies are needed to determine whether female patients with COVID-19 also present with increased cough sensitivity.

In China, 25.6% of adults (50.7% of men and 1.9% of women) are smokers [27]. The high proportion of nonsmoking female respondents in our study may explain why the proportion of smokers in our data was lower than that of the general population. Smoking has been reported as a risk factor for severe symptoms and/or progression of COVID-19 [28,29], and the prevalence of chronic cough and sputum was reported to be greater among current smokers [30]. Interestingly, smokers tended to report a nonsevere cough in the current survey. Many cigarette smokers usually have a chronic cough, but they scarcely seek medical attention unless a change in the pattern or intensity of their cough is noticed [31]. Cough reflex sensitivity and sensitivity to airway irritation were reported to be significantly decreased in current smokers compared to those of a similar population of nonsmokers [32,33]. Smoking was also found to be accompanied by increased activation in brain regions known to be involved in both cough sensory processing and cough suppression. Therefore, the smoking-induced sensitization of central cough neural circuits could be offset by concurrently enhanced central suppression [32].

Cough is a frequent and common complaint of patients with respiratory diseases such as asthma, chronic obstructive pulmonary disease, and interstitial lung disease. Nevertheless, cough could also be a sole or predominant symptom in extrapulmonary disorders, particularly GERD [34,35]. Most of the available evidence indicates that patients with respiratory diseases or cardiovascular diseases have the greatest odds of cough [9,36,37]. We also found an association of comorbidities, including asthma, chronic cough, coronary heart disease, GERD, and/or diabetes, with severe cough, persistent cough, and productive cough. Many studies have suggested a significant increase in the severity and mortality of COVID-19 in people with diabetes [38]. Self-reported chronic cough/phlegm was more common in patients with diabetes compared to that of the general population [39]. Glititin, a dipeptidyl peptidase-4 inhibitor used to treat diabetes mellitus, can cause cough as a side effect, which may be attributed to the persistent cough of COVID-19 [40]. In addition, diabetes, as an important risk factor, was found to influence the clinical severity of concomitant viral, bacterial, and fungal infections [41]. Therefore, attention should be paid to the possibility of coinfection or secondary bacterial infection in cases of persistent cough among patients with diabetes and COVID-19.

Approximately one-third of the individuals surveyed in this study reported having a productive cough, indicating the hypersecretion of mucus. In addition, the group with productive cough had a low proportion of individuals with respiratory comorbidities, which could not fully explain the excessive phlegm production. Excessive mucus production and accumulation is a common response to respiratory viral infections such as respiratory syncytial virus, rhinovirus, influenza virus, and SARS virus [42]. Recently, Kato et al [43] reported that SARS-CoV-2 induced the production of mucus (MUC5AC and MUC5B) throughout all airway regions via epidermal growth factor receptor/interleukin-1 receptor signaling activation in patients with COVID-19 [43]. This overproduction of airway mucin may increase the viscosity of the sputum, rendering it difficult to cough up. In addition, respiratory viruses infecting the human airway would impair mucociliary clearance, activate transient receptor potential vanilloid 1, induce the hypertrophy and metaplasia of goblet cells in the airway epithelium and the consequent enlargement of bronchial submucosal glands, leading to excessive fluid secretion and mucus plugs formation [42,44]. Intriguingly, we also observed that many individuals, especially the female participants, coughed up yellow or purulent sputum, suggesting coexistence of a bacterial infection. A previous study also suggested female sex as a susceptibility factor for bacterial infection [45]. However, it remains unclear whether these mechanisms play a pivotal role in mucus hypersecretion during Omicron infection.

Over 91% of individuals in our study had received a vaccine against SARS-CoV-2; however, we did not find a protective effect of the vaccine toward alleviating cough and mucus hypersecretion. The inactivated vaccines against SARS-CoV-2 were used in China; however, less than 15% of individuals had received a vaccine <6 months before the latest SARS-CoV-2 wave. Malik et al [46] demonstrated that the neutralizing antibody titer declines to near or below the seropositive threshold of a protective effect 6 months after vaccination with the inactivated vaccine. In addition, SARS-CoV-2 has been constantly mutating and most of the mutations are associated with the spike protein, a vital target for the action of vaccines [46]. Although a booster dose of the inactivated vaccine was associated with a lower risk of Omicron infection [47], compared with the ancestor strain, the production of neutralizing antibodies against Omicron was considerably impaired [48,49]. Another possible effect of the vaccine is the risk of antibody-dependent enhancement. According to in vitro studies, antibody-dependent enhancement might occur in COVID-19 infection [50,51], but current evidence indicates that this is an unlikely side effect induced by the vaccine [52,53].
There are some limitations of our study. First, all participants were nonhospitalized individuals with COVID-19, which may not fully reflect the cough profiles of severe cases of SARS-CoV-2 infection during the Omicron outbreak. Second, the data were obtained via online survey. Participants with low literacy or those of older age may have been neglected given the difficulties in filling out the survey and/or using a smartphone. In addition, clinical features and medical history were assessed by questionnaires, which may be prone to recall bias. However, most of the participants had been infected with SARS-CoV-2 within 1 month prior to completing the survey and many participants were still in the acute phase of COVID-19 at the time of the survey; hence, the impact of recall bias should be small. Lastly, we are following up with these respondents as we have only analyzed cross-sectional data; since many of the participants were still in acute phase of Omicron infection, the prevalence of persistent cough should be surveyed further.

In conclusion, over 90% of nonhospitalized individuals infected with the Omicron variant of SARS-CoV-2 presented with cough as a major symptom, with approximately one-third of individuals having a severe or productive cough, commonly with white thick and yellow purulent sputum, which developed into a persistent cough in a portion of these individuals. Female sex, chronic cough, asthma, GERD, diabetes, smoking, and/or vaccination for COVID-19 were associated with severe cough, productive cough, and/or persistent cough. Further studies are warranted to investigate the mechanism, treatment, and long-term prognosis of cough associated with Omicron variant infection, which will provide insight into how to treat SARS-CoV-2–induced cough.

Abstract

Background: The advent of the internet has changed the landscape of available nutrition information. However, little is known about people’s information-seeking behavior toward healthy eating and its potential consequences.

Objective: We aimed to examine the prevalence and correlates of nutrition information seeking from various web-based and offline media sources.

Methods: This cross-sectional study included 5998 Japanese adults aged 20 to 79 years participating in a web-based questionnaire survey (February and March 2023). The dependent variable was the regular use of web-based and offline media as a reliable source of nutrition information. The main independent variables included health literacy, food literacy, and diet quality, which were assessed using validated tools, as well as sociodemographic factors (sex, age, education level, and nutrition- and health-related occupations).

Results: The top source of nutrition information was television (1973/5998, 32.89%), followed by web searches (1333/5998, 22.22%), websites of government and medical manufacturers (997/5998, 16.62%), newspapers (901/5998, 15.02%), books and magazines (697/5998, 11.62%), and video sites (eg, YouTube; 634/5998, 10.57%). Multivariable logistic regression showed that higher health literacy was associated with higher odds of using all the individual sources examined; odds ratios (ORs) for 1-point score increase ranged from 1.27 (95% CI 1.09-1.49) to 1.81 (95% CI 1.57-2.09). By contrast, food literacy was inversely associated with the use of television (OR 0.65, 95% CI 0.55-0.77), whereas it was positively associated with the use of websites of government and medical manufacturers (OR 1.98, 95% CI 1.62-2.44), books and magazines (OR 2.09, 95% CI 1.64-2.66), and video sites (OR 1.53, 95% CI 1.19-1.96). Furthermore, diet quality was positively associated with the use of newspapers (OR 1.02, 95% CI 1.01-1.03) and books and magazines (OR 1.03, 95% CI 1.02-1.04). Being female was associated with using television and books and magazines, whereas being male was associated with using websites of government and medical manufacturers, newspapers, and video sites. Age was positively associated with using newspapers and inversely associated with using websites of government and medical manufacturers and video sites. People with higher education were more likely to refer to websites of government and medical manufacturers and newspapers but less likely to use television and video sites. Dietitians were more likely to use websites of government and medical manufacturers and books and magazines than the general public but less likely to use television and video sites.
Conclusions: We identified various web-based and offline media sources regularly used by Japanese adults when seeking nutrition information, and their correlates varied widely. A lack of positive associations between the use of the top 2 major sources (television and web searches) and food literacy or diet quality is highlighted. These findings provide useful insights into the potential for developing and disseminating evidence-based health promotion materials.

Introduction

Background

On a global scale, poor diet quality is a major risk factor for premature mortality and morbidity, accounting for 22% of total deaths and 15% of disability-adjusted life years annually; these estimates are even higher in East Asian countries, including Japan (30% and 21%, respectively) [1]. As diet is a key modifiable risk factor, it is not surprising that the focus on prevention of chronic diseases has become a priority [2], mainly by reducing the intake of foods high in sodium and added sugars (eg, ultraprocessed foods) [3] and increasing the intake of plant-based foods, including whole grains, nuts, legumes, fruits, and vegetables [4,5]. This robust evidence base connects food to human health and should satisfy the growing public demand for dietary and nutrition information.

However, the advent of the internet has permanently changed the landscape of information and its use [6,7]. In particular, the introduction of Web 2.0, in which people can create, edit, and share content, has irrevocably changed communication from that via initial static web pages (Web 1.0) and traditional media (eg, newspapers, television, and radio) [8,9]. For a large proportion of people, the internet has become an essential tool for improving health-related knowledge and behavior, including nutrition [10,11]. For example, a national survey estimated that 78% of Japan’s general population uses the internet, with 73% of them seeking health information [12]. However, owing to the lack of regulations and ease of creating and sharing web-based information, consumers have access to an abundance of web-based information of variable quality and accuracy [13,14]. Consequently, nutrition and health professionals increasingly struggle with disseminating evidence-based nutrition information in a web-based media landscape filled with unreliable and contradictory nutrition information (ie, misinformation) [14-17].

It is reasonable to assume that the level of health literacy (ie, the cognitive and social skills that determine an individual’s motivation and ability to access, understand, and use information in ways that promote and maintain health [18]) is probably related to the search for nutrition information and thus the acquisition of nutrition knowledge [19]. However, an appropriate level of health literacy does not automatically lead to proper nutrition knowledge, particularly regarding aspects related to correct dietary decision-making [20]. Consequently, increasing attention is now being directed toward food literacy, defined as “a collection of inter-related knowledge, skills and behaviors required to plan, manage, select, prepare and eat food to meet needs and determine intake” [21].
Methods

Study Procedure and Participants
This cross-sectional study was based on data obtained from a web-based questionnaire survey. This paper was prepared in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) [55], where applicable. Figure 1 shows a flow diagram of participant selection. The target sample consisted of 6600 Japanese adults aged 20 to 79 years, including not only the general public but also health professionals allied to nutrition (e.g., dietitians, registered dietitians, physicians, and dentists). Exclusion criteria were age outside the range of 20 to 79 years and working as an unrelated health professional (e.g., veterinarians, dental hygienists, assistant nurses, clinical psychologists, and nurse practitioners).

Registered panelists aged 20 to 79 years who were included in the present analysis (N=5998)
Data collection was conducted by an internet research agency, Rakuten Insight [56]. With 2.2 million monitors nationwide, Rakuten Insight monitors fraudulent registrants, such as impersonators and duplicate registrants, by sharing the basic registration information of members. Furthermore, as part of the quality control of survey results, Rakuten Insight implemented an automated computerized checking system. Participants were recruited from among the registered panelists of the research agency. An email with an invitation to participate and a web page link to the survey was sent to a randomized list (n=676,329, 26.1%) of registered panelists aged 20 to 79 years (n=2,603,155; unfortunately, information on the sociodemographic characteristics of all the registered panelists in Rakuten Insight is not available [56]). Initially, a study summary was provided, and only individuals who agreed to participate could proceed to the screening stage (76,845/676,329, 11.36%). As recruitment was stratified by age, sex, and occupation, participants could proceed to the main survey only if there was a vacancy in the relevant category (eg, male individuals aged 20 to 79 years; Figure 1). As a result, among the 76,845 individuals in the screening stage, 7722 (10.05%) proceeded to the main survey, of whom 1122 (14.53%) did not complete all questions. Data collection started on February 10, 2023, and ended on March 16, 2023, when quotas for the main survey were filled (n=6600). The sample size was determined primarily based on feasibility and financial limitations. For analysis, we excluded individuals whose answers were considered unreliable based on their answer to the following question: “This question is for the purpose of investigating ‘misplaced’ answers when responding to the survey. Please select neither agree or disagree from the following options.” As a result, of the 6600 individuals who completed the survey, 314 (4.76%) individuals whose responses were strongly agree, agree, disagree, or strongly disagree were excluded. Further, we excluded individuals whose data were considered unreliable with regard to body height (≥200 cm; 2/6600, 0.03%) or energy intake (<800 or >4200 kcal/day for male individuals and <500 or >3500 kcal/day for female individuals [57]; 286/6600, 4.33%). Consequently, the final analysis sample comprised 5998 individuals (male individuals: n=2687, 44.8%; female individuals: n=3311, 55.2%) aged 20 to 79 years. The respondents included in the present analysis (N=5998) differed somewhat from those excluded from the analysis (n=602). The excluded respondents were more likely to be male and have higher means of age and BMI, lower household income, and nongovernmental qualifications related to food and nutrition.

Ethical Considerations

The study was conducted according to the guidelines of the Declaration of Helsinki, and all procedures involving human participants were approved by the Ethics Committee of the University of Tokyo Faculty of Medicine (protocol code: 20222288NI; date of approval: January 13, 2023). Informed consent was obtained on the website from all individuals involved in the study. The participants were compensated with standard Rakuten Insight incentives (points redeemable for cash or merchandise) for completing the survey.

Assessment of Sociodemographic Characteristics

All the questions used in this study were prepared by the first, second, and third authors. Sex (assigned at birth) was self-selected as either male or female. Age (in years) was also self-reported. Body weight and height were self-reported and used to calculate BMI (in kg/m²), with 3 weight status categories: underweight (<18.5), normal weight (≥18.5 to <25), and overweight (≥25) [58]. The following variables were also used in this study (categorization shown in parentheses): education level (junior high or high school, junior college or technical school, university or higher, and others), household income (<4 million Japanese yen, 4 to 7 million Japanese yen, >7 million Japanese yen, and unknown or do not want to answer; US $1=JPY 148.22), employment status (none, student, part-time job, and full-time job), marital status (unmarried, married, and do not want to answer), living alone (no and yes), presence of chronic diseases (eg, hypertension, hyperlipidemia, and diabetes; no and yes), and smoking status (never, past, and current). In addition, based on the reported postal code of the home address, each participant was grouped into 1 of 6 regions (Hokkaido and Tohoku, Kanto, Hokuriku and Tokai, Kinki, Chugoku and Shikoku, and Kyushu). Participants were also grouped into 1 of 3 municipality levels (ward, city, and town and village). The category missing was created for those whose reported postal codes were incomplete for the municipality level variable. Further, participants were categorized according to nutrition and health-related occupations (Figure 1): none (ie, the general public), nongovernmental qualification related to food and nutrition, media, dietitian and registered dietitian, physician and dentist, and other health professional (ie, nurse, midwife, public health nurse, and pharmacist).

Assessment of Health Literacy

Health literacy was assessed using the Communicative and Critical Health Literacy scale, which was developed and validated for the Japanese population [48]. On the basis of a 5-point Likert scale (1 = strongly disagree; 5 = strongly agree), each participant was asked whether they were able to (1) collect health-related information from various sources, such as newspapers, books, television, and the internet; (2) extract the information they wanted; (3) understand and communicate the obtained information; (4) consider the credibility of the information; and (5) make decisions based on the information, specifically in the context of health-related issues. The health literacy score was calculated as the average of all items, meaning that the higher the score, the higher the health literacy (with possible scores ranging from 1 to 5) [48].

Assessment of Food Literacy

As described in detail in Multimedia Appendix 1 [49], food literacy was assessed using the Japanese version of the 29-item Dutch Self-Perceived Food Literacy scale [49]. This is an expert-based, theory-driven, and validated tool for measuring food literacy with respect to healthy eating and focuses on 8 domains: food preparation skills (6 items), resilience and resistance (6 items), healthy snack styles (4 items), social and conscious eating (3 items), examining food labels (2 items), daily food planning (2 items), healthy budgeting (2 items), and healthy food stockpiling (4 items) [49]. Participants were asked
to answer all the questions based on a 5-point Likert scale (1=not at all or never, 5=always or always). The food literacy score was calculated as the average of all items, with negative items reversed, indicating that the higher the score, the higher the food literacy (with possible scores ranging from 1 to 5) [49].

Assessment of Diet Quality

As a measure of diet quality, the Healthy Eating Index (HEI)-2020 [50] was used. The HEI-2020 is an established, 100-point scale to assess compliance with the 2020 to 2025 Dietary Guidelines for Americans [2], with a higher score indicating a better quality of overall diet. The HEI-2020 consists of 9 adequacy components (eg, fruits, vegetables, and whole grains) and 4 moderation components (eg, sodium and added sugars). The efficacy of the HEI-2015, which completely aligns with the HEI-2020 [50], in assessing the overall diet quality of Japanese people has been supported by our previous analyses [59,60]. Dietary intake information was collected using a validated, short version of the Meal-based Diet History Questionnaire [51,52,61]. A detailed description of the diet quality assessment is presented in Multimedia Appendix 2 [2,50-52,59-63].

Assessment of Dietary and Nutrition Information Seeking Through Various Media Sources

The assessment of dietary and nutrition information seeking through various web-based and offline media sources was conducted using a series of 2 questions, as informed by previous studies [11,25,27,28,30,35-38,64]. Participants were first asked the following question: “Which of the following sources do you routinely use as a source of information about diet and nutrition? Please select all that apply (as many as you want).” The list of sources of dietary and nutrition information shown was as follows: (1) television, (2) radio, (3) newspapers, (4) books and magazines, (5) municipal newsletters, (6) websites of government and medical manufacturers, (7) web searches, (8) news applications, (9) video sites (eg, YouTube [Google LLC]), and (10) social networking sites (eg, Twitter [Twitter Inc], Instagram [Meta Platforms Inc], and Facebook [Meta Platforms Inc]); 3 other face-to-face information sources (ie, hospitals and drug stores, family, and friends) were also shown, which are beyond the scope of this analysis. These were based on items used in a national survey conducted by the Ministry of Internal Affairs and Communications [65]. Participants were then asked the second question: “Do you think that dietary and nutrition information obtained from the sources listed below is reliable?” The list of dietary and nutrition information sources displayed was customized for each participant and contained only the sources the participant chose in the first question. For each of the dietary and nutrition information sources, a 5-point Likert scale category was provided (strongly disagree, agree, neither agree or disagree, agree, and strongly agree). Sources used to seek dietary and nutrition information were defined based on participants’ responses (agree or strongly agree) regarding the reliability of the sources.

Statistical Analysis

All statistical analyses were performed using the SAS statistical software (version 9.4; SAS Institute Inc). Descriptive data are presented as frequencies and percentages of participants for categorical variables and means and SDs for continuous variables. Associations among the top media sources (defined as a priori as >10% prevalence) used for seeking dietary and nutrition information were examined using a chi-square test. Associations of dietary and nutrition information seeking through the top media sources with participant characteristics were also examined using a chi-square test. Finally, multivariable odds ratios and their 95% CIs for dietary and nutrition information seeking through each media source according to participant characteristics were calculated using multiple logistic regression. For each media source, a model was constructed, which included dietary and nutrition information seeking through the media source as the dependent variable and sex (reference: male), age (continuous), weight status (reference: normal weight), education level (reference: junior high or high school), household income (reference: <4 million Japanese yen; US $1=JPY 148.22), employment status (reference: none), marital status (reference: unmarried), living alone (reference: no), presence of chronic disease (reference: no), smoking status (reference: never), region (reference: Kanto), municipality level (reference: ward), nutrition- and health-related occupations (reference: none, ie, general public), health literacy score (continuous), food literacy score (continuous), HEI-2020 score (continuous), and dietary and nutrition information seeking through 5 other media sources (reference: no for each) as the independent variables. The analysis was repeated separately for the general public and health professionals allied to nutrition. We considered 2-tailed P values <.05 statistically significant. We decided to treat age, health literacy score, and HEI-2020 score as continuous variables in our final analyses after observing similar findings when these variables were treated as categorical variables (20 to 39, 40 to 59, and 60 to 79 years for age and quartiles for others; data not shown).

Results

Basic Characteristics of Study Participants

This analysis included 5998 individuals (male individuals: n=2687, 44.8%; female individuals: n=3311, 55.2%) aged 20 to 79 years (Table 1).
Table 1. Basic characteristics of the study participants (N=5998).

</tbody>
</table>
The mean BMI was 22.1 (SD 3.6) kg/m²; 69.54% (4171/5998) of the participants were categorized as having normal weight. Most participants had a high educational background (university or higher: 3623/5998, 60.4%) and full-time jobs (3876/5998, 64.62%) and were never (3886/5998, 64.79%) or past (1213/5998, 20.22%) smokers. Owing to the sampling design, approximately half (3021/5998, 50.37%) of the participants were members of the general public, whereas the remainder were in nutrition- and health-related occupations, such as dietitians and registered dietitians (631/5998, 10.52%) and physicians and dentists (602/5998, 10.04%).

When participants were allowed to choose with multiple options, the prevalence of diet and nutrition information seeking through various media sources among Japanese adults was as follows: 32.89% (1973/5998) for television, 5.3% (318/5998) for radio, 15.02% (901/5998) for newspapers, 11.62% (697/5998) for books and magazines, 3.52% (211/5998) for municipal newsletters, 16.62% (997/5998) for websites of government and medical manufacturers, 22.22% (1333/5998) for web searches, 9.85% (591/5998) for news applications, 10.57% (634/5998) for video sites (eg, YouTube), and 8.65% (519/5998) for social networking sites (eg, Twitter, Instagram, and Facebook). Thus, the major sources of information (>10% of prevalence) were television (1973/5998, 32.89%), web searches (1333/5998, 22.22%), websites of government and medical manufacturers (997/5998, 16.62%), newspapers (901/5998, 15.02%), books and magazines (697/5998, 11.62%), and video sites (eg, YouTube; 634/5998, 10.57%). These were then examined in subsequent analyses as the top media sources. Dietary and nutrition information seeking through these top 6 media sources was significantly associated with each other, except for a null association between dietary and nutrition information seeking through newspapers and dietary and nutrition information seeking through video sites (Multimedia Appendix 3). Dietary and nutrition information seeking via the top 6 media sources differed significantly according to participant characteristics, with a few exceptions, such as weight status, region, and municipality level (Multimedia Appendix 4).

**Associations of Participant Characteristics With Diet and Nutrition Information Seeking Through the Top 6 Media Sources**

Multivariable odds ratios (with their 95% CIs) for dietary and nutrition information seeking through each media source are shown in Table 2 (for television, web searches, and websites of government and medical manufacturers) and Table 3 (for newspapers, books and magazines, and video sites).
Table 2. Associations of participant characteristics with diet and nutrition information seeking through the top 3 media sources (ie, television, web searches, and websites of government and medical manufacturers) among Japanese adults (N=5998).a

Note: OR: odds ratio.

Information seeking through watching television was associated with female sex, lower education, being married, living with someone, living in the Kyushu region (compared with living in the Kanto region), belonging to the general public (compared with having a nongovernmental qualification related to food and nutrition, being a dietitian or registered dietitian, and being a physician or dentist), a higher score of health literacy, and a lower score of food literacy. Web searches were associated with underweight (compared with normal weight), nonemployment status (compared with students), living in the Kanto region (compared with living in the Kyushu region), and a higher score of health literacy. Use of websites of government and medical manufacturers was associated with male sex; younger age; higher education; the presence of chronic disease; being a dietitian or registered dietitian, physician or dentist, or other health professional (compared with belonging to the general public); and higher scores for health literacy and food literacy. Seeking information from newspapers was associated with male sex; older age; higher education; living with someone; living in the Hokkaido and Tohoku, Chugoku and Shikoku, or Kyushu regions; working in the media (compared with belonging to the general public); and higher scores for health literacy and the HEI-2020. In addition, overweight and being a physician or dentist or other health professional (compared with belonging to the general public) were less likely to seek information from newspapers. Information seeking through books and magazines was associated with female sex; overweight; never smoking (compared with current smoking); working with nongovernmental qualifications related to food and nutrition or as a dietitian or registered dietitian (compared with belonging to the general public); and higher scores for health literacy, food literacy, and the HEI-2020. The use of video sites was associated with male sex, younger age, lower education, past and current smoking, belonging to the general public (compared with working in the media, as a dietitian or registered dietitian, or as other health professional), and higher scores for health literacy and food literacy. The analysis was repeated separately for the general public (Multimedia Appendix 5) and health professionals allied to nutrition (Multimedia Appendix 6). In general, similar findings were observed in approximately 90% (81/90) of the associations examined, although some did not reach statistical significance.

Discussion

Principal Findings

To our knowledge, this is the first study to comprehensively examine the prevalence and correlates of dietary and nutrition information seeking from web-based and offline media sources. In this cross-sectional study of 5998 Japanese adults aged 20 to 79 years, the principal dietary and nutrition information platforms used by >10% of participants were television (1973/5998, 32.89%), web searches (1333/5998, 22.22%), websites of government and medical manufacturers (997/5998, 16.62%), newspapers (901/5998, 15.02%), and video sites (697/5998, 11.62%), and books and magazines (634/5998, 10.57%). After adjustment for potential confounding factors, health literacy was positively associated with the use of each of these sources. By contrast, food literacy showed an inverse association with watching television, whereas it was positively associated with the use of websites of government and medical manufacturers, books and magazines, and video sites. In addition, the media sources that were positively associated with diet quality were websites and books and magazines. Regarding sociodemographic variables, being female was associated with watching television and reading books and magazines, whereas being male was more likely to be associated with using websites of government and medical manufacturers, newspapers, and video sites. Older people were more likely to read newspapers for nutrition information, whereas younger people were more attracted to websites of government and medical manufacturers and video sites. People with higher...
education levels were more likely to use websites of government and medical manufacturers and newspapers but less likely to rely on television and video sites. Compared with the general public, dietitians and registered dietitians were more likely to use websites of government and medical manufacturers and books and magazines but less likely to use television and video sites.

**Comparison With Prior Work**

To our knowledge, only a few studies have investigated the lifestyle (especially dietary) profiles of people seeking dietary and nutrition information from various media sources [25,26,35-40]. This type of study is of utmost importance, given not only that our eating habits have a significant impact on our health [1] but also that the general media landscape is filled with dietary misinformation [14-17]. In this study, after adjustment for potential confounding factors, nutrition information seeking from newspapers and books and magazines (but not television, web searches, websites of government and medical manufacturers, and video sites) was positively associated with diet quality. Thus, the association between nutrition information seeking and diet quality was only observed for offline media. This may be explained by the nature of offline media use, which permits the skimming, reading, and rereading of information, thereby encouraging an active learning process [26,35,38] that may lead to favorable dietary behaviors. Positive associations between the use of offline media and the consumption of fruits and vegetables have been consistently observed in previous studies [26,35,38], with the exception of 1 study [25]. Conversely, previous studies failed to find a significant association between the use of web-based media and fruit and vegetable consumption [25,26,36,37], with the exception of 1 study [35]. Null associations were also observed in this study despite our classification of internet use into several categories (ie, web searches, websites of government and medical manufacturers, video sites, news applications, and social networking sites). With regard to watching television, previous studies have generally not shown favorable associations with eating behaviors [25,26,35,38], which is consistent with the present findings. This fits well with the suggestion that television creates only a passive learning environment, which is unsuitable for the delivery of meaning, knowledge, or context [26,38].

In line with previous studies [19], we found that health literacy was positively associated with the use of all media sources for nutrition information seeking. A novel finding of our study was that food literacy was positively associated with nutrition information seeking using websites of government and medical manufacturers, books and magazines, and video sites. Although we are not aware of previous research on this topic, the findings are plausible, given that gathering information from these sources is an active process and is, therefore, more prevalent in health-information–oriented, health-concerned individuals [38], including people with higher food literacy. Interestingly, we found an inverse association between nutrition information seeking using television and food literacy. The exact reason is unclear, but this might be attributable to the definition and components of the food literacy score measured in this study, which do not necessarily include information seeking skills but rather represent a collection of interrelated knowledge, skills, and behaviors needed for healthy eating [21]. For people with lower food literacy scores and who are unlikely to be interested in nutrition-related topics, television may be the easiest way to obtain dietary and nutrition information.

In this study, the top dietary and nutrition information source was television, followed by web searches, websites of government and medical manufacturers, newspapers, books and magazines, and video sites. This is consistent with a finding from a national survey conducted in 2019 that showed that a larger portion of the general Japanese population considers traditional media, such as television (52%), books and magazines (23%), and newspapers (23%), as information sources that influence their dietary habits, compared with the internet (17% for websites and 8% for social media; multiple choices allowed) [34]. This was particularly apparent in older adults [34]. This tendency to rely on traditional mass media (particularly television and newspapers) for seeking health information has been repeatedly observed in Asian populations, such as Japanese [30-34] and Hong Kong Chinese populations [22,54]. The reason is unknown, but it may be because Asian cultures often prioritize values of obedience, duty, and in-group harmony [66,67].

A unique characteristic of this study is its inclusion of health professionals allied to nutrition, such as dietitians and registered dietitians. This design allowed us to describe interesting pictures of and build knowledge on how the general public and health professionals related to nutrition use and benefit from dietary and nutrition information seeking differently. As expected, we found that compared with the general public, dietitians and registered dietitians were more likely to refer to websites of government and medical manufacturers and books and magazines and less likely to use television or video sites for nutrition information. Taken together with our findings on food literacy and diet quality, this study does suggest that dietary and nutrition information obtained from websites of government and medical manufacturers and books and magazines would be relatively high in quality and usefulness, whereas information obtained from television (and video sites) would be relatively low in quality and useless. This interpretation is generally consistent with previous studies on the quality of nutrition-related information [13,68-74]. Nevertheless, no empirical evidence on the quality of web-based or offline dietary and nutrition information written in Japanese is available, and such investigations are warranted [17].

Studies have shown that being female and having a higher educational background are the strongest correlates of seeking health information from web-based sources [12,22,29,53,54]. Similar associations have also been suggested with regard to offline health information seeking [22,29,54], except for null or inverse associations between education and television exposure [38,75,76]. Studies also suggest that younger age is associated with web-based health information seeking [12,22,53], whereas older age is associated with offline health information seeking [22,28]. Our findings are generally consistent with these previous findings, except for findings regarding the role of sex. We found that being female was associated with the use of television and books and magazines, whereas being male was associated with the use of websites of...
In summary, although health-related information seeking varies across cultures and countries [23,80], all previous studies on nutrition information-seeking behaviors have been conducted in Western countries [11,25-28,35-38]. Therefore, our study of Japanese adults provides valuable insights into information-seeking behavior in relation to healthy eating and its potential consequences. This information may be used in future public health strategies aimed at improving health.

**Limitations**

This study has several limitations. First, it was conducted using a cross-sectional design. Because the temporality of the associations is unknown, it is not possible to address causality or its direction. For example, we cannot determine whether obtaining information about diet and nutrition from books and magazines contributes to improved food literacy and diet quality, or vice versa. More prospective research is needed on this topic. Second, our sample was confined to individuals registered with an internet research agency and, therefore, limited to people with access to the internet, and only a small percentage of these individuals expressed interest in participating in the study. Thus, compared with a nationally representative population, there is likely to be a higher use of web-based media for gathering information on diet and nutrition than what is observed online. In addition, by design, approximately half (2977/5998, 49.63%) of our participants were health professionals allied to nutrition. Consequently, the education level and household income of our participants were higher than those of a nationally representative sample (education: 54,760,800/100,247,800, 54.63% for junior high school or high school, 20,808,900/100,247,800, 20.76% for junior college or technical school, and 24,678,100/100,247,800, 24.62% for university or higher [81]; household income: 2943/5641, 45% for <4 million Japanese yen, 1760/6541, 26.9% for ≥4 to <7 million Japanese yen, and 1831/6541, 28% for ≥7 million Japanese yen [82]). Moreover, our participants appeared different from a nationally representative sample, at least in terms of mean (SD) height, weight, BMI, and HEI-2020 score (male individuals: 167.7, SD 6.9 cm; 67.4, SD 12.0 kg; 23.9, SD 3.6 kg/m²; and 51.3, SD 9.0, respectively; female individuals: 154.3, SD 6.7 cm; 53.6, SD 9.2 kg; 22.5, SD 3.7 kg/m²; and 52.9, SD 9.2, respectively) [34,59]. Taken together, although our sample size was large, the participants were not a nationally representative sample of the general Japanese population. For example, our study may have missed some socially susceptible groups (eg, people without homes or those receiving income support). By including these people, we may have found different correlates for seeking information about diet and nutrition from various web-based and offline media sources. Further research in a more representative sample is warranted.

Third, as with any survey based on a self-administered questionnaire, all the variables used in this study were based on self-report and may thus be subject to biased reporting despite our use of validated tools to assess health literacy [48], food literacy [49], and diet quality [50-52]. Regarding information-seeking behavior, several methodological studies have shown that self-reports of web-based activities [83], mobile phone use [84], and news exposure on television [85] often diverge from real behaviors. Thus, the self-reported responses regarding dietary and nutrition information seeking obtained in this study might be poor reflections of the truth. If so, the associations between media use for seeking dietary and nutrition information and the sociodemographic and lifestyle variables we observed may be generally diluted compared with the true associations. Therefore, the present findings should be interpreted with caution in this context, and efforts should be made to develop a validated scale to assess nutrition information-seeking behavior for use in future research. Fourth, as in many other studies [11,25-28,35-38,86], exposure to dietary and nutrition information sources was rather crudely measured in this study. The dichotomous nature of our measure did not permit a more refined measurement of variables, including an individual’s frequency of use (eg, yearly, weekly, and daily); the content, types, and quality of information participants were exposed to; and for whom the participants were seeking information. An in-depth analysis that incorporates these variables should be conducted to uncover the complexity of dietary and nutrition information-seeking behavior.

Fifth, although this study was conducted during a certain time window (February and March 2023), previous studies have suggested seasonal variations in dieting and weight loss attempts [87] and the frequency of internet searches for fitness and weight loss information [88]. Therefore, certain sociodemographic and lifestyle characteristics associated with media use for seeking dietary and nutrition information may manifest differently over time [86]. As such, it should be noted that this study provides only a snapshot in time. Future research should be designed to capture this dynamic nature of nutrition information-seeking behavior and its correlates. Finally, although we adjusted for various variables, we cannot rule out the possibility of residual confounding. Despite these limitations, the major strength of this study is its inclusion of a wide variety of dietary and nutrition information sources. Unlike a substantial majority of recent studies [11,23,36,37,86], our data allowed for differentiation among several web-based information sources (eg, web searches, websites of government and medical manufacturers, and video sites). This study also investigated more conventional, offline information sources (eg, television, newspapers, and books and magazines), which are still widely valued and used, in Asian countries at least [22,30-34,54]. People who use these information sources do not necessarily have the same approach and thus might not have the same profiles [89], which was clearly observed in this study.
Practical Implications

Our findings have implications for public health. First, the study demonstrates that a wide variety of sources are regularly used for seeking dietary and nutrition information in Japan. However, it was clear that each source was preferred by users with distinct characteristics. On the basis of these differences in potential users, we speculated that each media source should have suitable topics and optimal information dissemination strategies. For example, it is ideal to use television, an entertainment-oriented medium, for constantly disseminating easy-to-understand messages for chronic disease prevention (eg, “make half your plate fruits & vegetables”) [2] to instigate health-related conversations with family and friends for people with lower levels of formal education [38,76]. This may be particularly relevant, considering the multitasking agenda of women, who are frequent users of television and who play key roles as health managers and family caregivers [79,90,91]. In addition, newspapers (as well as books and magazines) should perhaps include only a small number of high-quality articles on the importance of overall dietary patterns, a topic for which the most powerful evidence is accumulated in nutritional epidemiology [1,2,4]. These articles should be written by reputable journalists with adequate training on issues related to scientific methodology, food, and health [92]. If successful, newspapers may play a vital role in chronic disease prevention and management [12] among middle-aged and older individuals with a higher educational background [38,76]. Further, for every web-based media source, nutrition professionals are ultimately responsible for and able to contribute to the creation and promotion of evidence-based content on topics that are popular [16,17,93] among the public [13,94]. Simultaneously, consideration should be given to the practicality and utility of the information [6] as well as to the affective needs (eg, enjoyment) and cognitive needs (eg, interest) of information [15], all of which are essential to the effective dissemination of dietary and nutrition information.

Ultimately, however, it is the consumers who decide from what and where they learn and what they eat. Research shows that although consumers say that they primarily look for the source, the presence of a professional design, and a variety of other criteria when assessing the credibility of a website, internet users do not in practice check the “about us” sections of websites, try to find out who the authors or owners of sites are, or read disclaimers or disclosure statements [95]. As an initial step, the general public should be sufficiently informed that there is a huge amount of misinformation (and potentially disinformation, ie, false information that is intentional spread) about nutrition, particularly on the internet and social media [7]. More fundamentally, critical thinking, or the ability to objectively analyze facts to make decisions successfully [96], appears to be an essential skill in the present age of highly developed information [6,7]. Excellence in this type of thinking does not come naturally but must be systematically cultivated [7]. Therefore, systematic learning of critical thinking skills should be introduced in the compulsory education system, with a focus on understanding the scientific process while eliminating the sole focus on results, thereby empowering consumers to evaluate evidence and understand the evolving nature of science [6].

Conclusions

This cross-sectional study identified various web-based and offline media sources regularly used by Japanese adults seeking nutrition information. Except for health literacy, each media source had unique correlates, suggesting large differences in potential users, relevant topics, and optimal information dissemination strategies among media sources. Perhaps the most concerning finding is the lack of positive associations between the use of 2 major sources (television and web searches) and food literacy and diet quality. By contrast, a promising finding is the positive associations of the use of websites of government and medical manufacturers, newspapers, books and magazines, and video sites with food literacy or diet quality. The present findings are a valuable scientific contribution to the development of effective promotional tactics and strategies for healthy eating.

Abstract

Background: Digital health literacy, also known as eHealth literacy, describes the ability to seek, find, understand, and apply health information from the internet to address health problems. The World Health Organization calls for actions to improve digital health literacy. To develop target group–specific digital health literacy interventions, it is necessary to know the digital health literacy of the general population and relevant subgroups.

Objective: This study aims to representatively assess the digital health literacy of the population in Germany and relevant subgroups. The results are meant to facilitate the development of target group–specific digital health literacy interventions. Additionally, this study further explores the associations between digital health literacy and physical health, mental health, life satisfaction, and diverse health behaviors.

Methods: Study participants were drawn from a representative panel of the German-speaking population with internet access. To further increase the representativeness of the sample, survey weights were calculated using an iterative proportional fitting procedure. Participants answered a series of questionnaires regarding their digital health literacy, physical health, mental health, life satisfaction, and diverse health behaviors. Two-sided independent sample t tests were conducted to determine the significant differences between societal subgroups. Pearson correlation coefficients were calculated to explore the correlates of digital health literacy.

Results: Digital health literacy is unevenly distributed within German society. The results of this study suggest that people with a low level of formal education and people with a low social status would benefit from digital health literacy interventions that address their competencies in the domains of information seeking and information appraisal. Furthermore, the results suggest that older people would likely benefit from digital health literacy interventions that address their competencies in the domains of information seeking and also information appraisal. Regarding sex, this study suggests that men might benefit from digital health literacy interventions that specifically address their competencies in the domain of information seeking. Furthermore, digital health literacy is weakly positively correlated with physical health, mental health, life satisfaction, exercise routines, fruit consumption, and vegetable consumption.

Conclusions: Overall, the results of this study demonstrate that digital health literacy is associated with diverse health outcomes and behaviors. Furthermore, the results provide a starting point for the development of target group–specific digital health literacy interventions.

Introduction
Digital health literacy, also known as eHealth literacy, can be defined as “the ability to seek, find, understand, and appraise health information from electronic sources and apply the knowledge gained to addressing or solving a health problem” [1]. Nowadays, these skills seem particularly important for two reasons. First, people from around the world regularly use the internet to acquire health information [2,3]. Second, when searching the internet for health information, people are often confronted with misinformation [4,5]. Furthermore, recent studies have found that evaluating the reliability of health information on the internet is not just difficult for the general population but also for better educated and younger subgroups like university students [6-8].

Besides its central role in the context of evaluating health information on the internet, digital health literacy seems important because it is associated with various health intentions and behaviors [9]. Studies in diverse contexts have shown, for example, that people with high digital health literacy demonstrate better physical exercise routines [10], eat more nutritionally balanced diets [11], and protect themselves better against viruses [12]. Furthermore, they have better cancer screening practices [13], are more confident about finding cancer information [14], and are less likely to fall prey to conspiracy beliefs [12]. Given these potential positive health effects, it is no surprise that the World Health Organization calls for actions to improve digital health literacy [15].

To develop target group-specific digital health literacy interventions, it is necessary to know the digital health literacy of the general population and relevant subgroups. Various instruments have been developed to measure digital health literacy [16]. One of the most widely used instruments is the eHealth Literacy Scale [17], which has already been translated into diverse languages, including Dutch [18], Chinese [19], and Korean [20]. A German version of the eHealth Literacy Scale was published in 2014 [21]. This instrument, however, was recently criticized because of content-related and methodological shortcomings, and a revised German eHealth Literacy Scale was published in 2022 [9].

This study aims to representatively assess the digital health literacy of the population in Germany and relevant subgroups, using the revised German eHealth Literacy Scale [9]. The results are meant to facilitate the development of target group-specific digital health literacy interventions. Additionally, this study further explores the associations between digital health literacy and physical health, mental health, life satisfaction, and diverse health behaviors (exercise routines, fruit consumption, vegetable consumption, soft drink consumption, alcohol consumption, cigarette consumption, and drug consumption).

Methods

Ethical Considerations
Before data collection, a detailed study protocol that included information on the procedures, measures, and statistical analyses was submitted to the ethics committee of the Berlin Medical Association. The ethics committee consisted of 2 medical doctors, a lawyer, a statistician, and a layperson. The ethics committee had no ethical or professional objections to the study protocol (reference Eth-39/22). Before the study started, participants provided their informed consent to take part in the study. Participants had the opportunity to opt out of the study at any time during the study. The independent, nonprofit foundation Stiftung Gesundheitswissen did not compensate the participants for their participation, and participants were informed that the foundation would only receive anonymized data.

Survey Methodology
The market research Institute Forsa Gesellschaft für Sozialforschung und Statistische Analysen mbH (Forsa) was responsible for data acquisition [22]. The survey was conducted using the representative web-based panel forsa-omninet, which is a representative panel for the German-speaking population with internet access and currently has around 100,000 participants. A continuous recruiting process adds new participants to the panel every month. In addition, the composition of the panel is continuously monitored based on key characteristics (eg, region, age, and sex), and recruitment is adjusted accordingly. Data acquisition took place from September 22 to October 12, 2022. A random sample was drawn from the representative web-based panel. All panelists selected for the survey were invited via email. The invitation email provided information on the topic and purpose of the survey. If necessary, the selected panelists were reminded about their participation in 2 further emails. In total, 3927 panelists were invited to take part in the survey. All responses were checked for plausibility, and a comprehensive speeder analysis was conducted based on the response times. A total of 2000 panelists completed the survey. This corresponds to a response rate of about 50.9% (2000/3927), which is quite high for a relatively long survey that is completed on a voluntary basis. On average, panelists took 20 minutes to finish the survey. The sample characteristics of the participants who were invited to participate in the study (invited sample) and the participants who were included in the data analyses before (unweighted sample) and after the weighting procedure (weighted sample) can be found in the Results section. Please note that the unweighted and weighted samples are based on the 1996 study participants who answered all items from the revised German eHealth Literacy Scale. Furthermore, please note that due to sample weighting and rounding, sample sizes may vary, and percentages may exceed or fall below 100%. There are differences between these groups. For example, 50.6% (1988/3927) of the invited sample...
All things considered, how satisfied are you with your life to assess life satisfaction [24]. Participants answered the question on scales ranging from 0 (not at all satisfied) to 10 (completely satisfied).

Health Behavior

Health behavior was assessed by asking participants questions about their health behavior within a typical week. Participants were asked about their exercise routines (On average, how many days a week do you exercise?), fruit consumption (On average, how many days a week do you eat fruit?), vegetable consumption (On average, how many days a week do you eat vegetables?), soft drink consumption (On average, how many days a week do you drink sugary soft drinks?), alcohol consumption (On average, how many days a week do you drink alcohol?), cigarette consumption (On average, how many days a week do you smoke cigarettes?), and drug consumption (On average, how many days a week do you use illegal drugs?). Participants answered the questions on scales ranging from 0 (0 days) to 7 (7 days). This study was part of a larger study, and therefore the raw data set contains further variables that have not been described because they exceed the scope of this study.

Statistical Analyses

All statistical analyses were conducted with the statistical software SPSS (version 29.0.0.0; IBM Corp). Cronbach α was calculated for the 2 subscales of the revised German eHealth Literacy Scale to ensure the quality of the measures. Two-sided independent sample t tests were conducted to determine the significant differences between the subgroups. For all 2-tailed t tests, unequal variance was assumed. Throughout the analyses, group differences were considered significant if P<.05, which should be taken into consideration when interpreting the results. Interested readers can find detailed information on when it is appropriate to adjust significance thresholds (eg, disjunction testing vs conjunction testing vs individual testing) elsewhere [25]. Pearson correlations were calculated to explore the associations between digital health literacy and physical health, mental health, life satisfaction, and health behaviors. Most of the instruments used in this study relied on Likert-like scales and therefore produced ordinal data. There has been a long debate about whether data from Likert-like scales should be analyzed using parametric statistics or less sensitive and less powerful nonparametric statistics (eg, 2-sample t test vs Wilcoxon rank sum test, Pearson coefficient of correlation vs Spearman rank correlation) [26-28]. Previous research has demonstrated that parametric statistics can be quite robust against violations of its assumptions, especially with large sample sizes [26-28]. One article concluded that “Parametric statistics can be used with Likert data, with small sample sizes, with unequal variances, and with non-normal distributions, with no fear of ‘coming to the wrong conclusion.’” These findings are consistent with empirical literature “dating back nearly 80 years” [26]. Hence, parametric statistics were chosen for this analysis to avoid an unnecessary loss of information. The final data analyses were based on the 1996 study participants who answered all items from the revised German eHealth Literacy Scale.

Digital Health Literacy

The revised German eHealth Literacy Scale was used to assess digital health literacy [9]. The instrument consists of 8 items that comprise 2 subscales assessing competencies in the domain of information seeking (4 items; eg, I know how to find helpful health resources on the Internet) and information appraisal (4 items; eg, I have the skills I need to evaluate the health resources I find on the Internet). Participants rated all items on scales ranging from 1 (strongly disagree) to 5 (strongly agree). A total score was generated for each subscale by calculating the mean.

Physical Health and Mental Health

Physical health was assessed by asking participants “Overall, how do you currently rate your physical health?” Mental health was assessed by asking participants “Overall, how do you currently rate your mental health?” Participants answered the questions on scales ranging from 0 (very bad) to 10 (very good).

Life Satisfaction

The 1-item General Life Satisfaction Short Scale (L-1) was used to assess life satisfaction [24]. Participants answered the question “All things considered, how satisfied are you with your life...
Subgroup Analysis

In Germany, the Health Literacy Survey Germany project has assessed the general health literacy of the population in Germany and relevant subgroups [8]. To simplify and facilitate comparisons between different studies, similar subgroups were chosen for this study. The subgroups were divided along the lines of level of education (low, middle, and high), social status (low, middle, and high), age (16-29 years, 30-45 years, 46-64 years, and 65 years and older), chronic disease (no and yes), migration background (no and yes), and sex (male and female). The German version of the MacArthur Scale was used to assess social status [29]. Scores were classified as low (1-4), middle (5-7), and high (8-10). Educational degrees (eg, low=no degree, middle=high school degree, and high=university degree) were used to assess participants’ level of education. Educational degrees were classified as low (ohne Haupt-/Volksschulabschluss; Haupt-/Volksschulabschluss; Mittlere Reife, Realschulabschluss, Fachschulreife; Abschluss der Polytechnischen Oberschule), middle (Fachhochschulreife, Abschluss einer Fachoberschule; Abitur, allgemeine oder fachgebundene Hochschulreife), and high (Fach-/Hochschulstudium).

Results

Sample Characteristics

To increase the representativeness of the sample, survey weights were calculated, and the sample was weighted accordingly. Table 1 provides invited, unweighted, and weighted sample characteristics by sex, age, state, level of education, migration background, chronic disease, and social status.
Table 1. Nationally representative survey of the population in Germany: invited, unweighted, and weighted sample characteristics by sex, age, state, level of education, migration background, chronic disease, and social status.

Quality of Measures

Using the unweighted data, Cronbach α was calculated for the 2 subscales of the revised German eHealth Literacy Scale to ensure the quality of the measures. Widely used conventions define Cronbach α values of .7 and higher as acceptable [30,31]. Both scales surpassed this widely used Cronbach α threshold (information seeking: .897 and information appraisal: .839).

Level of Education

On average, people with a high level of education had higher perceived competency levels in the domains of information seeking (t_{3,415}=1068.213; P<.001; d=0.177) and information appraisal (t_{6,406}=1118.823; P<.001; d=0.327) than people with a low level of education. Perceived competency levels did not differ significantly between people with a high level of education and people with a middle level of education (information seeking: t_{1,062}=809.769; P=.29; d=0.072 and information appraisal: t_{0.414}=818.391; P=.66; d=0.029). Furthermore, perceived competency levels in the domain of information seeking did not differ significantly between people with a middle level of education and people with a low level of education (t_{1,920}=701.099; P=.05; d=0.110). However, people with a middle level of education had higher perceived competency levels in the domain of information appraisal than people with a low level of education (t_{5,456}=750.726; P<.001; d=0.301).

Social Status

On average, people with a high social status had higher perceived competency levels in the domains of information seeking (t_{4,947}=606.910; P<.001; d=0.399) and information appraisal (t_{6,583}=598.474; P<.001; d=0.530) than people with a low social status. Furthermore, people with a high social status had higher perceived competency levels than people with a middle social status (information seeking: t_{2,222}=437.791; P=.03; d=0.140 and information appraisal: t_{2,751}=460.093; P=.006; d=0.166). Additionally, people with a middle social status had higher perceived competency levels than people with a low social status (information seeking: t_{4,089}=438.922; P<.001; d=0.271 and information appraisal: t_{5,526}=437.177; P<.001; d=0.368).

Age

On average, perceived competency levels in the domain of information seeking did not differ significantly between people aged 16-29 years and people aged 65 years and older (t_{1,880}=826.226; P=.06; d=0.127). However, people aged 16-29 years had higher perceived competency levels in the domain of information appraisal than people aged 65 years and older (t_{4,787}=831.799; P<.001; d=0.320). People aged 16-29 years had higher perceived competency levels than people aged 46-64 years (information seeking: t_{2,253}=761.604; P=.02; d=0.146 and information appraisal: t_{4,002}=783.957; P<.001; d=0.257). Perceived competency levels did not differ significantly between people aged 16-29 years and people aged 30-45 years (information seeking: t_{0.256}=754.114; P=.80; d=–0.018 and information appraisal: t_{0.184}=762.075; P=.85; d=–0.013). People aged 30-45 years had higher perceived competency levels than people aged 46-64 years (information seeking: t_{2,766}=1062.057; P=.006; d=0.165 and information appraisal: t_{2,542}=1069.427; P<.001; d=0.270) and people aged 65 years and older (information seeking: t_{2,997}=979.125; P=.02; d=0.145 and information appraisal: t_{5,301}=979.619; P<.001; d=0.335). However, perceived competency levels did not differ significantly between people aged 46-64 years and people aged 65 years and older (information seeking: t_{0.818}=1048.014; P=.86; d=–0.011 and information appraisal: t_{1,236}=1058.857; P=.22; d=0.074).

Chronic Disease

On average, perceived competency levels in the domains of information seeking (U=1548.068; P=.71; d=–0.017) and information appraisal (U=1512.596; P=.12; d=0.072) did not differ significantly between people without a chronic disease and people with a chronic disease.

Migration Background

On average, perceived competency levels in the domains of information seeking (t_{0.369}=139.851; P=.71; d=0.034) and information appraisal (t_{0.604}=142.612; P=.55; d=–0.052) did not differ significantly between people without a migration background and people with a migration background.

Sex

On average, women had higher perceived competency levels in the domain of information seeking than men (t_{2,333}=1992.953; P=.02; d=0.104). However, perceived competency levels in the domain of information appraisal did not differ significantly between women and men (t_{0.016}=1993.874; P=.99; d=0.001). Table 2 shows the digital health literacy of the population in Germany by level of education, social status, age, chronic disease, migration background, and sex.
Table 2. Nationally representative survey of the population in Germany: digital health literacy by the level of education, social status, age, chronic disease, migration background, and sex. Statistically significant differences are indicated by superscript letters.

**Correlates of Information Seeking**

Participants’ perceived competency levels in the domain of information seeking were weakly positively and significantly correlated with their physical health, mental health, life satisfaction, exercise routines, fruit consumption, and vegetable consumption. Furthermore, information seeking was weakly negatively and significantly correlated with alcohol consumption. There were no significant correlations between information seeking and soft drink consumption, cigarette consumption, and drug consumption. Table 3 provides further information about the correlation coefficients and their significance levels.

Correlates of Information Appraisal

Participants’ perceived competency levels in the domain of information appraisal were weakly positively and significantly correlated with their physical health, mental health, life satisfaction, exercise routines, fruit consumption, and vegetable consumption. There were no significant correlations between information appraisal and soft drink consumption, alcohol consumption, cigarette consumption, and drug consumption. Table 3 provides further information about the correlation coefficients and their significance levels.

Discussion

Principal Findings

To guide the development of target group–specific digital health literacy interventions, it is necessary to know the digital health literacy of different subgroups within a society. For Germany, such data have not been collected with appropriate and methodological sound measures. Therefore, this study representatively assessed the digital health literacy of the population in Germany and relevant subgroups. The results suggest that people with a low level of education and people with a low social status would benefit from digital health literacy interventions that address their competencies in the domains of information seeking and information appraisal. These findings align with previous research, which suggests that individuals with lower levels of education and lower social status tend to have lower general health literacy [8,32]. Furthermore, the results suggest that older people would likely benefit from digital health literacy interventions that address their competencies in the domains of information seeking and information appraisal. Once again, these findings are in line with results from general health literacy research, which highlights that older individuals may constitute a vulnerable group deserving special attention [8,32,33].

Previous research has found that people with chronic diseases and people with migration backgrounds have lower health literacy levels [8,34,35]. Such differences, however, were not found in this study. People with a chronic disease and people without a chronic disease did not significantly differ in regard to their digital health literacy. Neither did people with a migration background and people without a migration background significantly differ in regard to their digital health literacy. The last finding is in line with results from a study conducted in Israel, which suggests that the migration status of an individual may be linked to general health literacy but not necessarily to digital health literacy [36]. The authors of the study hypothesize that this finding might be attributed to the fact that certain language barriers are less prominent on the internet compared to real-world settings. Another contributing factor could be that the study sample might have contained individuals with migration backgrounds who possess particularly strong language skills. Regarding sex, this study suggests that men might benefit from digital health literacy interventions that specifically address their competencies in the domain of information seeking. These findings corroborate earlier research results which indicate that women have higher (digital) health literacy than men, even though the differences are often small [7,8,37].

Besides comparing the digital health literacy of different societal groups, this study explored the associations between digital health literacy and diverse health-related constructs and behaviors. The results suggest that digital health literacy is weakly positively correlated with physical health, mental health, life satisfaction, exercise routines, fruit consumption, and vegetable consumption. Moreover, higher perceived competency levels in the domain of information seeking were weakly negatively correlated with alcohol consumption. When interpreting these results, however, it must be stressed that the found associations were rather weak.

In line with previous research, information appraisal was more strongly associated with mental health, physical health, and life satisfaction than information seeking [9]. Interestingly, the results suggest that digital health literacy is more strongly associated with health perceptions (eg, mental health) than with health behaviors (eg, exercise routines). As a reviewer (EN) of this paper pointed out, this finding might be explained by methodological considerations. For example, 2 health perception variables (eg, “Overall, how do you currently rate your mental health?”) might show stronger associations with each other than a health perception variable and a health behavior variable (eg, “On average, how many days a week do you exercise?”). Future studies should develop adequate research designs to test this hypothesis.

Limitations and Future Directions

The results of this study demonstrate the importance of digital health literacy in society. There are, however, limitations that must be kept in mind when interpreting the results. Three of these limitations seem especially important and need to be discussed in more detail. The first limitation concerns the study design. This study used a cross-sectional study design, and therefore no causal inference can be drawn [23]. This study found, for example, that participants’ digital health literacy is positively and significantly correlated with their physical health. From this finding, however, one cannot conclude that digital health literacy causes physical health. To draw a causal inference like this, future studies could, for example, use an experimental study design and actively manipulate the digital health literacy of the study participants before assessing their physical health [38].

The second limitation concerns the data collection method of this study. Data collection took place via a web-based survey platform. Hence, participants needed basic technical skills and access to the internet to participate in the study. It is known, however, that older people use the internet less frequently than younger people [39]. Therefore, this study can only be representative of the German population with internet access.
People without any experience with the internet probably have lower digital health literacy scores. Hence, the data collection method should be taken into account when comparing the results of this study to other digital health literacy studies that might have used other data collection methods such as in-person or telephone interviews. There is another problem that might have affected the representativeness of the study results, which has already been raised in the survey methodology section and concerns the nonresponders and potential selection bias. As a reminder, 50.6% (1988/3927) of the invited sample were men, but only 47.8% (955/1996) of the unweighted sample were men. After the weighting procedure, 49% (978/1997) of the sample were counted as men. During the analyses, it was found that, on average, women had higher perceived competency levels in the domain of information seeking than men. One might argue that men with an above-average interest in the topic of digital health literacy were more likely to complete the study, and their response data were weighted. Hence, the found difference between women and men might be even more pronounced within the German population. Such an argument can also be made regarding other demographic factors. Since we have no information about the digital health literacy of the nonresponders, we currently cannot test this hypothesis. Nevertheless, it is important to bear in mind that there were demographic differences between responders and nonresponders, as can be seen in Table 1, and this might have affected the results, even after the weighting procedure.

The third limitation concerns the types of measures that were used in this study. Besides multi-item measures, this study also used single-item measures. Single-item measures are often criticized because they usually cannot assess complex constructs (eg, personality) and may be less reliable under specific circumstances [40-42]. In many situations, however, there are good arguments in favor of the use of single-item measures, and previous research has shown that these measures can be reliable and valid [40,43,44]. Nevertheless, it would be interesting to substitute the single-item measures with multi-item measures in future studies to investigate whether these changes would alter the general direction of the results. Furthermore, this study also relied on self-report measures. Self-report measures, however, are often criticized because they may produce inaccurate results [45-47]. When asked about their vegetable consumption within a typical week, for example, respondents might give an inaccurate answer because they usually do not track their eating habits very carefully. When asked about their drug consumption within a typical week, respondents might be inclined to lie because they do not want to make a bad impression or admit to themselves that they might have a drug problem. Therefore, to verify these results, it would be interesting to repeat this study with behavioral, observational, and performance measures instead of self-report measures.

**Conclusions**

Overall, the results of this study demonstrate that digital health literacy is associated with diverse health outcomes and behaviors. Furthermore, the results provide a starting point for the development of target group–specific digital health literacy interventions.

Abstract

Background: Maternal smoking during pregnancy (MSDP) is a known risk factor for offspring developing chronic obstructive pulmonary disease (COPD), but the underlying mechanism remains unclear.

Objective: This study aimed to explore whether the increased COPD risk associated with MSDP could be attributed to tobacco dependence (TD).

Methods: This case-control study used data from the nationwide cross-sectional China Pulmonary Health study, with controls matched for age, sex, and smoking status. TD was defined as smoking within 30 minutes of waking, and the severity of TD was assessed using the Fagerstrom Test for Nicotine Dependence. COPD was diagnosed when the ratio of forced expiratory volume in 1 second to forced vital capacity was <0.7 in a postbronchodilator pulmonary function test according to the 2017 Global Initiative for Chronic Obstructive Lung Disease criteria. Logistic regression was used to examine the correlation between MSDP and COPD, adjusting for age, sex, BMI, educational attainment, place of residence, ethnic background, occupation, childhood passive smoking, residential fine particulate matter, history of childhood pneumonia or bronchitis, average annual household income, and medical history (coronary heart disease, hypertension, and diabetes). Mediation analysis examined TD as a potential mediator in the link between MSDP and COPD risk. The significance of the indirect effect was assessed through 1000 iterations of the “bootstrap” method.

Results: The study included 5943 participants (2991 with COPD and 2952 controls). Mothers of the COPD group had higher pregnancy smoking rates (COPD: n=305, 10.20%; controls: n=211, 7.10%; P<.001). TD was more prevalent in the COPD group (COPD: n=582, 40.40%; controls: n=478, 33.90%; P<.001). After adjusting for covariates, MSDP had a significant effect on COPD (β=.097; P<.001). There was an association between MSDP and TD (β=.074; P<.001) as well as between TD and COPD (β=.048; P=.007). Mediation analysis of TD in the MSDP-COPD association showed significant direct and indirect effects (direct: β=.094; P<.001 and indirect: β=.004; P=.03). The indirect effect remains present in the smoking population (direct: β=.120; P<.001 and indirect: β=.002; P=.03).

Conclusions: This study highlighted the potential association between MSDP and the risk of COPD in offspring, revealing the mediating role of TD in this association. These findings contribute to a deeper understanding of the impact of prenatal tobacco exposure on lung health, laying the groundwork for the development of relevant prevention and treatment strategies.

KEYWORDS
chronic obstructive pulmonary disease; tobacco dependence; smoking; mediating effects; lung function

Introduction

Chronic obstructive pulmonary disease (COPD) is a global health challenge, ranking among the leading causes of both morbidity and mortality worldwide [1]. It was estimated that COPD affected a substantial portion of the global population with a prevalence rate of 10.3% among individuals, and the number of individuals afflicted with COPD has been on the rise [2]. Notably, China accounts for nearly a quarter of global COPD cases, with a 67% increase in prevalence among individuals aged 40 years and older between 2012 and 2015 [3].

COPD is influenced by various factors, including genetics, lifestyle, environmental factors, and other influencing factors.
Smoking, recognized as the most significant cause of COPD, leads to its development in approximately half of all smokers [6,7]. The prenatal and perinatal phases are crucial for lung development, with maternal smoking linked to offspring susceptibility to various health issues [8-10]. A systematic review suggested that maternal smoking during pregnancy (MSDP) is associated with an increased risk of COPD [11]. MSDP may directly impact fetal development, influencing the formation of the central nervous system and respiratory system [12]. Given the vulnerability of embryos and fetuses to the external environment, maternal smoking may exert a more pronounced effect on fetal development [13].

Despite widespread recognition of the adverse effects of MSDP on offspring COPD [11], the underlying mechanisms remain incompletely elucidated. Tobacco dependence (TD) is a complex condition influenced by genetic and environmental factors, classified as a mental disorder according to the International Classification of Diseases, and TD should be recognized as a lethal noncommunicable disease [14]. Previous studies have identified TD as an independent risk factor for atherosclerosis [15]. Notably, TD is prevalent among smokers, often associated with heightened smoking intensity and lower cessation rates [16], and approximately 40% of smokers experience impaired lung function and develop COPD [17]. A meta-analysis indicates an elevated risk of smoking and TD in offspring associated with MSDP [18]. Given these associations, our hypothesis posits that TD plays a pivotal mediating role in the association between MSDP and COPD.

Therefore, this study aims to investigate whether TD serves as a mediator in the association between MSDP and the risk of COPD in offspring. To achieve this, we used data from the national cross-sectional China Pulmonary Health (CPH) study [3] and conducted a case-control study to explore the role of TD in the association between MSDP and COPD. The findings will contribute to the development of targeted interventions focused on TD.

**Methods**

**Participants and Study Design**

The study population was drawn from the national cross-sectional CPH study [3,19,20], the largest study assessing the burden of COPD in China. The CPH study, encompassing a vast nationwide cross-sectional examination, encompassed 57,779 Chinese adults aged 20 years and older across 10 provinces in China. This extensive study incorporated 80 urban and 80 rural areas, using a multistage stratified cluster sampling approach. The details of recruitment for the CPH can be found elsewhere [3]. Trained health workers in local community health centers administered standardized questionnaire surveys to all participants, capturing essential information on sociodemographic status, medical history, lifestyle, and more. The questionnaire information involved in this study can be obtained in Table S1 in Multimedia Appendix 1.

In this study, a case-control design was used, and the workflow is illustrated in Figure 1. Inclusion criteria for the case group were as follows: (1) provision of signed informed consent, (2) age of 18 years or older, and (3) availability of complete questionnaire information. Individuals with other conditions such as asthma, tuberculosis, lung cancer, lung inflammation, and missing information were excluded. Control participants were matched for age, sex, and smoking from cohort. The matching tolerance can be found in Table S2 in Multimedia Appendix 1. Ultimately, a total of 2991 patients in the COPD group and 2952 controls were included in this study.
**Definition of MSDP and Evaluation of TD**

MSDP was self-reported through a questionnaire, with all participants asked to respond to the question, “Did your mother smoke during pregnancy? (yes or no).” Upon awakening, smoking within the first 30 minutes was defined as indicative of TD, based on prior study [21]. The severity of TD was assessed using the Fagerstrom Test for Nicotine Dependence (FTND) [22]. FTND is a standardized tool for evaluating the degree of physical nicotine addiction. It consists of six items: (1) How soon after waking do you smoke your first cigarette (within 5 minutes, 6 to 30 minutes, 31 to 60 minutes, and after 60 minutes)? (2) Do you find it difficult to refrain from smoking in places where it is prohibited (yes or no)? (3) Which cigarette would you find most difficult to give up (the first one in the morning or any other)? (4) How many cigarettes do you smoke per day (10 or less, 11 to 20, 21 to 30, and 31 or more)? (5) Do you smoke more frequently during the first hour after wakening compared to the rest of the day (yes or no)? and (6) Do you smoke when you are so ill that you are confined to bed most of the day (yes or no)? The FTND generates a total score ranging from 0 to 10, with scores calculated as the sum of individual items. Yes or no items are scored as 0 or 1, and multiple-choice items are scored as 0 to 3. The questionnaire provided a comprehensive assessment of cigarette consumption, compulsion, and dependence. A higher total FTND score indicates a greater degree of TD. All participants reported their smoking status (yes or no). Smoking was defined as having consumed 100 cigarettes in one’s lifetime, encompassing both current and former smokers.

To address potential recall bias in self-reported MSDP, we implemented rigorous quality control measures. Our questionnaire design emphasized clarity and comprehensibility, and interviewers received detailed training to ensure precise definitions of smoking behavior. Memory aids were provided to aid accurate recall, and privacy protection measures were emphasized to minimize bias.
Definition of COPD
All study participants underwent postbronchodilator pulmonary function tests, including measurements of forced expiratory volume in 1 second (FEV$_1$) and forced vital capacity (FVC) and FEV$_1$/FVC ratio. COPD was diagnosed in accordance with the criteria set forth by the 2017 Global Initiative for Chronic Obstructive Lung Disease [23] if the participant’s FEV$_1$/FVC ratio was <0.7.

Covariates
This study incorporated several covariates, including age (years), sex (male or female), BMI (calculated as weight in kilograms divided by the square of height in meters), educational attainment (primary and below, junior middle school, senior high school, or bachelor and above), place of residence (urban or rural), ethnic background (Han Chinese or other), occupation (farmer, worker, or other), childhood passive smoking, residential fine particulate matter (PM$_{2.5}$) exposure, history of childhood pneumonia or bronchitis (yes or no), average annual household income, and medical history (coronary heart disease, hypertension, and diabetes).

Statistical Analysis
For normally distributed continuous variables, descriptive statistics are presented as mean (SD). Categorical variables are expressed as numbers and percentages. The Kolmogorov-Smirnov test was used to assess the normality of continuous variables. Comparisons of continuous variables were conducted using the Mann-Whitney U test, while categorical variables were compared using the chi-square test.

Mediation analysis, as outlined by Baron and Kenny [24], was used to investigate the potential mediating role of TD in the association between MSDP and the risk of COPD. The association between MSDP and TD was modeled using logistic regression, whereas the association with FTND scores was assessed using linear regression. The total effect of the initial variable on the outcome was defined as the sum of its direct and indirect effects. The indirect effect was further defined as the product of the initial variable’s impact on the intermediate variable and the intermediate variable’s impact on the outcome, with adjustments made for the initial variable. The statistical significance of the indirect effect was assessed through 1000 repetitions of a bootstrap procedure. Regarding the sensitivity analysis, we conducted a similar analysis by defining TD as a total FTND score ≥4. The sample size for this study was determined using the Monte Carlo method [25]. The details of the sample size calculation process are provided in Table S3 in Multimedia Appendix 1. All statistical analyses were conducted using R (version 4.2.1; R Foundation for Statistical Computing), with the use of packages such as bruceR, interactions, and mediation to estimate mediating effects. A significance level of $P=0.05$ (2-tailed) was considered statistically significant.

Ethical Considerations
The study received approval from the ethics review committee of Beijing Capital Medical University (11-KE-42) and other collaborating institutes. Written informed consent was obtained from all study participants in accordance with the principles outlined in the Declaration of Helsinki. To ensure privacy and confidentiality, the data used in this study underwent anonymization and deidentification processes.

Results
Participants
A total of 5943 participants were enrolled in this study, comprising 2991 individuals with COPD and 2952 matched controls. The demographic characteristics of all participants are elaborated in Table 1. In the control group, the mean age was 59.17 (SD 11.44) years, while in the COPD group, it was 59.50 (SD 11.66) years. Among controls, there were 1783 (60.40%) male participants, and in the COPD group, 1816 (60.70%) male participants. Smoking was observed in 1442 (48.20%) individuals within the COPD group and 1412 (47.80%) individuals in the control group. For matching purposes, no statistically significant differences were detected between the 2 groups in terms of participants’ age, sex, and smoking. However, a higher proportion of mothers in the COPD group reported MSDP compared to the control group (COPD: n=305, 10.20% and controls: n=211, 7.10%; $P<0.001$).

### Differences of TD in Smokers Between the 2 Groups

As depicted in Table 2, the prevalence of TD was notably higher in the COPD group in comparison to the control group (COPD: n=582, 40.40%; controls: n=478, 33.90%; \(P=.001\)). Patients with COPD, when contrasted with the control group, exhibited a shorter time interval between waking up and the desire to smoke their first cigarette (Q1: \(P=.004\)) and encountered greater difficulty refraining from smoking in public places (Q2: \(P=.006\)). Among the COPD group, 19.40% (n=280) reported a tendency to smoke more frequently during the early hours after waking, whereas in the control group, this behavior was observed in 16.50% (n=233; \(P=.048\)). Additionally, the proportion of individuals smoking when unwell was higher in the COPD group than in the control group (Q6: \(P<.001\)). Q3 showed no statistically significant difference between the 2 groups, but with a \(P\) value <0.1, suggesting the potential presence of marginal effects.

**Direct and Indirect Effects of MSDP on COPD in All Participants**

The results of the mediation analysis for all participants are presented in Table 3. After adjusting for age, sex, BMI, educational attainment, place of residence, ethnicity, occupation, childhood passive smoking, residential PM\(_{2.5}\) exposure, history of childhood pneumonia or bronchitis, average annual household income, and medical history (coronary heart disease, hypertension, and diabetes), the total effect of MSDP on COPD was statistically significant (\(\beta=.097; P<.001\)). Furthermore, the direct effect of MSDP on COPD remained significant after adjusting for TD and other covariates (\(\beta=.094; P<.001\)). The indirect effect of TD was also found to be statistically significant.
The sensitivity analysis revealed similar results (Table S4 in Multimedia Appendix 1).

### Direct and Indirect Effects of MSDP on COPD in Smokers

The results of the mediation analysis for smokers are presented in Table 4. In this segment, all analyses were adjusted for age, sex, BMI, educational attainment, place of residence, ethnicity, occupation, childhood passive smoking, residential PM\(_{2.5}\) exposure, history of childhood pneumonia or bronchitis, average annual household income, and medical history (coronary heart disease, hypertension, and diabetes). Among smokers, both the total effect and direct effect (\(\beta\)) of MSDP on COPD were .123 and .120, respectively. Additionally, the indirect effect of TD was found to be statistically significant (\(\beta=.003\); \(P=.03\)). The sensitivity analysis revealed similar results (Table S5 in Multimedia Appendix 1).

Discussion

Principal Findings

The aim of this study was to investigate whether TD plays a role in the association between MSDP and COPD in offspring. A case-control study was conducted within the Chinese population. It was the first study to observe that MSDP has both a direct impact on COPD and an indirect influence mediated through TD. This mediation effect persists among the smoking population, and sensitivity analysis confirms the stability of these results.

It is well-established that smoking represents the primary risk factor for COPD, and an increasing body of evidence suggests that early life tobacco exposure plays a role in the onset and progression of COPD [26]. MSDP, as highlighted by Jaakkola et al [27], exerts substantial adverse effects on conditions such as asthma, chronic bronchitis, and chronic respiratory symptoms. Nevertheless, limited research has delved into the impact of prenatal tobacco smoke exposure on the development of COPD in later adulthood. This study, however, reveals an association between MSDP and the risk of COPD in offspring. Early life tobacco exposure has enduring consequences on lung function in offspring, with suboptimal intrauterine conditions leading to disturbances in lung development. As a result, affected individuals exhibit diminished lung function at birth, which often persists throughout their lifetime. This, in turn, elevates the risk of subsequent COPD, particularly in childhood wheeze disorders and genetically susceptible individuals [28]. To curb the current upward trend in COPD incidence, it is imperative to mitigate lung development risks by enhancing antenatal and neonatal care and reducing exposure to environmental pollutants, including passive tobacco smoke, both prenatally and postnatally.

In this study, MSDP emerges as a risk factor for TD in offspring, a finding consistent with prior research. Previous studies have established that individuals with a history of MSDP face an elevated risk of TD in adolescence and adulthood [18]. The precise mechanism underlying the connection between MSDP and offspring TD remains elusive. One plausible mechanism could involve the neurotoxic effects of harmful compounds present in tobacco smoke, which can readily traverse the placenta, potentially leading to smoking behavior and dependence in offspring [29]. Another conceivable mechanism is that MSDP is linked to preterm birth [30] and low birth weight [31], both of which could predispose offspring to various health challenges. Furthermore, it is essential for health care professionals to recognize that TD may be linked to early life tobacco exposure. Therefore, children exposed to MSDP should receive comprehensive education on topics such as diet, exercise, and smoking avoidance to mitigate their risk of developing COPD in adulthood.

This study revealed a direct association between TD and COPD. Previous research has identified smoking as one of the primary risk factors for COPD, causing inflammation and damage to the airways and lung tissue, ultimately leading to the development of COPD [32]. Recent studies have further suggested the correlation between TD and COPD [33]. Additionally, other studies suggest that TD may exacerbate the severity and progression of COPD [34]. Among individuals diagnosed with COPD, the presence of TD makes quitting smoking more challenging [35]. Thus, this study underscores the critical importance of addressing TD in the management and mitigation of COPD.

To our knowledge, we have discovered for the first time in this study that TD plays a mediating role in the association between MSDP and COPD. However, the specific reasons underlying this mediating mechanism remain unclear. There are several possible mechanisms to consider. First, genetic factors may be implicated, as MSDP has the potential to induce persistent epigenetic changes until adolescence [36]. These genetic alterations may contribute to the development of TD [37]. Consequently, TD can exacerbate challenges in smoking cessation and the progression of COPD [38]. Second, environmental factors may also be involved. Mothers who smoke during pregnancy may continue smoking during infancy, creating an early growth environment that promotes the risk of TD in offspring during lung development [39,40], subsequently leading to COPD. Our results highlight that TD serves as a partial mediator in the connection between MSDP and offspring COPD. Consequently, it becomes imperative to consider TD when addressing MSDP and smoking cessation efforts in offspring. Prior studies have advocated smoking cessation strategies for TD smokers, incorporating the use of medications such as varenicline, nicotine replacement therapy products, and bupropion [41]. Hence, clinicians should be cognizant of the necessity for appropriate smoking cessation interventions among individuals displaying signs of TD, ultimately contributing to the reduction of COPD risk.

Limitations

This study bears significant implications as it substantiates the partial mediating role of TD in the link between MSDP and COPD, underlining the importance of developing interventions targeting TD to mitigate the incidence of COPD in offspring. Nonetheless, it is essential to acknowledge the study’s limitations. First, the data concerning MSDP relied on questionnaire responses, introducing a potential source of recall bias. Due to the presence of recall bias, we cannot entirely rule out the possibility of uncertainty or erroneous memory in participants when reporting maternal smoking behavior during pregnancy. To enhance the accuracy of capturing MSDP information, future studies may consider using prospective cohort designs. Second, the absence of genetic data represents a significant limitation in this study. Despite the inclusion of various participant covariates, the intricate role of genetic factors in influencing COPD was not considered due to data constraints. Future research endeavors could overcome this limitation by integrating comprehensive genetic analyses into the study design. Finally, our classification of nonsmokers as nonnicotine-dependent during the overall analysis might introduce some bias. To fortify the robustness of our findings, we conducted a parallel subgroup analysis among the smoking population that consistently demonstrated the robustness of our results.
Conclusions
MSDP exerts an adverse influence on the risk of COPD in offspring, and TD plays a partially mediating role in this association. These findings underscore the potential for clinicians to mitigate the impact of MSDP on COPD in offspring by addressing TD. Consequently, early intervention strategies aimed at reducing TD become imperative in the endeavor to mitigate the risk of COPD.

Abstract

Background: The worldwide human monkeypox (mpox) outbreak in 2022 mainly affected men who have sex with men (MSM). In China, young men who have sex with men (YMSM) were at a potential high risk of mpox infection due to their sexual activeness and the eased COVID-19 restrictions at the end of 2022.

Objective: This study aimed to investigate the behavioral intention of receiving mpox vaccination and undergoing mpox testing in 4 different scenarios and explore their associations with background and behavioral theory–related factors among Chinese YMSM.

Methods: An online cross-sectional survey was conducted among YMSM aged 18-29 years from 6 representative provinces of China in September 2022. Participants recruited (recruitment rate=2918/4342, 67.2\%) were asked to self-administer an anonymous questionnaire designed based on prior knowledge about mpox and classic health behavior theories. Data on the participants’ background, mpox knowledge and cognition, mpox vaccination and testing cognition, and the behavioral intention of receiving mpox vaccination and undergoing mpox testing were collected. Descriptive analysis and univariate and multivariate linear regressions were performed. Geodetector was used to measure the stratified heterogeneity of behavioral intention.

Results: A total of 2493 YMSM with a mean age of 24.6 (SD 2.9) years were included. The prevalence of having a behavioral intention of receiving mpox vaccination ranged from 66.2\% to 88.4\% by scenario, varying in epidemic status and cost. The prevalence of having an mpox testing intention was above 90\% in all scenarios regardless of the presence of symptoms and the cost. The positive factors related to vaccination intention included mpox knowledge (b\textsubscript{a}=0.060, 95\% CI 0.016-0.103), perceived susceptibility of mpox (b\textsubscript{a}=0.091, 95\% CI 0.035-0.146), perceived severity of mpox (b\textsubscript{a}=0.230, 95\% CI 0.164-0.296), emotional distress caused by mpox (b\textsubscript{a}=0.270, 95\% CI 0.160-0.380), perceived benefits of mpox vaccination (b\textsubscript{a}=0.455, 95\% CI 0.411-0.498), self-efficacy of mpox vaccination (b\textsubscript{a}=0.586, 95\% CI 0.504-0.668), and having 1 male sex partner (b\textsubscript{a}=0.452, 95\% CI 0.098-0.806).
Introduction

Since May 2022, rapidly growing numbers of human monkeypox (moxp) cases have been reported from countries where the disease was not initially endemic [1,2]. The World Health Organization (WHO) declared the worldwide moxp outbreak a public health emergency of international concern on July 23 [3]. By September 28, 2023, a total of 90,618 confirmed cases were reported across 115 countries, with 1484 confirmed cases in China. Among cases with known data on sexual orientation, 83.2% patients were identified as men who have sex with men (MSM) worldwide [4]. In China, more than 90% cases were identified as MSM [5]. One potential reason for MSM being the most affected population is that moxp transmission can result from close contact with the skin lesions of an infected person [1] and MSM communities usually have highly interconnected sexual networks [6].

China has the largest MSM population in the world, with an estimated size of 8.3 million [7], and among them, approximately 1.9 million are young people attending universities [8]. The first moxp case in mainland China was reported on September 16, 2022, and the patient was an MSM. The risk of an moxp outbreak became a public concern due to the large MSM population and the eased COVID-19 restrictions (eg, travel restrictions, social distancing) [9]. WHO recommended that the state parties with recently imported cases (eg, travel restrictions, social distancing) [9]. By September 28, 2023, a total of 90,618 confirmed cases were reported across 115 countries, with 1484 confirmed cases in China. Among cases with known data on sexual orientation, 83.2% patients were identified as men who have sex with men (MSM) worldwide [4]. In China, more than 90% cases were identified as MSM [5]. One potential reason for MSM being the most affected population is that moxp transmission can result from close contact with the skin lesions of an infected person [1] and MSM communities usually have highly interconnected sexual networks [6].

Case detection and targeted immunization are powerful measures to fight the moxp outbreak [10-12]. Timely moxp testing can reduce moxp transmission, avoid delays in moxp treatment, and decrease the cost of health care [11-15]. Vaccination, such as that against smallpox, has been demonstrated to be highly cost-effective in preventing moxp infection [16]. Several classic theories postulate factors causing health-related behaviors and the underlying mechanisms. For example, the knowledge attitude practice (KAP) model [17] argues that knowledge of a disease and the related preventive/risk behaviors influences an individual’s attitude toward the behaviors and, in turn, affects the behaviors. The Health Belief Model (HBM) [18] proposes that people are more likely to take preventative actions if they perceive the threat of a health risk to be serious, feel they are personally susceptible, and perceive fewer costs than benefits of engaging in it. The theory of planned behavior (TPB) [19] says that attitudes, social norms, and perceived control of behaviors are predictors of behavioral intention. According to these theories and previous studies on other sexually associated infectious diseases, several factors may affect the behavioral intention of receiving moxp vaccination and undergoing moxp testing among MSM, including general factors (eg, sociodemographic characteristics, risk behaviors, disease knowledge, perceptions of health behaviors) and MSM-specific factors (eg, stigma) [20,21]. Although a large body of literature has examined preventive behaviors of diseases associated with MSM (eg, HIV/AIDS, sexually transmitted diseases [STDs], human papillomavirus [HPV]), the situation of moxp might be different, as it is a newly emerging disease in MSM communities. To timely inform the moxp prevention and control strategies in China, a comprehensive investigation on the behavioral intention of adopting moxp prevention measures and associated factors is warranted.

This study aimed to investigate the levels of the behavioral intention of receiving moxp vaccination and undergoing moxp testing among Chinese young men who have sex with men (YMSM) aged 18-29 years and to explore the associated factors. This age group was selected as it became the population with a high risk of moxp infection, especially after COVID-19 travel restrictions were eased in China. YMSM are the most socially active subgroup within MSM communities [22], have relatively more opportunities to meet people from abroad due to study or business reasons, and have not received smallpox vaccination, as China ended this immunization program in 1981 [23]. The hypotheses of potential factors were guided by the KAP model [17], the HBM [18], and the TPB [19].

Methods

Study Design

An online cross-sectional survey was conducted in September 2022 with participants from 6 provincial regions of China, which represented the country geographically and socioeconomically (based on the per capita gross domestic product [GDP] of 2020) to some extent [7,24]. These 6 regions were Beijing (the capital;
per capita GDP=Chinese yuan [CNY] 164,889 [US $22,932]), Zhejiang (east; per capita GDP=CNY 100,620 [US $13,994]), Sichuan (west; per capita GDP=CNY 58,126 [US $8084]), Guangdong (south; per capita GDP=CNY 88,521 [US $12,311]), Shandong (north; per capita GDP=CNY 72,151 [US $10,034]), and Anhui (central; per capita GDP=CNY 63,426 [US $8821]). Figure 1 shows the geographic location, per capita GDP, population size, and sample size of the study areas.

Figure 1. Map of the geographic location, per capita GDP, population size, and sample size of the 6 study sites in China. Note: The per capita GDP and population size of each study site were based on the data released by the National Bureau of Statistics of China in 2020. GDP: gross domestic product.

Participant Recruitment and Data Collection

The inclusion criteria were male participants, age 18-29 years, having ever had anal or oral sex with men, and ability to fill an electronic questionnaire and provide oral informed consent. The exclusion criteria were psychiatric disorders based on the recruiters’ report and refusal to participate.

The facility-based sampling method was used to recruit participants from each province with the assistance of local MSM-oriented community-based organizations (CBOs). The selected CBOs have rich experience in providing health services (eg, HIV/sexually transmitted infection [STI] testing) and conducting public health studies in MSM communities. First, CBO staff were trained as recruiters and asked to disseminate the invitation message to potentially eligible YMSM in their networks via commonly used messaging apps (eg, WeChat). YMSM who were interested in the study were then screened for eligibility and fully informed about the study. Next, they were sent a quick response (QR) code and a 1-time password to access the electronic anonymous questionnaire. The self-administered questionnaire took about 10-15 minutes to complete.

The recruitment rate of the study (number of returned questionnaires/number of invitations sent) was 67.2% (2918/4342). In each province, the recruitment rate ranged from 44.5% to 97.2%. The main reasons for nonparticipation (n=1424, 32.8%) reported by the recruiters were not meeting the inclusion criteria, lack of time, and privacy concerns. The 2918 participants completed the questionnaire, and 425 (14.6%) were excluded from analysis due to a failure in the quality check. The final sample size was 2493 (85.4%) participants.

Ethical Considerations

The study was approved by the Institutional Review Board of Tsinghua University, China (reference number: 20220140). Each participant was asked to carefully read the informed consent form before starting the survey, in which the objective, procedure, potential risks and benefits, and voluntary nature of the study were clearly stated. Oral informed consent was waived to protect the participants’ privacy. The questionnaire was fully anonymous and self-administered by the participants through a secure privacy-compliant platform (Wenjuanxing survey platform [25]). Each participant whose submitted questionnaire passed the quality check receive Chinese yuan [CNY] 15 (about US $2.10) via the survey platform for compensation of their time and effort. To ensure confidentiality, further deidentified data were used for analysis.

Measures

Behavioral Intention of Receiving Mpox Vaccination and Undergoing Mpox Testing

All the measures are described in detail in Multimedia Appendix 1. Regarding behavioral intention, the participants were asked to rate their likelihood (1=very unlikely to 5=very likely) of receiving mpox vaccination in 4 scenarios. A summative score was calculated, with a higher score indicating a higher level of intention (range 4–20, α=.90). Similarly, the participants were asked to rate their likelihood of undergoing an mpox test in 4
scenarios, with a higher summative score indicating a higher level of intention (range 4-20, $\alpha=0.94$).

**Mpx Knowledge**

Mpx knowledge was measured with a single yes/no question (“Have you heard of mpx?”) and 10 knowledge questions. A composite score of the knowledge scale was constructed by counting the number of correct responses to the questions; those who had not heard of mpx were assigned a score of 0 (score range 0-10). A higher score indicated a higher level of knowledge ($\alpha$ for the 10 knowledge questions=0.77).

**Mpx Cognition**

The perceived susceptibility of mpx was measured with 3 items, with responses ranging from 1 for very unlikely to 5 for very likely. A higher total score implied a higher level of perceived susceptibility (range 3-15, $\alpha=0.83$). The perceived severity of mpx was measured with 2 items, with responses ranging from 1 for very mild to 5 for very strong. A higher summative score indicated a higher level of perceived severity (range 2-10, $\alpha=0.90$). Emotional distress (eg, panic, anxiety) caused by the mpx outbreak was measured with a single item, with the response ranging from 1 for very mild to 5 for very strong.

**Cognition of Mpx Vaccination and Testing**

Participants were asked about the perceived benefits, barriers, and self-efficacy of mpx vaccination/testing, with responses ranging from 1 for strongly disagree to 5 for strongly agree. The perceived benefits of mpx vaccination were assessed with 4 items (range 4-20, $\alpha=0.90$), and the perceived benefits of mpx testing were measured with 3 items (range 3-15, $\alpha=0.91$), with a higher summative score indicating more perceived benefits. The perceived barriers to mpx vaccination were measured with 4 items (range 4-20, $\alpha=0.81$), and the perceived barriers to mpx testing were measured with 5 items (range 5-25, $\alpha=0.82$), with a higher total score indicating more perceived barriers. The self-efficacy of mpx vaccination was measured with 2 items, with a higher summative score indicating a higher level of self-efficacy (range 2-10, $\alpha=0.82$). The self-efficacy of mpx testing was similarly measured (range 2-10, $\alpha=0.85$).

**Background Information**

Background information was collected, including (1) sociodemographic characteristics, (2) mpx risk behaviors in the past 6 months (eg, overseas travel history, number of male sex partners, frequency of in-person gatherings with MSM, use of any psychoactive substance before/during sexual intercourse [chemsex]), (3) diagnosis of HIV and STDs, and (4) presence of mpx-related symptoms in the past 2 weeks.

**Statistical Analysis**

First, descriptive analyses were conducted, with means and SDs being reported for continuous variables and frequencies and percentages being reported for categorical variables. Second, the q-statistic Geodetector, a spatial variance analysis method that explains nonlinear associations, was used to measure and attribute the stratified heterogeneity [26]. The factor detector was applied to detect the spatial association between explanatory variables (ie, study sites, sociodemographic characteristics, and mpx risk behaviors) and response variables (ie, behavioral intention of receiving mpx vaccination and undergoing mpx testing). The q-statistic and P value of Geodetector were reported. Third, simple regression analyses were performed to explore the crude associations between the background/behavioral theory–related factors and behavioral intention. Fourth, multivariate linear regressions were performed, involving all the background and theoretical factors as independent variables. The point estimate and 95% CIs were reported. SPSS Statistics 24.0 (IBM Corporation) was used. Geodetector analysis was conducted using R version 4.3.1 (R Foundation for Statistical Computing).

**Results**

**Background Characteristics**

The participants’ mean age was 24.6 (SD 2.9) years. Most of the participants were Han Chinese (n=2392, 95.9%), employed (n=1755, 70.4%), and unmarried (n=2380, 95.5%); had completed college education or above (n=2086, 83.7%), reported a monthly income under CNY 6000 (US $836; n=1530, 61.3%), and self-identified as homosexual (n=2023, 81.1%). In the past 6 months, 51 (2%) reported an overseas travel history, 1336 (53.6%) had in-person gatherings with MSM for at least once, 1249 (50.6%) had more than 1 male sex partner, and 541 (21.7%) reported having had chemsex with MSM. A total of 2383 (95.6%) participants had ever undergone an HIV test, and 279 (11.2%) self-reported as HIV positive. In addition, 354 (14.2%) participants reported a history of STIs. Furthermore, 1923 (77.1%) participants reported they did not have any mpx-like symptoms in the past 2 weeks, and 113 (4.5%) reported they had close contact with people who showed mpx symptoms (Table 1).

### Mpox Knowledge and Cognition

In total, 2310 (92.7%) participants had heard of mpox, and the proportions of choosing the correct answers for the 10 knowledge questions among the whole sample ranged from 13.4% (n=334) to 81.7% (n=2037), with a mean knowledge score of 5.7 (SD 2.7). Regarding perceived susceptibility (mean 6.1, SD 2.3), 91 (3.7%), 157 (6.3%), and 425 (17%) participants reported a high likelihood (likely or very likely) of being infected, of being in close contact with patients with mpox, and of an mpox outbreak in China, respectively. For perceived severity, 2035 (81.6%) and 2073 (83.2%) participants perceived a strong/very strong severity of mpox regarding their health and life, respectively (mean 8.4, SD 1.9). In addition, 605 (24.3%) participants reported being emotionally distressed due to mpox (mean 2.7, SD 1.2). See Table 2 and Figure 2.

Figure 2. Level of cognition of mpox, mpox vaccination, and mpox testing among YMSM from 6 provinces in China in September 2022 (N=2493). mpox: monkeypox; YMSM: young men who have sex with men.

Cognition of Mpxo Vaccination and Testing
For the perceived benefits of mpox vaccination (mean 16.6, SD 2.9), the participants agreed/strongly agreed with the following 4 benefits presented: protecting oneself (n=1948, 78.1%), protecting others (n=1997, 80.1%), protecting the country (n=2187, 87.7%), and helping them live normally (n=1954, 78.4%). For the perceived barriers to mpox vaccination (mean 13.8, SD 3.5), the participants agreed/strongly agreed that the following 4 barriers are present: high cost of vaccination (n=1316, 52.8%), identity leakage (n=1002, 40.2%), inconvenience (n=1230, 49.3%), and side effects (n=1598, 64.1%). For self-efficacy (mean 7.5, SD 1.5), 1717 (68.9%) participants were confident in taking mpox vaccination and 1490 (59.8%) thought it would be easy to do so (Table 3 and Figure 2B).

\(^b\)YMSM: young men who have sex with men.
\(^c\)MSM: men who have sex with men.

For the perceived benefits of mpox testing (mean 13.4, SD 1.9), the participants agreed/strongly agreed with the following 3 benefits presented: timely finding out about the infection (n=2300, 92.3%), protecting others (n=2249, 90.2%), and protecting the country (n=2293, 92%). Regarding perceived barriers (mean 17.8, SD 4.4), the participants agreed/strongly agreed that the following 4 barriers are present: high cost (n=1495, 60%), inconvenience (n=1324, 53.1%), positive testing results (n=1370, 55%), identity leakage (n=1091, 43.8%), and leakage of testing results (n=1543, 61.9%). For self-efficacy (mean 7.9, SD 1.6), 1863 (74.7%) participants were confident in obtaining a mpox test and 1627 (65.3%) thought it would be easy to do so (Table 4 and Figure 2C).

**Behavioral Intention of Receiving Mpox Vaccination and Undergoing Mpox Testing**

The prevalence of having a behavioral intention of receiving mpox vaccination varied in different scenarios (n=1651, 66.2\%, when there was no local case reported; n=1971, 79.1\%, when there was no local case reported and the vaccine was free; n=2112, 84.7\%, when there were local cases reported; and n=2204, 88.4\%, when there were local cases reported and the vaccine was free; mean 16.8, SD 3.6). See Table 3 and Figure 3A.
Figure 3. Behavioral intention of receiving mpox vaccination and testing in different scenarios among YMSM from 6 provinces of China in September 2022 (N=2493). mpox: monkeypox; YMSM: young men who have sex with men.

The prevalence of having a behavioral intention of undergoing mpox testing was above 90% in different scenarios (n=2302, 92.3%, when they had mpox symptoms; n=2324, 93.2%, when they had mpox symptoms and testing was free; n=2320, 93.1%, when they had close contact with patients with mpox; and n=2342, 93.9%, when they had close contact with patients with mpox and testing was free; mean 18.5, SD 2.5). See Table 4 and Figure 3B.

Stratified Heterogeneity of Behavioral Intention of Receiving Mpox Vaccination and Undergoing Mpox Testing

As presented in Table 5, no heterogeneity was observed in the behavioral intention of receiving mpox vaccination and undergoing mpox testing across study sites and socioeconomic characteristics. However, heterogeneity was observed in the behavioral intention of receiving mpox vaccination in a number of male sexual partners (q=0.005, P=.04). In addition, heterogeneity was observed in the behavioral intention of undergoing mpox testing in in-person gatherings with MSM (q=0.002, P<.001).

Factors Associated with the Behavioral Intention of Receiving Mpox Vaccination and Undergoing Mpox Testing

Table 6 presents the results of univariate and multivariate regression analyses of the behavioral intention of receiving mpox vaccination. The multivariate regression model showed that vaccination intention was significantly and positively associated with having 1 male sex partner in the past 6 months \( (b_a=0.452, 95\% \ CI \ 0.098-0.806) \), mpox knowledge \( (b_a=0.060, 95\% \ CI \ 0.016-0.103) \), perceived susceptibility \( (b_a=0.091, 95\% \ CI \ 0.035-0.146) \), perceived severity \( (b_a=0.230, 95\% \ CI \ 0.164-0.296) \), emotional distress \( (b_a=0.270, 95\% \ CI \ 0.160-0.380) \), perceived benefits \( (b_a=0.455, 95\% \ CI \ 0.411-0.498) \), and self-efficacy \( (b_a=0.586, 95\% \ CI \ 0.504-0.668) \). Perceived barriers were negatively associated with the vaccination intention \( (b_a=-0.056, 95\% \ CI \ -0.090 \ to \ -0.022) \).

Discussion

Principal Findings

This was among the earliest studies in China examining the levels and factors of the behavioral intention of receiving mpox vaccination and undergoing mpox testing among YMSM. After the COVID-19 travel restrictions were eased in China at the end of 2022, this specific age population became the group with a high risk of mpox infection due to its social activeness. The study findings shed some light on the preparedness for mpox prevention and control in the country.

Comparison With Prior Work

Overall, about two-thirds of the surveyed YMSM intended to receive the mpox vaccination if there was no case present locally, and the prevalence increased to 84.7% if local cases were reported. The latter prevalence was higher than that in 2 other countries with an mpox outbreak. A recent study in the Netherlands showed that 70% of MSM (56.6% aged <45 years)
had an intention of getting vaccinated [27]. Another study in France found that 33.6% of MSM (80.6% between 30 and 59 years old) declared their hesitancy to get vaccinated against mpox [28]. Age may be a potential reason for the relatively high prevalence, as YMSM tend to be more open to newly emerging health services (eg, pre-exposure prophylaxis [PrEP], HPV vaccines) [29-31]. The finding implies that it is important to keep MSM informed about the most up-to-date mpox statistics. It may assist them in decision-making about adopting preventive behaviors. Furthermore, the study found the prevalence of vaccination intention increased to some extent if the vaccination was free. This indicates that cost may be a barrier to mpox vaccination. The study showed about half of the participants expressed a concern about the potential high cost of vaccination, which is consistent with previous research [32]. Therefore, free or subsidized immunization for the high-risk population is recommended to be considered in the future national response.

In this study, over 90% of the participants reported an intention of undergoing an mpox test regardless of the presence of symptoms and the cost. A possible explanation for the high prevalence is that the participants may be knowledgeable about the benefits of testing. As shown in the study, most participants agreed/strongly agreed with the stated benefits of testing. The mass HIV testing campaigns in the past decades may have contributed to these perceptions. Our data showed that only 4.4% of the participants had never been tested for HIV before. Furthermore, the COVID-19 battle since 2020 may have improved people's health literacy, which may, in turn, have positively affected their attitudes and practices of other health behaviors [33-35]. Lessons learned from the previous HIV testing campaigns targeting MSM and the COVID-19 testing campaign can be drawn by the future promotion of mpox testing in China [3,35]. For instance, it is imperative to remove structural barriers to testing (eg, provide anonymous tests) and offer culturally congruent services. Additionally, mpox testing is recommended to be provided in community settings, CBOs, and sexual health clinics trusted by MSM populations.

Guided by the classic health behavioral theories, we identified several factors associated with the behavioral intention of receiving mpox vaccination and undergoing mpox testing. First, according to the KAP model, knowledge is the foremost factor affecting the practice of preventive behaviors [17]. Previous studies have demonstrated that disease knowledge is positively associated with HIV testing and COVID-19–preventive behaviors [36,37]. Multivariate regression indicated a moderate association between mpox knowledge and vaccination intention and a statistically insignificant association between mpox knowledge and testing intention. The findings suggest that disease knowledge may play a role in motivating the intention of adopting preventive behaviors, but the strength and magnitude of the effect may be limited. Increasing mpox knowledge is important but far from enough in the future response to mpox in China.

The study found that 3 HBM constructs (perceived severity of mpox, perceived benefits of mpox vaccination/testing, and self-efficacy of mpox vaccination/testing) are independently and positively associated with vaccination and testing intentions. The findings are consistent with previous evidence on other diseases, such as COVID-19 and H1N1 [38,39]. Meanwhile, 2 other HBM constructs, perceived susceptibility of mpox and perceived barriers to the corresponding service, were also significantly associated with the vaccination intention but not with the testing intention. A possible reason is that the level of testing intention was particularly high in the study and the influence of the 2 factors were limited. Overall, these findings evidence that the HBM is a useful framework to predict health behaviors. Some related components are recommended for future mpox interventions, such as timely updating and disseminating mpox statistics, implementing targeted risk communication, educating the community about the benefits and ways of access to testing and vaccination, ensuring the privacy and confidentiality of services, and debunking and refuting misinformation promptly [40,41].

An interesting finding of this study was that the emotional distress caused by mpox is positively associated with the vaccination intention but negatively associated with the testing intention. It is understandable that YMSM who have experienced more emotional distress due to mpox might be more worried about mpox infection and thus intend to receive immunization. This is in line with previous research showing that people with more emotional distress caused by COVID-19 were more likely to receive COVID-19 vaccination [42]. In contrast, it is speculated that some YMSM were emotionally distressed because they were afraid that the testing result would be positive or the result would be revealed to others. Such fears consequently hindered their willingness to undergo testing. Our data showed that 55% of the participants were worried that their testing results might be positive, while 61.9% were worried that the testing results might be leaked to others. A previous HIV study also indicated that emotional distress is a major barrier to seeking HIV-testing services [43]. The opposite results remind us that it is necessary to monitor the mental status in the affected community during an emergency and provide timely advice on positive coping strategies.

Stratified heterogeneity analysis revealed variations in the behavioral intention among people with or without mpox risk behaviors. Certain mpox risk behaviors presented significant associations with the intention of receiving mpox vaccination and undergoing mpox testing. Those who had 1 male sex partner in the past 6 months were more intended to uptake both vaccination and testing services compared to those with none or multiple partners. It is understandable that MSM without sex partners recently might think they have no risk of infection and thus have no need to receive the vaccination or undergo testing, while MSM with multiple partners might possess a lower level of health literacy and risk perceptions [44]. The finding warns us that MSM with multiple sexual partners may have a lower intention of adopting preventive behaviors against mpox and should be given a priority focus in the future fight against mpox. In addition, attending in-person gatherings with MSM and traveling overseas in the past 6 months were both positively associated with the testing intention. The findings are expected because they are known risk factors of mpox infection [45,46]. It is worth noting that YMSM are at high risk of not only mpox but also HIV/AIDS. Evidence shows that mpox is an opportunistic infection of HIV/AIDS [47]. China has a
well-established comprehensive public health system for HIV/AIDS health promotion, testing, treatment, and management, which is considered highly effective for HIV/AIDS high-risk groups. Therefore, it is highly recommended to integrate mpox-related health services and prevention actions into the existing HIV/AIDS prevention and control system. For example, it may be feasible and cost-effective to provide mpox vaccination and testing services at the current HIV testing and counseling sites that are often operated by MSM-friendly CBOs and clinics. It is also important to empower MSM communities and highly involve them, especially the key persons in the communities, in targeted health communication, health counseling, and testing and treatment referrals. This integrated approach is key to addressing the interconnected health challenges faced by YMSM.

Limitations
The study has a few limitations. First, selection bias might exist due to the facility-based sampling and refusal to participate. YMSM who could be approached in this study might be more likely to interact positively with CBOs, receive health education information more frequently, and have a higher level of health literacy. Driven by self-selection, YMSM who were invited but refused to participate might tend to have more concerns about this sensitive topic and their privacy. These systematic difference biases potentially resulted in an overestimation of the behavioral intention related to mpox vaccination and testing. However, as MSM groups are hidden populations, the convenient sampling method is a common way for recruitment. In addition, data were collected from August to September 2022, when China was still under strict COVID-19 restrictions. The recruitment rate may have also been impacted by the pandemic. Second, due to self-reporting, social desirability bias might exist and lead to an overestimation of the behavioral intention. Third, the study was conducted in 6 provincial regions of China and focused on YMSM aged 18-29 years. The generalization of the study findings to broader populations should be made with caution. Fourth, the cross-sectional design allowed a limited ability of causal inferences. Longitudinal studies are warranted.

Conclusion
The majority of the YMSM in this study showed an intention of receiving mpox vaccination, and the intention was somewhat sensitive to the epidemic status and cost. Most of the YMSM had an intention of undergoing an mpox test regardless of scenarios. It is recommended that the future national response to mpox in China prioritize groups with high-risk exposure, raise their mpox knowledge, promote cognition of the disease and preventive measures, improve accessibility and privacy of health services, monitor the mental health status of the groups, and provide advice on positive coping strategies.

Acknowledgments
This study was supported by the Research Fund, Yanke School of Public Health, Tsinghua University (number: 100010001). We thank Mumu and Keke from the Home of the Red Ribbon in Beijing; Huzi from the Qingdao Qingtong AIDS Prevention Volunteer Service Center; Hui Yao from the Hefei Center for Disease Control and Prevention; Maomaoyu from the Hefei Qingwei Public Health Service Center; Xiaodong Wang and Haipeng Zha from the Chengdu Tongle Health Consultation Center; Han Shi, Chen Yang, and ToAlan from the Zhejiang Coastal Charity Volunteer Service Center; Huiyang Xu from the Guangdong Association of STD & AIDS Prevention and Control; Fang Yang from the Guangdong Provincial Center for Disease Control and Prevention; Jason and Shenghong Liang from the Shenzhen 158 Rainbow Volunteer Service Center; Xi He from the Zhuhai Xutong Volunteer Service Center; Jie Lu from the Guangzhou Lingnan Partnership Community Support Center; and all other field-workers for their contributions to participant recruitment and data collection. We also deeply appreciate the time and effort of all the participants.

Data Availability
All data generated and analyzed during this study are included in this published paper and its supplementary information files.

Authors’ Contributions
SL, WL, and FC conceptualized the study and contributed to the methodology. SL supervised the study. KJ, YZ, YX, JZ, SH, JS, QL, YL, YX, WM, LH, XR, and ZD contributed to the questionnaire design and data collection. KJ, YX, and SL conducted the formal analysis. Abstract

Background: Osteopenia and osteoporosis are posing a long-term influence on the aging population’s health contributing to a higher risk of mortality, loss of autonomy, hospitalization, and huge health system costs and social burden. Therefore, more pertinent data are needed to demonstrate the current state of osteoporosis.

Objective: This sampling survey seeks to assess the trends in the prevalence of osteopenia and osteoporosis in a Chinese Han population.

Methods: A community-based cross-sectional study involving 16,377 participants used a multistage sampling method. Bone mineral density was measured using the quantitative ultrasonic densitometry. Student t test and Mann-Whitney U test were used to test the difference between normally and nonnormally distributed quantitative variables between male and female participants. A chi-square (χ²) test was used to compare categorized variables. Stratified analysis was conducted to describe the prevalence rates of osteoporosis (T score ≤–2.5) and osteopenia (T score –2.5 to –1.0) across age, sex, calcium intake, and menopause. A direct standardization method was used to calculate the age-standardized prevalence rates of osteoporosis and osteopenia. T-score was further categorized into quartiles (T1-T4) by age- and sex-specified groups.

Results: The prevalence rates of osteopenia and osteoporosis were 40.5% (6633/16,377) and 7.93% (1299/16,377), respectively, and the age-standardized prevalence rates were 27.32% (287,877,129.4/1,053,861,940) and 3.51% (36,974,582.3/1,053,861,940), respectively. There was an increase in osteopenia and osteoporosis prevalence from 21.47% (120/559) to 56.23% (754/1341) and 0.89% (5/559) to 17.23% (231/1341), respectively, as age increased from 18 years to 75 years old. The prevalence rates of osteopenia and osteoporosis were significantly higher in female participants (4238/9645, 43.94% and 1130/9645, 11.72%) than in male participants (2395/6732, 35.58% and 169/6732, 2.51%; P<.001), and in postmenopausal female participants (3638/7493, 48.55% and 1053/7493, 14.05%) than in premenopausal female participants (538/2026, 26.55% and 53/2026, 2.62%; P<.001). In addition, female participants with a history of calcium intake had a lower osteoporosis prevalence rate than female participants without any history of calcium intake in all age groups (P=.004). From low quartile to high quartile of T-Score, the prevalence of diabetes mellitus (752/4037, 18.63%; 779/4029, 19.33%; 769/3894, 19.75%; and 869/3879, 22.4%) and dyslipidemia (2228/4036, 55.2%; 2304/4027, 57.21%; 2306/3891, 59.26%; and 2379/3878, 61.35%) were linearly increased (P<.001), while the prevalence of cancer (112/4037, 2.77%; 110/4029, 2.73%; 103/3894, 2.65%; and 77/3879, 1.99%) was decreased (P=.03).
Conclusions: Our data imply that as people age, osteopenia and osteoporosis are more common in females than in males, particularly in postmenopausal females than in premenopausal females, and bone mineral density significantly affects the prevalence of chronic diseases. These findings offer information that can be applied to intervention programs meant to prevent or lessen the burden of osteoporosis in China.

KEYWORDS

cross-sectional study; osteopenia; osteoporosis; prevalence; quantitative ultrasound

Introduction

Osteoporosis is a degenerative condition that affects the entire body’s bones. It is characterized by decreased bone mineral density (BMD) with low bone mass and deterioration of bone tissue microstructure, which makes bones more fragile and increases the risk of fracture [1]. Osteopenia refers to BMD levels that are below the normal range but not as low as osteoporosis [2]. The prevalence rates of osteopenia and osteoporosis are estimated to be 40.40% and 19.75% globally [3], respectively, and their burden has been increasing for nearly 3 decades. From 1990 to 2019, the disability-adjusted life years (DALYs) and global death of both osteopenia and osteoporosis increased by 93.82% and 111.16% globally [4], respectively. The DALY and death count of both osteopenia and osteoporosis-related fractures increased by 121.07% and 148.65%, respectively during the same period, and China is among the top 5 countries with the highest DALYs number in the osteopenia and osteoporosis-related fractures [4].

The risk factors of osteoporosis include family history, abnormal BMI, unhealthy lifestyles, being a woman, and aging [5]. It is estimated that by 2050, the proportion of the older adult population in China will represent 26.1% of the total Chinese population [6]. With the rapid increase in the proportion of older adults globally and in China, osteoporosis might pose a major threat to public health. Osteoporosis frequently induces fragile fractures of the spine, hip, distal forearm, and proximal humerus even with little strength stress force [7,8]. Generally, the clinical symptoms of osteoporosis appear after fracture occurrence and can result in significant disability and excruciating pain, which interferes with normal activities and frequently lowers the quality of life [9,10]. In addition, osteoporosis and its related fractures also increase the risk of mortality, loss of autonomy, nursing home referral, and hospitalization, leading to long-term disability, public health system costs, and a huge social burden [10,11].

It is estimated that by 2050, the annual osteoporosis-related fractures will increase to 5.99 million in China, with a projected cost of US $25.43 billion, representing a 2.7-fold increase compared to 2010 [12]. With the varying socioeconomic conditions, varied lifestyles, and expanding older population in a sizable developing nation like China, more pertinent data are needed to demonstrate the current state of osteoporosis. In addition, the prevalence of aging-related diseases such as type 2 diabetes mellitus (T2DM), coronary heart disease (CHD), and cardiovascular and cerebrovascular diseases (CCVD) is also increasing. These diseases not only often coexist with osteopenia and osteoporosis in older people but also share some common risk factors such as abnormal BMI, unhealthy lifestyles, and aging [5,13,14]. However, the relationship between osteoporosis and T2DM [15,16], CHD [17,18], and CCVD [19,20] remains controversial across studies. Therefore, to aid in the development of health care strategies for the expanding population, high-quality epidemiological studies are required to periodically estimate the prevalence of osteoporosis. Herein, we aimed to investigate the trends in the prevalence of osteoporosis and osteopenia and evaluate the impact of decreased BMD on common chronic diseases in a 2-stage sampling epidemiological survey.

Methods

Study Design and Participants

The baseline survey of the Jurong cohort study was carried out using a multistage sampling method in 16 towns in Jiangsu Province, in the south of China [21]. Eligible participants included were adult inhabitants (who lived locally for more than 6 months in the past 12 months and aged older than 18 years), with over 80% (13,682/17,102) coming from rural areas and having resided locally for more than 6 months in the past year. Individuals not included in this study were those having acute or severe medical conditions and those who were unwilling to take part in the study survey. The recruitment of the study population was done in 2 stages: the first stage included 11,150 participants from October to November 2015 and the second stage included 5952 participants from November to December 2018. Because this study aimed to observe the prevalence of chronic diseases including osteoporosis, stroke, and CHD, the 2-stage sampling was undertaken to have an efficient sample size for the need to estimate risk factors. The participants with missing information (n=6) and without measures of BMD (n=719) were excluded, and finally, 16,377 participants were included in the study (Figure 1).
Questionnaire

The questionnaire included demographic information, smoking and drinking habits, nutritional status, physical activity (PA), menopausal status, and history of chronic diseases (Multimedia Appendix 1). PA encompasses dynamic behavior and static behavior. Dynamic behaviors include PAs at work, transportation, and leisure time, while static behaviors include total static behavior and spare time static behavior. Using the International Physical Activity Questionnaire as a reference, the level of PA was quantified by metabolic equivalent (MET). The average daily activity duration was calculated by dividing the time of participating in dynamic behavior by 7 times the daily activity duration. Physical activity index (PAI), the ratio of an individual’s total energy consumption and basic metabolic energy consumption in one day, was calculated as follows:

\[
PAI = \frac{X \times Y}{7 \times 24}
\]

where \(X\) is the intensity of an activity and \(Y\) is the time for this activity (minutes).

BMI was calculated as the ratio of the weight (kg) to squared height (m\(^2\)). Participants with a BMI of 18.5-24, 24-28, and >28 kg/m\(^2\) were defined as normal weight, overweight, and obese, respectively [22]. The history of calcium and drug intake and the history of fracture or fall were self-reported by participants. To ensure the accuracy of medication information, participants who were taking drugs were required to bring the package of their medicines.

Menopause is defined as the absence of menstruation for 12 months after the last menstruation or self-reported removal of the uterus or ovaries surgically. The history of CHD, stroke, and cancer were also self-reported by participants. CCVD was defined as a history of CHD, stroke, or both. Hypertension was defined as an average systolic blood pressure/diastolic blood pressure level ≥140/90 mm Hg or self-reported by participants or those taking antihypertensive medicine. Diabetes mellitus (DM) was defined as an average fasting blood glucose ≥7.0 mmol/L, or as self-reported by participants, or those taking hypoglycemic agents or insulin injections. Dyslipidemia was defined as total cholesterol (TC) ≥5.2 mmol/L or low-density lipoprotein cholesterol ≥3.4 mmol/L or high-density lipoprotein cholesterol <1.0 mmol/L or triglyceride (TG) ≥1.7 mmol/L or self-reported participants about the history of dyslipidemia according to the Guidelines for the Prevention and Treatment of Dyslipidemia in Chinese Adults (Revised edition, 2016).

BMD Measurement

BMD measurement was performed using CM-200. The BMD values of the left side of the heel were measured while seated. Before measurement, the age and sex of participants were entered into the quantitative ultrasound system (QUS), and the instrument automatically converted them to a T-score. The BMD was grouped into 3 based on the updated World Health...
Organization–recommended criteria: T-score ≤ −2.5 was defined as osteoporosis, −2.5 to −1.0 was defined as osteopenia, and T-score > −1.0 was defined as normal BMD [23].

Biochemistry Measurements
After fasting over 8 hours, venous blood was drawn to measure the serum level of high-density lipoprotein cholesterol, TC, TG, and the plasma level of glucose. Low-density lipoprotein (μmol/L) = TC – (high-density lipoprotein + TG/2.2). Blood samples were tested within 4 hours using a Cobas 6000 analyzer (Roche Diagnostics GmbH).

Statistical Analysis
The normally distributed continuous variables were described by mean (SD). The nonnormally distributed variables were described by the median and IQR. Student t test and Mann-Whitney U test were used to test the difference of variables between male and female participants. A chi-square (χ²) test was used to compare categorized variables. Stratified analysis was conducted to describe the prevalence rates of osteoporosis and osteopenia across age, sex, and calcium intake. Based on the 2010 national census data for the Chinese population, we used a direct standardization method to calculate the age-standardized prevalence rate of osteoporosis and osteopenia. Logistic regression analyses were performed, and the association was estimated with an odds ratio (OR) and 95% confidence interval (CI). T-score was categorized into quartiles (T1-T4) by age- and sex-specified groups. A 2-tailed P value less than .05 was considered to indicate statistical significance.

All statistical analyses were performed using SPSS Statistics (version 24.0; IBM Corp).

Ethical Considerations
Nanjing Medical University’s Research Ethics Committee approved the study (2015077). The study was performed following the Declaration of Helsinki. The study’s scope, objectives, and advantages were thoroughly communicated to people who were invited to participate. All survey participants gave written informed consent. The collected information was kept confidential and used solely for research purposes.

Results

General Characteristics of Participants
Of the 16,377 participants included in this study, 6732 (41.1%) were male participants with an average age of 61.51 (10.84) years, and 9645 (58.9%) were female participants with an average age of 59.48 (SD 10.93) years. Participants with chronic diseases were identified, including 1287 (7.9%) with fracture or fall, 9558 (58.4%) with hypertension, 3113 (19%) with DM, 9523 (58.2%) with dyslipidemia, 267 (1.6%) with CHD, 890 (5.4%) with strokes, and 439 (2.7%) with cancer. In total, 8709 (53.4%) individuals self-reported a history of taking drugs in the past year, and among those, 766 (4.7%) people had taken calcium tablets. About 77.7% (7493/9645) of the female participants were postmenopausal, with 3.3% (247/7493) having their uterus or ovaries removed surgically (Table 1).

\(^c\) FBG: fasting blood glucose.

\(^d\) TC: total cholesterol.

\(^e\) TG: triglycerides.

\(^f\) HDL-C: high-density lipoprotein cholesterol.
Male participants had higher prevalence of hypertension (4220/6732, 62.7%), CHD (133/6732, 2%), and cancer (227/6732, 3.4%) than female participants (5338/9645, 55.3%; 134/9645, 1.4%; and 212/9645, 2.2%) at a significant level of $P<.05$ but had a lower prevalence of dyslipidemia (3651/6730, 54.2%) than female participants (5872/9640, 60.9%; $P<.05$). As expected, male participants had a higher proportion of smoking (3522/6732, 52.3%) and drinking (3673/6732, 54.6%) than female participants (129/9644, 1.3%; and 869/9643, 9%; $P<.001$). Male participants had lower levels of PAI (median 3.36, IQR 1.18-16.00), BMI (mean 24.74, SD 3.26 kg/m$^2$), TC (mean 4.95, SD 0.91 mmol/L), and TG (mean 1.63, SD 1.42 mmol/L) than female participants (median 5.03, IQR 1.37-14.67; mean 25.17, SD 3.44 kg/m$^2$; mean 5.13, SD 0.93 mmol/L; and mean 1.68, SD 1.19 mmol/L; $P<.05$).

**Prevalence of Osteopenia and Osteoporosis Among Age Groups**

The prevalence rates of osteopenia and osteoporosis were 40.5% (6633/16,377) and 7.93% (1299/16,377), respectively. The age-standardized prevalence rates of osteopenia and osteoporosis were 27.32% (287,877,129.4/1,053,861,940) and 3.51% (36,974,582.3/1,053,861,940), respectively. In the population aged 50 years and older, the age-standardized prevalence rates of osteopenia and osteoporosis were 42.34% (142,938,163.8/337,624,151) and 8.96% (30,253,250.83/337,624,151), respectively. There was an increase in osteopenia prevalence rate from 21.47% (120/559) in the 18-year-old group to 56.23% (754/1341) in the 75-year-old group (Figure 2A). Meanwhile, the prevalence rate of osteoporosis increased from 0.89% (5/559) in the 18-year-old group to 17.23% (231/1341) in the 75-year-old group (Figure 2B).

7 CHD: coronary heart disease.
Sex-Specific Prevalence Changes of Osteopenia and Osteoporosis With Age

The prevalence rates of osteopenia and osteoporosis among female participants were 4238/9645, 43.94% and 1130/9645, 11.72% were higher than in male participants 2395/6732, 35.58% and 169/6732, 2.51%, respectively; $P<0.001$. In the study population, the age-standardized prevalence rates of osteopenia and osteoporosis were 22.38% (119,148,921.4/532,444,837) and 0.94% (5,022,330.82/532,444,837) for male participants, while it was 30.97% (161,470,215.4/521,417,103) and 5.52% (28,781,912.82/521,417,103) for female participants. In the population aged 50 years and older, the age-standardized prevalence of osteopenia and osteoporosis was 36.1% (60,821,276.55/168,477,281) and 2.65% (4,471,495.81/168,477,281) for male participants and 47.14% (79,727,904.8/169,146,870) and 14.26% (24,113,222.94/169,146,870) for female participants. Among male participants, the observed prevalence rates of osteopenia (Figure 2A) and osteoporosis (Figure 2B) were 20.71% (41/198) and 0% (0/198) in the 18-year-old group and increased to 51.54% (351/681) and 5.43% (37/681) in the 75-year-old group, respectively. Among female participants, the observed prevalence rates of osteopenia (Figure 2A) and osteoporosis (Figure 2B) were 21.88% (79/361) and 1.39% (5/361) in the 18-year-old group and increased to 61.06% (403/660) and 29.39% (194/660) in the 75-year-old group, respectively. The prevalence rates of osteopenia and osteoporosis among age groups are shown in Multimedia Appendix 2.

Prevalence of Osteopenia and Osteoporosis Between Postmenopausal and Premenopausal Female Participants

The prevalence rates of osteopenia and osteoporosis in postmenopausal female participants were higher (3638/7493, 48.88% and 1130/7493, 15.03%) than in premenopausal female participants 2395/6732, 35.58% and 169/6732, 2.51%, respectively; $P<0.001$. In the study population, the age-standardized prevalence rates of osteopenia and osteoporosis were 22.38% (119,148,921.4/532,444,837) and 0.94% (5,022,330.82/532,444,837) for male participants, while it was 30.97% (161,470,215.4/521,417,103) and 5.52% (28,781,912.82/521,417,103) for female participants. In the population aged 50 years and older, the age-standardized prevalence of osteopenia and osteoporosis was 36.1% (60,821,276.55/168,477,281) and 2.65% (4,471,495.81/168,477,281) for male participants and 47.14% (79,727,904.8/169,146,870) and 14.26% (24,113,222.94/169,146,870) for female participants. Among postmenopausal female participants, the observed prevalence rates of osteopenia (Figure 2A) and osteoporosis (Figure 2B) were 20.71% (41/198) and 0% (0/198) in the 18-year-old group and increased to 51.54% (351/681) and 5.43% (37/681) in the 75-year-old group, respectively. Among premenopausal female participants, the observed prevalence rates of osteopenia (Figure 2A) and osteoporosis (Figure 2B) were 21.88% (79/361) and 1.39% (5/361) in the 18-year-old group and increased to 61.06% (403/660) and 29.39% (194/660) in the 75-year-old group, respectively. The prevalence rates of osteopenia and osteoporosis among age groups are shown in Multimedia Appendix 2.
48.55% and 1053/7493, 14.05%) than in premenopausal female participants (538/2026, 26.55% and 53/2026, 2.62%; \( P < .001 \)).

In premenopausal female participants, the observed prevalence of osteopenia was 21.41% (76/355) among the 18-year-old group and increased as the age increased. In postmenopausal female participants, the observed prevalence of osteopenia was 23.81% (5/21) in the 40-year-old group and increased to 61.37% (394/642) in the 75-year-old group (Figure 3A).

**Figure 3.** Prevalence of osteopenia and osteoporosis between postmenopausal and premenopausal female participants. In this cross-sectional study, the age-specific prevalence of osteoporosis and osteopenia was calculated for 7493 Chinese postmenopausal female participants and 2162 premenopausal female participants. The prevalence rates of osteopenia significantly increased with age in premenopausal and postmenopausal female participants, and all \( P \text{trend} \) values were less than .001, the results were statistically significant (A). Prevalence of osteopenia showed a significant statistical difference between premenopausal and postmenopausal female participants in the age group 50 years, \( P \) value was less than .001. The prevalence rate of osteoporosis significantly increased with age in premenopausal and postmenopausal female participants and all \( P \text{trend} \) values were less than .001, the results were statistically significant (B). Prevalence rates of osteoporosis showed a significant statistical difference between premenopausal and postmenopausal female participants in the age group 50 years (\( P < .05 \)).

In premenopausal female participants, the observed prevalence of osteoporosis was 1.25% (5/400) among the 40-year-old group and increased to 14.29% (2/14) among the 60-year-old group. In postmenopausal female participants, the observed prevalence of osteoporosis was 6.56% (17/259) among the 45-year-old group and increased to 29.28% (188/642) in the 75-year-old group (Figure 3B). The prevalence rates of osteopenia and osteoporosis in postmenopausal and premenopausal female participants are shown in Multimedia Appendix 3.

**Prevalence of Osteopenia and Osteoporosis in the Subgroups With and Without a History of Calcium Intake**

Among participants with and without a history of calcium intake, the prevalence rate of osteopenia and osteoporosis was 44.52% (341/766), 40.28% (6276/15,581), 6.27% (48/766), and 8.02% (1250/15,581), respectively. For male participants, the prevalence rate of osteopenia was lower among those taking calcium (55/197, 27.92%) than those not taking calcium (2339/6527 35.84%; \( P = .03 \)). The prevalence rate of osteopenia was higher among female participants taking calcium (286/569, 50.26%) than those not taking calcium (3937/9054, 43.48%; \( P = .04 \); Figure 4A). The prevalence rates of osteoporosis among
the overall study participants taking calcium and not taking calcium were 4.06% (8/197) and 2.47% (161/6527) in male participants and 7.03% (40/569) and 12.03% (1089/9054) in female participants, respectively, with significant differences among female participants ($P=0.004$; Figure 4B). The prevalence rates of osteopenia and osteoporosis in subgroups with and without taking calcium are shown in Multimedia Appendix 4.

**Figure 4.** Prevalence of osteopenia and osteoporosis in the subgroups with and without a history of calcium intake. In this cross-sectional study, the age-specific prevalence of osteoporosis and osteopenia were calculated for 766 Chinese adults taking calcium and separately for 197 male participants and 569 female participants as well as for 15,581 Chinese adults not taking calcium and separately for 6527 male participants and 9054 female participants. The prevalence rate of osteopenia significantly increased with the age in the whole study population, male, and female participants with and without a history of taking calcium (A). All $P$-trend values were less than .001, the results were statistically significant except in male participants with a history of taking calcium. The prevalence rates of osteoporosis significantly increased with the age in the whole study population, male and female participants with and without a history of taking calcium (B). All $P$-trend values were less than .001, the results were statistically significant. The prevalence rates of osteopenia and osteoporosis showed no significant statistical difference between participants with and without a history of taking calcium in all age groups.

**Association Analysis of Taking Calcium With Osteopenia and Osteoporosis**

After adjustment for age, sex, PAI, occupation, history of hypertension, history of T2DM, history of dyslipidemia, history of CHD, history of stroke, and history of cancer, there was no significant association between calcium intake and osteopenia and osteoporosis, and the corresponding ORs (95% CIs) were 1.10 (0.94-1.29) and 0.90 (0.61-1.34), respectively.

Furthermore, sex-stratified analysis showed that calcium intake increased the risk of osteopenia in female participants (OR 1.26, 95% CI 1.04-1.52; Multimedia Appendix 5) after adjusting age, PAI, occupation, history of hypertension, history of T2DM, history of dyslipidemia, history of CHD, history of stroke, and history of cancer.

**Prevalence of Chronic Disease Among Different T-Score Groups**

In the total study population, the prevalence of DM, dyslipidemia, CHD, and CCVD differed among the low, medium-low, medium-high, and high quartiles of the T-score. From the low quartile to the high quartile of the T-score, the prevalence rates of DM (752/4037, 18.63%; 779/4029, 19.33%; 769/3894, 19.75%; and 869/3879, 22.4%) and dyslipidemia (2228/4036, 55.2%; 2304/4027, 57.21%; 2306/3891, 59.26%; and 2379/3878, 61.35%) were linearly increased ($P<.001$), while the prevalence rate of cancer (112/4037, 2.77%; 110/4029, 2.73%; 103/3894, 2.65%; and 77/3879, 1.99%) was decreased ($P=.03$). The prevalence rate of CHD was 1.29% (52/4037), 1.54% (62/4029), 2.16% (84/3894), and 1.99% (77/3879) from low quartile to high quartile. The prevalence rate of CCVD was
Further stratified analysis by BMI showed that in the normal weight group, the prevalence rates of DM were 13.49% (241/1786), 13.03% (214/1642), 13.27% (206/1552), and 16.25% (217/1335) among the lowest, second, third, and highest quartile values of the T-score. In the overweight group, the prevalence rates of dyslipidemia were 64.75% (395/610), 71.33% (510/715), 72.83% (520/714), and 71.6% (580/810), and the prevalence rates of CHD were 0.82% (5/610), 2.09% (15/716), 2.66% (19/714), and 3.46% (28/810) from the lowest quartile to the highest quartile. All the P values were less than .05 (Multimedia Appendix 6).

Discussion

Principal Findings

With a growing older adult population, the public health issue caused by osteoporosis and osteopenia is worthy of attention. However, the prevalence of osteoporosis varied across different studies because of inconsistent measuring instruments [24], bone sites [25], age group, sample size, region [26], and diagnosis criteria. This study investigated the prevalence of osteoporosis and osteopenia in a relatively large sample size Chinese population and explored the impact of chronic common disorders on BMD. With these results, interventions can be carried out for the target population to reduce the burden that osteoporosis poses to public health.

In this study, the age-standardized prevalence rates of osteoporosis and osteopenia were 3.51% (36,974,582.3/1,053,861,940) and 27.32% (287,877,129.4/1,053,861,940), respectively. Similarly, Qiao et al [27] analyzed the prevalence of osteoporosis and osteopenia using the same measuring instruments at the same bone site with this study in rural areas of Henan province in Middle-Eastern China and reported the age-standardized prevalence rates to be 11.76% and 42.09%, respectively. Another study reported that Shanghai had the lowest prevalence rates of osteoporosis and osteopenia compared with other regions in China [28]. A possible reason for the differences in the prevalence of osteopenia and osteoporosis is that each province in China may have different lifestyle-related characteristics that are population specific due to educational, sociocultural, and geographic considerations. For instance, a study has shown that provinces where alcohol is produced, such as Jiangsu, Anhui, Shandong, and Sichuan, had higher alcohol consumption proportions compared with the national level [29]. Meanwhile, lifestyle factors including alcohol are associated with poor bone health [30].

Similarly, Zeng et al [31] measured the BMD values using GE Lunar dual-energy X-ray absorptiometry (DXA) in China and estimated the age-standardized prevalence rate of osteoporosis in male and female participants older than 50 years old to be 6.46% and 29.13%, respectively. Wang et al [32] measured the BMD values using DXA and reported that the prevalence rate of osteoporosis among male participants aged 40 years or older was 5% and 20.6% among female participants of the same age group in China. A previous study has shown that QUS and X-ray density measurement BMD methods (DXA and central quantitative computed tomography) showed the same ability to distinguish between normal populations and osteoporosis [33]. Many epidemiological studies use QUS as a screening tool for osteoporosis because it is easier to expand the sample size, simplify the measuring method, and reduce the cost [34,35].

Other important prospective studies have assessed fracture risk through calcaneal QUS [36,37]. The EPIC-Norfolk prospective population study [37] demonstrated that measuring BMD by QUS at the calcaneus can effectively predict fracture risk in the future. It is worth noting that the QUS T-score may be more adaptable for clinically detecting the risk of osteoporosis in female patients [38]. However, the age-standardized prevalence of osteoporosis at different sites (lumbar spine, femoral neck, and total femur) is also different [31]. Wang et al [39] and Chen et al [40] reported gaps in the prevalence of osteoporosis. Wang et al [28] detected the BMD in the lumbar vertebra and left hip joint by DXA and also confirmed that the prevalence of osteoporosis would be greatly reduced if diagnosed with BMD in every single region only. It is worth noting that the prevalence rates of postmenopausal female participants in this study are close to the results of Wang et al [28], which diagnosed hip BMD. Thus, we speculated that the relative differences in prevalence rates may be due to different measurement regions and a single region. The prevalence rates of osteopenia and osteoporosis in the current population were moderate compared to the previous studies. Importantly, the age-standardized prevalence rates of osteopenia and osteoporosis were higher (79,727,904.8/169,146,870, 47.14% and 24,113,222.94/169,146,870, 14.26%) in female participants aged 50 years and older.

There are significant sex differences in the prevalence and pathogenesis of osteoporosis [41]. Previous studies found that osteoporosis was more prevalent among female than male participants, especially among postmenopausal female participants [27,31]. For menopausal females, the sudden change in hormonal levels can contribute to increased bone loss. Our results are consistent with the previous reports.

A prospective cohort study in an Italian population assessed the association between dietary calcium intake and osteoporosis and a fragility fracture. Their results indicated that low calcium intake was a risk factor for low BMD in Italy [42]. However, in one of the central populations of the Canadian Multicentre Osteoporosis Study, it was found that older female participants taking calcium supplements had no significant BMD preservation [43]. In this study, the prevalence of osteopenia was higher in female participants taking calcium than in those who did not. That may be attributed to the fact that more patients with osteopenia receive diagnosis and treatment advice and take a calcium supplement. Moreover, considering the design of our study is a cross-sectional study, a causal association between calcium supplementation and BMD cannot be stated.
This study indicated that patients with T2DM, dyslipidemia, CHD, and CCVD were associated with higher BMD. In reality, previous observations reported that the association of BMD value with T2DM was inconclusive [15,16]. Recently, Wang et al [28] also found that T2DM was associated with higher BMD. Even some large clinical studies revealed the same results [44,45]. Some researchers have speculated the anabolic effect of insulin on bone tissue [46]. Hyperinsulinemia caused by insulin resistance in T2DM may negatively affect sex hormone–binding globulin, leading to higher free sex hormone levels that may protect patients with T2DM from bone loss [47,48]. However, animal models have indicated that although bone density is greater in diabetes, the bone structure is more fragile, with fractures occurring under a smaller load and the bones exhibiting reduced mechanical indices [49]. Thus, even though the BMD was high in T2DM, it still should pay more attention to patients with T2DM.

As a marker of bone turnover, osteoprotegerin (OPG) can reflect the level of bone metabolism and is used to treat osteoporosis. The animal study results found that OPG-deficient mice develop osteoporosis and premature arterial calcification, suggesting that the OPG system affects vascular calcification [50]. The human study showed that increased OPG levels were associated with the risk of fatal stroke and raised the possibility that the OPG system may be involved in vascular calcification [51]. However, this study was unable to confirm the association between BMD and stroke, although the results indicated the association between BMD and CHD and CCVD.

The findings of our investigation have significant implications for public health. With the increase of Chinese older adults, the prevalence and burden of osteoporosis and osteopenia are expected to increase in the coming years. This study offers information that can be applied to intervention programs meant to prevent or lessen the burden of osteoporosis in China.

**Strengths and Limitations**

This study has a relatively large sample size of a Chinese population involving a fairly broad spectrum of ages taken to boost the statistical power. The study also explored the trend of prevalence of osteopenia and osteoporosis across different age groups and identified high-risk individuals and some protective factors such as early calcium supplementation. However, this study has some limitations. First, a causal association between calcium and osteoporosis cannot be drawn since this was a cross-sectional study. A distinct temporal order in which the cause comes before the result is necessary for causality. It is difficult to discern the direction of the relationship when using cross-sectional research because they can only reveal associations at a single point in time. Although cross-sectional research can yield useful findings, it can only reveal information regarding potential protective or risk factors. Therefore, to support the findings of this investigation, experimental studies should be carried out. Second, the average age of the participants in this study was 60 years, while the number of individuals younger than 40 years old was relatively small. Thus, the estimated prevalence rate of young people may not be sufficient and stable; further studies involving a larger number of participants aged younger than 40 years old might verify the prevalence of osteoporosis and osteopenia for that age group. Third, patients with chronic diseases affecting BMD were self-reported and did not include patients who were bedridden for a long time, which might underestimate the prevalence rates of osteoporosis and osteopenia. Despite this, the necessity of a positive response to promoting bone health and intervention measures for osteopenia and osteoporosis is more strongly suggested.

**Conclusions**

Our findings suggest that as age increases, females had a higher increase in the prevalence of osteopenia and osteoporosis than males. Importantly, postmenopausal females had higher prevalence rates of osteopenia and osteoporosis than premenopausal females. Higher BMD is associated with an increased risk of DM, dyslipidemia, CHD, and CCVD but a decreased risk of cancer. This research will help develop aging coping strategies to promote bone health and prevent osteoporosis.

Abstract

Background: Existing literature on the association between the frequency of muscle-strengthening exercise (MSE) and depression among adolescents is limited and contradictory.

Objective: This study aimed to elucidate the association of MSE frequency with depression symptoms among middle and high school students in China.

Methods: A total of 27,070 students in grades 7-12 from 376 middle and high schools were surveyed using an anonymous self-administered questionnaire between April and June 2022. Information on engaging in MSE was self-reported, and depression symptoms were assessed using the Patient Health Questionnaire-9 (PHQ-9). Poisson regression was used to examine the association between MSE frequency and depression symptoms.

Results: Among the 27,006 eligible students, 51.6% (n=13,933) were boys, and the mean age was 15.6 (SD 1.7) years. The overall prevalence of meeting MSE recommendations (ie, engaging in MSE ≥3 days/week) was 34.6% (95% CI 32.6%-36.6%; n=9145); the prevalence was higher in boys (43.8%, 95% CI 41.8%-45.8%; 6067/13,933) than in girls (24.3%, 95% CI 22%-26.6%; 3078/13,073; P<.001). A total of 5882 (21.8%) students reported having depression symptoms. After adjustment for sociodemographic status, lifestyle factors, academic performance, and experience of physical fighting, compared to students who did not engage in MSE, the prevalence ratios (PRs) for depression symptoms were 0.98 (95% CI 0.97-0.99) for those engaging in MSE once a week, 0.95 (95% CI 0.93-0.97) for 2 days/week, 0.93 (95% CI 0.90-0.96) for 3 days/week, 0.90 (95% CI 0.87-0.94) for 4 days/week, 0.88 (95% CI 0.84-0.93) for 5 days/week, 0.86 (95% CI 0.81-0.92) for 6 days/week, and 0.84 (95% CI 0.78-0.90) for 7 days/week, respectively.

Conclusions: The overall prevalence of meeting MSE recommendations among Chinese adolescents is low. The frequency of MSE was inversely associated with depression symptoms.

Introduction

Depression disorders account for a large and increasing health burden among adolescents aged 10 to 19 years worldwide [1]. The estimated number of disability-adjusted life years among adolescents aged 10 to 19 years diagnosed with depression disorders increased worldwide from 3.4 million to 4.3 million between 1990 and 2019 [2], and in 2019, there were 22.9 million adolescents aged 10 to 19 years with depression disorders worldwide, of whom 1.5 million were in China [2]. Depression among adolescents may contribute to many negative consequences, including functional impairment, poor cognitive development, poor academic performance, and suicide [3,4]. Depression is also associated with a wide variety of chronic physical disorders, including arthritis, asthma, cancer, cardiovascular disease, diabetes, obesity, hypertension, chronic respiratory disorders, and dementia, acting via multiple mechanisms that are not yet completely clear [5].

Muscle-strengthening exercise (MSE) is defined as physical exercise that increases skeletal muscle strength, power, endurance, and mass (eg, strength training, resistance training, or muscular strength and endurance exercises) [6]. Although MSE is now included in many national public health guidelines, in comparison to physical activity guidance on aerobic activities, there is still a lack of emphasis and guidance on MSE throughout public health policies in various countries [7-9]. Prevalence rates for meeting MSE recommendations (ie, engaging in MSE ≥3 days/week) among adolescents vary across countries and regions, as do secular trends. For instance, the prevalence rate of adhering to MSE guidelines is 44.9% in the United States [10], 53.7% in Canada [11], and 39.3% in China [12]. The prevalence in US adolescents decreased from 55.6% in 2011 to 49.5% in 2019 [13], while among Korean adolescents it slightly increased from 20.1% in 2009 to 21.9% in 2019 [14]. More recently, emerging epidemiological and clinical evidence has demonstrated that engagement in MSE could reduce the risk of chronic diseases, including obesity [14,15], hypertension [16], osteoporosis [17], and metabolic syndrome [18]; it can also enhance cardiometabolic health [19] and improve physical fitness [20].

Previous studies documented that MSE was inversely associated with depression. However, the majority of this research focused on adults [21-24], and little is known about adolescents. Furthermore, existing literature on the association of MSE frequency with depression among adolescents is contradictory. While one study indicated that meeting MSE recommendations was inversely associated with depression [25], a null association was found among US high school students and young adults aged 20-39 years [26,27]. Hence, this study was designed to evaluate the association between MSE frequency and depression symptoms among school students in China.

Methods

Study Design

This cross-sectional survey applied a multistage cluster sampling method to recruit participants. In stage 1, 30 counties or districts were sampled randomly from all 90 counties and districts in Zhejiang Province. In stage 2, 11 middle school classes, 6 academic high school classes, and 6 vocational high school classes were selected randomly within each chosen county or district. In stage 3, all students in the selected classes were invited to participate in the study. Students in the selected classes who also returned signed informed consent forms were included in the analysis unless they had serious health problems or illnesses that would restrict them from participating, including intellectual disabilities or language disorders.

A self-administered anonymous questionnaire was filled in by students in a classroom setting without school teachers’ supervision. The field survey was implemented by trained staff from county centers for disease control and prevention (CDC) using standardized procedures.

Outcome Variables

The severity of depressive symptoms was assessed using the Patient Health Questionnaire-9 (PHQ-9) [28]. The PHQ-9, widely used among adolescents [29-32], is a brief scale designed to screen for symptoms of major depressive disorder within the past 2 weeks based on the codes of the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition. Participants were asked to score the following 9 items [33]: (1) “little interest or pleasure in doing things,” (2) “feeling down, depressed, or hopeless,” (3) “trouble falling or staying asleep, or sleeping too much,” (4) “feeling tired or having little energy,” (5) “poor appetite or overeating,” (6) “feeling bad about yourself,” (7) “trouble concentrating,” (8) “moving or speaking so slowly that other people could notice,” and (9) “thoughts that you would be better off dead or of hurting yourself.” Scores for each item ranged from 0 (not at all) to 3 (nearly every day); therefore, the total combined score ranged between 0 and 27. Following the current recommendation [28], depression was defined as having a total PHQ-9 score of no less than 10. A previous study documented high specificity (85%) and high sensitivity (88%) of the PHQ-9 scale in detecting depression using the cutoff value of 10 [34]. In addition, depression was divided into 4 groups according to the sum of the PHQ-9 score (5-9: mild depression; 10-14: moderate depression; 15-19: moderately severe depression; and 20-27: severe depression) [35].

Exposure Variables

The frequency of engaging in MSE was evaluated through the question “During the past 7 days, on how many days did you do exercises to strengthen or tone your muscles, such as push-ups, sit-ups, or weight lifting?” Response options included “none,” “1 day,” “2 days,” “3 days,” “4 days,” “5 days,” “6 days,” and “7 days.” This item, with an acceptable reliability for children and adolescents (κ coefficient >0.55) [36], has been widely used for health behavior surveillance worldwide [10,11]. Meeting MSE recommendations was defined as engaging in MSE at least 3 days in the past 7 days, which is in accordance with World Health Organization (WHO) guidelines [6].

Ethical Considerations

The study was approved by the Ethics Committee of the Zhejiang Provincial CDC (grant number 2022-007-01). The survey was anonymous, and participants did not need to write down their name on the questionnaire. Every student who...
finished the questionnaire received a gift as compensation (a pencil box). A written consent form was provided by all students and their guardians 2 weeks prior to the survey.

**Statistical Analysis**

Continuous variables are presented as the mean (SD). Categorical variables are presented as the percentage (95% CI). Weighted prevalences were calculated. A modified Poisson regression, which is considered to be more robust than the traditionally used logistic regression [37], was used to examine the association between MSE frequency and depression symptoms [38]. Potential confounding factors comprised sociodemographic status, behavioral lifestyle factors, academic performance, and experience of physical fighting. Prevalence ratios (PRs) were calculated using two regression models: model 1 was adjusted for age (≤13 years, 14-15 years, or ≥16 years), sex (boy or girl), region (urban or rural), and type of school (middle school, academic high school, or vocational high school); model 2 was additionally adjusted for paternal and maternal education level (middle school or below, high school, or college or above), parental marital status (married or other), household income (very poor/poor, fair, or rich/very rich), cigarette smoking (yes or no), alcohol drinking (yes or no), physical activity (none, 1-2 days/week, 3-5 days/week, or 6-7 days/week), academic performance (excellent, middle, or poor), and being involved in physical fighting (yes or no). In addition, both exposure (ie, frequency of engaging in MSE) and outcome (ie, depression symptom score) variables were considered to be continuous variables, and multiple linear regression analyses were used to ascertain the association of days of engaging in MSE with depression symptom score. In sensitivity analyses, additional adjustment for experience of being bullied was performed. All statistical analyses were performed using SAS (version 9.4; SAS Institute). The statistical significance level was set at a P value <.05 using a 2-sided test.

**Results**

**Descriptive Statistics**

Overall, 28,043 students from 376 schools were invited and a total of 27,070 students participated in the survey (114 refused to participate and 859 were absent from school on the survey day), resulting in a response rate of 96.5%. Out of 27,070 students, a total of 64 were excluded because of either an incomplete questionnaire (n=40), missing at least 1 of the 9 items in the PHQ-9 questionnaire (n=17), or missing information on engaging in MSE (n=7). Ultimately, 27,006 students, consisting of 13,933 boys and 13,073 girls, were included in the current analyses (Figure S1 in Multimedia Appendix 1). The mean age was 15.6 (SD 1.7) years. A total of 21.8% (n=5882) of students reported experiencing depression symptoms. In addition, the prevalence of mild, moderate, moderately severe, and severe depression symptoms was 39.9% (95% CI 38.8%-40.9%; 10,902/27,006), 14.4% (95% CI 13.7%-15%; 3746/27,006), 5.3% (95% CI 5%-5.7%; 1407/27,006), and 2.7% (95% CI 2.4%-3%; 729/27,006), respectively (Table S1 in Multimedia Appendix 1).

Compared to students who did not perform MSE, students engaging in MSE were more likely to be young, male, from an urban area, attend middle school, live in an intact family, have parents educated to the college level or above, come from a high-income family, be physically active, achieve excellent academic performance, smoke cigarettes, and drink alcohol (Table 1).

Prevalence of Meeting MSE Recommendations

The prevalence of meeting MSE recommendations was 34.6% (95% CI 32.6%-36.6%; 9145/27,006) overall and 41.4% (95% CI 37.4%-45.5%), 42.2% (95% CI 38.3%-46.2%), and 25.2% (95% CI 23.3%-27.1%) for students aged ≤13 years, 14-15 years, and ≥16 years, respectively (P<.001). The prevalence was higher among boys (43.8%, 95% CI 41.8%-45.8%) than among girls (24.3%, 95% CI 22%-26.6%; P<.001). In addition, the prevalence among students attending middle school, academic high school, and vocational high school was 43.6% (95% CI 40.3%-46.9%), 25.5% (95% CI 23.2%-27.8%), and 24.1% (95% CI 21.3%-27%), respectively (P<.001) (Table 2).

Association Between Frequency of Engaging in MSE and Depression Symptoms

After adjusting for sociodemographic factors, behavioral lifestyle, academic performance, and physical fighting, engaging in MSE was inversely associated with the prevalence of depression in an apparent exposure-response manner. Compared to those who did not take part in MSE, the PRs for depression symptoms were 0.98 (95% CI 0.97-0.99), 0.95 (95% CI 0.93-0.97), 0.93 (95% CI 0.90-0.96), 0.90 (95% CI 0.87-0.94), 0.88 (95% CI 0.84-0.93), 0.86 (95% CI 0.81-0.92), and 0.84 (95% CI 0.78-0.90), respectively, for those performing MSE for 1 to 7 days/week (Table 3). In multiple linear regression analyses, the adjusted $\beta$ coefficient of the association between days of performing MSE and depression symptoms scores was $-0.05$ (95% CI $-0.08$ to $-0.02$). An increment of 1 day of MSE was associated with a 0.05 decrease in PHQ-9 score among the adolescents (Table S2 in Multimedia Appendix 1).

Model 1: adjusted for age, gender, region, and type of school.
Model 2: adjusted for age, gender, region, type of school, parental education level, parental marital status, family income, cigarette smoking, alcohol drinking, physical activity, academic performance, and physical fighting.

**Sensitivity Analyses**

The sensitivity analysis (ie, additional adjustment for experience of being bullied) did not essentially change the association of engaging in MSE with depression symptoms (Table S3 in Multimedia Appendix 1).

**Discussion**

**Principal Findings**

To our knowledge, this is the first study examining the association between MSE frequency and depression in a provincially representative sample of Chinese middle and high school students. Our findings show that performing MSE was associated with a lower prevalence of depression symptoms among adolescents. In addition, our data also provide the latest information on the prevalence of meeting the MSE recommendations among Chinese adolescents.

**Prevalence of Meeting MSE Recommendations**

In this study, the overall prevalence of meeting MSE recommendations was 34.6%, much lower than in other studies performed in high-income countries and a previous study conducted in China. For instance, one nationally representative survey conducted in 2021 among 17,232 US students reported that 44.9% of high school students exercised $\geq 3$ days/week to strengthen or tone their muscles [10]. Another study conducted in 2013 and 2014 of 35,297 grade 9-12 Canadian students...
reported that 53.7% of students performed MSE ≥3 days per week [11]. One nationally representative survey implemented in 2019 of 56,636 Chinese middle and high school students found that 43.4% of middle school students and 28.1% of high school students met the WHO MSE recommendations [12]. Physical activity guidelines for Chinese people published in 2021 recommend that children and adolescents aged 6-17 years should engage in moderate- to vigorous-intensity physical activity at least 60 minutes daily and engage in MSE at least 3 days a week [39]. The Chinese government has formulated many regulations to ensure that there are at least 3 physical education (PE) classes per week for middle school students and at least 2 PE classes per week for high school students [40]. However, each 45-minute PE class in China comprises learning and training for basic sports skills, confrontational competitions, and muscle stretching and relaxing [40], and MSE was not specifically emphasized for PE classes. Hence, a closer focus should be placed on MSE, and consideration should be given to incorporating it into PE classes as an important component in the future.

Correlates of meeting the MSE recommendations observed in this study included household income, parental education level, and overall physical activity level. This is similar to findings from a report from Xin et al [12] showing that students who were from low-income households, had poorly-educated parents, and were physically inactive were less likely to meet the MSE recommendations. Consistent with this previous study [12], the prevalence of meeting MSE recommendations was lower among high school students than among middle school students. Also in line with previous studies [12,13], the prevalence of meeting MSE recommendations was lower among girls than among boys. In contrast to the study by Miller et al [41], which found a null significant association between cigarette smoking and meeting the MSE recommendations among 8383 adolescents aged 12-17 years, the more frequently students engaged in MSE, the more likely they were to smoke and drink in this study.

**Association Between Frequency of Engaging in MSE and Depression Symptoms**

Although an accumulating body of research has focused on the association of engaging in MSE with depression symptoms, the results remain conflicting and inconclusive. In this study, MSE frequency was inversely associated with depression symptoms among adolescents, which is consistent with previous findings. For example, in a cross-sectional study of 411,080 US adults aged ≥18 years without any moderate-to-vigorous intensity physical activity, engaging in MSE was significantly and inversely associated with the prevalence of clinically diagnosed depression, with a PR of 0.89 (95% CI 0.85-0.93) for MSE 3 times/week and 0.89 (95% CI 0.85-0.93) for MSE ≥4 times/week in comparison to those did not engage in MSE [21]. Another cross-sectional study of 601 Irish participants aged ≥18 years observed that higher frequency and intensity of MSE protected against depression [42]. However, results from a nationally representative cross-sectional study of 13,677 US high school students in grades 9-12 indicated no statistical significance in the association of engaging in MSE ≥3 days/week with depression symptoms [26]. Another study of 2088 US participants aged 20-39 years, with data retrieved from the National Health and Nutrition Examination Survey, demonstrated that it was physical activity, not MSE, that was independently associated with depressive symptoms [27].

Interestingly, several cohort studies have documented that handgrip strength was inversely associated with the incidence of depression [43-45]. For example, a UK Biobank prospective cohort study of 162,167 participants with a median follow-up of 10 years indicated that compared with participants in the highest tertile of handgrip strength, those in the medium and lowest tertiles had an 11% (hazard ratio [HR] 1.11, 95% CI 1.04-1.19) and 24% (HR 1.24, 95% CI 1.16-1.33) higher risk of depression, respectively [43]. Handgrip strength is often recognized as an indicator of overall muscle strength [46].

The underpinning mechanisms through which engaging in MSE could reduce the development of depression symptoms are largely unclear. First, engaging in MSE could improve muscle strength, which has been recognized as a health indicator and constituent of physical fitness, and enhance physical function and quality of life [20,47]. Second, exercise could increase feelings of self-efficacy and self-esteem, which may contribute to preventing mental health disorders [47,48].

The findings of this study are of practical public health importance and provide vital evidence that may inform the assessment of MSE and prevention of adolescent depression. First, only one-third of middle and high school students met the MSE recommendations, suggesting that insufficient MSE prevails among students of this age, and more comprehensive and effective efforts are needed to address these issues in China. These might include raising social awareness of the beneficial effect of engaging in MSE, incorporating MSE into PE classes, encouraging students to engage in MSE regularly, and evaluating the effects of MSE on physical and mental health among adolescents. Second, the American Heart Association updated a statement in September 2023 to clearly state that MSE is a safe, effective, and essential component of the overall physical activity regimen for cardiovascular disease risk reduction [49]. This study fills a gap in knowledge of the association of MSE frequency and depression symptoms among Chinese adolescents.

**Strengths and Limitations**

The strengths of this study included a large sample size, a high response rate, and a standardized procedure. The study also had several limitations. First, because the study was cross-sectional in design, engaging in MSE and depression symptoms cannot be temporally ordered. It is highly possible that bidirectional associations exist between MSE and depression, because adolescents who have depressive symptoms may be less likely to engage in MSE. Large prospective studies using genetic tools (eg, Mendelian randomization methods) may help with clarifying the association structure between these 2 factors. Second, we only collected the number of days of engaging in MSE in the past week and did not collect detailed information on intensity and duration of MSE. Third, all data were self-reported, and the findings presented may be susceptible to recall or social desirability biases.
Conclusions
In summary, our study sheds light on the association between MSE frequency and depression symptoms among middle and high school students in China. We found that the prevalence of meeting MSE recommendations was low, and that frequency of MSE was inversely associated with depression symptoms among students, although the exact direction of the association could not be determined. Once approved, it would be appropriate to incorporate MSE into methods for targeted prevention of adolescent depression.

Acknowledgments
We express our gratitude to all the students, parents, teachers, and local officials for their participation, assistance, and cooperation. This work was supported by Program of Zhejiang Federation of Humanities and Social Sciences (grant 2023B059) and Program of Zhejiang Youth Research (grant ZQ2023093).

Data Availability
The data sets used and/or analyzed during this study are available from the corresponding author on reasonable request.

Authors’ Contributions
HW designed the study, drafted the manuscript, and analyzed the data. NL, YG, and JP collected the data. JZ and MY were involved in data interpretation. HD provided important comments on the manuscript and revised the manuscript.

Abstract

Background: Health literacy involves individuals’ knowledge, personal skills, and confidence to take action to evaluate and appraise health-related information and improve their health or that of their community.

Objective: This study aimed to analyze the association between health literacy and attitude toward vaccines, adjusted with other factors.

Methods: We used the SLAVACO Wave 3, a survey conducted in December 2021 among a sample of 2022 individuals, representative of the French adult population. We investigated factors associated with the attitude toward vaccines using respondents’ different sociodemographic data, health literacy levels, and the health care system confidence levels using a multinomial logistic regression analysis.

Results: Among the participants, 440.4 (21.8%) were classified as “distrustful of vaccines in general,” 729.2 (36.1%) were “selectively hesitant,” and 852.4 (42.2%) were “nonhesitant.” In our model, the level of health literacy was not statistically different between the “distrustful of vaccines in general” and the “selectively hesitant” (P=.48), but it was associated with being a “nonhesitant” (adjusted odds ratio [aOR] 1.86, 95% CI 1.25-2.76). The confidence in the health care system was a strong predictor for a “nonhesitant” attitude toward vaccines (aOR 12.4, 95% CI 7.97-19.2). We found a positive correlation of 0.34 (P<.001) between health literacy and confidence in the health care system, but the interaction term between health literacy and health care system confidence was not significant in our model.

Conclusions: Health literacy was associated with a “nonhesitant” attitude toward vaccines. The findings demonstrated that health literacy and confidence in the health care system are modestly correlated. Therefore, to tackle the subject of vaccine hesitancy, the main focus should be on increasing the population’s confidence and on increasing their health literacy levels or providing vaccine information addressing the needs of less literate citizens.

KEYWORDS

vaccine hesitancy; health literacy; trust; attitude toward vaccines; public health; vaccination; COVID-19; adult; sociodemographic factor
Introduction

Vaccination is an essential component of primary health care, preventing over 20 potential fatal infectious diseases [1]. Vaccine hesitancy is defined as the refusal or hesitation in accepting vaccines when immunization services are available [2]. It has been designated by the World Health Organization [3] as one of the top 10 challenges in public health, underlining the need to research, understand, and tackle this global issue. It is dynamic and complex, affected by external factors such as time, location, and type of vaccine but also by individual factors such as complacency, convenience, and confidence [4,5].

Vaccine hesitancy is particularly strong in France, which is one of the most vaccine-hesitant countries in the world [6]. At the same time, France has reached a high level of vaccination coverage against COVID-19 [7]. During the COVID-19 vaccination campaign, many factors have been found to be strongly correlated with attitudes to vaccination in general and to vaccination against COVID-19, in particular, age, gender, complacency, political opinions, perception of one’s health status, trust in health authorities and professionals, and health literacy [8-10]. The ability of people to understand vaccine-related information as well as their understanding of medicine have focused much of the debates on the rise of vaccine hesitancy [11]. These observations resonate with the concept of “health literacy.” This term has emerged in the 1970s and refers to the motivation and skills used by individuals to access, understand, evaluate, and apply health information for their own health and that of their family and community; to make judgments and decisions about health care, prevention, and health promotion; and to maintain and promote quality of life throughout [12,13]. Health literacy includes abilities to evaluate and criticize health-related information; it involves a level of knowledge, personal skills, and confidence to take action to improve one’s personal health and the health of one’s community by changing one’s lifestyle and living conditions [14,15]. Low health literacy is directly associated with preventable undesirable health outcomes, including poorer general health, mortality, and inadequate decisions for preventive measures [16,17]. It has also been associated with a higher risk of being “hesitant” rather than “provaccination” [18].

Because health literacy bears heavily on people’s ability to access medical information and health care providers as well as their treatment of this information, it stands to reason that it constitutes a significant determinant of attitudes to vaccinations. However, very few papers have empirically investigated this relationship, which is far from straightforward [19]. Indeed, health literacy interplays with the components of the “3C” model, as described earlier.

Most studies assess functional health literacy mainly using tools like S-TOFHLA (Short Test of Functional Health Literacy in Adults), thereby focusing only on the ability to understand medical information [20,21]. This is restrictive compared with more recent definitions of health literacy, which include the ability to discuss and ultimately make decisions to promote one’s health, lacking the use of rigorously validated scales as we will in our research. This study aims to contribute comprehensively to the understanding of the relationship between health literacy and vaccine hesitancy. In this paper, we will not only investigate the role of health literacy but also the importance of trust in the health care system and their combined impact on vaccine hesitancy. By examining these factors simultaneously, we aim to offer a more holistic perspective on the phenomenon of vaccine hesitancy, ultimately contributing to more effective public health interventions and strategies.

Methods

Recruitment Procedure and Study Sample

Between December 2 and December 17, 2021, invitations to participate in the study were sent to 25,800 French adults, randomly selected from an digital panel of more than 700,000 respondents (provided by Bilendi [22]). The self-administered web-based questionnaires, lasting approximately 15 minutes, were completed during this period. Participants received remuneration in the form of points for completing these surveys. Ultimately, participants could exchange the accumulated points for gift cards, further acknowledging their invaluable contributions to the survey. We then used the quota sampling method to finally obtain a study sample of 2022 respondents matching the French mainland adult population in terms of age (18-24, 25-34, 35-49 50-64, 75+ years), sex (male and female), occupation (farmers, craftsmen, executives, intermediate professions, employees, workers, retirees, and other inactives), population size of the area of residence (<2000, 2000-20,000, 20,000-100,000, and >100,000 inhabitants), and region (Alsace, Aquitaine, Auvergne, Burgundy, Brittany, Center, Île-de-France, Languedoc, Nord-Pas-de-Calais, Normandy, Pays de la Loire, and Provence-Alpes-Côte d’Azur). A weighting procedure was applied to further match the sample to these characteristics when the quota was not perfectly met. To do so, we used the raking ratio method using the SAS Calmar macro developed in France by the National Institute of Statistics and Economic Studies.

Data Collected and Outcome

After the participants’ consent was obtained, we collected information on respondents’ sociodemographic characteristics such as age, sex, educational attainment, and income, as well as their attitudes and practices on a number of issues including vaccination, politics, alternative medicine, and trust in various institutions. Our main outcome is the attitude of the French adult population toward vaccines, using a widely recognized typology for assessing attitudes toward vaccines in France [23,24]. We made a typology in 3 categories based on the answers to 5 questions with the same format, asking whether the responders were in favor of (1) vaccines in general, (2) the flu vaccine, (3) the hepatitis B virus (HBV) vaccine, (4) the human papillomavirus (HPV) vaccine, and (5) the measles vaccine. The categories were built as follows:

- Category 1 (nonhesitant): All respondents who answered favorably to all 5 questions (ie, individuals who are favorable for vaccines in general and 100% accepting all types of vaccines).
- Category 2 (provaccine but selectively hesitant): All respondents who answered “favorable” to the question on...
vaccines in general but who answered “unfavorable” or “I do not know” to at least 1 of the 4 questions on specific vaccines. These represent the people who are favorable to vaccines in general but have doubts or reservations about specific vaccines.

• Category 3 (distrustful of vaccines in general): All respondents who answered “unfavorable” to vaccines in general.

Assessment of Health Literacy Level and Health Care System Confidence Level

We calculated 2 scores: a health literacy score (HLS_{19-Q12}) and a confidence score. The health literacy score was based on a series of 12 questions with a 4-point Likert scale on the ability of each participant to understand, evaluate, and make health decisions in their everyday life using a 48-point score (Multimedia Appendix 1). A score between 4 and 48 was obtained summing the 12 responses, with a higher score indicating a higher health literacy level. We divided the population into quartiles for the analysis: “very high” for a score >36, “high” for a score between 32 and 36, “low” for a score between 26 and 31, and “very low” for a score <26. The health care system confidence score was based on a series of 5 questions about the confidence in science, government agencies that monitor health and environmental risks, government, physicians, and drug manufacturers using a 20-point score with a 4-point scale (Multimedia Appendix 2). A higher score indicates a higher confidence level. The confidence levels score was categorized as follows based on a quartile division: “confident” for a score ≥19, “somewhat confident” for a score between 17 and 19, “somewhat not confident” for a score between 13 and 16, and “not confident” for a score <13. To estimate the internal validity of our scores, we calculated the Cronbach coefficient, in which a result of >0.9 for the health literacy score and the confidence score was considered as a strong internal validity criterion.

Statistical Analysis

Participants’ baseline characteristics were described for each level of vaccine hesitancy. We used chi-square test with Rao and Scott’s second-order correction in cross-tabulations, a univariate regression model to select statistically significant variables by a forward stepwise selection method (entry threshold $P<.2$), and a multinomial logistic regression to investigate factors associated with the attitude of the French adult population toward vaccines using respondents’ different background data, health literacy levels, and confidence levels. Our model was adjusted on gender, age, level of education, income, health care system confidence level, and health literacy level. Because of weighting, frequency counts including decimal points, odds ratios, and adjusted odds ratio (aOR) were reported with 95% CI. We also tested the first-order interaction between health literacy and confidence level to uncover hidden or conditional relationships in data that would not be apparent when looking at individual variables in isolation. A further sensitivity analysis was conducted based on our model excluding health care system confidence.

Pearson correlation tests were used to test the relationship between health literacy and health care system confidence to assess whether there is an association or linear relationship between them, which also provides information about the strength and direction of the association. This test will help us identify whether these 2 factors are positively, negatively, or not significantly associated with each other.

Ethical Considerations

Informed consent to participate in this study (including analyses presented in this paper) was collected before the completion of the questionnaire. Researchers did not have access to identifying data on participants following standard practices for web-based surveys. Participants received points after completing the surveys. Ultimately, participants could exchange all the points they received as gift cards. The methodology of the study was reviewed and approved by the ethical committee of the INSERM (IRB00003888, #21-770).

Results

Characteristics of the Population

In our study population, 208.1 (10.3%) were young adults, 1276.3 (63.1%) were 25-64 years of age, and 537.4 (26.6%) were 64 years and older with a sex ratio of 91 male participants per 100 female participants. Regarding the level of education, 1322.5 (65.4%) achieved secondary education, and 743.4 (36.7%) earned less than €2000 per month (a currency exchange rate of €1=US $1.183 is applicable). Baseline characteristics of the study population, overall and by the level of vaccine hesitancy, are described in Table 1.

### Pattern of Vaccine Hesitancy in the Population

Among the 2022 participants, 852.4 (42.2%) were “nonhesitant,” 729.2 (36.1%) were “selectively hesitant” (among which, n=678.2, 93% were not favorable to 1 or 2 vaccines), and 440.4 (21.8%) were “distrustful of vaccines in general.” The “nonhesitant” group was older with a higher male or female sex ratio. Regarding health literacy score, the “nonhesitant” group had the highest proportion 275.4 (32.3%) with a “very high” score, whereas the “distrustful of vaccines in general” group had the highest proportion 166.6 (37.8%) with a “very low” score. Regarding confidence scores, the “nonhesitant” group had the highest proportion 346.7 (40.7%) of “confident” (>19/24), whereas the “distrustful of vaccines in general” group had the highest proportion 185.2 (42.1%) of “not confident.”
Of note, a large majority of “distrustful of vaccines in general” individuals 355.8 (80.8%) belong to either “somewhat not confident” or “not confident” categories.

Factors Associated With Vaccine Hesitancy

We examined our multinomial logistic regression model factors associated with attitude toward vaccination taking the “distrustful of vaccines in general” group as a reference (Table 2). The sex ratio of male and female participants was not significantly different with the “selectively hesitant” group but was higher among the “nonhesitant” with an aOR of 1.43 (95% CI 1.09-1.88). Age was higher in the “selectively hesitant” population, and the aOR varied from 2.72 (95% CI 1.72-4.29) for the 50- to 64-year age group to 4.01 (95% CI 1.94-8.27) for the 75+-year age group. In the “nonhesitant” group, aOR passed from 1.93 (95% CI 1.16-3.20) for the 50- to 64-year age category to 3.28 (95% CI 1.57-6.86) for the 75+-year category. No association was found for the younger age group. The level of education was also associated with vaccine hesitancy: participants having a postgraduate degree yielded an aOR of 2.63 (95% CI 1.58-4.40) in the “selectively hesitant” group and an aOR of 2.21 (95% CI 1.33-3.68) in the “nonhesitant” group, taking the “distrustful of vaccines in general” as reference. Confidence was a strong predictor of the attitude toward vaccination in both categories, with a higher confidence score leading to a higher aOR. In the “selectively hesitant” category, aOR varied from 1.60 (95% CI 1.16-2.20) for “somewhat not confident” level to 4.13 (95% CI 2.64-6.46) for the “confident” level. In the “nonhesitant” group, aOR varied from 2.77 (95% CI 1.91-4.01) for the “somewhat not confident” level to 12.4 (95% CI 7.97-19.2) for the “confident” level. While the health literacy levels did not appear statistically significant in the “selectively hesitant” group, a statistical difference was observed in the “nonhesitant” group compared to the “distrustful of vaccines in general” group: aOR increased from 1.50 (95% CI 1.04-2.16) for the “low” level of health literacy to 1.69 (95% CI 1.14-2.50) for the “high” level of health literacy and eventually 1.86 (95% CI 1.25-2.76) for the “very high” level of health literacy.
Table 2. Multinomial logistic regression results: exploring determinants of vaccine attitudes and hesitancy in France (SLAVACO Wave 3, 2021; N=2022).

The robustness of these results was tested by conducting a multivariable regression model for each type of vaccine included in the questionnaire (vaccine in general, flu vaccine, HPV vaccine, HBV vaccine, and measles vaccine) with the same covariables and found that for each vaccine, health care system confidence was highly associated with a positive attitude toward vaccine (P<.001), but health literacy was no longer associated with a positive attitude toward each vaccine (P>.05) with no interaction term between these 2 variables (P>.10). The results of the Pearson correlation coefficient showed a modest positive
correlation of 0.34 (P<.001) between health literacy and the health care system confidence.

To explore these findings, our multivariable regression model for each of the vaccination types listed in the questionnaire (vaccine in general, flu vaccine, HPV vaccine, HBV vaccine, and measles vaccine) showed that in all of the regression models, vaccine acceptance for each of the vaccines mentioned was strongly associated with the confidence level but not with health literacy with no interaction between health literacy and confidence (P value of interaction >.1). We found a modest correlation (Pearson correlation coefficient=0.34) between health literacy and confidence. Another multinomial logistic regression was performed by removing the health care system confidence indicator from our model (Table 3). In this model, the effect of health literacy on vaccine hesitancy appeared to be significant (P<.001) with higher aOR.

Table 3. Sensitivity analysis on multinomial logistic regression model: exploring determinants of vaccine attitudes and hesitancy in France (SLAVACO Wave 3, 2021; N=2022) with the exclusion of the health care system confidence variable.

Discussion

Principal Findings

This study confirms a relationship between vaccine hesitancy and health literacy in this study sample, representative of the French population, in which only 852.4 (42.2%) are “nonhesitant.” In a regression model looking at factors associated with vaccine hesitancy, we found that higher age, male sex, health care system confidence, health literacy, and educational attainment were independently associated with less vaccine hesitancy. Health care system confidence was notably a strong predictor: a person with the highest level of confidence is 12 times less likely to be “distrustful of vaccines in general” and 4 times less likely to be “selectively hesitant.”

The level of vaccine hesitancy in this study sample is consistent with other studies conducted in France [23,24]. Our regression model confirms the “confidence, complacency, constrain” (so-called “3C”) model developed by the Strategic Advisory Group of Experts on Immunization Working Group [2]. However, confidence is multileveled: it includes confidence in health care professionals but also in the health care system, and the national state. This study specifically addressed confidence in the health care system. While primary care providers are often among the most trusted, confidence in the state and policy makers can be much more difficult to build or regain. In this study, we found a widespread mistrust of government and the pharmaceutical industry that logically translates into mistrust of vaccines (n=355.8, 80% of the “distrustful of vaccines in general” participants belonged to the nonconfident categories).

We also looked at the role of health literacy in vaccine confidence. A recent systematic review that looked at the association of health literacy with intention to vaccinate and vaccination status found high heterogeneity in the assessment of health literacy, inconsistent results, or a weak association when analyzing 21 papers [19]. Studies have hypothesized a mediating role of health literacy on the relationship between health care system distrust and vaccine hesitancy [25], while in other context, researchers studied, for example, the potential mediating effect of trust in one’s physician on the association of health literacy and medication adherence [26]. This could reflect the fact that health literacy is often associated with other properties that are also likely to affect attitudes to vaccines such as mistrust of actors in vaccination policies, but it could also reflect the paradoxical effect that health literacy is likely to have on attitudes to vaccines. Indeed, health literacy can both help to navigate the health care system and gain access to medical professionals who provide evidence-based information, but it can also favor “doing your own research” and coming across vaccine-critical information. This potentially paradoxical effect of the ability and propensity to look for information regarding health has been well documented by work on the relationship between healthism—the tendency for individuals to exercise control over their own choices in order to maximize their life expectancy—and vaccine hesitancy [27]. Our results contribute to these reflections. We found that a higher health literacy level is associated with being “nonhesitant,” whereas it was not statistically significant in selective hesitancy when controlling for confidence in health care actors.

The relationship between confidence in the health care system and health literacy was also examined. We found that these 2 factors were independent in our model (no interactions found) but modestly correlated. The correlation between the 2 variables seems to be less strong in France than in other countries. For instance, a cross-sectional survey conducted in Taiwan to measure the association between health literacy and trust in physicians and health care systems with a population of 2199 adults showed that respondents’ level of confidence in medical professionals and the health care system was higher among those with better health literacy [28]. After adjusting for respondents’ sociodemographic factors, health literacy remained significantly and positively associated with confidence. Our results therefore suggest that literacy in itself might be less important in France compared to trust. This could reflect the fact that distrust of public actors is particularly strong in France. Comparative work could shed light on national differences in the relationship between trust in health care actors and health literacy. The relationship between the 2 is likely to be affected—among other factors—by the organization of health care and how social inequalities are reflected in health. The absence of interaction effect between health literacy and trust in health care actors is also interesting. We could expect that a higher level of literacy combined with a higher distrust of health care actors would favor the tendency to find and appreciate vaccine-critical sources. It is possible that these tendencies are counterbalanced by a greater propensity among the more literate to identify the public signals denouncing the antivaccine rhetoric as antiscientific, which tend to be pervasive in the mainstream media, especially in France [29,30]. One possible avenue of research in future work could be to explore the relationship between health literacy and information-seeking practices on social media. Inspiration could come from research on how political attitudes interact with social media use and with educational attainment in the inception of vaccine attitudes (for reviews of the literature, see [31,32]).

We found that the male sex was associated with the “nonhesitant” group (aOR 1.43, 95% CI 1.09-1.88). These findings confirm that male sex had more often positive attitudes toward vaccines, whereas women are more likely to be hesitant. These findings are in line with previous studies on vaccine hesitancy [33-35].

Level of education and educational attainment were found to be an independent factor on vaccine acceptance after adjusting for health literacy and health care system confidence. Finally, in our model, the level of income did not appear to be statistically significant with vaccine acceptability. Despite not achieving statistical significance in the multinomial regression model, it is worth noting that the estimated aORs for vaccine hesitancy showed a trend to enhance vaccine acceptance with a salary in the range of €2000-4000 per month for the “selectively hesitant” group and for a salary of more than €4000 per month for the “nonhesitant” group. These results confirm prior study results, which indicates that families in the lowest income categories in Brazil, which account for one-third of the

JMRI Public Health Surveill 2024 | vol. 10 | e45837 | p.1258
(page number not for citation purposes)
population, are reported to be the most vaccine hesitant [36]. Given that those in lower income brackets (income <€1500 per month) make up about 15% of the French population in 2018 [37] and showed the lowest vaccination acceptance rates (23.05%) and the greatest vaccine hesitancy rates (33.04%) [38].

Limitations
This study also has several limitations: health literacy is complex. Our questionnaires using close-ended questions may not capture the whole dimensions of this concept. For example, our questionnaire could not separate health literacy from scientific literacy. The same limitation applies for confidence. These limits could only be resolved using qualitative methods that could examine how health literacy and confidence translate in reality with vaccine providers. The second limitation of this study was the recruitment procedure, which uses quota sampling and can lead to more biases than random sampling. However, the frequency of vaccine hesitancy appeared to be consistent with the frequency previously reported in the literature.

Strengths
Finally, this study has several strengths: the study population was representative of the French population, which has one of the highest vaccine hesitancy rates; we used a validated tool to assess vaccine hesitancy; and the large sample size of this study allows to examine various factors that have been separately associated with vaccine hesitancy in previous studies as well as different vaccines.

Conclusions
Interventions aiming to reduce vaccine hesitancy should prioritize confidence-building measures, which are difficult. Improving health literacy may also help, and public health interventions demonstrated their ability to increase health literacy. We believe that there is a possibility that improving health literacy can also lead to enhanced confidence in the health care system in the long run. Public health campaigns and educational programs should enhance health literacy, while health care providers engage in open, empathetic vaccine discussions. Community leaders and organizations play a role in promoting vaccination. Further research on the relationship between confidence and health literacy is essential. Transparency, timely updates, and public-private partnerships are vital. Tailored interventions should address gender disparities and involve continuous monitoring. Fostering understanding, trust, and tailored strategies can enhance vaccine acceptance and coverage in France.

Abstract

Background: Multimorbidity is a crucial factor that influences premature death rates, poor health, depression, quality of life, and use of health care. Approximately one-fifth of the global workforce is involved in shift work, which is associated with increased risk for several chronic diseases and multimorbidity. About 12% to 14% of wage workers in Korea are shift workers. However, the prevalence of multimorbidity and its associated factors in Korean shift workers are rarely reported.

Objective: This study aimed to assess multimorbidity prevalence, examine the factors associated with multimorbidity, and identify multimorbidity patterns among shift workers in Korea.

Methods: This study is a population-based cross-sectional study using Korea National Health and Nutrition Examination Survey data from 2016 to 2020. The study included 1704 (weighted n=2,697,228) Korean shift workers aged 19 years and older. Multimorbidity was defined as participants having 2 or more chronic diseases. Demographic and job-related variables, including regular work status, average working hours per week, and shift work type, as well as health behaviors, including BMI, smoking status, alcohol use, physical activity, and sleep duration, were included in the analysis. A survey-corrected logistic regression analysis was performed to identify factors influencing multimorbidity among the workers, and multimorbidity patterns were identified with a network analysis.

Results: The overall prevalence of multimorbidity was 13.7% (302/1704). Logistic regression indicated that age, income, regular work, and obesity were significant factors influencing multimorbidity. Network analysis results revealed that chronic diseases clustered into three groups: (1) cardiometabolic multimorbidity (hypertension, dyslipidemia, diabetes, coronary heart disease, and stroke), (2) musculoskeletal multimorbidity (arthritis and osteoporosis), and (3) unclassified diseases (depression, chronic liver disease, thyroid disease, asthma, cancer, and chronic kidney disease).

Conclusions: The findings revealed that several socioeconomic and behavioral factors were associated with multimorbidity among shift workers, indicating the need for policy development related to work schedule modification. Further organization-level screening and intervention programs are needed to prevent and manage multimorbidity among shift workers. We also recommend longitudinal studies to confirm the effects of job-related factors and health behaviors on multimorbidity among shift workers in the future.

Introduction

Shift work includes any work schedule that is outside of the conventional 7 AM to 6 PM working hours. Shift work is prevalent and inevitable in some workforces, including healthcare, law enforcement, and manufacturing [1]. Globally, a total of approximately one-fifth of the workforce is involved in shift work [2]. While shift work allows workplace flexibility and may provide economic benefits, it may also be associated with adverse chronic health outcomes [3].

Shift work is known to disrupt circadian rhythms and affect sleep patterns, hormone secretion, and other biological processes [4]. Furthermore, these disruptions have been associated with chronic diseases among shift workers, such as metabolic disorders, diabetes, cardiovascular disease, stroke, cancer, and depression [5,6]. However, most epidemiological studies and systematic reviews examining the relationships between shift work and chronic diseases only examined the effect of shift work on a single chronic disease, despite the potential for chronic disease comorbidities. Few studies have examined the coexistence of chronic disease and shift work. For example, Yang et al [7] examined shift work and the risk of cardiometabolic multimorbidity among patients with hypertension and found that shift work was associated with cardiometabolic multimorbidity. In the Korean population, shift work was found to be associated with mental health problems, such as depression and suicide ideation in electronics workers [8], chronic kidney disease in female manual laborers [9], and metabolic syndrome in female workers [10].

Multimorbidity refers to the existence of 2 or more chronic diseases in an individual [11,12]. Unlike comorbidity, which refers to the combined effects of chronic diseases related to a primary chronic disease, multimorbidity examines all chronic diseases simultaneously, which means that no single condition is more important than any other [13]. Multimorbidity is person centered and does not assign priority to a single condition [14]. Worldwide, approximately 37% of the general population has multimorbidity [15], and it is associated with premature death [16], poor health [17,18], depression [19], poor quality of life [20], and increased use of health care [21]. Additionally, age, gender, educational level, smoking, and obesity were associated with multimorbidity in previous research among adults aged 50 years and older [22]. Multimorbidity has become increasingly important as changing health behaviors, such as physical activity and obesity, are a core focus in multimorbidity prevention. Screening and behavioral changes, as well as developing intervention programs, may be important for prevention among people with multimorbidity.

About 12% to 14% of wage workers in Korea are shift workers, and weekly working hours vary from 50 hours to 58 hours depending upon the shift types, which is significantly higher than for day workers [23]. Shift work and long working hours are well-known risk factors for several chronic diseases.

However, the prevalence of multimorbidity and its associated factors in Korean shift workers are rarely reported. Identifying and understanding the prevalence of multimorbidity may yield important information for focused care of shift workers and help develop policies related to shift work schedules in Korea, as well as interventions needed to prevent and manage shift workers’ multimorbidity. We additionally performed a network analysis to determine multimorbidity patterns, as certain chronic diseases are likely to co-occur because their pathophysiological pathways are similar [24]. Understanding the patterns of these co-occurring chronic diseases may be beneficial as it may provide vital information for clinicians and policy makers to develop and implement intervention programs for specific groups with similar multimorbidity. Therefore, the purposes of this study are to (1) assess the prevalence of multimorbidity, (2) examine the factors associated with multimorbidity among shift workers in Korea, and (3) identify patterns of multimorbidity.

Methods

This study follows the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines [25].

Design

This is a population-based, cross-sectional study using Korea National Health and Nutrition Examination Survey (KNHANES) data from 2016 to 2020.

Data Source

KNHANES uses a nationally representative sample based on a complex, stratified, multistage cluster sampling method that includes geographical area, gender, and age to provide a representation of the Korean population that is freely available to the public. KNHANES uses a series of cross-sectional national surveys that have been conducted by the Korean Centers for Disease Control and Prevention. These consist of a health survey, a health examination, and a nutrition survey [26].

Study Sample

The participants of this study were shift workers aged 19 years and older. Shift workers were defined as those who work at night or are nonday workers. This included both evening work, night work, day/night regular shift work, and irregular shift work. The exclusion criteria were as follows: (1) those who were younger than 19 years, (2) those who were nonworkers, and (3) those with missing data on any of the chronic diseases. The detailed sample selection flow is shown in Multimedia Appendix 1, Figure S1.

Ethical Considerations

This study was exempted from ethical review and approval by the institutional review board of Chung-Ang University, HCH’s institution (1041078-20230518-HR-139), as this study was a secondary analysis of preexisting data. The primary data (from
Measures

Multimorbidity
We defined multimorbidity as participants having 2 or more chronic conditions simultaneously. Based on previous studies [27-29], 13 common worldwide chronic diseases were included. These included hypertension, dyslipidemia, diabetes, arthritis, cancer, asthma, depression, osteoporosis, thyroid disease, coronary heart disease (CHD), chronic liver disease (CLD), stroke, and chronic kidney disease (CKD). The presence of disease was determined by self-reporting by the participants as to whether they had ever been diagnosed with each disease by a physician. The multimorbidity group was operationally defined as shift workers with 2 or more of the 13 diseases. The nonmultimorbidity group was defined as healthy participants or participants with only 1 chronic condition among the 13 diseases.

Demographic and Job-Related Variables
Sex, age, household income, education, and marital status were considered as demographic characteristics. Household income was divided into quartiles, which were calculated annually to evenly distribute the population into 4 groups by sex and age using the monthly average equivalized income. Education was divided into 4 groups: elementary school or less, middle school, high school, and university and above. Marital status was categorized as married or single. Job-related variables included regularity of work and average working hours per week. The type of shift work was divided into evening work, night work, regular shift work, and irregular shift work. Regular work was defined as that conducted by permanent workers or full-time employees, while nonregular work included work conducted by contract workers, contractors, and part-time workers.

Health Behaviors
This study used multiple health behavior variables, including BMI, smoking status, alcohol use, physical activity, and poor sleep duration. BMI was categorized as underweight (<18.5 kg/m^2), normal (≥18.5 to <23 kg/m^2), overweight (≥23 to <25 kg/m^2), and obese (≥25 kg/m^2) based on the World Health Organization cutoffs for Asia-Pacific countries [30]. Smoking status was categorized as nonsmoker, ex-smoker, and current smoker. Alcohol use was categorized into low-risk drinking, at-risk drinking, alcohol abuse, and alcohol dependence using the Korean version of the Alcohol Use Disorders Identification Test–Concise (AUDIT-C) [31]. Physical activity was measured by aerobic physical activity rate. If participants exercised for at least 2 hours and 30 minutes of moderate-intensity physical activity per week, or at least 1 hour and 15 minutes of high-intensity physical activity, or a mixture of moderate and high-intensity physical activities (1 min of high-intensity activity equals 2 min of moderate-intensity activity), then it was counted as “yes” for aerobic physical activity. Poor sleep duration was defined as either less than 7 hours or more than 9 hours per day; therefore, 7 to 9 hours of sleep per day was considered a good sleep duration [32,33].

Data Analysis
Data were analyzed using Stata (version 16.1; StataCorp LLC) and JASP (version 0.17.1; Eric-Jan Wagenmakers). Additionally, the KNHANES analytic guidelines were followed to adjust the data for complex sampling designs to estimate the population-level statistics for Korea. We conducted a complete case analysis without any imputation following the analytic guidelines [26]. All statistical tests were based on point estimation using a 2-sided P value (<.05) and interval estimation using 95% CIs. Specific analyses was conducted as follows: first, descriptive statistics were used, including weighted N, N, weighted percentage, weighted mean, and SE to present the population characteristics and their multimorbidity characteristics. Second, univariate analyses using the survey-corrected Rao-Scott χ² test and adjusted Wald test were conducted to reveal the differing characteristics between the multimorbidity and the nonmultimorbidity shift worker groups. Third, survey-corrected logistic regression analyses were used to identify factors influencing multimorbidity among shift workers. In the final model, variables that were statistically significant in the univariate analysis were included. We additionally conducted a subgroup analysis based on age, using 50 years as the threshold. Lastly, network analysis was used for exploring the patterns of multimorbidity clusters among shift workers. The network model was graphically represented by nodes (circles representing each morbidity) and edges (lines connecting the nodes). The structural importance of multimorbidity patterns was analyzed using node centrality measures, including closeness, betweenness, strength, and expected influence. Clustering and naming of subgroups within multimorbidity groups were determined through discussion among the researchers based on prior studies [7,34].

Results

Participant Characteristics
The final selected shift worker sample size was 1704 and the weighted population size was 2,697,228. The weighted percentage of male workers (56.7%) was slightly more than female workers, and the mean age of the participants was 41.93 (SE 0.42; SD 13.74) years, with an age range of 19 to 80 years (Table 1). The majority of the participants had household incomes in the third (n=538, 32.9%) and fourth (n=561, 33.4%) quartiles. As for educational attainment levels, 87.2% (n=1419) of participants had a high school education or higher. Additionally, there were more married (n=1209, 64.6%) than single participants. Participants were divided by shift work type: 920 (53.4%) in evening work, 191 (12.2%) in night work, 454 (27.3%) in regular shift work, and 139 (7.1%) in irregular shift work. The proportion of nonregular workers was high at 63.7% (n=821), and the average number of working hours per week was 38.01 (SD 17.67).
Table 1. General characteristics of shift workers (N=1704; weighted N=2,697,228).

The mean BMI was 24.20 (SE 0.11; SD 3.47) kg/m\(^2\), and overweight and obese participants (those with a BMI of 23.0 kg/m\(^2\) or higher) accounted for 60.3% of the total. Nonsmokers were the most common at 51.9% (n=954), and low-risk drinking was engaged in by the majority of the workers at 67.2% (n=969). The proportion of workers engaged in aerobic physical activity was 50.05% (n=808), which was similar to the proportion of participants not engaged in aerobic physical activity. The average sleep time was 7.34 (SD 1.33) hours, and workers who showed a poor sleep pattern accounted for the majority at 55.9% (n=940).

**Multimorbidity Characteristics of Shift Workers**

Table 2 shows the multimorbidity characteristics of the shift workers. Hypertension (n=287, 14.2%) was the most common of the 13 chronic conditions, followed by dyslipidemia (n=235, 11%), diabetes (n=107, 5.3%), and arthritis (n=126, 5.1%). The multimorbidity prevalence in shift workers was found to be 13.7% (n=302) and the number of chronic conditions ranged from 0 to 6.

*The order of chronic conditions is from the highest weighted percentage to the lowest.*

*The average number of chronic conditions was 0.54 (SE 0.02; SD 0.87; range 0-6 for the total of 13 chronic conditions).*

**Differences in Characteristics by Presence of Multimorbidity**

The differences between the multimorbidity group and the nonmultimorbidity group are presented in Table 3. The average age of the multimorbidity group was 57.21 (SE 0.69; SD 10.47) years, which was statistically significantly higher than that of the nonmultimorbidity group (mean 39.51, SE 0.42, SD 12.69 years). The multimorbidity group had lower household income and educational level, a lower number of unmarried people, higher irregular work level, higher BMI, fewer current smokers, less physical activity, and a higher proportion of participants with poor sleep compared to the nonmultimorbidity group, with all differences being statistically significant.
Table 3. Differences in characteristics of the multimorbidity and nonmultimorbidity groups of shift workers (N=1704; weighted N=2,697,228).

Table 4 presents the factors affecting multimorbidity in shift workers. Examining the relationship between each influencing factor and the 2 variables (crude odds ratio [OR]) of multimorbidity showed that age, household income, education, marital status, regularity of work, BMI, smoking, physical activity, and poor sleep quality were all factors influencing multimorbidity. In the final adjusted logistic model, factors affecting multimorbidity were age (OR 1.106, 95% CI 1.069-1.144; P<.001) third-quartile (OR 0.302, 95% CI 0.119-0.768; P=.01) vs first-quartile household income, fourth-quartile (OR 0.366, 95% CI 0.142-0.942; P=.04) vs first-quartile household income, nonregular work (OR 1.804, 95% CI 1.008-3.228; P=.047), and obese BMI (OR 2.152, 95% CI 1.155-4.010; P=.02) vs normal BMI. That is, when the age increased by 1 year, the risk of multimorbidity increased by 1.11 times, and the risk of multimorbidity in the third-quartile and fourth-quartile household income groups decreased by 69.8% and 63.4%, respectively, compared to the first-quartile household income group. The risk of multimorbidity in the nonregular work group increased by 1.8 times compared with the regular work group, and the risk of multimorbidity in the obese group increased by 2.15 times compared to the normal BMI group. Subgroup analysis showed that age, regular work, and obese BMI were associated with multimorbidity in the subgroup younger than 50 years, while household income, education, marital status, and obese BMI were associated in the subgroup aged 50 years and older (Multimedia Appendix 2, Table S1).

Network Analysis

As presented in Figure 1, the network analysis revealed that chronic diseases were clustered into three groups: (1) cardiometabolic multimorbidity (hypertension, dyslipidemia, diabetes, CHD, and stroke), (2) musculoskeletal multimorbidity (arthritis and osteoporosis), and (3) unclassified diseases (depression, CLD, thyroid disease, asthma, cancer, and CKD). A centrality plot of multimorbidity patterns in shift workers shows hypertension, dyslipidemia, arthritis, diabetes, and osteoporosis by strength and expected influence in order (Multimedia Appendix 3, Figure S2).
Figure 1. Multimorbidity network in shift workers. CKD: chronic kidney disease; HNT: hypertension; CHD: coronary heart disease; CLD: chronic liver disease.

Discussion

Overview

This study aimed to identify patterns of multimorbidity and examine the factors associated with multimorbidity among shift workers in Korea. Among the 1704 shift workers included in the study, approximately 14% had multimorbidity. A recent meta-analysis of multimorbidity in the worldwide adult population found that there was a prevalence of approximately 37% [15]. The difference in prevalence could be due to several factors. First, the mean age of our sample was relatively low at 41.9 (SD 13.7) years, compared to 56.9 years in the meta-analysis. It has been recognized that older age is associated with an increased number of chronic diseases [35]. Furthermore, women are more prone to developing chronic diseases than men [36,37], and a higher proportion of our sample was male.

It is recognized that shift work is associated with adverse health outcomes. Previous research reported that shift work increases the risk of cardiovascular incidence and mortality, cancer, and stroke [1,7,38-40]. Approximately 14% of the Korean population is involved in shift work, and although some shift work is inevitable and may provide economic benefits, policies are needed to modify and manage shift schedules. Socioeconomic and behavioral factors are also known to increase the risk for multimorbidity. Consistent with previous research, we found that shift workers in the low-income and obese groups had increased risks of developing multimorbidity. The relationship between low income and the development of chronic diseases and multimorbidity may be explained by less physical activity and lower fruit and vegetable consumption in the low-income group [41,42]. Furthermore, obesity is a major risk factor associated with developing several chronic diseases, including diabetes, heart disease, asthma, arthritis, and depression [43]. We found that a high proportion of Korean workers are involved in nonregular work (63.7%), and having regular work was a significant factor influencing multimorbidity. Many nonregular workers are paid low wages (less than US $10 per hour), are employed on 2-year fixed-term contracts, and may be required to extend their employment or ask to terminate the employment every 2 years. Those who work less than a certain number of hours per week are not covered by social insurance and are not entitled to weekly holidays or paid annual leave, which could be important factors contributing to poor health outcomes among nonregular workers in Korea [44]. Labor laws may require reform so that nonregular workers are guaranteed stability in their jobs, social insurance coverage, and proper wages to enable a minimum standard of living. However, longitudinal and cohort studies are needed to assess and analyze the relationships between shift work, socioeconomic and behavioral factors, and multimorbidity. Further, the subgroup analysis revealed that education and marital status were significant factors influencing multimorbidity in shift workers aged 50 years and older. Consistent with previous research, the risk of multimorbidity increased when workers were less educated and when they were single [45,46]. A deeper understanding of these relationships

https://publichealth.jmir.org/2024/1/e55014

JMIR Public Health Surveill 2024 | vol. 10 | e55014 | p.1271

(page number not for citation purposes)
may require further analysis to identify the subgroups at greatest risk for multimorbidity and develop targeted interventions, as there could be interactions between socioeconomic and demographic factors.

The most common chronic disease in this study was hypertension, followed by dyslipidemia, diabetes, and arthritis. This is similar to the findings of a previous meta-analysis of multimorbidity in the United States, United Kingdom, and Spain [20]. Additionally, we performed a network analysis and found 2 distinct groups: hypertension, dyslipidemia, diabetes, CHD, and stroke clustered as one group; arthritis and osteoporosis clustered as another group. Previous research found that the coexistence of hypertension and at least 1 other comorbidity was most common among patients with multimorbidity [47]. Similar to our findings, Yang et al [7] found that shift workers with hypertension in the United Kingdom were more prone to cardiometabolic multimorbidity, including diabetes, coronary artery disease, and stroke. However, the only known multimorbidity cluster is cardiovascular multimorbidity, and the evidence on multimorbidity in other chronic diseases and their clusters in shift workers remains limited. In the general population, cardiovascular diseases and metabolic diseases tend to cluster together, and osteoarthritis tended to cluster together in an Australian sample, finding that is similar to ours [48]. Some chronic diseases are more likely to cluster together, as seen in our study and the studies in the United Kingdom and Australia. Some chronic diseases are more likely to cluster together as they may share similar pathophysiological pathways [24]. Also, shift work is known to disrupt circadian rhythms and sleep and is associated with overweight and with blood glucose levels, which are important factors for developing cardiometabolic diseases [49,50]. Although it is controversial, some have suggested that patients with arthritis may have greater bone loss [51]. Considering the relationship between arthritis and osteoporosis and that the incidence of both conditions increases with age [52,53], and that the mean age of our participants with multimorbidity was 57 (SD 10.47) years, the co-occurrence of these chronic disease may be understandable. Identifying these disease clusters can be important, as we can target and tailor interventions for specific groups. However, caution is needed when interpreting and comparing clusters of multimorbidity or patterns across studies, as researchers use different statistical methods to analyze clusters or patterns and may include a different list of chronic diseases in their analyses. Further research is needed to better understand and assess multimorbidity clusters and their trajectories and patterns over time among shift workers using unified and valid analytic methods with the most prevalent chronic diseases in shift workers.

Most chronic care models and guidelines focus on the treatment and management of individual chronic diseases [54]. Multimorbidity requires more complex care that prioritizes what is most important for each patient. Several types of interventions for multimorbidity have been implemented in the past, but the evidence to deliver specific interventions remains limited. Furthermore, interventions specific for shift workers with multimorbidity are relatively unknown, despite shift workers being at greater risk for developing multimorbidity than nonshift workers. Nevertheless, occupational or organization-based interventions may benefit shift workers. These potentially include policy development regarding shift schedules, early screening diagnostic interventions, and diet and physical activity programs. However, additional research remains necessary to confirm the multimorbidity clusters in shift workers and to confirm the differences between socioeconomic and behavioral factors to enable the development of specific intervention programs for each cluster group.

To our knowledge, this study is the first to assess multimorbidity and its associated factors in Korean shift workers. We analyzed a 2016-2020 series of national population-based study data (KNHANES) using network analysis to reveal multimorbidity patterns. However, this study has some limitations. First, KNHANES is a cross-sectional study; thus, we cannot assume temporal relationships between variables. We also could not assess the long-term patterns of multimorbidity development and the effect of socioeconomic behavioral factors on multimorbidity. Therefore, we recommend longitudinal studies on multimorbidity among shift workers in the future. Second, the data were based on self-reports from participants. Thus, recall bias cannot be excluded. Some objective data, for example, medical records to identify multimorbidity, may be needed in a future study. Third, the specific patterns of shift work were not specified in the current data set. For example, we do not know if the shift workers had rotating shifts, only night shifts, or how many night or evening shifts were included in their work schedules. Further studies should specify the shift work schedules; a subgroup analysis may be beneficial. Fourth, we also recommend subgroup analysis of different work sectors, since working conditions and shift schedules may differ. For example, the health care and manufacturing industries may use more complex shift schedules and require more specific interventions based on subgroup analysis. Fifth, network analysis provides only a graphical presentation of multimorbidity patterns and does not allow for statistical analyses, such as regression, to identify factors associated with each multimorbidity pattern. Future studies may consider using other statistical analyses, such as latent class analysis, if researchers are interested in exploring factors associated with multimorbidity patterns in shift workers. Finally, the study results may have excluded some confounding variables, such as family support and use of health care, that may have influenced multimorbidity.

Conclusion

Multimorbidity is a crucial factor influencing premature death, poor health and quality of life, and use of health care. Our findings indicate that approximately 14% of Korean shift workers have multimorbidity and that several socioeconomic and behavioral factors are associated with multimorbidity. This suggests that policy development regarding work schedule modification is necessary. Furthermore, screening and tailored intervention programs at the organizational level may benefit efforts to prevent and monitor multimorbidity among shift workers. However, we also suggest a future longitudinal study to assess and confirm multimorbidity patterns among shift workers.

Abstract

Background: Information on the public’s preferences for current public health and social measures (PHSMs) and people’s mental health under PHSMs is insufficient.

Objective: This study aimed to quantify the public’s preferences for varied PHSMs and measure the level of pandemic fatigue in the COVID-19 normalization stage in China.

Methods: A nationwide cross-sectional study with a discrete choice experiment and psychometric scales was conducted to assess public preferences for and attitudes toward PHSMs, using the quota sampling method. The COVID-19 Pandemic Fatigue Scale (CPFS) was used to screen fatigue levels among respondents. The multinomial logit model, latent class model, and Mann-Whitney test were used for statistical analysis. We also conducted subgroup analysis based on sex, age, monthly income, mental health status, and pandemic fatigue status.

Results: A total of 689 respondents across China completed the survey. The discrete choice experiment revealed that respondents attached the greatest importance to the risk of COVID-19 infection within 3 months (45.53%), followed by loss of income within 3 months (30.69%). Vulnerable populations (low-income populations and elderly people) were more sensitive to the risk of infection, while younger respondents were more sensitive to income loss and preferred nonsuspension of social places and transportation. Migrants and those with pandemic fatigue had less acceptance of the mandatory booster vaccination and suspension of transportation. Additionally, a higher pandemic fatigue level was observed in female respondents, younger respondents, migrants, and relatively lower-income respondents (CPFS correlation with age: r=–0.274, P<.001; correlation with monthly income: r=–0.25, P<.001). Mandatory booster COVID-19 vaccination was also not preferred by respondents with a higher level of pandemic fatigue, while universal COVID-19 booster vaccination was preferred by respondents with a lower level of pandemic fatigue.

Conclusions: Pandemic fatigue is widely prevalent in respondents across China, and respondents desired the resumption of normal social life while being confronted with the fear of COVID-19 infection in the normalization stage of COVID-19 in China. During future pandemics, the mental burden and adherence of residents should be considered for the proper implementation of PHSMs.

Introduction

The transmission of the SARS-CoV-2 Omicron variant led to a sharp rise in infected cases in mainland China, spreading from major cities like Guangzhou and Shanghai to the entire country [1]. To contain the transmission of the virus, various public health and social measures (PHSMs) have been adopted at municipal and provincial levels in China under the dynamic zero-COVID policy [2]. These measures include suspension of public transport, closure of public places, closed-off community management, mandatory nucleic acid testing, home quarantine, and isolation of infected and suspected cases, among others [3-5]. However, the severity of the epidemic combined with high-level public health policies during the Omicron wave had significant impacts on the normal life of citizens from different dimensions and may have resulted in mental health issues [6].

Fatigue issues have been noticeable during the COVID-19 pandemic, especially the adverse psychological impacts of nonpharmacological interventions (NPIs) [7]. In China, the prevalences of anxiety and depression symptoms were reported to be 29% and 37.1%, respectively, during the COVID-19 pandemic in 2020 [8]. A study in Italy found that 38% of the general population had psychological distress during the early stage of the COVID-19 pandemic [9]. Among them, vulnerable populations, including elderly people [10,11], migrant workers [12,13], children [14-16], adolescents [16,17], and individuals with pre-existing mental illness [18,19], may have a greater risk of psychological disturbances due to increased exposure to external adverse circumstances. The prevalence of mental disorders was found to be higher during the Omicron wave than during the wild-type wave. For example, the study by Lu et al [20] found that among nonmedical and medical staff, the prevalence rates of anxiety were 55.0% and 47.3%, respectively, and the rates of depression were 62.4% and 53.4%, respectively.

Long-term COVID-19 public health policy may result in pandemic fatigue [21,22], causing a decline in public compliance [23,24]. Changes in people’s perceptions of risk assessment have also led to behavioral changes [23,25]. Rayani et al [26] reported that higher levels of risk perception might allow people to maintain positive preventive behaviors. A study by Alijanzadeh et al [27] in Iran also showed that the risk perception of individuals can influence preventive COVID-19 behaviors through their fear of COVID-19 and trust in the health care system. Meanwhile, public participation at the policy level in preventive behavior, disease response, and surveillance has become increasingly important [28]. Information on public perceptions and attitudes toward social distancing measures is prominent in the unofficial media. In contrast, formal research evidence on the public’s preferences toward the current PHSMs and people’s mental health problems during the Omicron wave under the strengthened COVID-19 policy has been insufficient. Moreover, no studies to date have captured the desirability of the different PHSMs toward the pandemic in China or have captured the general public’s willingness to trade. Such insufficient information on the general public’s pandemic fatigue and preference may hinder priority settings when no single PHSM can sufficiently combat the transmission of the virus.

In the context of PHSMs, this study aimed to explore the public’s preferences and preference homogeneities and heterogeneities for varied PHSMs. Furthermore, based on an assessment of the current level of prevention and control measures in participants’ regions, this study considered the impact of PHSM fatigue on preferences according to the epidemiological fatigue scale [29,30].

Methods

Overview

In this study, we used various instruments to investigate mental health problems among the general population, especially migrant workers and those who work in nonregistered locations for 3 months or more [31]. The first instrument was a discrete choice experiment (DCE) questionnaire, which had a survey-based experiment design that solicited and quantified respondents’ utilities and preferences toward a set of attributes and levels of PHSMs. Following the DCE questionnaire, a Likert psychometric scale of pandemic fatigue was used to measure the respondents’ perceptions of the current PHSMs and levels of pandemic fatigue. Additionally, we conducted a subgroup analysis [32] to explore the heterogeneities based on demographic information and socioeconomic status, and a comparison was conducted of the preferences of respondents with relatively low pandemic fatigue levels and those with high fatigue levels.

Respondents

The inclusion criteria of this study were age of at least 18 years and absence of cognitive impairments (self-report). Respondents were recruited and selected through an online social media advertising platform (Credamo Inc), which has over 3 million samples and covers all provincial administrative regions in China [33-36]. Credamo randomly distributed the survey in 31 provinces of China (excluding Hong Kong, Macao, and Taiwan). Specifically, we provided a quota size of 350 per sex group and 140 per age group (oversampled). According to this census, the population of China was approximately 1.411 billion, with 51.24% male individuals (723.34 million) and 48.76% female individuals (688.44 million) [37,38], leading to a sex ratio of approximately 105.07 male individuals for every 100 female individuals. We also referred to the National Bureau of Statistics of China [37] for age-specific quota design, with 63.35% in the age group of 15 to 59 years and 21.76% in the age group of 60 years or older. However, due to budget restrictions and practical issues during the pandemic, we considered a 1:1 ratio per sex group and 140 individuals per age group for the data collection platform. No personally identifiable information was collected as the survey was anonymous. Consent was obtained when the respondents actively pressed the button marked “I have been informed with sufficient information of the study and agree to participate in this study” after viewing the introductory section.
of the questionnaire where the background and objectives of the study were presented. Respondents could only access the questionnaire if they consented and reported that they were 18 years or older and did not have cognitive impairments. The translation of the original survey has been provided in Multimedia Appendix 1. Respondents received RMB 20 (US $2.76) as an incentive for participation.

Data Collection
An anonymous self-administered survey created using Lighthouse Studio (version 9.9.1; Sawtooth Software) was distributed from July 01, 2022, to September 30, 2022, and respondents from the entire country were considered for inclusion. The minimum sample size requirement of this study was calculated using the rule of thumb approach proposed previously [39]. Specifically, the equation for sample size calculation was as follows:

\[ N > \frac{500c}{(t \times a)} \]

where \( t \) refers to the choice tasks in the survey, \( a \) refers to the number of alternatives, and \( c \) refers to the number of analysis cells. Specifically, the number of analysis cells \( c \) in this study refers to the largest number of levels for any of the attributes. As such, the minimum sample size in this study should be 125 respondents. Moreover, according to the standard parametric approach [40] of sample size calculation, the minimum sample size is 267 (Multimedia Appendix 2).

All the questions were close-ended, with tick boxes provided for responses and no question skipping allowed. No data were stored if the questionnaire website was closed before the completion of the survey.

Survey and DCE Design
The survey of this study had 4 main sections. Specifically, in the first section, we aimed to solicit respondents’ demographic information, including socioeconomic information (age, sex, education level, religion, marital status, occupation, income level, current residence, and registered permanent residence city).

In the second section of the survey, respondents’ vaccination history and medical history were collected. Respondents were asked how many doses of COVID-19 vaccination they have received, whether they have ever been diagnosed with or are currently experiencing psychological diseases (eg, depression, anxiety, obsessive-compulsive disorder, phobia, bipolar disorder, neurasthenia, schizophrenia, and personality disorder), and whether they have ever been infected with COVID-19. If respondents answered that they had been diagnosed with or are currently experiencing psychological diseases, they were required to answer what specific disease they encountered, the severity of the disease, and whether they have ever received or are currently receiving treatment. In addition, if respondents indicated that they had been infected with COVID-19, they were required to provide information about how they found out that they had been infected, their symptoms and complications, and their date of hospitalization and discharge.

The third section of the survey was the DCE. Respondents were presented with 9 sets of scenarios, and in each scenario, respondents faced 3 hypothetical responses, namely, “option A,” “option B,” and “neither.” Respondents were required to select the measure that they felt most satisfied with. The attributes and levels of different measures of the DCE were determined by a literature review [32,41,42] and consultation with local epidemiologists and experts, and according to design guidelines for DCE [43]. As a result, we determined 8 attributes in our study: (1) Risk of COVID-19 infection within 3 months; (2) Closure of social occasions; (3) Suspension of on-campus educational activities; (4) Suspension of public transportation; (5) Contact tracing, isolation, and quarantine; (6) Nucleic acid screening program; (7) Mandatory booster vaccination; and (8) Loss of income in 3 months. All the attributes and levels selected in the study have been summarized in Table 1.

A sample of a hypothetical choice task is shown in Figure 1. The levels in task choices of different versions were designed according to the principles of (1) orthogonality and (2) balance. The task choices in the DCE section were 8 random choices and 1 fixed choice. We used the fixed choice for further data quality control. Since the DCE questionnaire is relatively more complicated for respondents to understand and such cognitive burden imposed on respondents may lead to some bias in their selection, we added specific text and forced respondents to stay on the questionnaire page for at least 1 minute and carefully read the text to help them better understand what discrete choice tasks are and how to select the choices subsequently. Details are provided in Multimedia Appendix 1.
Figure 1. A sample of a hypothetical choice task in the discrete choice experiment (DCE) survey. Nine task choices in total were present in the DCE part. Each task choice contained 2 options (option 1 and option 2) and an “opt-out” option (none of both). Options were characterized by 8 attributes and random levels. Respondents were required to select an option from among the 2 options and the “opt-out” option.

Assuming that the government will implement two different sets of public health measures to mitigate the spread of the coronavirus, please select one of the following two hypothetical public health measures that you prefer.

(Q1. 9 questions in total) Please note: some scenarios may not be realistic, but please also choose the one that better suits your preference based on the information given.

The description was as follows:

In this part, you will face a series of tasks; these are called discrete choice tasks, a method we use to understand preferences and decision-making processes. Each task will offer you two hypothetical options and a “none” option, each with a set of attributes or features. Your task is to choose the option that you prefer or that you would most likely choose in real life. Please read the descriptions of each option carefully. Each option is different, with its unique set of attributes or characteristics. Remember, there’s no right or wrong answer here. We are interested in your genuine preferences. Choose the option that best aligns with what you
would prefer in real life, based on the attributes presented. Some scenarios may not happen in real life since they were hypothetical; however, please also select an alternative based on your own preferences.

According to the full factorial design, there were 11,664 (6×2×2×3×3×3×6) policies and 11,664×11,663 task choices. To significantly reduce the complication of the design in order to ensure that respondents could complete the tasks, we applied a fractional factorial design based on balance (the frequencies of attribute levels are roughly equal across all tasks) and orthogonality (the frequencies of attribute pairs are roughly equal across the tasks) principles.

Psychological Likert scales were included in the fourth section of the survey, and pandemic fatigue was assessed on a 5-point Likert scale. The reliability (α=.885) and validity (Kaiser-Meyer-Olkin measure=0.737) of the Likert scale for pandemic fatigue were tested. The pandemic fatigue model designed by Lilleholt et al [29] was used to ask about demotivation toward COVID-19 PHSMs and the desire to know the development of the epidemic. We adjusted the pandemic fatigue model in our study. The adjusted pandemic fatigue model contained a series of questions on public attitudes or views on the strengthening of relevant measures for epidemic prevention and control at the current stage and a series of scales to measure the public’s pandemic fatigue. The first question asked about local confirmed cases in the respondent’s living area (town, county, and district), and it was followed by a question that asked about the current PHSMs in that area. The third question contained a scale on the respondent’s perceived risk of being infected with COVID-19. The fourth question contained a scale to measure the respondent’s perceptions of the current measures. Subsequently, the fifth question assessed the epidemic prevention fatigue situation under the current situation of strengthened epidemic prevention measures.

Statistical Analysis

Descriptive analysis was performed to describe respondents’ demographic information and socioeconomic information, as well as information regarding migration, COVID-19 vaccination history, mental health disease history, exposure to COVID-19, infection with COVID-19, and experience of closed-off community management (entrance numbers were minimized, checking points were set up in communities, entry permits were limited, face mask wearing was required, health monitoring was enhanced, and only registered personnel and vehicles were allowed to pass through).

We used the multinomial logit (MNL) model to quantify respondents’ relative utilities among all respondents. The MNL model of this study followed the random utility maximization theory [44]. We calculated the odds ratio (OR) and 95% CI based on respondents’ relative utilities among levels and attributes to further measure respondents’ preferences. In addition, we applied the latent class model (LCM) to determine how respondents’ preferences differed according to group membership. We used the Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC) to determine the appropriate number of groups among the respondents. The Mann-Whitney test was applied for the analysis of quantitative variables. The scale data were analyzed using SPSS version 23 (IBM Corp), and the MNL model and LCM were adopted in Lighthouse Studio (version 9.9.1).

Subgroup Analysis Procedure

The LCM was robust in identifying unobserved heterogeneity within the data, and this method allowed for the identification of latent classes of individuals who exhibited similar preferences or characteristics. However, the LCM was not appropriate for investigating the association between pandemic fatigue and preference heterogeneities, as covariates, such as sex, age, and mental health status, were not controlled. Therefore, to further explore the preference heterogeneities among the respondents on controlling sex, age, and mental health status, we also conducted subgroup analyses based on respondents’ demographic information, including sex, age, monthly income, and mental health status. Moreover, we conducted a subgroup analysis based on respondents’ levels (high level or low level) of pandemic fatigue according to the results of the pandemic fatigue scale.

Ethical Considerations

We collected consent from respondents through an online consent form in the survey. This study has been approved by the Institutional Review Board (IRB) at the City University of Hong Kong (reference number: 11-2022-65-E). We adhered to the International Society for Pharmacoeconomics and Outcome Research (ISPOR) reporting guidelines for designing and reporting the research questions, assessing attributes and levels, and performing statistical analysis for the DCE.

Results

Respondent Characteristics

A total of 1183 respondents clicked on the link of our survey, and of these, 855 completed the survey. After the control process for data quality involving the exclusion of respondents who wrongly answered a trap question, 689 respondents were included in the final analysis. Among the 689 respondents, 341 (49.5%) were male and 348 (50.5%) were female. Additionally, 286 (41.5%) respondents were aged 35 years or younger. Most respondents (509/689, 73.9%) had a monthly income equal to or less than RMB 10,000 (US $1378.15), and 30.5% (210/689) of respondents were migrants (Table 2).

Preferences for Public Health Measures

The attribute that had the most weighted importance in respondents’ decision-making was the risk of being infected with COVID-19 in 3 months (45.53%), followed by the loss of income due to COVID-19 measure (30.69%). Suspension of on-campus educational activities (1.29%) had the weakest weighted preference (Figure 2). Weaker preferences were observed when increasing the risk of infection with COVID-19. Compared with the full suspension of public transportation, respondents believed that suspension in only high-risk areas (areas with 10 or more local confirmed cases were designated as high-risk areas) would be associated with larger utility (OR 1.168, 95% CI 1.106-1.234; *P*<.002). Moreover, compulsory contact tracing was favored by respondents compared with voluntary contact tracing (OR 1.294, 95% CI 1.225-1.366; *P*<.001). In addition, respondents were willing to accept booster doses of COVID-19 vaccines, and their utility decreased along with loss of income within 3 months due to PHSMs (Table 3).
Figure 2. Weighted attribute importance among public and different latent classes of respondents. (A) Weighted attribute importance among all respondents. (B-E) Weighted attribute importance among 4 latent classes of respondents (groups 1-4). A larger proportion represents a higher attribute importance.

Subgroup Analysis of Preferences for PHSMs

To better trace the heterogeneities of the preferences, subgroup analyses were conducted in terms of age and different monthly income levels (Figure 3). Compared with respondents having high monthly income, those having low monthly income were less sensitive to the risk of infection with COVID-19 within 3 months but more sensitive to the loss of income due to the measure within 3 months. Moreover, low-income respondents cared more about nucleic acid test screening for all and preferred the suspension of public transportation in only high-risk areas. Additionally, low-income respondents preferred not to be close to social and living places, which was in contrast with the findings for high-income respondents.

Figure 3. Subgroup analysis based on sex, age, mental health disease history, and residence status. (A) Subgroup analysis of preferences of respondents with a monthly income of ≤10,000 or >10,000 RMB. A currency exchange rate of 1 RMB=0.138 USD is applicable. (B) Subgroup analysis of preferences of respondents aged ≤35 years or >35 years. (C) Subgroup analysis of preferences of respondents with or without mental health diseases diagnosed previously. (D) Subgroup analysis of preferences of nonmigrant or migrant respondents.

Similarly, respondents older than 35 years were more sensitive to the risk of COVID-19 infection and less sensitive to the loss of income within 3 months. Moreover, compared with older respondents, younger respondents preferred nucleic acid test screening for only high-risk units, workplaces, and vulnerable public, while older respondents preferred screening for all. Furthermore, younger respondents preferred not suspending on-campus educational activities and not closing social and living places.

Respondents diagnosed with mental health diseases did not favor contact tracing, isolation, and quarantine, as well as closure of social and living places compared with those without mental health diseases. The subgroup analysis for migrants and nonmigrants indicated that migrants had less acceptance of the mandatory booster vaccination and accepted the suspension of transportation in high-risk areas or normal operations.
Subgroup Analysis of Pandemic Fatigue and Preference Heterogeneities

A higher pandemic fatigue level was observed in female respondents, younger respondents, migrants, and relatively lower-income respondents (COVID-19 Pandemic Fatigue Scale [CPFS] correlation with age: \( r = -0.274, P < .001 \); correlation with monthly income: \( r = -0.25, P < .001 \) (Table 4). Based on the results of the CPFS, some preference heterogeneities were also found among respondents with a lower or higher level of pandemic fatigue (Figure 4). Respondents with a higher level of fatigue tended to be less sensitive to the risk of COVID-19 infection within 3 months and more sensitive to income loss within 3 months. Additionally, compared with respondents with a lower level of pandemic fatigue, those with a higher level of fatigue preferred the nonsuspension of social places and nonsuspension of on-campus educational activities. Mandatory booster COVID-19 vaccination was also not preferred by respondents with a higher level of pandemic fatigue, while universal COVID-19 booster vaccination was preferred by respondents with a lower level of pandemic fatigue.

Figure 4. Weighted importance of attributes and levels among respondents based on pandemic fatigue levels. (A) Weighted attribute importance among respondents with a lower level of COVID-19 pandemic fatigue. (B) Weighted attribute importance among respondents with a higher level of COVID-19 pandemic fatigue. (C) Relative utility of levels among the 2 groups of respondents.

Latent Class Analysis

According to the AIC and BIC of the LCM, 4 latent groups of respondents were determined, with the lowest BIC value of 9680.29 and AIC value of 9104.82. All the other model fitting values have been presented in Multimedia Appendix 3. The segmented sizes were 15.1%, 16.5%, 34.6%, and 33.8% for groups 1, 2, 3, and 4, respectively. As shown in Figure 2, respondents in groups 1 and 4 attached the most importance to the risk of COVID-19 infection within 3 months, while respondents in groups 2 and 3 attached importance to the loss of income within 3 months. Additionally, following the risk of COVID-19 infection and loss of income within 3 months, groups 2 and 4 considered contact tracing and nucleic acid test screening to be the third and fourth most important attributes,
respectively. Group 3 believed that nucleic acid test screening and suspension of public transportation were very essential.

Discussion

The COVID-19 pandemic posed tremendous challenges for delivering mental and physiological health services throughout China. This study sought to comprehensively investigate public mental health and preferences for PHSMs. This is the first study to estimate public preferences for PHSMs using a DCE for a nationally representative population in China. The risk of COVID-19 infection within 3 months; contact tracing, isolation, and quarantine; nucleic acid screening program; and loss of income within 3 months significantly influenced the preferences for PHSMs.

In our study, we found that the respondents placed the greatest importance on the risk of COVID-19 infection in the last 3 months when considering public health measures for COVID-19 mitigation. With its rapid spread and serious complications, COVID-19 caused fear in the vast majority of people irrespective of whether they were in the risk group. In a population-based survey conducted in America [45], the population was fearful, worried, and uncertain about COVID-19, especially in more densely populated communities, communities with higher presumptive and reported COVID-19 case concentrations, and urban locations. Additionally, an online survey in Italy that asked about health behaviors and the psychological and overall impact of COVID-19 found that only the fear of infection significantly dissuaded people from violating epidemic prevention rules [46]. Hence, the risks of infection and adverse outcomes secondary to infection should be clearly outlined by the media or the government to the public to enhance mutual understanding, reduce their psychological burden, and improve the compliance of people’s epidemic prevention behavior.

Furthermore, the respondents in our survey attached more importance to income loss in their preferences. According to an analysis based on economic forecasts in the European Union, the COVID-19 crisis had an indispensable impact on household disposable income, similar to the one experienced during the 2008-2009 financial crisis, with lower-income households being more severely hit [47]. The high preference may be due to the large negative economic, living, and psychological effects of lower income [48]. This was consistent with the fact that migrant workers, accounting for about one-fifth of the whole Chinese population, were faced with large housing stress and psychological burden from the sudden loss of income and further quarantine enforcement during the COVID-19 pandemic [31]. Therefore, the government should consider subsidies related to epidemic prevention, particularly for the low-income population; take fiscal policy measures as appropriate to reduce the risk and scale of income reduction; and cushion the impact of the epidemic crisis on inequality and poverty through policy interventions.

Respondents in our study showed preference heterogeneity for epidemic prevention measures. Understanding the heterogeneity of information and differences in personal values toward epidemic prevention measures can help policy makers understand individuals’ preferences so that more rational and customized PHSMs can be formulated to reduce the negative emotions caused by epidemic prevention. For example, younger participants preferred not to undergo nucleic acid screening, but older people were more afraid of having novel coronavirus pneumonia. The probable cause is that the case fatality rate of novel coronavirus pneumonia is low in young people and increases in a log-linear model by age among individuals older than 30 years [49]. Therefore, relevant departments should be responsible for community humanistic care, appeasing the mood of the masses, eliminating panic, guiding the community to carry out scientific and orderly epidemic prevention work, implementing vaccine booster shots in the population, and publicizing the scientific knowledge of COVID-19.

Our study showed that migrant workers had a high level of pandemic fatigue related to the suspension of transportation and closure of social places, which aligned with existing literature [31,50]. These findings indicate that vulnerable groups, including migrants and the older population [51], are more prone to experience psychological pressure due to unemployment, suspension of the public transportation network, and loss of income [12,52]. These findings emphasize the importance of psychological placation for susceptible populations during the outbreak to help provide support and managed care for individuals at risk of psychological impact. On the other hand, we found higher pandemic fatigue scores in young participants than in participants from other age groups, which is consistent with the finding in a previous study [53] reporting that university students had significantly reduced mood and reduced social interactions during lockdown periods. For migrant workers, elderly people, and other susceptible populations, governments should develop effective mental health interventions and strategies, carefully assess and manage the mental health needs of vulnerable groups, and provide mental health services through community management or digital platforms during the epidemic.

Although COVID-19 PHSMs are dynamic, our findings contributed to the existing literature by providing a better understanding of the psychological impact of the pandemic, and this may be useful for formulating and planning effective prevention strategies and psychological counseling for the public and susceptible populations. Moreover, the findings of this study may provide insights for PHSM design when managing epidemic outbreaks in the future. Through the analysis of heterogeneous populations that have been affected by the pandemic mentally and emotionally, our research provides key insights that can inform formulation and priority settings and the planning of more effective prevention strategies and psychological support mechanisms. This is particularly relevant for public health authorities and policy makers who are challenged and tasked with conditions involving the physical and mental well-being of the public and vulnerable groups during such crises. Furthermore, the implications of our findings extend far beyond the current pandemic context. As we investigated the psychological effects of COVID-19 and the preferences of various PHSMs for mitigating these impacts, we were able to provide insights that can be pivotal in the face of future infectious disease outbreaks. Moreover, our research
highlights the necessity of incorporating psychological considerations into the priority settings of PHSMs. This approach ensures that interventions are holistic, addressing both the epidemiological and emotional aspects of disease control.

There are limitations in this study, especially in the sampling methods. As we applied quota sampling without providing the quotas of regions in this study owing to budget issues, the results may have a potential bias for inferring the general population, and selection bias may also exist. Moreover, in our study, we collected preference data from 689 respondents living in 31 provinces in China. However, considering the 1.4 billion population in China, the presence of only around 22 respondents in each province may reduce the representativeness of the sampling. Owing to the limited budget for data collection and the restricted offline sampling procedure related to the COVID-19 pandemic lockdown, the flexibility of the sampling was largely limited. Further studies with larger and more representative samples for investigating the mental health of the general population under the conditions of the pandemic may be required to more accurately quantify the perspectives for PHSMs. In addition, the study acknowledges the limitations imposed by the use of quota sampling, particularly the equal representation of sexes and the simplified categorization of age groups, which may not accurately reflect the complex demographics of the adult population in China. Owing to the challenges posed by the pandemic and the budgetary constraints for data collection, the study could not completely adhere to the exact adult age structure of the Chinese population in the sampling methods. This limitation may affect the generalizability of the findings to the entire adult population of China. This is a limitation that future research might overcome with alternative strategies or under different circumstances. Finally, we acknowledge that the DCE questionnaire may impose some cognitive burden on respondents, and this may lead to some biases when selecting among the alternative options. Therefore, a face-to-face approach is considered to be better than an online approach. However, due to the pandemic lockdown, a face-to-face approach was not feasible. In future research performed to understand people’s pandemic fatigue and preferences, a face-to-face approach should be applied if there is no lockdown.

Variability in the preference for COVID-19 policies was found between different groups. Pandemic fatigue and fear of COVID-19 infection contributed to the public’s mental health problems. Hence, at the late stage of the pandemic, policy makers should consider reducing people’s mental burden by introducing approaches to relieve people’s fear of infection when PHSMs are being relaxed. The findings provide insights on PHSM implementation for outbreaks in the future as our research highlights the necessity of incorporating heterogeneous psychological considerations into the priority settings of PHSMs. This may ensure that interventions are holistic, addressing both the epidemiological and emotional aspects of disease control.

Abstract

Background: Vaccination plays an important role in preventing COVID-19 infection and reducing the severity of the disease. There are usually differences in vaccination rates between urban and rural areas. Measuring these differences can aid in developing more coordinated and sustainable solutions. This information also serves as a reference for the prevention and control of emerging infectious diseases in the future.

Objective: This study aims to assess the current coverage rate and influencing factors of COVID-19 (second booster) vaccination among Chinese residents, as well as the disparities between urban and rural areas in China.

Methods: This cross-sectional study used a stratified random sampling approach to select representative samples from 11 communities and 10 villages in eastern (Changzhou), central (Zhengzhou), western (Xining), and northeast (Mudanjiang) Mainland China from February 1 to February 18, 2023. The questionnaires were developed by experienced epidemiologists and contained the following: sociodemographic information, health conditions, vaccine-related information, information related to the Protective Motivation Theory (PMT), and the level of trust in the health care system. Vaccination rates among the participants were evaluated based on self-reported information provided. Binary logistic regression models were performed to explore influencing factors of vaccination among urban and rural participants. Urban-rural disparities in the vaccination rate were assessed using propensity score matching (PSM).

Results: A total of 5780 participants were included, with 53.04% (3066/5780) being female. The vaccination rate was 12.18% (704/5780; 95% CI 11.34-13.02) in the total sample, 13.76% (341/2478; 95% CI 12.40-15.12) among the rural participants, and 10.99% (363/3302; 95% CI 9.93-12.06) among the urban participants. For rural participants, self-reported health condition, self-efficacy, educational level, vaccine knowledge, susceptibility, benefits, and trust in the health care system were independent factors associated with vaccination (all \( P < .05 \)). For urban participants, chronic conditions, COVID-19 infection, subjective community level, vaccine knowledge, self-efficacy, and trust in the health care system were independent factors associated with vaccination (all \( P < .05 \)). PSM analysis uncovered a 3.42% difference in vaccination rates between urban and rural participants.

Conclusions: The fourth COVID-19 vaccination coverage rate (second booster) among the Chinese population was extremely low, significantly lower than the previous vaccine coverage rate. Given that COVID-19 infection is still prevalent at low levels, efforts should focus on enhancing self-efficacy to expand the vaccine coverage rate among the Chinese population. For rural residents, building awareness of the vaccine’s benefits and improving their overall health status should be prioritized. In urban areas, a larger proportion of people with COVID-19 and patients with chronic illness should be vaccinated.

https://publichealth.jmir.org/2024/1/e50595
Introduction

Vaccination plays an important role in preventing COVID-19 infection, reducing the severity of the disease and the case fatality rate [1-4]. Currently, the prevalence of COVID-19 infection rate is low [5]. However, COVID-19 still has a significant impact on people's health, causing issues such as long COVID-19, preterm birth, stillbirth, myocarditis, and pericarditis [6-8]. A study from Australia has shown that vaccination is effective in protecting the population [9]. Similar studies carried out in the United States indicated that COVID-19 vaccines have reduced the severity of the disease and prevented serious complications such as respiratory failure and death [10]. Other studies have shown that individuals who received booster doses of COVID-19 vaccine have stronger immune protection than those who received only a single dose [11,12]. Therefore, for countries and regions aiming to reduce the spread of COVID-19 by expanding the protection of immune barriers, increasing vaccination rates remains an important task for health care systems at this stage [13].

Establishing herd immunity through COVID-19 vaccination requires a vaccination rate ranging from 50% to 85% of the population [14,15]. An intensive vaccination campaign during the initial phase of the pandemic wave led to a lower optimal level of doses administered per 100 inhabitants (roughly 47 doses of vaccines administered) to reduce the number of infected individuals; however, as the pandemic wave progressed, the optimal level of vaccines increased to about 90 doses per 100 inhabitants to produce the same effect [16]. The maximum vaccination rate that could be achieved without a mandate was 70%, with the remaining 30% associated with people’s hesitancy toward vaccinations [17]. The factors influencing COVID-19 vaccination are complex and only partially explored. Previous studies have shown that COVID-19 vaccination was related to the severity of the outbreak, perceived susceptibility to the disease, and concerns related to the vaccine’s safety and effectiveness [18-21]. Our previous research reported correlations between COVID-19 vaccination and trust in the health care system, vaccine accessibility, lifestyle, and psychological experience [22,23]. Additionally, our previous nationwide investigation conducted during primary COVID-19 vaccination hesitancy confirmed a 2.38% gap between rural residents in China and their urban compatriots [24]. Similar findings were reported in studies related to influenza and HPV vaccines [25,26].

Disparities in COVID-19 vaccination rates between rural and urban regions are meaningful [27]. In China and other limited-income countries, frequent movement of the population between urban and rural areas is common [28]. Given the extremely high transmission capacity of COVID-2019, increasing vaccination rates among urban or rural residents unilaterally is not cost-effective in building herd immunity [29]. Currently, India, Brazil, and other limited-income countries are experiencing significant internal migration patterns similar to China’s [30,31]. Effective public governance improves prevention and preparedness to face pandemic threats [32-34]. Quantifying disparities in COVID-19 vaccination rates in rural and urban areas based on Chinese national-level evidence is crucial for global efforts to end the COVID-19 pandemic and can provide a reference for the prevention and control of emerging infectious diseases.

Therefore, we conducted a nationwide survey during the fourth COVID-19 (second booster) vaccination period. This study aims to assess the current coverage rate of COVID-19 vaccination among Chinese residents, identify influencing factors, and examine disparities between urban and rural areas in China. This study’s findings will reveal the real-time status of COVID-19 vaccination among people in China. A quantitative assessment of the disparity between urban and rural areas will deepen our understanding of the complexity of COVID-19 infection prevention, helping produce a more coordinated and sustainable solution to end the pandemic.

Methods

Sample and Data

From February 1 to February 18, 2023, we selected 11 communities and 10 villages in eastern, central, western, and northeastern Mainland Chinese as representative samples using stratified random sampling. Within each region, namely Changzhou, Zhengzhou, Xining, and Mudanjiang, a random sampling approach was employed to select representative urban and rural areas. Specifically, 2 or more communities and villages were randomly chosen from each city. Furthermore, to ensure comprehensive coverage, households were also randomly selected within each region. Finally, all members of the selected family (aged ≥18 years) participated in the survey and completed a web-based or paper-based questionnaire with the investigator’s assistance. To ensure data consistency and reliability, questionnaires that contained contradictory responses to key questions were excluded. Additionally, questionnaires completed in less than 5 minutes were excluded to maintain an adequate level of response detail. Furthermore, to prevent duplicate entries and potential bias in the analysis, questionnaires that were filled out repeatedly by the same individuals were excluded. Finally, questionnaires that lacked clear identification of the survey object’s source were excluded to ensure transparency and accuracy in the data collection process. Following the exclusion criteria, the questionnaires underwent a thorough review process conducted by trained staff. From this review, a total of 5891 questionnaires were collected. Subsequently, after further screening and data validation, a final sample of 5780 participants was included in our study. Figure 1 shows the study flowchart.
Measures of Variables

Experienced epidemiologists developed the questionnaires, which contained the following components: sociodemographic information (sex, age, religion, marital status, educational level, career, social status in China, and social status in community), health conditions (chronic disease, history of allergy, self-reported health condition, and COVID-19 infection), vaccine-related information (vaccine knowledge and vaccine accessibility), information related to the Protective Motivation Theory (PMT; severity, susceptibility, benefits, barriers and self-efficacy), and the level of trust in the health care system (trust in doctors and vaccine developers).

We assigned a unique code to each participant, which was used to distinguish whether the participant came from an urban or a rural area.

COVID-19 vaccination status was measured based on participants' responses to 3 items. The first item asked, “Have you been vaccinated with the COVID-19 basic vaccine?” We set 3 answers: 1 (“Yes, I have completed COVID-19 basic vaccination”) 2 (“Yes, but I haven't completed COVID-19 basic vaccination”), and 3 (“No”). The second question was, “Have you been vaccinated with the third COVID-19 (first booster) vaccine?” We set 2 answers: 1 (“Yes”) and 2 (“No”). The third question was, “Have you been vaccinated with the fourth COVID-19 (second booster) vaccine?” We set 2 answers: 1 (“Yes”) and 2 (“No”). We defined participants who completed all 3 items as those who had been vaccinated with the fourth COVID-19 (second booster) vaccine.

Data Analysis Procedure

An independent sample t test or chi-square test was carried out to test the differences in COVID-19 vaccination across groups between the urban and rural participants. Binary logistic regression models were performed to explore the factors influencing vaccination among the urban and rural participants. Both univariate and multivariate analyses for urban and rural participants were conducted separately. PSM was used to minimize potential confounding biases. A probit regression model was used to estimate the propensity scores for urban and rural participants. Finally, 1956 pairs of homogeneous participants were matched in a 1:1 ratio using propensity scores from a total of 5780 participants. Differences were deemed statistically significant if \( P < .05 \). We performed all statistical analyses using Stata software (version 16.1; StataCorp).

Ethical Considerations

This study was reviewed and approved by the Life Science Ethics Review Committee of Zhengzhou University (2021-01-12-05). Written informed consent outlining the study’s objectives was obtained from each participant before the survey commenced. All data were used solely for research purposes. The study data are anonymous, and the answers are protected by privacy laws.
**Results**

**Prevalence Of COVID-19 Vaccination and Characteristics Among Urban and Rural Participants**

A total of 5780 participants, among them 57.13% (3302/5780) urban residents, completed the survey. A summary of COVID-19 vaccination rates, along with characteristics like sociodemographic information, health conditions, vaccine-related information, information related to PMT, and trust in the health care system between the urban and rural participants is shown in Table S1 in Multimedia Appendix 1. In the total sample, 12.18% (704/5780) of participants (95% CI 11.34-13.02) expressed they had been vaccinated with the fourth COVID-19 (second booster) vaccine. Additionally, 10.99% (363/3302) of urban participants (95% CI 9.93-12.06) had a relatively lower COVID-19 vaccination rate than rural participants at 13.76% (341/2478; 95% CI 12.40-15.12). Individuals aged 30 to 39 years, without chronic disease or previous COVID-19 infection, who had a higher subjective community level, higher level of vaccine knowledge, higher perceived benefits, higher self-efficacy, and trust doctors and vaccine developers (at levels 1 and 4) were more likely to receive a COVID-19 vaccination in urban areas (all P<.05). Conversely, individuals aged 18 to 29 years, without chronic disease, with vaccine accessibility within 15 minutes, higher self-reported health condition, lower level of vaccine knowledge, lower perceived benefits, higher perceived barriers, lower self-efficacy, and lower trust in doctors and vaccine developers were more likely to receive a COVID-19 vaccination in rural areas (all P<.05).

Additionally, we discovered that rural participants tended to be older and less educated, with fewer reporting a history of COVID-19 infection compared to urban participants. In both rural and urban participants, the proportion of female (n=1488, 45.06%) and male (n=1226, 49.48%) participants was relatively similar. Moreover, 45.34% (n=1497) of urban participants and 38.58% (n=956) of rural participants took less than 15 minutes to reach the vaccination site (Table S2 in Multimedia Appendix 1).

**Factors Influencing COVID-19 Vaccination Among Urban and Rural Participants**

After adjusting for potential confounding variables, we discovered that urban participants without chronic disease (adjusted odds ratio [AOR] 1.629, 95% CI 1.108-2.396), without COVID-19 infection (AOR 1.977, 95% CI 1.977-2.479), who had a higher subjective community level (AOR 1.073, 95% CI 1.013-1.136), level 2 self-efficacy (AOR 2.162, 95% CI 1.550-3.014), and level 3 self-efficacy (AOR 1.842, 95% CI 1.120-3.029) had a higher COVID-19 vaccination rate. Participants from urban areas who had level 4 vaccine knowledge (AOR 0.667, 95% CI 0.476-0.935), level 2 trust in doctors (AOR 0.530: 95% CI 0.377-0.743), and level 3 trust in vaccine developers (AOR 0.638, 95% CI 0.425-0.959) had a lower COVID-19 vaccination rate. The results showed that rural participants who had a higher self-reported health condition (AOR 1.009, 95% CI 1.001-1.017), level 2 self-efficacy (AOR 2.524, 95% CI 1.753-3.633), and level 3 self-efficacy (AOR 4.162, 95% CI 2.369-7.315) had a higher COVID-19 vaccination rate. Participants from rural areas who had a university degree or above (AOR 0.619, 95% CI 0.427-0.898), level 2 vaccine knowledge (AOR 0.680, 95% CI 0.501-0.923), level 4 vaccine knowledge (AOR 0.522, 95% CI 0.351-0.776), level 2 susceptibility (AOR 0.591, 95% CI 0.416-0.840), level 2 benefits (AOR 0.537, 95% CI 0.376-0.765), level 3 benefits (AOR 0.539, 95% CI 0.312-0.933), level 2 trust in doctors (AOR 0.665, 95% CI 0.456-0.969), level 3 trust in doctors (AOR 0.545, 95% CI 0.340-0.874), level 4 trust in doctors (AOR 0.364, 95% CI 0.200-0.661), and level 4 trust in vaccine developers (AOR 0.489, 95% CI 0.253-0.945) had a lower COVID-19 vaccination rate (Table S3 in Multimedia Appendix 1).

**Propensity Score Matching Analysis**

In total, 3912 samples were captured using propensity score matching (PSM) from the 5780 participants. After PSM for sex, age, religion, career, self-reported health condition, educational level, COVID-19 infection, vaccine accessibility, vaccine knowledge, susceptibility, barriers, trust in doctors, and trust in vaccine developers, no statistically significant discrepancies were discerned between the urban and rural participants in all covariates (all P>.05). The balance test and common support domain of PSM for urban and rural samples are shown in Table S4 and Figure S1 in Multimedia Appendix 1. Based on the balanced samples, differences in COVID-19 vaccination rates among the urban and rural participants were assessed. As shown in Figure 2, the prevalence of COVID-19 vaccination among rural participants (14.57%; 95% CI 13.01-16.14) was still higher than that among urban participants (11.15%; 95% CI 9.75-12.54) by 3.42% (P<.05) after PSM. In addition, the vaccination rate of COVID-19 in uninfected participants was higher than that of participants who were infected in most age groups (Figure 3).
**Discussion**

**Principal Findings**

This study showed that 12.18% (704/5780) participants completed the fourth COVID-19 (second booster) vaccination, with 10.99% (363/3302) urban participants and 13.76% (341/2478) rural participants completing the fourth COVID-19 (second booster) vaccination, respectively. Vaccine knowledge, self-efficacy, and trust in the health care system had an impact on vaccination rates among both urban and rural residents. Educational level, self-reported health condition, susceptibility, and benefits had an impact on the vaccination rate among rural residents. According to the PSM analysis, a 42% disparity in vaccine coverage rates was confirmed between urban and rural participants. In addition, the vaccination rate in uninfected participants was higher than that of participants who were infected in most age groups.

Our study unveiled differences in vaccination coverage rates between urban and rural residents, with rural residents having a higher COVID-19 vaccination rate than urban residents. This finding is consistent with those of previous studies, not only for COVID-19 but also for other vaccines [35-37]. Prior research has shown that the vaccination rate in rural areas is higher than that in urban areas [38,39]. In a survey of men who have sex
with men in England, the vaccination rate for human papillomavirus (HPV) was higher in rural areas than in urban areas [38]. A COVID-19 vaccination coverage survey conducted among US veterans showed that the vaccination rate of rural veterans was higher than that of urban veterans [39]. On the other hand, some research results showed higher vaccination rates in urban areas compared to rural areas [40,41]. In a survey of COVID-19 vaccination in the United States, the findings showed that the vaccination rate in urban areas was higher compared to rural areas [40]. In a survey of influenza vaccination among adults in the United States, results showed that the vaccination rate was higher in cities than in rural areas [36]. A survey conducted among adolescents in the United States assessing the use of vaccination services for vaccines, such as MenACWY (meningococcal serogroups A, C, W, and Y), Tdap (tetanus, diphtheria, pertussis), HPV, and influenza, revealed that urban adolescents had a higher rate of utilization compared to their rural counterparts [41].

Differences in vaccination rates between urban and rural areas can be influenced by many factors [42]. We believe that there are several reasons that the rural residents had a higher COVID-19 vaccination rate than their urban counterparts. First, due to the unbalanced allocation of medical resources, rural residents have a higher mortality rate related to COVID-19, and they are more willing to be vaccinated for their own safety [43,44]. Second, with the development of urbanization in China, rural population mobility and the increase in migrant workers have led to a smaller rural population base, resulting in a higher vaccination rate [45]. Third, the Chinese government has begun paying more attention to health issues faced by the rural older adult population and has taken relevant measures to ensure that every rural older adult is vaccinated [46]. Finally, the decision to vaccinate is also easily influenced by information found on the internet. Because rural residents have lower education levels, they have higher trust in web-based information and a stronger intention to vaccinate than urban residents [47-49].

Our results showed that several factors, including vaccine knowledge level, self-efficacy, trust in medical staff, and trust in vaccine developers, had an impact on the decision to vaccinate among urban and rural residents. Studies have shown that an individual's comprehension of vaccine knowledge influences their decision to get vaccinated [50,51]. Individuals who lack sufficient vaccine knowledge may be hesitant about vaccination [52]. The same applies to other types of vaccines, such as influenza vaccines, where individuals with higher levels of vaccine knowledge are more likely to receive the influenza vaccine [53]. This is similar to the results of other studies showing that an individual's self-efficacy influences their decision to receive vaccinations. Higher self-efficacy encourages individuals to get vaccinated [54,55]. Similarly, trust in doctors and vaccine developers also affects an individual's decision to get vaccinated [56,57]. A survey in Germany showed that trust in the medical establishment impacts the intention to receive the COVID-19 vaccine [58]. Confidence in public service delivery also leads to favorable responses to mass immunization efforts [59].

In summary, when formulating a vaccination plan, it is important to focus on early promotion and publicity, highlighting the necessity, safety, effectiveness, and other relevant information about the vaccine. In addition, emphasis should be placed on improving residents' self-efficacy and on doctor-patient communication to increase vaccination rates [60].

Furthermore, our analysis revealed that in both urban and rural areas, the rate of fourth COVID-19 (second booster) vaccination was generally higher among residents without a history of infection compared to those who had been previously infected with COVID-19. SARS-CoV-2 constantly changes through mutations that generate variants [61]. A study showed that the antibody response produced after vaccination better neutralizes certain prevalent variants [62]. A statistically significant decreased risk for reinfection was found among individuals who were previously infected and then vaccinated versus those who were previously infected but remained unvaccinated [63]. In addition, there was a decreased risk for symptomatic disease among previously infected and vaccinated persons compared with those who were not vaccinated after infection [64]. Therefore, even if residents have a history of infection, they should be vaccinated again to safeguard against future infections. We suggest that when promoting booster vaccinations, it should be emphasized that individuals should receive the booster even if they have been infected with SARS-CoV-2 and have acquired antibodies.

**Strengths and Limitations**

This study was the first nationwide survey on the vaccination status of residents in China during the fourth COVID-19 (second booster) vaccination campaign. Given the complexity of factors influencing COVID-19 vaccination, we used PSM for the first time to mitigate confounding variables and quantify disparities in COVID-19 vaccination rates in rural and urban areas.

Additionally, this study used 1:1 matching with PSM, highlighting 2 advantages. First, the PSM method ensured that all indicators were collected from homogeneous respondents from both urban and rural areas. Second, 1:1 matching maximized the utilization of group information to ensure that individuals within each group were closely matched, enhancing the strength of the principal findings.

However, this study has numerous limitations that must be acknowledged. First, the assessment of COVID-19 vaccination relied on self-reported questionnaires, which inevitably introduced subjectivity, self-bias, and response bias in the data collection. Second, while the study employed the PSM framework to comprehensively collect COVID-19 vaccination covariates, it is possible that some unknown related factors were not collected.

**Conclusion**

The fourth COVID-19 (second booster) vaccination coverage rate among the Chinese population was exceptionally low, significantly lower than previous vaccine coverage rates. With COVID-19 infections still prevalent at a low level, efforts should be concentrated on enhancing self-efficacy and building trust in the health care system to expand vaccine coverage among the Chinese population. For rural residents, building confidence in vaccination benefits and improving overall health status must be prioritized. In urban areas, focusing on vaccinating a larger
proportion of people with COVID-19 and patients with chronic disease is crucial. In conclusion, the vaccination rate is higher in rural areas than in urban areas. Therefore, attention should be given to urban-rural differences and targeted vaccination plans should be formulated when implementing vaccination programs. The results of this study offer valuable insights for future responses to emerging major infectious diseases.

Abstract

Background: Heart failure (HF) is one of the most common initial manifestations of cardiovascular disease in patients with type 2 diabetes. Although smoking is an independent risk factor for HF, there is a lack of data for the incidence of HF according to changes in smoking behaviors in patients with type 2 diabetes.

Objective: We aimed to examine the association between interval changes in smoking behavior and the risk of HF among patients with type 2 diabetes.

Methods: We conducted a retrospective cohort study using the National Health Insurance Service database. We identified 365,352 current smokers with type 2 diabetes who had 2 consecutive health screenings (2009-2012) and followed them until December 31, 2018, for the incident HF. Based on smoking behavior changes between 2 consecutive health screenings, participants were categorized into quitter, reducer I (≥50% reduction) and II (<50% reduction), sustainer (reference group), and increaser groups.

Results: During a median follow-up of 5.1 (IQR 4.0-6.1) years, there were 13,879 HF cases (7.8 per 1000 person-years). Compared to sustainers, smoking cessation was associated with lower risks of HF (adjusted hazard ratio [aHR] 0.90, 95% CI 0.86-0.95), whereas increasers showed higher risks of HF than sustainers; heavy smokers who increased their level of smoking had a higher risk of HF (aHR 1.13, 95% CI 1.04-1.24). In the case of reducers, the risk of HF was not reduced but rather increased slightly (reducer I: aHR 1.14, 95% CI 1.08-1.21; reducer II: aHR 1.03, 95% CI 0.98-1.09). Consistent results were noted for subgroup analyses including type 2 diabetes severity, age, and sex.
Conclusions: Smoking cessation was associated with a lower risk of HF among patients with type 2 diabetes, while increasing smoking amount was associated with a higher risk for HF than in those sustaining their smoking amount. There was no benefit from reduction in smoking amount.

Introduction

Background

We are currently in a global type 2 diabetes public health crisis; an estimated 426 million individuals have type 2 diabetes [1]. Patients with type 2 diabetes are at increased risk of cardiovascular disease, and heart failure (HF) is one of the most common initial manifestations of cardiovascular disease in patients with type 2 diabetes [2]. Furthermore, type 2 diabetes contributes greatly to the increased morbidity and mortality associated with HF [3]. Thus, identifying modifiable risk factors for HF is critical in this population at high risk of type 2 diabetes.

Smoking is the leading predictor of death in patients with type 2 diabetes [4] and also an independent risk factor for HF and contributes to coronary heart disease, a major cause of HF [5-7]. In particular, smoking has been linked with several factors associated with left ventricular hypertrophy and cardiac dysfunction [8,9]. In addition, recent studies have found that individuals who smoke have at least twice the risk of developing HF than those who never smoke [8,10,11]. The risk is almost 4-fold among smokers who smoke ≥25 cigarettes per day [10].

Limited evidence is currently available, demonstrating that smoking cessation is associated with a reduced risk of incident HF and adverse events related to HF [5]. Some studies have reported that the risks of HF decreased over time after smoking cessation [11,12]. Those who ceased smoking for over 30 years experienced a similar HF risk to never smokers [13]. Former smokers also had similar cardiac structure and function as measured by echocardiography when compared with never smokers [9].

Given the increased risk for HF posed by type 2 diabetes, defining the effect of smoking cessation for HF in a type 2 diabetes cohort is important. Indeed, smoking and type 2 diabetes interrelate in the generation of cardiovascular events [14]. However, most studies have not focused on this high-risk population, and the HF incidence associations between current smoking and smoking cessation with type 2 diabetes are still unknown. Indeed, although smoking behavior can change over time, previous studies measured the association at only 1 timepoint [8-12,15,16], and there is a lack of data for the incidence of HF according to changes in smoking frequency among current smokers. One additional limitation of the previous studies is that the study population was comprised of only older individuals (aged ≥65 years [11]). Another limitation was the small sample sizes and the small number of outcomes of interest. The largest previous study had 3874 HF events among 188,167 individuals [10].

Study Design and Aim

To fill this knowledge gap, we conducted a nationwide cohort study to investigate whether changes in smoking behavior among patients with type 2 diabetes resulted in subsequent altered risk of HF. By measuring smoking behavior repetitively, we were able to investigate the effects of reduction, increase, and cessation of smoking.
