Abstract

Background: Stimulants are potent treatments for central hypersomnolence disorders or attention-deficit/hyperactivity disorders/attention deficit disorders but concerns have been raised about their potential negative consequences and their increasing prescription rates.

Objective: We aimed to describe stimulant prescription trends in Switzerland from 2014 to 2021. Second, we aimed to analyze the characteristics of individuals who received stimulant prescriptions in 2021 and investigate the link between stimulant prescriptions and hospitalization rates in 2021, using hospitalization as a potential indicator of adverse health outcomes.

Methods: Longitudinal and cross-sectional data from a large Swiss health care insurance were analyzed from all insureds older than 6 years. The results were extrapolated to the Swiss general population. We identified prescriptions for methylphenidate, lisdexamfetamine, modafinil, and sodium oxybate and calculated prevalences of each drug prescription over the period from 2014 to 2021. For 2021 we provide detailed information on the prescribers and evaluate the association of stimulant prescription and the number and duration of hospitalization using logistic regression models.

Results: We observed increasing prescription rates of all stimulants in all age groups from 2014 to 2021 (0.55% to 0.81%, 43,848 to 66,113 insureds with a prescription). In 2021, 37.1% (28,057 prescriptions) of the medications were prescribed by psychiatrists, followed by 36.1% (n=27,323) prescribed by general practitioners and 1% (n=748) by neurologists. Only sodium oxybate, which is highly specific for narcolepsy treatment, was most frequently prescribed by neurologists (27.8%, 37 prescriptions). Comorbid psychiatric disorders were common in patients receiving stimulants. Patients hospitalized in a psychiatric institution were 5.3 times (odds ratio 5.3, 95% CI 4.63 - 6.08, P<.001) more likely to have a stimulant prescription than those without hospitalization. There were no significant associations between stimulant prescription and the total length of inpatient stay (odds ratio 1, 95% CI 1 - 1, P=.13).

Conclusions: The prescription of stimulant medication in Switzerland increased slightly but continuously over years, but at lower rates compared to the estimated prevalence of central hypersomnolence disorders and attention-deficit/hyperactivity disorders/attention deficit disorders. Most stimulants are prescribed by psychiatrists, closely followed by general practitioners. The increased odds for hospitalization to psychiatric institutions for stimulant receivers reflects the severity of disease and the higher psychiatric comorbidities in these patients.

Introduction

Stimulants such as methylphenidate, lisdexamfetamine, and modafinil are highly potent pharmacologic treatment options for hypersomnolence disorders, including narcolepsy or attention-deficit/hyperactivity disorders/attention deficit disorders (ADHDs/ADDs).

ADHDs/ADDs are some of the most common diagnosed psychiatric disorders worldwide with a prevalence of 5.3% worldwide in the years of 1978 to 2010 among people aged 18 years or younger [1]. Prevalence can be different due to varying diagnostic methods per country. In Switzerland, a prevalence of 5.2% was found in children aged 7 to 17 years and in adult men a prevalence of 4% [2,3].

Prescriptions of stimulant drugs have been increasing at various rates over the past decades, with methylphenidate showing an 8.2 fold increase from 1996 to 2013 [4,5]. In the United States, amphetamine and methylphenidate increased from 5.6% to 6.1% in adults aged 20 years or older between 2014 and 2019 [4,5]. In New Zealand, 1.06% of adolescents received stimulants in 2016, an increase of 41.3% from 0.75% in 2011 [6]. Denmark observed a trend in stimulant prescriptions rising from 0.31 per 1000 person-years in 1996 to 7.29 per 1000 person-years in 2010 [7]. In Switzerland, data on stimulant prescription rates is scarce. A Swiss study from 2015 found a lifetime prevalence of stimulants and other substances enhancing cognitive abilities of about 1.4% in employees and students [8]. No sufficient data have, however, been collected in a nationwide study.

Stimulant medication is used for diseases often manifesting during childhood or adolescence and in many cases long-term pharmacological treatment throughout adulthood is needed. Prescription of stimulant agents in this age group is therefore of special interest to balance the need of medication and potential risk by over prescription or under prescription. Prescription of stimulants in young age groups increased from 0.02% to 0.26% over time in Asia, Australia, Europe, and North America in children and 0.003% to 1.48% in adults [9]. Among Swiss school children between 2002 and 2005, methylphenidate prescription increased from 0.74% to 1.02% for children aged 5 to 14 years [10].

This rapid prescription increase may indicate over prescription or even misuse. Misuse of stimulants is common, with up to 17% prevalence in US college students according to a meta-analysis. Misuse can lead to a range of negative consequences such as decreased appetite, insomnia, and increases in heart rate and blood pressure with increased long-term cardiovascular risk and possibly lead to increased hospitalization rates [11-13].

Properly identifying current stimulant prescription rates and discovering the prescription patterns or circumstances of their prescription (prescriber, package size, and comorbidities) may help to further identify alarming prescription increases and potential misuse in Switzerland, and the possible causes.

We therefore had 2 objectives: first, we aim to describe the rate of stimulant prescriptions in Switzerland from 2014 to 2021, focusing on both minors and adults. We hypothesize that the rate of stimulant prescriptions in Switzerland, similar to international trends, has increased over the last decade, with the highest prescription rates being recorded in 2021.

Second, we aimed at analyzing the characteristics of individuals who received stimulant prescriptions in 2021. This analysis will include factors such as comorbidities, age, and prescription details such as package size and health care providers most frequently issuing these prescriptions. Our hypotheses are that recipients likely mirror the characteristics of ADHDs/ADDs and central hypersomnolence disorders, most are minors with few comorbidities, and the likelihood of receiving a prescription decreases with age. Specialists, particularly psychiatrists and neurologists, are expected to be the primary prescribers.

Lastly, this study aims to investigate the link between stimulant prescriptions and hospitalization rates in 2021, using hospitalization as a potential indicator of adverse health outcomes. Given the expected increase in stimulant prescriptions until 2021, the hypothesis is that individuals prescribed stimulants may have a higher risk of hospitalization, particularly if prescription rates are on the rise.

Methods

Study Design

This study is a longitudinal and cross-sectional analysis of the Helsana health care insurance data of around 1.5 million people in Switzerland insured over the period of 2014 to 2021. Helsana belongs to a group of the biggest insurance companies in Switzerland and insures 14% of the Swiss population, with insureds in 26/26 cantons of Switzerland. Data describes general information on the insured persons and all their invoices for health services directed to the insurance. These invoices are representative of all health care costs of the insureds, except for the costs that were not sent as invoices to the insurance and paid by the insureds themselves (ie, over the counter drug costs and dental costs). We decided to provide more detailed descriptive statistics for data in 2021, since it was the most recent data available to us and presumably with the highest rate of stimulant prescription.

Identification of Drugs

We identified the drug invoices through their Anatomical Therapeutic Chemical code, which classifies chemical substances based on their therapeutical properties. The identification was performed for the following drugs: methylphenidate (N06BA04), lisdexamfetamine (N06BA12), modafinil (N06BA07), and sodium oxybate (N07XX04) which is a specific medication for narcolepsy treatment and used to estimate the treatment prevalence of narcolepsy patients in the dataset. Pitolisant (N07XX11) was identified too as a stimulant with specific use for narcolepsy but was excluded from further analysis, as it was only authorized for use in 2020 but had neglectable low prescription rates. We also identified the Swissmedic code of the medications, which is specific not only for the chemical substance but also the producer of the medication and package size. These drugs are only accessible through prescription by a medical professional and reimbursed by the insurance company. Overlapping prescriptions of the 4

XSL•FO
RenderX

drugs was defined as 1 prescription of one of the 4 drugs invoiced with at least one of the other drugs once or multiple times during the year of 2021.

Variables

The dataset consisted of all insureds aged ≥6 years with information on their age, sex, region of language, and region of residence. We categorized 5 age groups (6 - 17 y, 18 - 35 y, 36 - 65 y, 66 - 75 y, and 76+ y). We divided the insureds` residential regions into "rural," "intermediate," and "urban" subgroups according to the Swiss federal office for statistics.

The insureds had various health care plans including standard care and managed care models (eg family physician model). These health insurance plans were identified and categorized into standard care and managed care (ie, the combination of telemedical care and general practitioner [GP] care).

Chronic health condition status was identified by substance prescriptions related to chronic diseases. This was carried out according to approaches developed in previous research on the dataset [14]. We classified 22 different chronic conditions and categorized them into psychiatric, cardiologic, rheumatologic, respiratory comorbidities, or all other.

All invoices for hospitalization (ie, hospitals of all sizes providing acute care and psychiatric clinics) and the length of stay were included in our analysis.

Based on the medical prescriber who issued the invoices, several prescriber categories were defined: GP, psychiatrist, neurologist, other specialists (combining all other prescribers, such as nonspecific group practices, cardiologists, pulmonologists, rheumatologists, etc). Only health care personnel in Switzerland are allowed to prescribe medication. We further grouped them into "only prescriber" of the medication when a describer prescribed all medication exclusively for single individuals, ">50% prescriber" meaning more than 50% of the prescriptions for single individuals were invoiced by the prescriber, and "rest" with all other prescription proportions.

Within the prescriber categories (inpatient psychiatry, inpatient acute, and rehabilitation, nursing) we differentiated between inpatient (during a hospital stay) and outpatient invoices.

Statistical Analysis

For our first objective we provide descriptive statistics for prescription trends among different age groups across the years 2014 and 2021 by identifying individuals in the dataset with at least one prescription of the predefined drugs. To obtain representative data for Swiss population we extrapolated these data by current residency numbers and populations statistics of the Federal Statistical Office.

For our second objective we restricted the descriptive statistics to the year 2021 and provide detailed information on age, sex, region of residence, health insurance status, comorbidities, prescribers, and package size. Logistic regression models were performed to evaluate the association of at least one stimulant prescription versus no prescription (ie, the dependent variable is prescription yes or no), number of hospitalization, and length of stay, adjusted for age, sex, region of residence, health insurance status, and number of chronic diseases for the year 2021.

All data management, graphic generation, and analysis was performed with the statistics program R (version 4.2.1; R Foundation).

Data Availability

The authors were permitted access to the data by collaboration with the insurance companies research team. The datasets generated and analyzed during this study are available from the corresponding author on reasonable request. AI was not used in any way in data generation, analysis, and presentation of results.

Ethical Considerations

According to ethical and legal regulations in Switzerland no ethical approval or patient consent was needed for this study, as all data complied with privacy regulations and personal data protection, data was anonymized when presented to the research team. The Swiss Human Research Act (REQ-2017 - 00280) did not apply to this project. The exploratory statistical analyses of the feasibility test complied with the Swiss Federal Law on data protection. All data were anonymized and deidentified prior to the performed analysis to protect the privacy of patients, physicians, and hospitals. According to the national ethical and legal regulation, an ethical approval was not needed because the data were pre-existing and deidentified. Since data was anonymized, no consent of patients was required.

Results

Trend of Stimulant Prescription Per Year

As baseline we refer to the prescription period in 2014. Between baseline and 2021, on average 14% of Swiss people were at any time insured with the Helsana Group.

In the year 2014, 0.55% (42,848 insureds) of insured people of any age received at least 1 stimulant agent (or stimulant prescription). This number increased up to 0.8% (66,113 insureds) in the year of 2021. The largest growing percentage of stimulus prescriptions were in the youngest age group with an increase of prescription of 0.6 percentage points (17,972, 1.8% to 24,982, 2.4%) between 2014 and 2021 (Table 1).

Between 2014 and 2021, 32,2418 packages of methylphenidate were the most prescribed stimulant, followed by 46,074 packages of lisdexamfetamine, 8797 packages of modafinil, and 3115 packages of sodium oxybate. We found a prescription increase of all identified medications in younger and middle age groups over the years of 2014 to 2021, extrapolated by the Swiss population. The increase in prescription was steady in age groups aged 36 - 65 years, whereas in other age groups prescription stagnated from 2018 to 2020, with a steep increase from 2020 to 2021.

Methylphenidate prescription increased overall in all age groups with a steady increase in insureds aged 36 - 65 years. All other age groups experienced a steep increase after 2020. Only insureds aged 66 - 75 years and 76+ years ever experienced a

XSL•FO
RenderX

smaller prescription rate than at baseline in 2014, with a drop to 89% (664/746) in 2017 (Figure 1).

Lisdexamfetamine prescription was low at baseline and increased steadily in all age groups with great increase from 0 prescriptions at baseline to 39 in insureds aged 60 - 65 years. Smaller increase in prescription was seen in age groups aged 66 - 75 years and 76+ years (Figure 1).

Prescription rates of modafinil—only prescribed to few—increased the most in the youngest age group (6 - 17 y). The prescribing trend in this age group strongly fluctuated. From its highest peak in 2019 rates decreased from around 1100% (66/6) to slightly less than 300% (15/6) prescription compared to the baseline in 2014. In 2021, modafinil was most frequently prescribed in age groups aged 6 - 17 years and 76+ years. All other age groups had only a moderate increase in modafinil prescriptions over the years 2014 to 2021.

Sodium oxybate overall increased the most in insureds aged 18 - 35 years and 6 - 17 years from 100% to 175% in 2021. Prescription rates for sodium oxybate only decreased overall in insureds aged 66 - 75 years. Age groups aged 36 - 65 years and 76+ experienced a similar prescription trend over the years with overall increase but declining prescription rates after 2020.

Table . Proportions of Swiss insureds with at least 1 stimulant agent or other narcolepsy treatment prescription within age groups for each year between 2014 and 2021.

Factors Associated With Prescription in 2021

Characteristics of Stimulant Users

Most stimulant receivers in the year of 2021 were male representing 61% (42,803/70,396) of our population. Only modafinil was more often prescribed to women than to men with 55% (970/1776) female receivers. The highest proportion of prescriptions was provided to people living in urban areas with a proportion of 67% (46,968/70,396) of all stimulants compared to intermediate and rural area residents. Managed care was the preferred health care plan for patients receiving stimulants with 72% (50,513/70,396) receiving. A total of 45% (798/1776) of all modafinil receivers had 3+ chronic illnesses, 55% (775/1399) of those had psychiatric comorbidities, followed by cardiological and rheumatological diseases. A total of 42% (49/121) of sodium oxybate users had no comorbidities. Most common chronic illness in sodium oxybate users was psychiatric (43/72, 60%) or cardiologic (31/72, 43%). Additionally, half of the methylphenidate users had comorbidities (28,619/57,128, 50%, 28,509 had no chronic illness identified) with psychological (14,396/28,619, 50%) and other chronic conditions (7034/28,619, 25%) as the most common identified chronic diseases. Similar results were found for lisdexamfetamine users, that is, 43% (4908/11,371) users had no comorbidities and psychological (3556/6463, 55%) and other (1989/6463, 31%) comorbidities were the most common chronic diseases (Table 2).

Prescribers

In 2021, psychiatrists were the most frequent prescribers with 42.4% (28,057/66,172) of all the prescribed medications. Lisdexamfetamine (6222/11,396, 54.6%), followed by methylphenidate with 41.3% (23,553/57,038) were mainly prescribed by them. By contrast modafinil and sodium oxybate were rarely prescribed by psychiatrists as 19% and 4.2% (336/1769 and 5/120), respectively. If chosen as a prescriber, psychiatrists are often the only source of prescription for 82.9% (23,267/28,057) insured individuals of all medication of 2021.

The second most frequent prescribers were GPs, with a similar high proportion of 41.3% (27,323/66,172) of all drug prescriptions. More specifically 42.3% (24,127/57,038) methylphenidate was prescribed by GPs followed by modafinil (639/1769, 36.1%), lisdexamfetamine (3529/11,396, 31%), and smaller proportions for sodium oxybate (10/120, 8.3%). GPs were most often the exclusive prescribers of the medications (22,578/27,323, 82.6%). Only 10.4% (2834/27,323) of prescriptions by GPs shared the prescribing job with other medical specialists.

Neurologists were rarely prescribers of stimulants or narcolepsy treatments, as only 1.1% (748/66,172) of all prescriptions were invoiced by them. Only sodium oxybate was the most frequent (37/120, 30.8%) medication prescribed by neurologists. If chosen as the prescriber, they are often the only source (558/748, 74.6%) from which individuals received the prescriptions in 2021 (Table 3).

Concerning invoices handed in by hospitals or psychiatric clinics or rehabilitation facilities, they only made up a small part of overall stimulant invoices. An exception is sodium oxybate, of which 45.1% (60/133) of invoices are issued by an acute clinic, rehabilitation clinic, or nursing home (Table 3).

Association of Stimulant Use and Outcomes

We found an association with patients receiving a stimulant or narcolepsy treatment prescription and increased hospitalizations in a psychiatric facility (odds ratio [OR] 5.30, 95% CI 4.63 - 6.08, *P*<.001). In contrast, there was a negative association between stimulant prescription and hospitalization in an acute medical care facility (OR 0.77, 95% CI 0.73 - 0.82, *P*<.001). There were no significant associations between stimulant prescription and the total length of inpatient stay (OR 1, 95% CI 1 - 1, *P*=.13; Table 4).

Table . Regression model of predicting the outcomes of hospitalization and length of stay in Swiss insureds, who received stimulant prescription in the year 2021.

When only focusing on methylphenidate or lisdexamfetamine compared to a balanced sample of nonstimulant users, we found a positive association between their prescription and hospitalization in a psychiatric facility (OR 6.85, 95% CI 5.89 - 7.99, *P*<.001). No significant association was found between the prescription rate and the total inpatient length of stay (OR 1, 95% CI 1 - 1, *P*=.1). Hospitalization in an acute medical care facility was less likely (OR 0.76, 95% CI 0.71 - 0.8, *P*<.001) to prescribe methylphenidate or lisdexamfetamine (Table 5).

Table . Regression models of predicting the outcomes of hospitalization and length of stay in Swiss insureds who received stimulant prescriptions in the year 2021. Prescriptions of methylphenidate or lisdexamfetamine are shown in the left columns, prescriptions of modafinil or sodium oxybate are shown in the right columns.

When only focusing on modafinil or sodium oxybate compared to a balanced sample of nonstimulant users, we found a positive association between their prescription and hospitalization in a psychiatric facility (OR of 2.15, 95% CI 1.17-4.23, *P*=.02). We found no significant association between total inpatient length of stay (OR 1, 95% CI 1 - 1, *P*=.80) and hospitalization in an acute medical care facility (OR 1.23, 95% CI 0.96 - 1.56, *P*=.10; Table 5).

Discussion

Summary

We found an increasing trend of stimulant and narcoleptic drug prescriptions in Switzerland from 0.6% to 0.8% over the years 2014 to 2021. Most stimulants are prescribed continuously with more than 5 packages in 1 year per insured to underaged individuals with no comorbidities. Psychiatrists and GPs are often the prescribers of stimulants, much more frequently than neurologists.

Context in Research

Compared with data on global stimulant prescription rates, our results are notably lower, showing a smaller increase in prescription rates than in the United States (5.6% - 6.1%), New Zealand (0.75% - 1.06%), and Denmark (0.03% - 0.73%) [5-7]. Given the ADHDs/ADDs prevalence rates of 4% in adult men and 5.3% in children in Switzerland [2,3], compared to a worldwide prevalence of between 5% and 11.4% [1,15,16], it is reasonable to interpret the lower Swiss prescription rates as either an indication of underprescription or as lower stimulant misuse rates in Switzerland [15]. Even when taking all stimulants together, current prescription rates do not reach the prevalence rate of ADHDs/ADDs in Switzerland. The fact that

XSL•FO
RenderX

ADHDs/ADDs are also treated nonpharmacologically is another argument for assuming that our result of low prescription prevalence is lower than the disease prevalence. Unfortunately, there are no data that quantifies the extent of drug or nonpharmacological treatment for ADHDs/ADDs and thus could help define the normal gap between prescription rate and disease prevalence. Our distribution of prescription rates corresponds to the disease distribution in different age groups, with prescriptions and prevalence of ADHDs/ADDs being higher in the younger age groups [17]. The distribution of prescriptions by gender reflects the current disease prevalence of ADHDs/ADDs, as we found a slightly lower proportion of females than males, in line with another summary by Thapar and Cooper [17]

Stimulants were predominantly prescribed in urban areas. A higher population compared to rural areas, a higher density of prescribing physicians, and a higher number of hospitals specialized in diagnosis and treatment of these diseases in urban settings may account for this predominant prescription pattern. Vice versa underprescription in rural areas could be due to reduced access to adequate health care services.

Methylphenidate was by far the most prescribed stimulant agent, followed by lisdexamfetamine, a new stimulant showing promising results for treatment of ADHDs/ADDs [18]. The prescription characteristics were very similar between the two stimulants, with lisdexamfetamine more often prescribed to older adults than methylphenidate. This shows that lisdexamfetamine is possibly used as a second medication after methylphenidate was prescribed in the young and did not give continuous results while the patients aged.

Prescriptions were most frequently issued by psychiatrists. Since methylphenidate and lisdexamfetamine are standard treatment for the psychiatric diseases ADHDs and ADDs, this prescription pattern makes sense from a health provider perspective and is confirmed by other findings about prescribers of stimulants [19].

Prescription characteristics of sodium oxybate should reflect its specificity for narcolepsy because it is not indicated for any other disease. Here we find most of the prescriptions in middle aged groups and fewer in children and teenagers, with a nearly even distribution between women and men. This grouping does not match with the expected narcolepsy features of young patients with a possible second peak in the late forties [20]. The lack of prescription in young patients is best explained by a missed or severely delayed diagnosis of narcolepsy, which is in line with the recently published delayed diagnosis for Switzerland and other European countries [21,22]. Surprisingly, neurologists who diagnose and treat narcolepsy, are rarely the patients' prescription source, even for highly specific and not easy to handle medication, such as sodium oxybate. Multiple reasons may account for this prescription practice, among them is the lower barrier for receiving an appointment with GPs before prescriptions expires, compared to neurologists.

We found no significant change in the odds of at least one stimulant prescription in patients hospitalized in an acute hospital but a significant increase in the odds of patients hospitalized in a psychiatric facility. This reflects the fact that ADHDs/ADDs are often overlapping or comorbid with other psychiatric diseases which can lead to hospitalization, such as addiction, disruptive disorders, anxiety disorders, or bipolar disorders [23-26], and by the severity of disease.

We assume that our data is representative for Switzerland, since we analyzed claims data extrapolated to the entire population from one of the biggest insurance companies in Switzerland, with a nearly equal distribution across the country. As stimulant agents are only accessed through prescription, we were able to register all invoices for the medication in question in real world; therefore, our data minimize sampling bias and recall bias that frequently influence the accuracy and reliability of retrospective studies.

Limitations

This study is an analysis of health insurance claims data, which does not contain any information on the clinical reason of why a medication was indicated. We therefore could not distinguish between prescriptions according to current treatment guidelines and prescriptions of pharmacological treatment for diseases without proper diagnosis.

We identified prescribers by Zahlsteller register (registered number for medical personel allowed to bill insurance companies) number and medication prescription pattern, which may lead in some cases to misclassification, as some physicians share Zahlsteller register numbers in group practices and GPs go sometimes through additional training as psychiatrists or neurologists.

Conclusion

The prescription of stimulants and sodium oxybate in Switzerland increased slightly but continuously over the past years, but at lower rates compared to the estimated prevalence of central hypersomnolence disorders and ADHDs/ADDs. Most stimulants are prescribed by psychiatrists, closely followed by GPs. The increased odds for hospitalization to psychiatric institutions for stimulant receivers reflects the severity of disease and the higher psychiatric comorbidities in these patients.

Abstract

Background: The global aging population faces increasing risks of cognitive and physical decline, yet the bidirectional and nonlinear dynamics between these domains remain poorly understood.

Objective: This study aims to investigate the bidirectional and nonlinear associations between cognitive function and physical performance in older adults and to identify threshold effects and population subgroups at elevated risk.

Methods: This multicenter study of 20,671 older adults in China analyzed the bidirectional asymmetric and threshold-response associations between cognitive and physical function using logistic or linear regression and restricted cubic spline, with subgroup and interaction analyses.

Results: The study revealed an asymmetrical bidirectional relationship between cognitive function and physical performance, with cognitive impairment having a stronger association with physical function (Short Physical Performance Battery [SPPB], odds ratio [OR] 2.45, *P*<.05 vs 1.16,*P*=.051; gait speed: OR 2.36,*P*<.05 vs 1.89, *P*<.050). Restricted cubic spline analysis identified 3 key inflection points at Mini-Mental State Examination (MMSE) scores of 19, 24, and 29. When MMSE <24, cognitive improvement significantly protected physical performance (SPPB: OR 0.86, 95% CI 0.84 - 0.87; gait speed: OR 0.84, 95% CI 0.82 - 0.85). The critical intervention window was between MMSE 19 - 24 (SPPB, OR 0.66, 95% CI 0.57-0.77). At MMSE ≥24, balance protection remained significant (OR 0.69, 95% CI 0.68 - 0.70), but overall physical performance showed diminished effects, with SPPB demonstrating a weaker, marginal association (*P*=.051). A paradoxical reversal effect was observed for gait speed (OR 1.05, 95% CI 1.04 - 1.07). High-income (OR 5.24, 95% CI 3.91 - 7.02) and high-education subgroups (OR 3.98, 95% CI 1.48 - 10.70) exhibited heightened vulnerability.

Conclusions: This study demonstrates a bidirectional, asymmetric relationship between cognitive function and physical performance, identifies a nonlinear threshold effect, and highlights population heterogeneity.

KEYWORDS

cognitive function; physical performance; threshold effect; aging; bidirectional association

Introduction

The global population is aging at an accelerated rate, with the proportion of individuals aged ≥60 years projected to reach 2.1 billion by 2050 [1]. This demographic shift amplifies the dual burden of cognitive decline and physical disability, which synergistically exacerbate risks of falls, hospitalization, and dependency [2-4]. Cognitive function, encompassing memory, executive control, and information processing, deteriorates progressively from mild cognitive impairment to dementia. Concurrently, physical performance, as measured by the Short Physical Performance Battery (SPPB) [5], declines linearly with age, marked by reduced balance, gait speed, and muscle strength [6,7]. Critically, lower SPPB scores predict mortality and institutionalization [8-11], while cognitive impairment further compounds these risks through bidirectional pathways [4].

Extensive research [12-14] has demonstrated that impaired physical performance can significantly affect cognitive function, with slow gait speed being recognized as an early indicator for predicting cognitive decline and dementia. In addition, cognitive decline can also lead to impaired physical performance, with studies highlighting a bidirectional relationship between physical and cognitive health [15,16]. However, critical gaps persist. First, balance and muscle strength, key components of physical function, are rarely examined in relation to cognition. Second, evidence on bidirectionality is contradictory; one study [17] reported cognitive effects on gait speed but not balance, another linked balance deficits to cognitive impairment [18], and longitudinal data suggest cognitive decline drives physical deterioration more strongly than the reverse [15,19]. Third, prior studies predominantly assume linear relationships, neglecting potential thresholds where cognitive deterioration disproportionately escalates physical disability—a limitation obscuring precision intervention targets.

Our nationwide multicenter study explores bidirectional, nonlinear links between cognition and physical performance in older adults, identifying critical cognitive thresholds that increase physical risks. These findings guide precision interventions for dual decline, offering scalable strategies to reduce disability in aging populations.

Methods

Study Design

This study adopts a nationwide cross-sectional design to explore the relationship between cognitive function and physical performance, following the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) guidelines [20].

Participants

A multistage stratified sampling method was used to recruit 20,868 community-dwelling adults aged 60+ years from 6 provinces in China (Fujian, Guangdong, Nanjing, Sichuan, Xinjiang, and Guizhou) between January and August 2022. The required sample size was calculated using the formula , yielding a sample size of 13,830 for a 95% CI with a margin of error of 0.05 and SD of 3 [21]. To account for invalid questionnaires, a 20% adjustment was made, resulting in a final sample size of 17,288. Inclusion criteria: participants aged 60+ with adequate communication and complete assessments. Exclusion criteria: participants with severe physical disabilities preventing SPPB testing or acute medical conditions (eg, postoperative recovery).

Measures

Physical Performance

Physical performance was evaluated using the SPPB, a validated tool from the National Institute on Aging [22]. The SPPB comprises 3 subtests: balance, gait speed, and muscle strength, each component scored 0 - 4, with a total score ranging from 0 to 12. Participants were classified as having normal (10–12) or poor (0 - 9) physical performance [8,23]. In addition, a score of 4 in any subtest indicated normal function, while 0 - 3 suggested impairment [24].

Balance Test

Three standing positions were feet-together, semi-tandem, and tandem. Point distribution was as follows: participants held the position for >10 seconds in feet-together or semi-tandem, earning them 1 point; standing for 3 - 9.9 seconds in the tandem position earned 1 point, while standing for ≥10 seconds earned 2 points.

Gait Speed Test

The 2.44-meter walking speed test assigned scores based on speed: <0.43 m/s (1 point), 0.44 - 0.60 m/s (2 points), 0.61 - 0.77 m/s (3 points), and ≥0.78 m/s (4 points).

Muscle Strength Test

The Five-Times-Sit-to-Stand Test (FTSST) was used to assess lower limb muscle strength, with scores based on the time taken: 16.70 - 60 seconds (1 point), 13.70 - 16.69 seconds (2 points), 11.20 - 13.69 seconds (3 points), and ≤11.19 seconds (4 points).

Cognitive Function

Cognitive function was evaluated using the Mini-Mental State Examination (MMSE) [25], with the Chinese version validated by Wang et al [26] showing high test-retest reliability (intraclass correlation coefficient=0.91). The MMSE assesses five cognitive domains: orientation (time and place), memory (immediate and delayed recall), attention and calculation, language, and visuospatial ability. Scores ranged from 0 to 30, with higher scores indicating better cognitive function. The criteria for normal cognitive function vary by educational level: (1) middle school or above: score >24 (normal), ≤24 (impairment); (2) primary school: score >20 (normal), ≤20 (impairment); (3) illiteracy: score >17 (normal), ≤17 (impairment).

XSL•FO
RenderX

Covariates

Sociodemographic characteristics and health behaviors were considered covariates. Sociodemographic characteristics included age, sex (male and female); BMI (<18.5, 18.5 - 23.9, ≥24 kg/m^2), educational level (primary school or below, middle school, high school or vocational school, and college or above), marital status (married vs other, including divorced, widowed, or single), number of children (none, 1, 2, 3, or more), residential area (rural, urban), living arrangement (living alone, living with relatives, living with a spouse), geographic region (eastern or western), data source (home-based or community health service center), and monthly household income (<5000 or ≥5000).

Health behaviors included the presence of chronic diseases (defined as having at least one: hypertension, coronary heart disease, cerebrovascular disease, or diabetes), long-term medications use (none, 1 - 2, or ≥3), alcohol consumption (never, formerly, or currently), smoking status (never, formerly, or currently), weekly social participation frequency (none, 1 - 3, or ≥4 d), weekly exercise frequency (none, 1 - 3, or ≥4 d), self-reported social support (insufficient, inadequate, or sufficient), and self-reported visual and hearing impairment (no or yes).

Data Collection

A designated assessor was assigned to each research site to oversee data collection using the "Jingyice Elderly Function Assessment Platform," a WeChat (Tencent) mini-program developed by the research team. All assessors, registered nurses from community health centers, nursing homes, or hospitals, received uniform online training on the platform and study procedures. Before assessment, participants were informed of the study's aims and procedures, and written informed consent was obtained. Assessors conducted face-to-face interviews and functional tests, entering responses and test results (eg, cognitive assessments and physical performance measures) into the mini-program, which synchronized data to a secure web-based platform for real-time monitoring. To ensure data quality, the backend recorded the time and duration of each evaluation, and the research team reviewed data weekly, focusing on submissions completed between 10 PM and 8 AM or within 15 minutes. Questionnaires and test records with incomplete scale data, >15% missing demographic information, patterned responses, or logical inconsistencies were excluded.

Statistical Analysis

Continuous variables are presented as mean SD, while categorical variables are summarized as frequencies (%) via Pearson chi-square tests. To assess bidirectional associations, cognitive function (MMSE score) was modeled as both continuously and categorically (impaired or normal), whereas physical performance (SPPB total score) was analyzed as a continuous variable in linear regression and dichotomized (poor or normal) in logistic regression. All models were adjusted for covariates listed in the "Measures" section.

Nonlinear relationships were assessed using restricted cubic splines (RCS), with the optimal model fit chosen based on the Akaike Information Criterion from models with 3 to 6 knots. A 2-stage segmented linear regression approach identified threshold effects using the likelihood ratio test, and the optimal threshold was determined via an iterative grid search.

Subgroup analyses by sociodemographic factors (eg, age, education, and income) were conducted, and interaction effects were assessed using product terms (eg, MMSE×income). All analyses were performed with R (version 4.2; R Core Team) and SPSS (version 25.0; IBM Corp). Statistical significance was set at a 2-tailed P value <.05.

Ethical Considerations

This study was approved by the Ethics Committee of Beijing Hospital (approval number 2023BJYYEC-446 - 02). Written informed consent was obtained from all participants prior to participation. All data were anonymized, participants received no compensation, and no identifiable images are included in the article or supplementary materials. The study was conducted in accordance with the ethical standards of the Declaration of Helsinki.

Results

Baseline Characteristics

A total of 20,671 participants were included in the final analysis, with a mean age of 72.19 (SD 12.238) years; 48% (9931/20,671) were male and 52% (10,740/20,671) were female (Table 1). The majority of participants (12,703/20,671, 61.5%) had low education levels. Cognitive impairment was identified in 14.4% (2975/20,671), and 62.2% (12,857/20,671) exhibited poor physical performance with a mean SPPB score of 8.4 (SD 2.94). Domain-specific impairments were prevalent: 26.7% (5521/20,671) had balance deficits, 67.3% (13,906/20,671) showed reduced gait speed, and 58.4% (12,071/20,671) demonstrated muscle weakness, with gait speed showing the most pronounced deficit (mean score 2.34, SD 1.36; Figure 1). Furthermore, there were also differences in SPPB physical performance across various covariate subgroups (Table 1).

Bidirectional Relationship Between Cognitive Function and Physical Performance

Association of Cognitive Function on Physical Performance

Logistic regression models, adjusted for sociodemographic and behavioral covariates, demonstrated graded protective effects of cognitive function on physical performance. For each 1-point increase in the MMSE score, the risk of poor SPPB decreased by 7% (odds ratio [OR] 0.93, 95% CI 0.92 - 0.93). Improvements were also observed in specific domains, including balance (OR 0.90, 95% CI 0.89 - 0.90), gait speed (OR 0.94, 95% CI 0.94 - 0.95), and muscle strength (OR 0.90, 95% CI 0.90 - 0.91). Individuals with cognitive impairment had nearly double the risk of poor physical performance compared to those without (OR 2.45, 95% CI 2.22 - 2.70), with gait speed (OR 2.36, 95% CI 2.13 - 2.62) and muscle weakness (OR 2.23, 95% CI 2.03 - 2.44) more strongly linked to cognitive impairment (Table 2).

[a]SPPB: Short Physical Performance Battery.

[b]FTSST: Five-Times-Sit-to-Stand-Test.

[c]Crude model: unadjusted covariates.

[d]MMSE: Mini-Mental State Examination.

[e]*P*<.001.

[f]Model 1: adjusted for sociodemographic characteristics adjusted for sociodemographic characteristics (age, gender, BMI, education level, marital status, number of children, residential category, living arrangement, geographic region, data source, monthly household income).

[g]Model 2: adjusted for Model 1 variables plus health and behavioral factors(chronic diseases, types of long-term medication, alcohol consumption, smoking, frequency of weekly social activities, frequency of weekly exercise, self-reported social support, and self-reported vision and hearing impairments).

Linear regression analyses corroborated these findings. After full adjustment, each MMSE point increase predicted higher physical performance scores (SPPB: β=0.18, 95% CI 0.17 - 0.19; balance: β=0.05, 95% CI 0.05 - 0.06; gait speed: β=0.04, 95% CI 0.04 - 0.05; FTSST: β=0.08, 95% CI 0.07 - 0.08; all *Ps*<.001). Cognitive impairment persisted as a robust predictor of physical decline (SPPB: β=−1.35, 95% CI −1.46 to −1.24, *P*<.001) (Table S1 in Multimedia Appendix 1).

Association of Physical Performance on Cognitive Function

After adjusting for all covariates, the association of physical performance on cognitive function was further examined, revealing a significant impact on cognitive health (Table 3). Better physical performance, particularly better gait speed scores (OR 0.82, 95% CI 0.79 - 0.85), was associated with a reduced risk of cognitive impairment. The SPPB impairments showed a marginal association with cognitive status (OR 1.16, 95% CI 1 - 1.34; *P*=.051), while balance impairments (OR 1.71, 95% CI 1.57 - 1.88), gait speed limitations (OR 1.89, 95% CI 1.66 - 2.16), and muscle weakness (OR 1.66, 95% CI 1.47 - 1.86) were significantly associated with cognitive impairment (*P*<.001).

Balance group	1.71 (1.57 - 1.88)[b]
Gait speed group	1.89 (1.66 - 2.16)[b]
FTSST group	1.66 (1.47 - 1.86)[b]
SPPB group	1.16 (1.00 - 1.34)

[a]Crude model: unadjusted covariates.

[b]*P*<.001.

[c]FTSST: Five-Times-Sit-to-Stand-Test.

[d]SPPB: Short Physical Performance Battery.

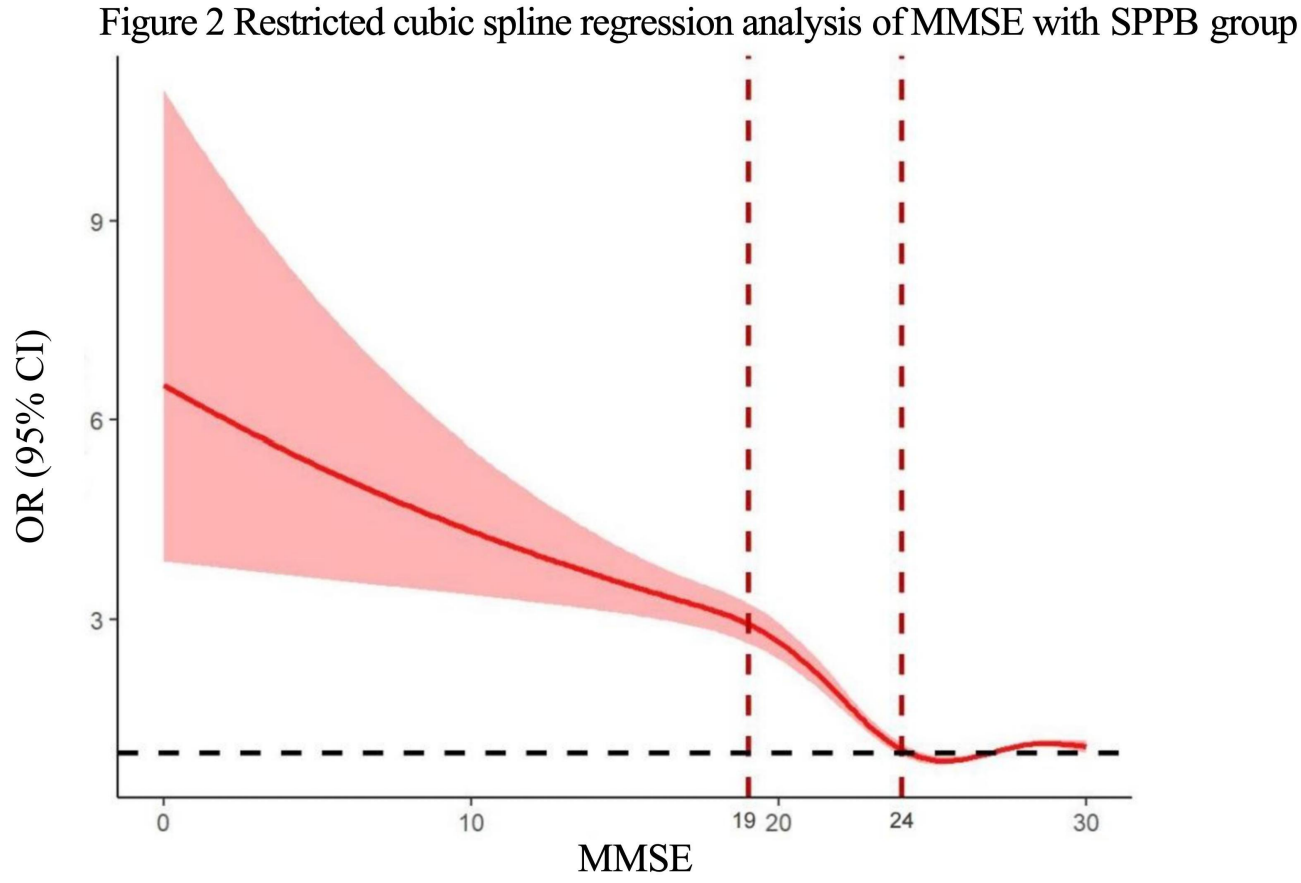
[e]*P*<.05.

[f]Model 1: adjusted for sociodemographic characteristics adjusted for sociodemographic characteristics (age, gender, BMI, education level, marital status, number of children, residential category, living arrangement, geographic region, data source, monthly household income).

[g]Model 2: adjusted for Model 1 variables plus health and behavioral factors (chronic diseases, types of long-term medication, alcohol consumption, smoking, frequency of weekly social activities, frequency of weekly exercise, self-reported social support, and self-reported vision and hearing impairments).

Linear regression analysis confirmed our findings. In the fully adjusted model, higher scores in the SPPB, balance, gait speed, and muscle strength were associated with higher MMSE scores, while individuals with impaired physical performance had lower MMSE scores (*P*<.001), with balance ability showing the strongest association (β=1.01, 95% CI 0.96 - 1.07). Those with balance impairments had an average MMSE score 2.02 points lower than those with normal balance (95% CI −2.15 to −1.89; Table S2 in Multimedia Appendix 1). These findings highlight

XSL•FO
RenderX



gait speed and balance as key biomarkers for cognitive risk stratification.

This study shows a significant bidirectional and asymmetric relationship between cognitive function and physical performance. Cognitive impairment strongly affects physical performance, increasing the risk of SPPB (OR=2.45, 95% CI 2.22 - 2.70), gait speed (OR=2.36, 95% CI 2.13 - 2.62), muscle strength deficits (OR=2.32, 95% CI 2.03 - 2.44), and balance impairments (OR=1.16, 95% CI 1 - 1.34). In contrast, physical performance has a weaker association with cognitive function, with balance ability (OR 1.71, 95% CI 1.57 - 1.88) being the strongest, and gait speed (OR 1.89, 95% CI 1.66 - 2.16), muscle strength (OR 1.66, 95% CI 1.47 - 1.86), and SPPB showing weaker, marginal associations (*P*=.051). This asymmetry suggests that maintaining cognitive health can better support physical function in older adults, offering dual benefits for both.

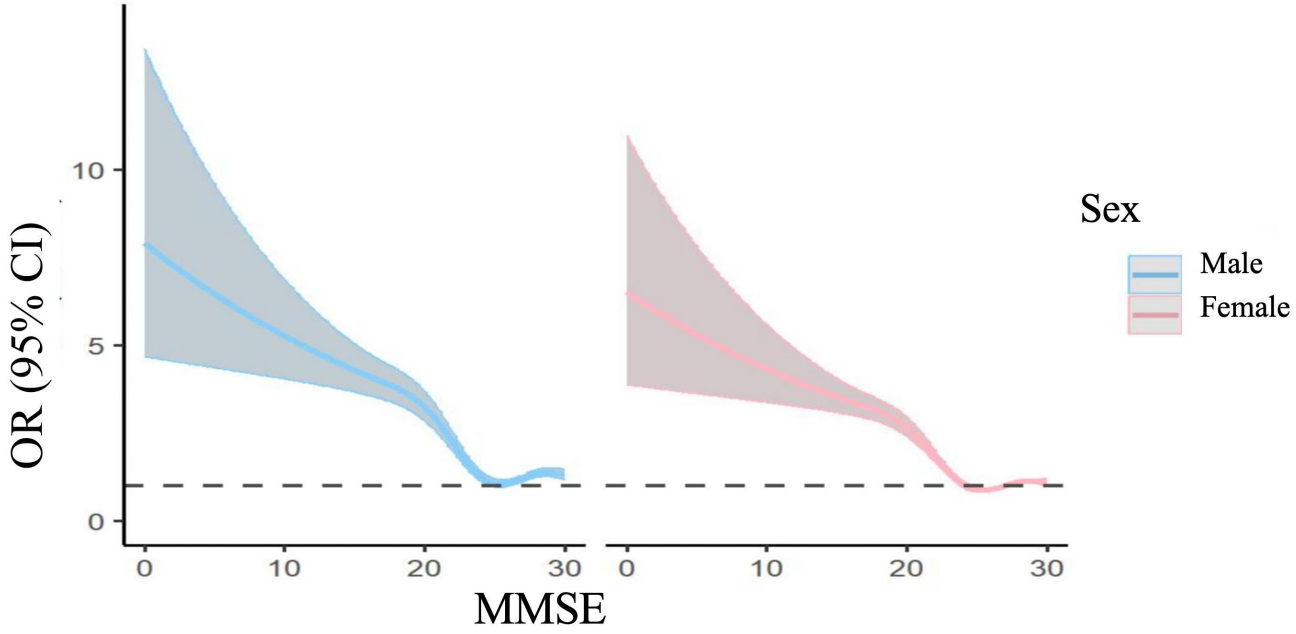
RCS and Threshold Effect Analysis of Cognitive Function on Physical Performance

RCS analyses showed significant nonlinear associations between cognitive function (MMSE) and physical performance measures (SPPB, gait speed, balance, and muscle strength; Figure 2 ; Figures S1-S3 in Multimedia Appendix 1). These relationships remained consistent in gender and education-stratified analyses (Figures 3 and 4; Figures S1A-S3B in Multimedia Appendix 1), confirming robustness across demographic subgroups.

Figure 2. Restricted cubic spline regression analysis of Mini-Mental State Examination with Short Physical Performance Battery group. MMSE: Mini-Mental State Examination; SPPB: Short Physical Performance Battery.

XSL•FO
RenderX

Figure 3. Gender stratification. MMSE: Mini-Mental State Examination.



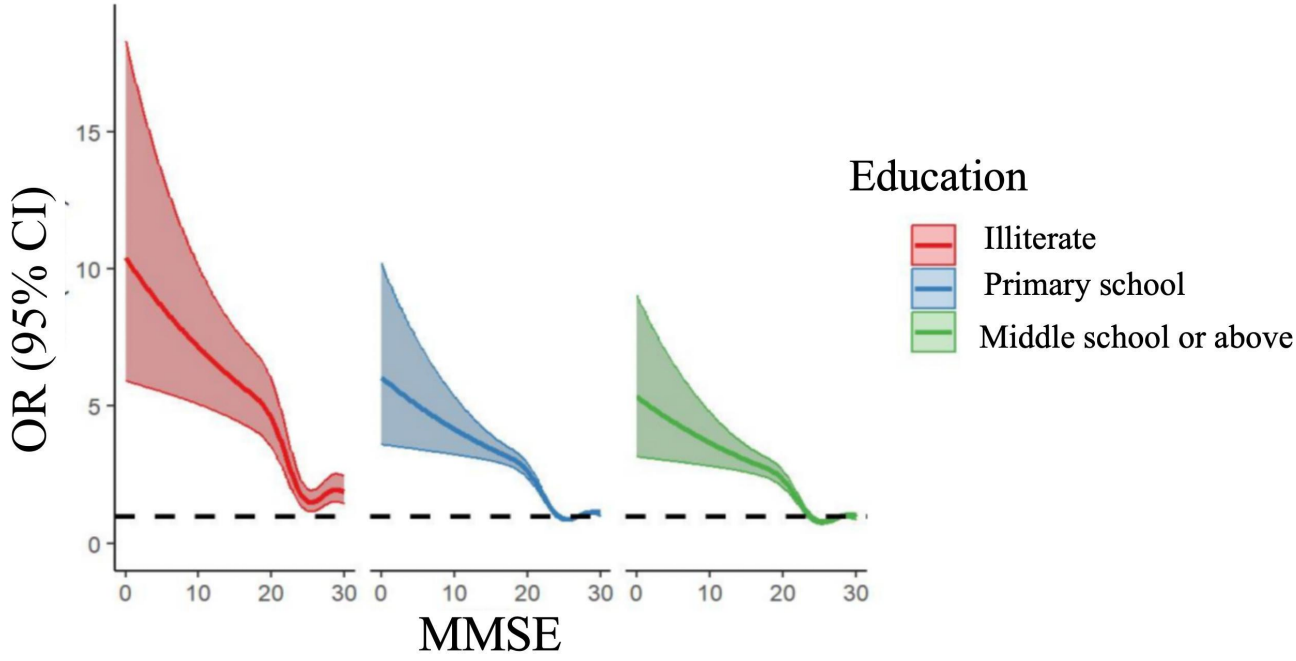


Figure 4. Education level stratification. MMSE: Mini-Mental State Examination.

This study revealed threshold effects and dynamic changes between cognitive function and physical performance using RCS analyses. Significant inflection points were found at MMSE=24 for overall performance (SPPB), balance, and gait speed, and at MMSE=29 for FTSST (Table 4). In the impaired cognitive period (MMSE <24), cognition improvements protected physical performance, reducing the risk of SPPB by 14% (OR 0.86, 95 CI 0.84 - 0.87), gait speed by 16% (OR 0.84, 95% CI 0.82 - 0.85), and balance by 4.8% (OR 1.05, 95% CI 1.03 - 1.06). In the optimal cognitive period (MMSE ≥24), the protective association remained significant for balance (risk reduced by 31%, OR 0.69, 95% CI 0.68 - 0.70) but weakened for overall performance (SPPB,*P*=.054), and a marginal positive association was observed for gait speed (OR 1.05, 95% CI 1.04-1.07), likely because cognitively intact individuals were already near the upper limit of normal performance, rather than reflecting a harmful relationship. The protective association on muscle strength persisted, with the most significant impact at MMSE >29 (risk reduced by 32%; OR 0.68, 95% CI 0.63 - 0.74).

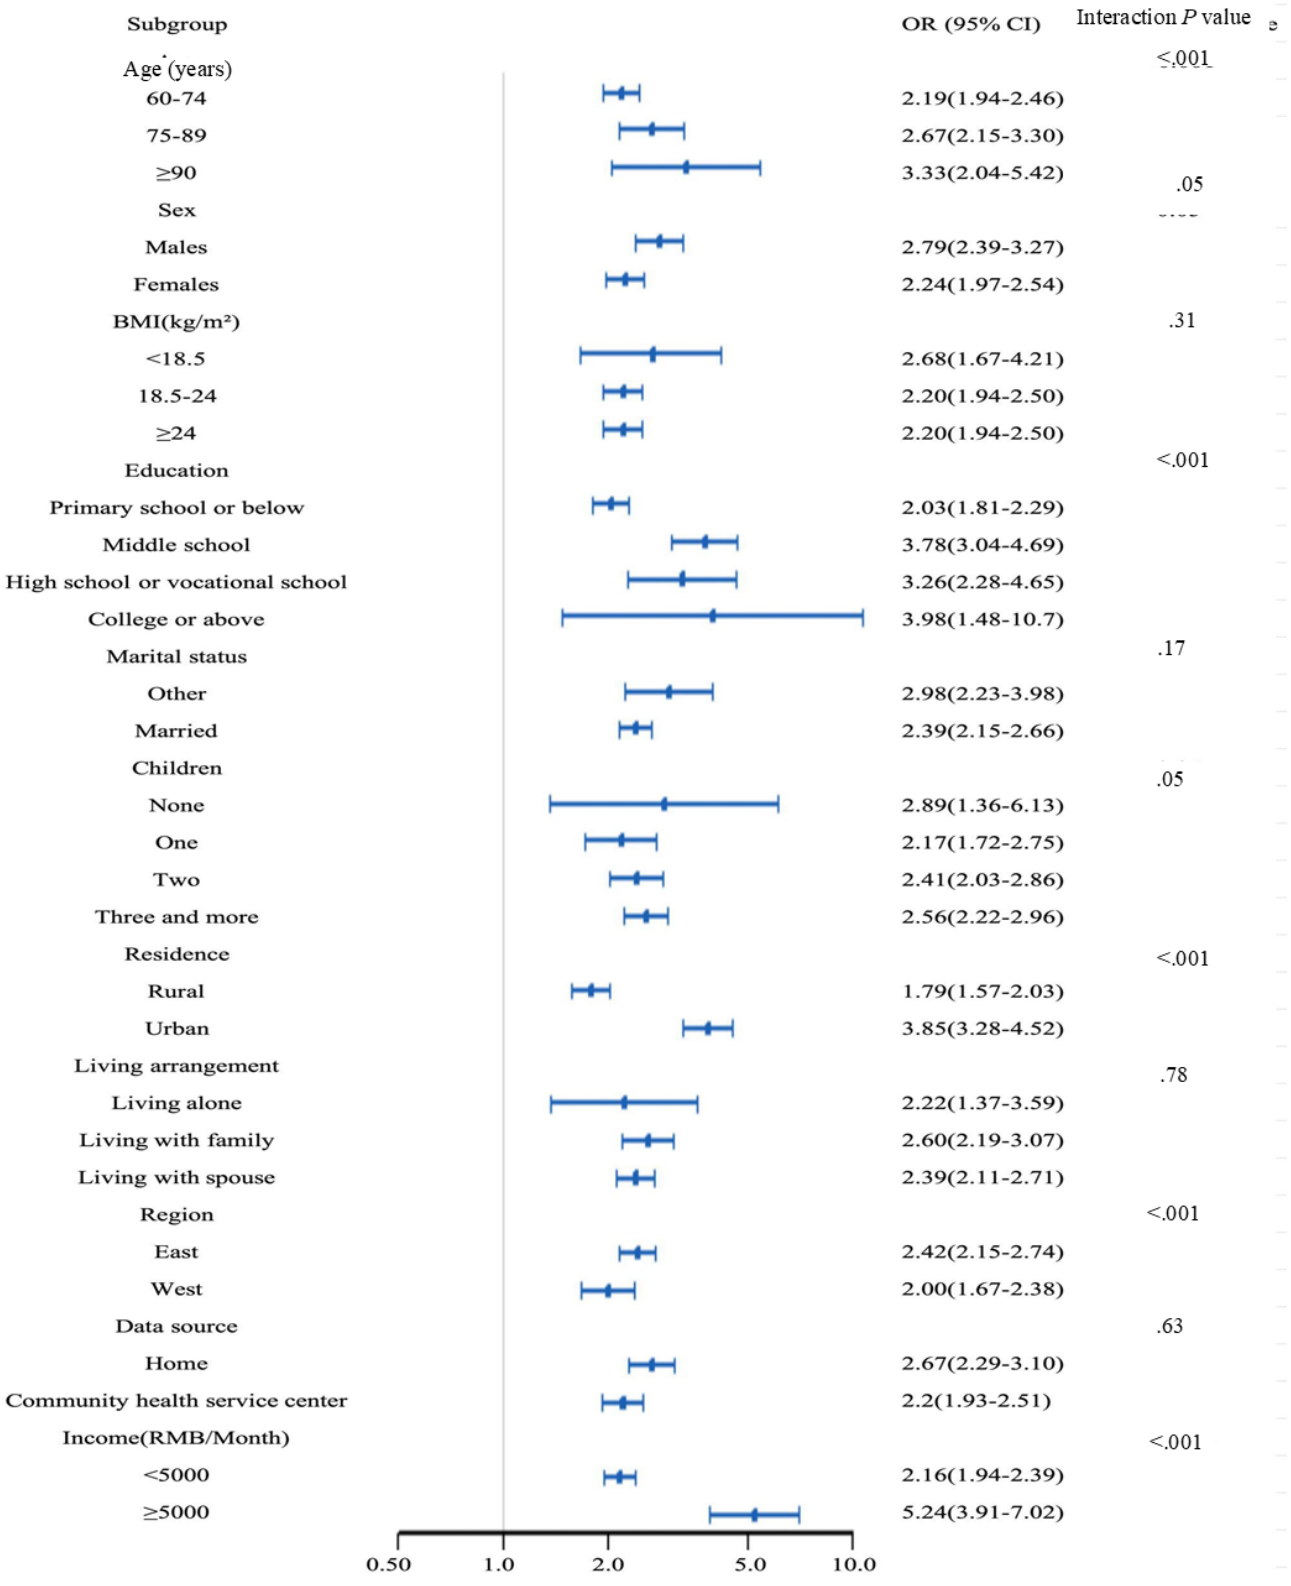
[b]Adjusted for age, gender, body mass index (BMI), education level, marital status, number of children, residential category, living arrangement, geographic region, data source, monthly household income, chronic diseases, types of long-term medication, alcohol consumption, smoking, frequency of weekly social activities, frequency of weekly exercise, self-reported social support, and self-reported vision and hearing impairments.

[c]SPPB: Short Physical Performance Battery.

[d]Not applicable.

[e]FTSST: Five-Times-Sit-to-Stand-Test.

In addition, we identified a second inflection point in over physical performance (SPPB) at MMSE=19 using second derivative analysis (Figure S4 in Multimedia Appendix 1). After adjusting for confounding factors, the MMSE 19 - 24 group showed a 34% lower risk of physical performance impairment (SPPB) compared to the MMSE <19 group (OR 0.66, 95% CI 0.57 - 0.77) (Table S3 in Multimedia Appendix 1).



Subgroup Analysis and Interaction Analysis

Subgroup analyses revealed significant heterogeneity in the association between cognitive impairment and physical performance across demographic and socioeconomic strata (Figure 5). The strongest associations were observed in older adults aged ≥90 years (OR 3.33, 95% CI 2.04 - 5.42), those with college or above level education (OR 3.98, 95% CI 1.48 - 10.70), high-income households (≥5000 yuan per month [US $1 = ¥7.113]: OR 5.24, 95% CI 3.91 - 7.02), and urban

XSL•FO
RenderX

residents (OR 3.85, 95% CI 3.28 - 4.52). Interaction models further demonstrated graded effects: the detrimental impact of cognitive impairment increased with advancing age (β=0.45 - 0.71 per age group), higher education (β=0.55 - 0.77), and socioeconomic advantage (β=0.64 - 0.85 for urban residency and high income), suggesting these factors may amplify vulnerability to physical decline (Table S4 in Multimedia Appendix 1).

Discussion

Principal Findings

This study advances the understanding of the cognitive-physical performance relationship through 3 key innovations. First, we demonstrated a bidirectional yet asymmetric relationship: cognitive impairment exerted a stronger detrimental association on physical function than vice versa. Second, our nonlinear threshold analysis revealed critical inflection points (MMSE=19, 24, 29), defining distinct intervention phases. The MMSE 19‐24 range marked a critical intervention window where cognitive improvements maximally protected physical function, whereas MMSE >24 signaled a ceiling effect for global physical performance and a paradoxical reversal in gait speed, aligning with the cautious gait hypothesis. Finally, subgroup analyses uncovered a socioeconomic paradox: higher socioeconomic status (SES), indicated by advanced education, income, and living in an urban area, exhibited heightened vulnerability to physical functional decline. These innovations combine mechanistic research with clinical applications, offering strategies to address the disability burden in an aging society.

Our findings corroborate and extend the evidence on cognitive-physical interdependencies, while challenging the prevailing assumption of symmetrical reciprocity. Longitudinal studies have shown cognitive function as a predictor of physical decline, particularly fall risk [27] and gait deterioration [28]. A cross-sectional study [29] found that increased cognitive impairment severity leads to worsened balance control, consistent with our observation of bidirectional associations. Notably, while Li et al [28] reported a bidirectional relationship between cognitive function and gait speed, our analysis revealed a critical asymmetry: cognitive impairment exerted a disproportionately stronger impact on physical disability than the reverse. This divergence challenges the notion of equivalent bidirectional association and positions cognitive preservation as a pivotal strategy to disrupt the disability cascade.

This study found a nonlinear relationship between cognitive function and physical performance across individuals of various genders and educational levels. It identified 3 protective thresholds at scores of 19, 24, and 29, offering key evidence for developing precise intervention strategies to maintain functionality in older individuals. At the stage where cognitive function may be impaired (MMSE <24), it significantly protects all physical performance dimensions, with the greatest association observed in the 19‐24 score range, suggesting it should be a target for clinical intervention. These results align with previous research [30], which found a positive correlation between cognitive and physical function, suggesting cognitive intervention can delay physical decline. Our study further quantifies cognitive function threshold points. Thus, it is recommended to assess functional levels at this stage and conduct adaptive dual-task training targeting both cognitive and physical functions to enhance both [31].

In the optimal cognitive function stage (MMSE ≥24), physical performance exhibits dimension-specific changes: overall physical performance (SPPB) shows a clear “ceiling effect,” suggesting that further improvements in physical performance may have reached physiological limits, leaving limited room for cognitive function to contribute. Gait speed, however, exhibits an unusual reversal phenomenon, consistent with George et al [32] inverted U-shaped gait-cognition curve, attributed to the “cautious gait hypothesis.” This hypothesis suggests that older adults with higher cognitive function consciously regulate their movements, resulting in a more cautious and controlled walking pattern [33]. Cognitive function exerts a continuous protective association on balance ability, most pronounced when MMSE >29. This finding supports the view of Kuan et al [34] that early-stage mild cognitive impairment, regardless of musculoskeletal function, can impact balance, potentially due to the weakening of the cortical-vestibular network in individuals with cognitive impairment, particularly in key brain areas involved in integrating visual, auditory, and vestibular signals, correlating with the decline in balance ability [35].

Interestingly, our subgroup and interaction analyses revealed a socioeconomic paradox:

older individuals with higher SES, as measured by education and income, exhibited amplified risks of concurrent cognitive-physical decline, contradicting the conventional SES-health gradient. This counterintuitive association necessitates a multidimensional interpretation rooted in the Cognitive Reserve Hypothesis. While enhanced neurocompensatory mechanisms in high-SES populations may initially delay clinical manifestations of cognitive impairment [36], prolonged compensatory demands could deplete neural resources, precipitating accelerated physical deterioration once pathological thresholds are breached—a” double-edged sword” effect [37]. Moreover, behavior patterns related to occupational characteristics warrant attention. This group may have maintained an imbalanced “high cognitive load-low physical activity” state throughout their careers, leading to accelerated degeneration of motor function neural circuits [38]. These insights advocate for dual-target interventions prioritizing simultaneous cognitive reinforcement and physical activation in high-SES older adults, particularly during the identified critical window (MMSE 19‐24), to counteract reserve depletion trajectories.

Of course, our study has several limitations. First, as this study uses a cross-sectional design, future research should adopt longitudinal approaches to explore causal relationships and developmental trajectories. Second, due to the feasibility constraints of large-scale studies, many variables were assessed via self-report measures, potentially introducing reporting bias. Third, we did not directly measure occupational type or physical activity levels using validated instruments. Future studies are recommended to further investigate the “high cognitive load–low physical activity” hypothesis. Finally, this study evaluated overall cognitive function but did not assess specific cognitive domains, such as memory or executive function. Future research should investigate these domains to better understand the relationship between cognitive function and physical performance.

XSL•FO
RenderX

Conclusions

This study demonstrates a bidirectional, asymmetric relationship between cognitive function and physical performance, identifies a nonlinear threshold effect, and highlights substantial population heterogeneity. These findings offer novel insights into the interaction between cognitive decline and physical disability, particularly in older individuals, and provide guidance for developing targeted interventions for high-risk subgroups in an aging society.

Abstract

Background: Voluntary counseling and testing (VCT) for HIV/AIDS is characterized by several key components, including pretest and posttest counseling, as well as the formulation of individualized risk reduction plans. Adolescents, including secondary school students, represent a population particularly vulnerable to HIV infection due to various biological, psychological, and social factors.

Objective: The present study aimed to assess the knowledge, perception, attitude, and barriers toward VCT for HIV/AIDS among secondary school students in Iringa Rural District, Tanzania.

Methods: A descriptive cross-sectional study was conducted in Iringa Rural District, targeting secondary school students. A random sampling technique was employed to select the participating schools. Data were collected through self-administered questionnaires, which were completed solely by students who voluntarily consented to participate in the study. Data management and analysis were carried out using Epi Info™ 7.2 software.

Results: The study involved 127 secondary school students aged 15 - 25 years from three schools in Iringa Rural District, with 69 (54.3%) female and 58 (45.7%) male participants. All students were aware of the VCT services. The primary source of VCT information was school-based education (92, 33.3%), followed by radio/TV (65, 23.6%), friends/family (46, 16.7%), and magazines (35, 12.7%). Some students also cited health centers, hospitals, and religious seminars (38, 13.8%) as sources. Knowledge of VCT increased with education level, with Form IV students showing the highest awareness (67, 55.4%). Most students understood VCT's main purpose: 88 (50.6%) of them linked it to knowing one's HIV status, 58 (33.3%) to HIV prevention, and 28 (16.1%) to preparing for test results. No misconceptions about VCT's purpose were reported. Attitudes toward HIV testing showed that stigma concerns increased with age, particularly among those aged 17 - 18 years, where 26 (60.5%) were unwilling to be identified as HIV-positive. Nonetheless, 65 (51.2%) students supported knowing their HIV status and 86 (54.4%) said they would inform others and change their behavior after testing. Key barriers to VCT uptake included fear of stigma (71, 50.6%), lack of confidentiality, insufficient trained personnel, and poor infrastructure.

Conclusions: The study found that secondary school students in Iringa Rural District had generally high awareness and positive attitudes toward VCT, mainly informed through schools and media. Awareness increased with education level, but willingness to disclose test results remained low due to stigma and confidentiality concerns. While many students were ready to take responsible actions after testing, barriers such as fear, misinformation, and limited access to services persisted. The study emphasizes the need for improved school-based VCT programs, better-trained staff, community education, and strategies to address stigma and infrastructural gaps.

Introduction

Since the year 2000, approximately 38.1 million individuals have contracted HIV, and about 25.3 million have lost their lives due to illnesses related to AIDS. Despite better access to antiretroviral therapy and health care in many parts of the world, the AIDS epidemic still claimed 1.2 million lives in 2014 alone, and globally, youth aged 15 - 24 years account for nearly one-third of new HIV infections [1,2]. Despite this, uptake of voluntary counseling and testing (VCT) services among youth remains low. The majority of these cases occurred in sub-Saharan Africa, which is home to 66.6% of all people living with HIV, and most HIV transmissions happen through heterosexual sex, from mother to child during childbirth or breastfeeding, and through unsafe blood transfusions [1,3]. Moreover, since there is no effective vaccine or cure, VCT for HIV has served as a key entry point, providing access to a range of prevention and care services, including antiretroviral therapy.

Sub-Saharan Africa's burden is particularly evident in countries like Tanzania, where rural regions face distinct challenges. HIV/AIDS remains a major public health concern in Tanzania, with approximately 1.6 million people living with HIV as of 2023 [4]. While the national prevalence stands at 4.7% among adults aged 15 - 49 years [5], some regions, particularly in the southern highlands, report significantly higher rates. Iringa Region, including its rural districts, has one of the highest HIV prevalence rates in the country, reported at 11.1% after Njombe region, which is the leading region with highest HIV infection of 12.3% [6]. This high prevalence underscores the need for targeted interventions, especially among vulnerable populations such as secondary school students. Rural communities in Tanzania experience unique challenges related to HIV, including limited access to health care services, stigma, and lower awareness levels [7]. These issues are compounded by traditional gender norms, low literacy rates, and poverty, which hinder HIV prevention and testing efforts [8].

VCT is a critical component in HIV prevention and control strategies. However, its uptake among secondary school students in Tanzania remains suboptimal. Studies have shown that while awareness of VCT services is relatively high, actual utilization is low due to factors such as fear of positive results, stigma, and lack of perceived risk [9,10]. In Iringa Rural District, specific data on VCT uptake among secondary school students is limited, highlighting the need for focused research in this demographic to inform targeted interventions. Adolescents and young people, particularly those in secondary schools, represent a vulnerable group in the HIV epidemic. In rural Tanzania, multiple structural, social, and cultural factors inhibit youth from accessing VCT.

A predominant barrier to VCT uptake is the fear of receiving a positive HIV result, which is often associated with social stigma. Students express concerns about being ostracized by peers and community members if they tested positive, leading to reluctance in seeking testing services. This fear is compounded by misconceptions about HIV transmission and the belief that a positive result equates to imminent death [11-13]. Students often worry about the confidentiality of their test results, fearing that health workers may disclose their status to others in the community. This concern is particularly acute in tight-knit rural communities where privacy is hard to maintain. Ensuring strict confidentiality protocols and training for health workers is crucial. In tight-knit rural communities, concerns about privacy can discourage individuals from utilizing local testing services [11].

The absence of youth-friendly VCT services tailored to adolescents' needs and concerns contributes to low uptake. Health facilities may not provide an environment that is welcoming or comfortable for young people, deterring them from seeking services. Implementing adolescent-focused approaches and involving youth in service design can enhance engagement. Many health facilities are not tailored to meet the specific needs of adolescents, making them less likely to seek testing [11]. Geographical barriers and inadequate health care infrastructure in rural areas hinder access to testing facilities [14]. In rural districts like Iringa, access to VCT services is hindered by geographical barriers, including long distances to health facilities and lack of transportation. Additionally, the operating hours of VCT centers may not align with students' schedules, further limiting accessibility. A significant number of youths underestimate their risk of HIV infection, leading to lower testing rates. Many secondary school students in rural Tanzania perceive themselves to be at low risk of HIV infection, even when engaging in high-risk behaviors. This low-risk perception diminishes the perceived need for testing, thereby reducing VCT uptake [11,15]. Similar youth-focused barriers have been reported in other low-resource settings, underscoring the global challenge of VCT uptake [16-18].

Employing diverse strategies to fight against HIV and minimize its effects on individuals, families, and society is crucial. These approaches encompass VCT, provider-initiated counseling and testing, diagnosing HIV in infants and young children, providing family care and partner testing, detecting and managing sexually transmitted infections, offering counseling on safer sex and risk reduction, promoting male circumcision, and implementing targeted interventions for sex workers and individuals who identify as homosexual [19].

While there is some data on the awareness and usage of VCT services in a few regions in Tanzania, there is a noticeable gap in research regarding the knowledge, attitudes, and perceptions of secondary school students toward VCT services. This is worrisome because the secondary school setting is conducive to engaging in risky HIV behaviors, like unprotected sex. Secondary school students are especially susceptible to these behaviors due to their inclination toward sexual experimentation, involvement with multiple partners, and inconsistent condom use [20].

To our knowledge, there is a lack of studies assessing knowledge, attitudes, and perceptions among secondary school students in Iringa Rural District. Also, the provision of VCT services in Iringa has been inconsistent, and even when these services are accessible, the number of people utilizing these, especially youths, has been relatively low. To ensure effective VCT services, it was essential to evaluate the awareness, usage, and willingness of secondary school students toward VCT

XSL•FO
RenderX

services. Consequently, this study focused on examining the knowledge, attitudes, and perceptions of secondary school students toward VCT services in the Iringa Rural District in the Iringa region.

Methods

Study Setting and Study Design

This study employed a cross-sectional descriptive study to assess the knowledge, perception, and attitude toward VCT among secondary school students in Iringa Rural District. This study was done at three secondary schools (Lipuli, Kalenga, and Kidamali) from September to December 2023. Iringa Rural District is one of the four districts of the Iringa Region of Tanzania, East Africa. It is bordered to the north by the Dodoma Region, to the east by Kilolo District and encircles Iringa Urban District, to the south by the Mufindi District, to the southwest by the Mbeya Region, and to the northwest by the Singida Region. Iringa district has a cold climate, which favors agricultural activities and livestock keeping; thus, the majority of the people are peasant farmers. Original occupants are the Hehe tribe, but due to the migration of people, the district has been occupied by people of different ethnicity.

Study Population

The target population was students from three secondary schools and comprised both males and females aged between 15 and 25 years. This age group was chosen due to their vulnerability to HIV infection and the relevance of VCT in their health-seeking behavior.

Sample Size

Sample size was calculated from the formula $N=Z^2PQ/E^2$, where N=minimum sample size; Z=standard normal deviation, usually set at 1.96, which corresponds to 95% CI; Q=(1–P); P=the prevalence of HIV/AIDS in Iringa region (9.1%) [Tanzania HIV Impact Survey (THIS 2022)–National AIDS Control Programme, Tanzania [21], and US President'S Emergency Plan for AIDS Relief (PEPFAR) Tanzania Country Operational Plan (COP 2023)–PEPFAR [22]], E=standard error of estimate, 0.05. Therefore, the sample size required was 127.

Sampling Technique

A multistage sampling technique was used. Stage 1: Three wards were randomly selected from Iringa Rural District. Stage 2: From each ward, one public secondary school was selected using simple random sampling. Stage 3: Within each school, a list of eligible students was obtained and systematic random sampling was used to select participants proportional to the school size.

Inclusion Criteria

The inclusion criteria for the study were secondary school students, aged between 15 and 25 years, willing to be interviewed and participate in the study, enrolled in Form I-IV.

Exclusion Criteria

This study excluded students who were below 15 years and above 25 years of age, who declined to participate in the study, who were absent on the day of data collection, and who had cognitive impairments that limited their ability to participate.

Data Collection

Data Collection Tools

The data were collected from secondary school students using self-administered questionnaires. The questionnaire was developed based on validated tools from similar studies and included the following sections: demographics (age, sex, grade level), knowledge on HIV and VCT, perception of risk and benefits of VCT, attitudes toward VCT services, and barriers to accessing VCT services. The questionnaire was pretested among 20 students from a school not included in the main sample to assess clarity and reliability.

Data Collection Procedure

Data collection was conducted by trained research assistants fluent in both Kiswahili and English. Prior to administration, participants were informed about the study objectives and provided with instructions, allowing them to make an informed decision about their own participation. Their questions were addressed. Participants were informed that their involvement in the study was voluntary. To ensure anonymity, participants were instructed not to provide their names on the questionnaire forms. Confidentiality was also assured and confidentiality guarantees given.

Data Entry and Analysis

Coding, entry, cleaning, and analysis of data were done using Epi Info™ 7.2 software (Centers for Disease Control and Prevention). Descriptive statistics (frequencies and percentages) were computed.

Ethical Considerations

Ethical approval of the study was obtained from the Review Board of the University of Dodoma (DJ.232/238/0 - 28) and Iringa district council (FA.255/265/01/PART 'C;/72), with a waiver of written informed consent. To maintain confidentiality, unique identification codes were assigned to the study subjects. The principal investigators securely stored and controlled access to the data, limiting it to authorized personnel only. The study was performed in accordance with the University of Dodoma ethical guidelines for research involving human subjects and the ethical standards of the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards.

Results

Characteristics of the Study Participants

A total of 127 students from three secondary schools aged 15 - 25 years were enrolled in the study. Out of the 127 students, 69 (54.3%) and 58 (45.7%) students were females and males, respectively. Participants were mostly within the adolescent age group. A majority of 72 (56.7%) students were aged 17 - 18 years, followed by 41 (32.3%) aged 15 - 16 years, and only 14 (11%) aged 19 - 20 years. This age range is particularly significant, as adolescents are a key population for HIV prevention strategies due to their increased vulnerability and evolving risk behaviors. In terms of academic level, the largest

XSL•FO
RenderX

proportion of students 70 (55.1%) were in Form IV, followed by Form III 48 (37.8%), and a small group 9 (7.1%) in Form II. This distribution indicates that most participants were senior students who are likely to have greater exposure to sexual and reproductive health education. All the students were aware of VCT services. The source of information on VCT for HIV/AIDS among students was determined. The primary source of information that involved describing whether they have heard of VCT or not was their schools, accounting for 92 (33.3%) participants. Radios or TV were the second common source, with 65 (33.3%) participants obtaining information from this medium. Friends or family were another significant source, with 46 (16.7%) participants relying on them. Magazines were the least utilized source, with only 35 (12.7%) participants obtaining information from them. On the other hand, approximately 38 (13.8%) participants reported obtaining information from health centers, hospitals, mosques, and church seminars (Table 1).

Table . Demographic characteristics of the study group.

Characteristics	n (%)
Gender	
Female	69 (54.3)
Male	58 (45.7)
Age (years)	
15-16	41 (32.3)
17-18	72 (56.7)

[a]VCT: voluntary counseling and testing.

Knowledge Toward the Importance of VCT Services

Table 2 and Table 3 present two key elements: (1) the level of students' awareness of the importance of VCT services by education level and (2) students' understanding of specific reasons why VCT services are important.

Table . The students' knowledge about the importance of VCT[a] services (N=127). The categorical variables are represented in numbers and percentages.

Level of education	Do you know the importance of VCT services? n (%)	
	Yes	No
Form II	8 (6.6)	1 (16.7)
Form III	46 (38.0)	2 (33.3)
Form IV	67 (55.4)	3 (50.0)

Table . Perceived importance of VCT[a] services (N=127). The categorical variables are represented in numbers and percentages.

Importance of VCT services	n (%)
To know HIV status	88 (50.6)
Prepares you to accept HIV test results	28 (16.1)
Important in HIV prevention	58 (33.3)
Stigmatization to infected	-
Confuse infected person	-

[a]VCT: voluntary counseling and testing.

Awareness of the Importance of VCT by Education Level

The distribution of responses by form level indicates a trend of increasing awareness with educational progression. Among Form II students, 8 out of 9 (88.9%) reported knowing the importance of VCT services, while 1 (11.1%) student did not. In Form III, 46 (95.8%) students demonstrated awareness, with only 2 (4.2%) students responding “No.” Among Form IV students, the highest level of awareness was observed, with 67 (95.7%) students, and only 3 (4.3%) students reporting no awareness (Table 2 and Table 3).

Perceived Importance of VCT Services

When asked about why VCT is important, students identified three major reasons: (1) To know HIV status (88, 50.6%); this was the most frequently cited reason. (2) Important in HIV prevention (58, 33.3%), significant proportion recognized VCT’s preventive value. (3) Prepares you to accept HIV test results (28, 16.1%); this shows that some students understood the emotional or psychological support role that VCT provides, though this was less frequently mentioned. No students associated VCT with negative outcomes such as stigmatization or confusing the infected person (Table 2 and Table 3).

Attitudes of Participants Towards VCT Services of Secondary School Students

Regarding attitudes of secondary school students toward uptake of VCT, Table 4 shows three dimensions: (1) readiness to be known for their HIV status by age, (2) general acceptability of HIV testing, and (3) willingness to disclose HIV test results.

Table . Attitudes of secondary school students toward HIV tests (N=127). The categorical variables were represented in numbers and percentages.

	Acceptance level, n (%)				
Attitudes	Strongly disagree	Disagree	Agree	Strongly agree	Not sure
Are you ready to be known for your HIV status?					
Age (years)					
15 - 16	12 (27.9)	11 (40.7)	5 (22.7)	9 (33.3)	4 (50.0)
17 - 18	26 (60.5)	12 (44.4)	15 (68.2)	15 (55.6)	4 (50.0)
19 - 20	5 (11.6)	4 (14.8)	2 (9.1)	3 (11.1)	—[a]
Acceptability of secondary school students towards HIV test	6 (4.7)	8 (6.3)	40 (31.5)	65 (51.2)	8 (6.3)
Willingness of secondary school students to disclose the HIV test results	43 (33.9)	27 (21.3)	22 (17.3)	27 (21.3)	8 (6.3)

[a]not applicable.

Readiness to Be Known for Their HIV Status By Age

Responses varied across age groups, with the 17 - to 18-year-old group showing the highest level of acceptance; among those who agreed or strongly agreed to being known for their HIV status, the 17 - to 18-year-old group made up the majority, accounting for 15 (68.2%) agreeing and 15 (55.6%) strongly agreeing. In contrast, the 15 - to 16-year-old group had relatively higher percentages in disagreement or uncertainty, where 12 (27.9%) strongly disagreed, 11 (40.7%) disagreed, and 4 (50%) were not sure. The 19 - to 20-year age group showed lower engagement across all categories (Table 4).

Acceptability of HIV Testing

Overall, the acceptability of HIV testing among students was encouraging, where a large majority either agreed (40, 31.5%) or strongly agreed (65, 51.2%) with the idea of HIV testing. Only 14 (11%) (6 strongly disagree +8 disagree) rejected the idea of testing, and 8 (6.3%) were unsure. This positive attitude toward testing reflects a generally favorable view of VCT among

XSL•FO
RenderX

the student population, showing potential for increased VCT uptake (Table 4).

Willingness to Disclose HIV Test Results

When it comes to disclosing HIV status, students were less willing; out of 127 students, a significant proportion of 43 (33.9%) strongly disagreed and 27 (21.3%) disagreed with the idea of disclosing their HIV test results. However, only 22 (17.3%) agreed and 27 (21.3%) strongly agreed to disclose their results, while 8 (6.3%) remained unsure, indicating a substantial level of concern over confidentiality, stigma, or social repercussions associated with a known HIV status—even among those who accept testing (Table 4).

Perception of Participants Toward VCT Services of Secondary School Students

Insights into students' anticipated actions after receiving HIV test results and their expected reactions if they tested HIV-positive were determined. These perceptions reflected both their understanding of the implications of testing and their emotional and behavioral readiness to cope with outcomes.

Actions to Be Taken After Testing for HIV

Out of 150 responses, 86 (54.4%) students responded that they will tell their parents or close friends, indicating a relatively positive perception of social support. Also, 50 (31.7%) students responded to changing behavior. This significant proportion of students reported that they would modify their behavior after an HIV test, which is a highly encouraging sign. While 14 (8.9%) students reported using condoms, reflecting that awareness or acceptance of specific protective practices like condom use may still be limited. Cultural taboos or misinformation may be contributing factors. However, 8 (5.1%) students responded not telling anyone (Table 5). A minority of students indicated they would remain silent about their results. This may reflect concerns about stigma, fear of discrimination, or lack of trust in confidentiality.

Table . Perception of secondary school students toward VCT[a] services for HIV testing (N=127). The categorical variables were represented in numbers and percentages.

Variable	n (%)
Action to be taken by secondary school students after having tested for HIV	
I will tell my parents/close friends	86 (54.4)
I won't tell anybody	8 (5.1)
I will change my behavior	50 (31.7)
I will start using condom	14 (8.9)
Students' reaction if tested positive for HIV	
Kill myself	1 (0.5)
Return to God	14 (7.4)
Follow doctor's order	122 (64.2)
Inform my parents/close friends	23 (12.1)
Continue with my normal life	14 (7.4)
Others	—[b]

[a]VCT: voluntary counseling and testing.

[b]not applicable.

Reactions if Tested Positive for HIV

Out of 174 students' responses, 122 (64.2%) students responded to follow doctor's orders, the overwhelmingly dominant response showing a strong level of health-seeking behavior and trust in medical professionals. Also, 23 (12.1%) students showed that they will inform their parents or close friends, showing a willingness by some to seek emotional support and maintain open communication. Returning to God was reported by 14 (7.4%) students, and 14 (7.4%) students reported continuing with normal life, indicating spiritual and psychological coping mechanisms.

Suicidal ideation was reported by 1 (0.5%) student; the fact that even one student reported this highlights the psychological distress and fear that can be associated with an HIV-positive diagnosis. It underscores the importance of counseling services and mental health support within VCT programs (Table 5).

Barriers Toward Not Using VCT Services Among Secondary School Students

Barriers among secondary school students toward utilization of VCT services were determined. Out of 140 students' responses, most students (71, 50.6%) responded that stigmatization from society was the great obstacle to having an HIV test. While 26 (18.6%) students said that they will die early, reflecting fear-based misconceptions about HIV. On the other hand, 25 (17.86%) students said that a lack of confidentiality still exists among health care workers, making it harder for them to know their HIV statuses. Thirteen (9.3%) students believed that they are too young to get HIV, reflecting low perceived susceptibility. However, 5 (3.6%) students reported perceived cost of VCT

XSL•FO
RenderX

services, reflecting that VCT services are usually free in Tanzania (Table 6).

Table . Barriers among secondary school students towards utilization of VCT[a] services (N=127). The categorical variables were represented in numbers and percentages.

Variable	n (%)
Barriers to students not to use VCT services	
Stigmatization	71 (50.6)
I'm very young; therefore, I can't get HIV	13 (9.3)
I will die early	26 (18.6)
VCT services are expensive	5 (3.6)
Lack of confidentiality among health workers	25 (17.9)
Reason for lack of coverage of VCT services for secondary school students	
Poor infrastructure	17 (21.1)
Lack of personnel for VCT services	46 (56.8)
I don't want this service	2 (2.5)
It brings conflicts among people	9 (11.1)
I don't believe in this service	2 (2.5)
Others	5 (6.2)

[a]VCT: voluntary counseling and testing.

Reasons for Lack of VCT Service Coverage for Students

Reasons for lack of coverage for VCT services for secondary school students were determined. Out of 81 total responses of students, 46 (56.8%) students reported lack of personnel response, revealing a critical shortage of trained staff to provide VCT in schools or nearby health centers. Poor infrastructure was reported by 17 (21.1%) students, reflecting a broader health systems challenge. Conflicts among people were reported by 9 (11.1%) students, and mistrust and disinterest were reported by 2 (2.5% each) students, suggesting low health literacy or resistance to external influence (Table 6).

Discussion

The Main Findings

Accurately measuring VCT service uptake among young adults is imperative and essential, not only due to their heightened vulnerability to HIV infection but also because this population frequently encounters significant structural and socioeconomic impediments to accessing these critical services. The findings reveal a critical paradox; although student awareness of VCT services was widespread and views on its importance were predominantly positive, alongside strong endorsement for the acceptability of HIV testing itself, significant barriers persist that account for the low utilization rates observed in Iringa Rural District. Among these barriers are a pronounced reluctance to disclose HIV status, rooted primarily in fear of societal stigmatization, concerns about confidentiality breaches, and prevalent misconceptions regarding HIV/AIDS and VCT outcomes. Furthermore, systemic challenges, notably severe shortages of trained personnel and inadequate infrastructure, directly contribute to the inconsistent VCT service provision in Iringa Rural District. These findings collectively demonstrate that high awareness is necessary but insufficient for effective VCT uptake.

Participant Characteristics and Implications for VCT Uptake

This study enrolled 127 secondary school students aged 15 - 25 years from three secondary schools, with a relatively balanced gender distribution, consistent with school-based demographic trends in rural Tanzania. The majority were aged 17 - 18 years, suggesting that mid-adolescence is the key period for interventions promoting VCT services. This age group typically experiences increased autonomy, sexual debut, and curiosity—factors that elevate HIV risk and underline the importance of early preventive strategies. Similar demographic trends were found in a study conducted by Mkumbo and Ingham in Mwanza [23], which emphasized that students aged 16 - 18 years were more receptive to sexual and reproductive health interventions due to greater maturity and exposure to sexual reproductive health topics in school curricula. This supports the current finding that students in higher academic levels (Form III and IV) showed greater awareness and more positive attitudes toward VCT, emphasizing the educational system's critical role in shaping health behaviors.

Knowledge of VCT and Information Sources

All students reported awareness of VCT services, and schools were identified as the main source of this information, followed by radio/TV and friends/family. This aligns with findings by Anastasia et al in Uganda, where school-based interventions were the leading source of HIV-related knowledge among adolescents [24]. The prominence of mass media as a secondary source supports the notion that integrating media campaigns with school-based programs can reinforce HIV prevention

XSL•FO
RenderX

messages. However, the low reliance on interpersonal sources like family or health centers suggests a missed opportunity for community-based health promotion. This is consistent with Mahmoud et al who reported that youth often perceive HIV as a "school topic" rather than a family concern, emphasizing the need to involve parents and local health care workers in sensitization campaigns to bridge this communication gap [25]. Our study findings were different from the study conducted by Shedura et al, who found that most of the students did not know about VCT services for HIV/AIDS. Moreover, 157 (68.0%) students have never heard of VCT, while only 74 (32.0%) students have heard of VCT, but higher findings from mass media by the study conducted by Sisay et al found that the most frequently mentioned sources of information for HIV/AIDS were mass media 211 (62.2%) followed by health professionals 177 (52.2%) [26,27]. This signifies that our study found a very low rate of VCT services information from mass media by secondary school students. Our study showed that there is a need to develop a policy that will be beneficial to have VCT training programs and seminars in all mass media in Tanzania on VCT education, so as to facilitate the awareness of VCT services for HIV/AIDS among youths.

Awareness of the importance of VCT improved with educational level, with Form IV students demonstrating the highest levels of awareness. This echoes findings from Mboya et al in Southern Highlands, Tanzania, where older students and those in upper forms exhibited significantly higher knowledge and appreciation of VCT's role in HIV prevention and care [28]. Students primarily cited knowing one's HIV status and preventing HIV as key reasons for seeking VCT, indicating a sound understanding of VCT's core objectives. Nevertheless, the relatively low mention of emotional preparedness reflects a gap in psychological aspects of VCT counseling. Comprehensive VCT services should therefore include components that prepare youth emotionally, not just medically, for their HIV test results. Similarly, a study by Mshana et al in rural Tanzania found that upper-secondary students (Forms III–IV) had significantly higher VCT knowledge than Form I students, attributing this to cumulative exposure to HIV education in school curricula [10]. In Kenya, Maitino et al observed that Form IV students were twice as likely to accurately describe VCT benefits compared to Form I peers, linking this to peer-led interventions in higher grades [29]. A Ugandan study by Nabaggala et al reported similar trends, with senior students (aged 17 - 19 years) showing 95% awareness of VCT versus 68% among juniors, due to repeated sensitization in advanced biology and life-skills classes [30]. Banda et al. in their study showed that, in terms of peer influence, senior students act as information conduits [31]. The consistency of these findings suggests that scaling up age-appropriate, curriculum-based VCT education—particularly in lower secondary levels—could bridge awareness gaps. Pairing this with peer-led initiatives (eg, Form IV ambassadors) may amplify impact.

In terms of anticipated posttest behavior, the most common actions were informing parents or close friends and changing risky behavior. These findings indicate a positive perception of VCT as a preventive and supportive service. However, the low number of students indicating condom use as a posttest action suggests persistent gaps in knowledge or cultural taboos around condom use. A study by Culyba et al in rural Morogoro found that misconceptions and sociocultural norms significantly deterred condom acceptance, even among informed youth [32]. The vast majority of students said they would follow doctors' orders if tested HIV-positive, which is encouraging. However, the fact that one student reported suicidal ideation highlights the urgent need for school-based mental health services and counseling support integrated into VCT programs. Furthermore, in our study, many respondents cited fear and anxiety as the main reasons for their reluctance to disclose their HIV test results. They worried about the emotional distress and disruption to their lives that could result from a positive test result. This reflects the reason why there is still a prevalence of HIV infection in Iringa, accounting for a second leading region after Njombe region, as most young population who are sexually active continue their inclination toward sexual experimentation, involvement with multiple partners, and inconsistent condom use while fearing to disclose their HIV statuses to their counter sexual partners. The lack of knowledge and confidence in dealing with the outcome, as well as uncertainty about posttest support and care, contributed to their concerns. These findings are consistent with a study conducted in Ethiopia, which also identified fear and anxiety as influential factors in the uptake of VCT among young people [33,34].

The majority of students expressed positive attitudes toward HIV testing, with 51.2% strongly agreeing and 31.5% agreeing to be tested. However, only 38.6% were willing to disclose their HIV test results, while 55.2% disagreed or strongly disagreed. Furthermore, the fact that even one student reported suicidal ideation highlights the psychological distress and fear that can be associated with an HIV-positive diagnosis. It reveals an important barrier to open dialog and follow-up care and highlights the need for strengthening counseling services, promoting confidential testing environments, and conducting anti-stigma campaigns within schools and communities and highlighting the need for follow-up care. It underscores the importance of counseling services and mental health support within VCT programs. This dichotomy reflects a tension between individual health behavior and social repercussions, likely fueled by ongoing stigma. Comparable concerns were found in Wandera et al in Kenya, where stigma was a major deterrent to disclosure despite high testing willingness [35]. Similarly, students who perceived high community stigma were 5 times more likely to refuse disclosure, even if they tested [31]. In Zimbabwe, Fulton et al, in their study, reported that school-based stigma reduction programs increased willingness to disclose by 22%, highlighting the need for psychosocial support in VCT services [36].

The 17 - to 18-year-old group exhibited the highest acceptance of being known for their HIV status, suggesting this group may serve as peer educators or ambassadors in youth-centered VCT campaigns. On the contrary, the 15 - to 16-year-old group showed higher levels of uncertainty and fear—highlighting the importance of age-specific sensitization. Older students (19 - 25 y) may exhibit greater reluctance due to heightened awareness of social stigma or fear of impacts on future opportunities, necessitating targeted interventions such as private counseling

XSL•FO
RenderX

sessions. The findings from this study align with a study in South Africa by Owen et al, who found that 17‐to 19-year-olds were more likely to test for HIV and disclose their status than younger adolescents, attributing this to increased maturity and sexual health awareness [37]. Research in Kenya by Maitino et al highlighted that peer educators aged 16‐18 years significantly improved VCT uptake in schools, supporting the idea that this age group can effectively influence testing behaviors [29]. Similarly, studies have reported that 15‐to 16-year-olds often exhibit higher HIV testing hesitancy due to fear of parental disclosure or lack of autonomy. Younger adolescents required school-based sensitization programs to reduce misconceptions, mirroring this study's call for age-tailored interventions [10,38]. Older youth (19‐25 y) frequently avoid testing due to anticipated stigma, particularly in settings where HIV status can affect employment or relationships [39]. Confidentiality-guaranteed services, such as mobile or after-hours clinics, have proven effective for this group [40].

Barriers Toward Utilization of VCT Services by Secondary School Students

In this study, Stigma emerged as the most reported barrier, consistent with nearly all recent adolescent HIV studies in sub-Saharan Africa. For instance, Mugisha et al in Uganda reported that perceived stigma was the leading reason adolescents avoided VCT services, despite widespread awareness [41]. In the current study, students also cited fear of dying and concerns about confidentiality, indicating that both misinformation and systemic trust issues with health care workers remain significant challenges, and the belief that they are expensive may indicate poor communication about service accessibility. These findings support the need for community-wide destigmatization campaigns and robust training for health care providers in confidentiality. Similar findings were found by Shedura et al [26], Anaba et al [9], and Adulo et al [42]. Lack of confidentiality among health care providers was also the hindering factor for secondary school students toward VCT services utilization, while others have the notion that they are too young; therefore, they cannot get HIV, which in fact contributes to the continuous prevailing of high spread of HIV infection among young population in the Iringa region.

Our study also identified a lack of trained personnel and poor infrastructure as major constraints to VCT accessibility. These are structural barriers that mirror findings from the Joint United Nations for Acquired Immune Deficiency Syndrome (UNAIDS) (2023), which stressed that youth-friendly HIV services are severely under-resourced in rural areas. Efforts to decentralize and strengthen VCT services in school environments are therefore paramount [43].

Implications of the Study Findings

School-Centered Interventions Are Effective

The high levels of awareness and acceptance of VCT among Form III and IV students affirm the value of integrating VCT education into school curricula. Education ministries should consider expanding such programs to lower forms to reach younger adolescents early.

Addressing Stigma and Confidentiality

The reluctance to disclose HIV status and the perceived breach of confidentiality point to urgent needs for stigma-reduction campaigns and the implementation of trusted, youth-friendly VCT centers with strict confidentiality policies.

Targeted Behavioral Change Communication

The limited mention of condoms as a preventive method and misconceptions about HIV's fatality indicate a need for targeted behavioral interventions that challenge myths and promote accurate knowledge, especially around prevention and healthy living.

Engaging Families and Communities

Since interpersonal sources like families and health workers play a minor role in VCT education, strategies should involve parents, religious leaders, and community health workers to normalize discussions about HIV and reduce shame.

Mental Health Integration

The instance of suicidal ideation underscores the need to include psychosocial support services within VCT frameworks. Adolescents require reassurance and coping mechanisms to handle positive diagnoses constructively.

Resource Allocation and Infrastructure

The findings highlight that for VCT programs to scale up in rural districts, investments are needed in human resources, mobile clinics, and infrastructure to bridge current service delivery gaps.

Limitations of the Study

Although this study provides valuable insights, it recognizes several limitations. This study was conducted in only three secondary schools within Iringa Rural District. The findings may not be generalizable. Future longitudinal research is needed to cover these areas in large geographical populations of multiple regions along the country, compounded with large sample size.

Conclusion

This study explored the knowledge, perceptions, and attitudes of secondary school students in Iringa Rural District regarding VCT for HIV. The findings revealed a generally high level of awareness and positive attitudes toward VCT services among students, with schools and mass media being the primary sources of information. Awareness of the importance of VCT increased with educational level, reflecting the significant role of school-based health education. Most students recognized the value of VCT in knowing one's HIV status and preventing the spread of HIV, although fewer acknowledged its psychological support functions. The overall acceptability of VCT was encouraging; however, willingness to disclose test results remained low, underscoring ongoing concerns around confidentiality and stigma. Students demonstrated a readiness to act responsibly upon receiving HIV test results, including informing trusted individuals and adopting safer behaviors. However, some also expressed reluctance to disclose results or misconceptions about HIV, pointing to lingering stigma and misinformation. Key barriers to VCT utilization included societal stigma, fear of early death, perceived lack of

XSL•FO
RenderX

confidentiality, and insufficient knowledge. Structural challenges such as a shortage of trained personnel and inadequate infrastructure further limit access to VCT services within schools. These findings provide a roadmap for designing youth-centered VCT programs that tackle stigma, enhance confidentiality, and improve rural access, significantly advancing HIV prevention in Tanzania.

Acknowledgments

We would like to express our sincere gratitude to Dr. Shakilu Jumanne Kayungo, our first clinical instructor, for his invaluable guidance, unwavering support, and dedicated mentorship throughout the development of our research proposal and the compilation of the final report. His commitment and encouragement were instrumental to the successful completion of this study.

Our heartfelt appreciation also goes to Professor Youping Deng, our second clinical instructor, whose intellectual insights and constructive feedback significantly contributed to shaping the foundation of this research. Her guidance has been vital to our academic growth and understanding.

We are deeply grateful to the District Medical Officer of Iringa Rural District and the District Education Officer, Mr. Chiza D. N., for granting us permission to carry out this study within the district. We extend special thanks to the headmasters of Lipuli Secondary School, Kalenga Secondary School, and Kidamali Secondary School for their continued cooperation and support throughout the approval process, data collection phase, and our departure from the schools.

Finally, we extend our sincere appreciation to all secondary students who participated in this study. Their willingness to contribute made this research possible, and their input is the cornerstone of our findings.

Data Availability

Data used to support the findings for this study are included in the article.

Authors' Contributions

The authors MCM, SJK, and YD had full access to all the data and take responsibility of the integrity of the data and accuracy of the data analysis.

Abstract

Background: Scalable and accurate screening tools are critical for public mental health strategies, especially in low- and middle-income countries (LMICs). While the Generalized Anxiety Disorder Scale (GAD-7) and Patient Health Questionnaire (PHQ-9) are widely used, their full application in large-scale programs can pose feasibility challenges. By contrast, shorter versions like GAD-2 and PHQ-2 reduce burdens but fail to capture symptom diversity.

Objective: This study aimed to optimize screening for anxiety and depression severity using classification and regression tree (CART) models, identifying concise and high-performing decision rules based on the GAD-7 and PHQ-9 items, and to test their reproducibility in 5 independent datasets.

Methods: A cross-sectional, nonprobabilistic study was conducted with 20,585 Brazilian adults from all 27 states and more than 3,000 cities, collected using digital outreach. Anxiety and depression symptoms were assessed using the GAD-7 and PHQ-9. CART models were trained and tested on bootstrapped samples (70% training, 30% testing), totaling 45,000 trees per scale. Each model used combinations of scale items and sociodemographic predictors. Robustness was evaluated via 10-fold cross-validation and evaluation across 3 hyperparameter configurations (*minsplit* and *minbucket*=500, 1000, 2000). Performance metrics included accuracy, sensitivity, specificity, precision, F1-score, and area under the curve (AUC).

Results: The CART models produced concise, high-performing decision rules—using only 2 items for the GAD-7 and 3 for the PHQ-9. No sociodemographic variable appeared in the final classification paths. For GAD-7, the models achieved an accuracy of 86.1% for minimal or mild severity and 85.1% for severe cases, with both categories showing AUC values above 0.900. By contrast, the moderate severity class had lower performance, with accuracy around 51% and an AUC of 0.728. For PHQ-9, the models achieved 81.7% accuracy for minimal or mild cases and 78.8% for severe cases, with AUCs again exceeding 0.900 for the extreme classes; the moderate or moderately severe class showed 66.9% accuracy and an AUC of 0.776. The most frequently repeated rules included the following: “GAD2<2 and GAD4<2” for identifying minimal or mild anxiety and “GAD2≥2 and GAD4=3” for severe anxiety; for depression, “PHQ2<2and PHQ4<2” for minimal or mild cases and “PHQ2≥2 and PHQ8≥2” for severe cases. These rule-based models demonstrated stable performance across thousands of bootstrapped replications and showed reproducibility in 5 independent datasets through external validation.

Conclusions: CART models enabled simplified, symptom-specific pathways for stratifying anxiety and depression severity with high precision and minimal item burden. These rule-based shortcuts offer an efficient alternative to fixed short forms (eg, GAD-2, PHQ-2) by preserving symptom diversity and severity discrimination. The findings support and lay the groundwork for adaptive, cost-effective screening and intervention models, especially in resource-limited settings and LMICs.

Introduction

Public mental health has become a central focus in the 21st century due to the global mental illness epidemic [1,2]. The extensive global impact of the COVID-19 pandemic has increased the urgency for public mental health [3,4]. Common mental disorders (CMDs), particularly anxiety and depression, are significant challenges for public health institutions in both high-income and low- and middle-income countries (LMICs) for the foreseeable future, with the latter bearing a disproportionately higher burden [5-9]. Even before the pandemic, high CMD prevalence underscored the need for tailored national and global strategies [1,10-12].

At national levels, comprehensive mental health strategies must include regular screening and a care model capable of addressing the full spectrum of needs—from prevention and basic psychological care to outpatient interventions and emergency support during crises [1,13]. Such an approach should be routine, not limited to critical periods; include health professional training to provide basic mental care, equipping specialists and nonspecialists to address anxiety and depression symptoms (at least regarding basic psychological care); and ensure resource availability during high-pressure periods [2,14]. A robust mental health surveillance system capable of detecting varying CMD risk levels can play a vital role in building an effective care system [6,8,15]. Using brief protocols or simple instruments to stratify risks can provide actionable insights and support targeted intervention planning [16-19].

A care model with tailored strategies based on the presence and severity of health outcomes is more feasible if it is brief; moreover, reliable tools are available for both individual assessments and widespread screenings [20-24]. The Generalized Anxiety Disorder Scale-7 (GAD-7) and Patient Health Questionnaire-9 (PHQ-9) are widely used for measuring anxiety and depression symptoms, respectively, and match several important qualities [25-27]. However, they may pose a burden on participants in large-scale mental health initiatives, especially in resource-limited settings, in which the GAD-2 and PHQ-2 are used as alternatives. Notwithstanding, these shorter versions do not differentiate mental health condition severity and revert to the first 2 questions after a binary screening diagnostic [28-30], rather than more specifically screening the severity or specific symptoms of anxiety or depression.

By focusing on only two symptoms of each disorder—nervousness and worrying in GAD-2 and anhedonia and hopelessness in PHQ-2—these scales overlook other relevant symptoms, such as fatigue, sleep disturbances, difficulty concentrating, and irritability (common in anxiety disorders) or changes in appetite, guilt, and suicidal ideation (common in depression) [31]. Consequently, they are limited in capturing important symptom profiles across diverse populations, which is crucial for tailoring interventions. This restricts a comprehensive understanding of anxiety and depression when compared to the broader symptomatology outlined in the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) [31].

Machine learning (ML), a subfield of artificial intelligence (AI), identifies hidden patterns in datasets through data-driven algorithms, enabling explanatory or predictive model creation [32-35]. In the mental health field, ML models provide evidence of predicting risks and streamlining assessments [36-40]. ML algorithms can support shorter, more accurate tool development, addressing challenges such as participant fatigue and low response rates while maintaining scalability and cost-effectiveness as end points [41,42]. Furthermore, within ML algorithms, decision tree models offer a distinct approach to streamlining the path from individual items to diagnostic classification (eg, by identifying the most relevant features, thereby preserving predictive accuracy and improving efficiency). By incorporating additional variables (eg, sociodemographic data, psychological constructs, and other health outcomes), decision trees allow for adaptive and personalized analyses [43-46]. ML-based scale reduction techniques, combined with logical “shortcuts” (or rules) for case classification, offer a promising approach to balancing precision and brevity in public mental health.

This study aims to leverage ML algorithms, particularly decision tree models, to enhance the efficiency and precision of GAD-7 and PHQ-9 assessments by identifying the most predictive components across severity levels. To further examine the robustness and generalizability of the derived rules, their performance was evaluated across 5 independent datasets, including 1 collected nationwide in Brazil and 4 from international samples. We hypothesized that classification and regression tree (CART) models can identify concise, high-performing decision rules using less items from the GAD-7 and PHQ-9 scales, enabling accurate stratification of disorders into minimal/mild, moderate, and severe categories, thereby optimizing mental health screening in public health applications.

Methods

Study Design

This study adopted a cross-sectional, nonprobabilistic design and used a digital convenience sampling method. Data were collected between March and June 2024 through online recruitment via social media, primarily Instagram and Facebook. Digitally boosted posts promoted participation across all regions of Brazil. A university-based research laboratory specializing in public mental health managed the campaign through its official page. Upon accessing the study link, participants were directed to a landing page describing the study objectives and procedures. Participants completed the survey independently using their own devices in home or personal settings, without any direct researcher supervision. Only individuals aged 18 years or older could participate. The final sample included 20,585 respondents from all 27 Brazilian states and more than 3,000 cities, encompassing both rural and urban regions. The average completion time for the questionnaire was approximately 5 minutes. Incomplete responses were excluded, resulting in a withdrawal rate of approximately 8%.

Ethical Considerations

This study was approved by Brazil’s National Council for Ethics in Research (Conselho Nacional de Ética em Pesquisa [CONEP];

XSL•FO
RenderX

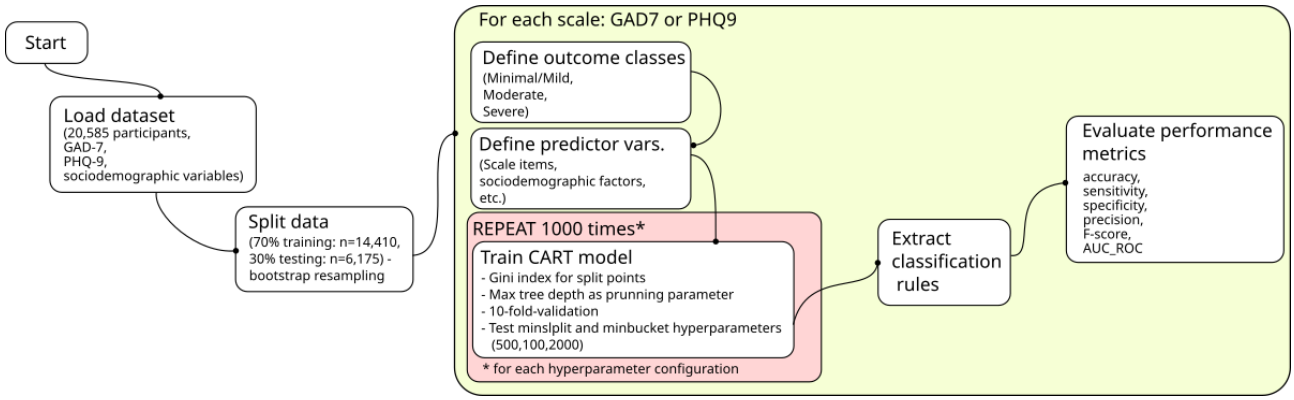
protocol number 30485420.6.0000.0008). All procedures complied with Brazilian and international regulations for research involving human participants. Informed consent was obtained electronically from all participants before survey participation. Participants were first presented with the study objectives, procedures, and data protection measures. Only individuals who explicitly agreed to participate were then granted access to the survey instruments. All data were collected anonymously, and no personally identifiable information was recorded. The dataset was anonymized before analysis to ensure confidentiality and data protection, and no supplementary materials contain any information that could lead to the identification of individual participants. In accordance with Brazilian research ethics policies involving human subjects, no monetary or material compensation was provided to participants. No generative AI tools were used in the manuscript writing, ideation, or drafting.

Instruments

The GAD-7 is a 7-item measure for assessing anxiety [47], with each item rated on a scale from 0 (not at all) to 3 (nearly every day) and the final score ranging from 0 to 21. It has demonstrated satisfactory psychometric properties and validity evidence in Brazil [48]. Specifically, studies using the Brazilian-Portuguese version have reported adequate internal consistency (eg, Cronbach α values typically above .80) and construct validity, supporting its use for assessing generalized anxiety symptoms in this population. The PHQ-9 is a 9-item scale for assessing depression [49] with the same Likert response format as the GAD-7 and the total score ranging from 0 to 27. It has also shown satisfactory psychometrics in the Brazilian population [50] with good internal consistency (eg, Cronbach α often exceeding .85) and strong evidence of both construct and criterion validity, making it a reliable tool for depression assessment [51]. Additionally, a sociodemographic questionnaire was administered, including items on sex/gender, age, education level, and self-reported skin color/ethnicity.

A common cutoff score of 10 is often used for GAD-7 and PHQ-9 to distinguish clinical from nonclinical cases. However, alternative stratifications based on severity levels offer a more nuanced differentiation between subclinical and extreme cases (see [27]). One alternative involves classifying noncases (“minimal or mild” severity, scores <10 on both GAD-7 and PHQ-9) and cases, including the stratification of 2 levels of severity: “moderate” (“moderate” [GAD-7, scores 10 - 14] and “moderate and moderately severe” [PHQ-9, scores 10 - 19]) and “severe” (GAD-7, score ≥ 15 and PHQ-9, score ≥ 20). We adopted this tripartite stratification due to its parsimonious approach to prioritizing individuals as it supports different care strategies under a straightforward interpretation.

Decision Tree



The CART method, originally proposed by Breiman, Friedman, Olshen, and Stone [52], is one of the most widely used recursive partitioning decision tree algorithms and implemented through the rpart package in R. This ML algorithm begins with the complete dataset and recursively partitions it into smaller subsets based on both the predictor values and the outcome classes (see [53-56]). In this study, the classes were defined by the trichotomized GAD-7 and PHQ-9 scores, whereas the variables included both the scale items and sociodemographic factors.

Data Modeling

A combination of bootstrapping and cross-validation was used to mitigate overly optimistic estimations. In this, the entire dataset was resampled multiple times, with 70% of the samples (n=14,410) used for training the ML model and the remaining 30% (n=6175) for testing its performance. This approach helps incorporate sample variability while reducing the risk of overfitting by ensuring the model is not trained on a single dataset. Generalization performance was assessed by estimating accuracy and area under the receiver operating characteristic curves (AUC-ROC) for each repetition. Classification trees were constructed using the Gini index method to determine split points, with maximum tree depth as a pruning parameter and a 10-fold cross-validation strategy implemented via the rpart2 command from the caret package. To test model robustness, the following values for the hyperparameters minsplit (minimum number of observations required in a node) and minbucket (minimum number of observations in a terminal node) were systematically explored: 500, 1000, and 2000. These values were chosen to represent a range from more flexible (500, allowing for smaller nodes and potentially more complex trees) to more constrained (2000, leading to larger nodes and simpler trees), ensuring that the identified rules were not overly specific to a single set of parameters and thus enhancing generalizability (see Figure 1). Each hyperparameter configuration was tested 1000 times to assess the stability and consistency of the derived rules across multiple bootstrapped samples (see [57-59]).

XSL•FO
RenderX

Figure 1. Flowchart of the data modeling procedure for generating decision tree rules to classify anxiety and depression severity in a national sample of Brazilian adults (2024). CART: classification and regression tree; GAD-7: Generalized Anxiety Disorder Scale; PHQ-9: Patient Health Questionnaire (PHQ-9).

Each scale was analyzed separately, with GAD-7 and PHQ-9 scores as predictor variables (features) and severity levels from each scale as outcomes (targets). Four additional models for each scale incorporated demographic variables as additional features. From the 45,000 decision trees generated for each scale, classification rules for each class were extracted. The most frequent rules for each class were evaluated using common performance metrics, including accuracy, sensitivity, specificity, precision, F-score, and AUC-ROC curve. These metrics are widely recognized for classifier performance evaluation (see [60]).

The confusion matrix compared actual classifications (cutoffs) with model predictions. For example, GAD-7 scores categorized anxiety as minimum/mild (0 - 9), moderate (10-14), or severe (15+). Correct classification of a severe case (eg, score 16) is a true positive, and misclassification is a false negative. Similarly, if a nonsevere case (eg, score 6) is correctly classified, it is a true negative and otherwise, a false positive. Confusion matrices summarize classification accuracy, with higher accuracy reflecting better alignment between predicted and actual severity levels. Sensitivity measures the model's ability to detect true positives, while specificity assesses correct identification of true negatives. Higher sensitivity ensures better detection of severe cases, and higher specificity improves nonsevere classification. Precision minimizes false positives, with the F-score balancing precision and recall. The AUC-ROC curve evaluates performance by plotting the true-positive versus false-positive rates, with higher values indicating better classification (see [60]). Variable importance analysis examined demographic predictors' impact on model performance.

External Validation

To evaluate the stability and generalizability of the rules derived from the main sample, we performed an external validation with 5 datasets: 4 collected by other research groups and available in open repositories and 1 collected between November and December 2024 in Brazil using the same recruitment procedures as in the primary study. A description of these datasets is provided in Table 1 of the Supplementary Material. The rules identified in the main analyses were applied unchanged to these datasets to assess reproducibility and to verify that the models were not overfitted to the initial sample but could generalize to a broader population. Model performance was assessed using the same metrics used in the main analyses: accuracy, sensitivity, specificity, precision, and F1-score for each class of each rule.

Software

R (R Development Core Team, 2024) plus RStudio were used to perform all analyses. The decision trees were built using the combination of the *rpart* and *caret* R packages [61] to perform cross-validation as a pruning criterion. Additionally, the values of 500, 1000, and 2000 and their combinations were used to set the *minsplit* and *minbucket* hyperparameters. The R package *pROC* [62] was used to estimate the AUC-ROC curve. All R scripts used for the data analysis are available at the Open Science Framework (OSF) repository [63].

Results

Overview

Based on the total sample, more than 90% were women (n=18,844, 91.5%). Approximately half of the participants declared having white skin color (n=10,405, 50.5%) and high school level education (n=10,083, 49%). The most common age groups were 40 - 49 (n=6071, 29.5%) and 30 - 39 years (n=5927, 28.8%). The mean age was 41.1 years (SD=12.9, range=18 - 80) (Table 1).

Variables	Main sample (n=20,585)
Sex/gender, n (%)	
Male	7.6 (1564)
Female	91.5 (18,844)
Nonbinary	0.9 (177)
Skin color/ethnicity, n (%)	
White	50.5 (10,405)
Black	10.5 (2153)
Parda (mixed race)	36.7 (7575)
Other	2.2 (452)
Education level, n (%)	
Up to high school	36.3 (7062)
Undergraduate students	16.7 (3440)
Graduate school	49.0 (10,083)
Age group (years), n (%)	
18 - 29	18.1 (3730)
30 - 39	28.8 (5927)
40 - 49	29.5 (6071)
50 - 60	14.9 (3062)
More than 60	8.7 (1795)

Generalized Anxiety Disorder Scale-7

All trees for the GAD-7 scale showed satisfactory accuracy with a mean of 0.742 and over 0.850 for the “minimal or mild” and “severe” levels, respectively. In total, 159 distinct rules were identified, collectively repeated 206,900 times across the trees, and no demographic variable appeared as part of any rule. The most repeated rules from each GAD-7 class (see Table 2) accounted for more than 59% of all rule repetitions. Table 2 presents the rules for each GAD-7 severity class along with the mean and SD of several classification performance metrics. The most frequently repeated rules for the “minimal or mild” and “severe” severity levels exhibited the highest performance across the metrics. The “moderate” level demonstrated a lower performance than others but with satisfactory indices. Figure 2 displays the ROC curves estimated for all repetitions of the most frequently repeated rules.

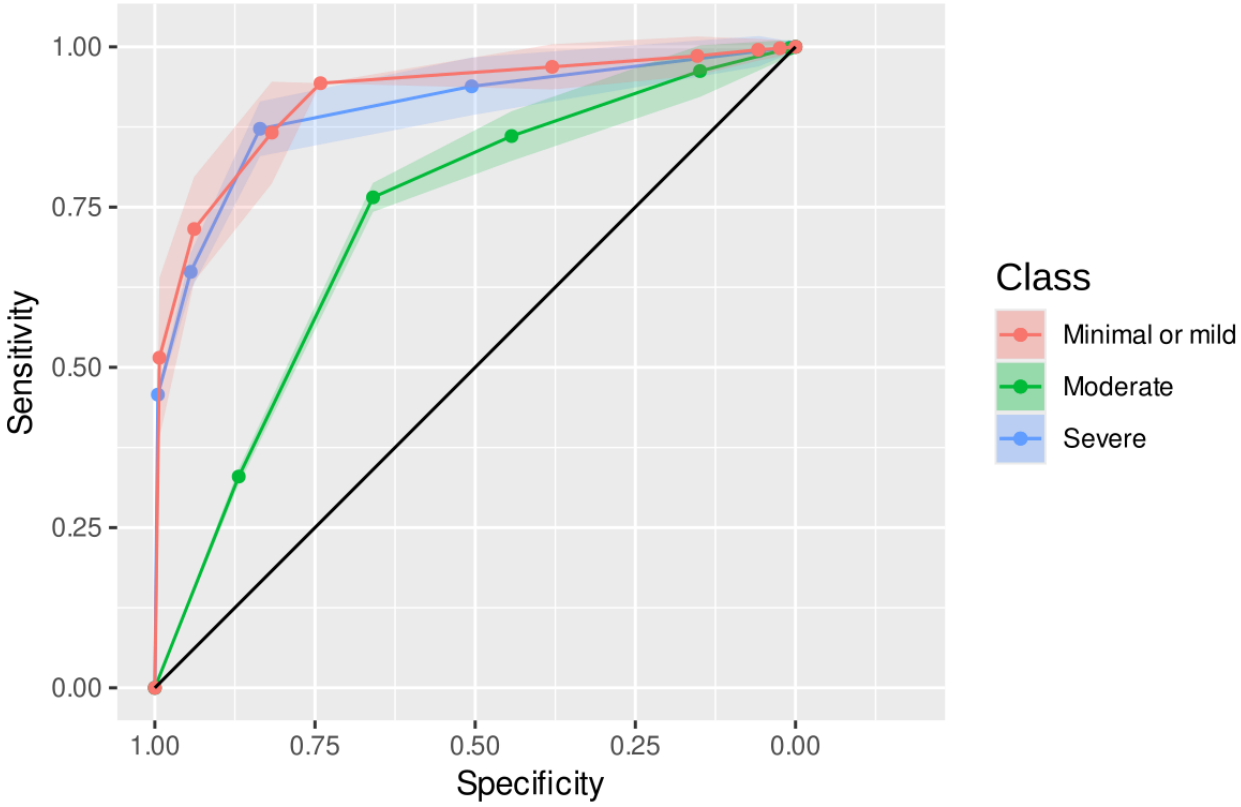

Table . Performance metrics for the most frequently repeated decision tree rules for each severity level of the Generalized Anxiety Disorder (GAD) Scale-7 in a cross-sectional study of Brazilian adults (n=20,585), 2024.[a]

Class	Rule	Repetition	Accuracy	Sensitivity	Specificity	Precision	F-score	AUC[b]
Minimal or mild	GAD2<2 and GAD4<2	43155	0.861(0.003)	0.744 (0.023)	0.942 (0.009)	0.857 (0.015)	0.796 (0.008)	0.923 (0.004)
Moderate	GAD2<2 and GAD4≥2	41780	0.515 (0.066)	0.606 (0.054)	0.798 (0.031)	0.534 (0.021)	0.566 (0.019)	0.728 (0.013)
	GAD2≥2 and GAD4<3	9270	0.507 (0.005)	0.680 (0.009)	0.749 (0.005)	0.507 (0.008)	0.580 (0.007)	0.728 (0.013)
Severe	GAD2≥2 and GAD4=3	27800	0.851 (0.033)	0.831 (0.063)	0.877 (0.030)	0.824 (0.025)	0.825 (0.022)	0.902 (0.009)

RenderX

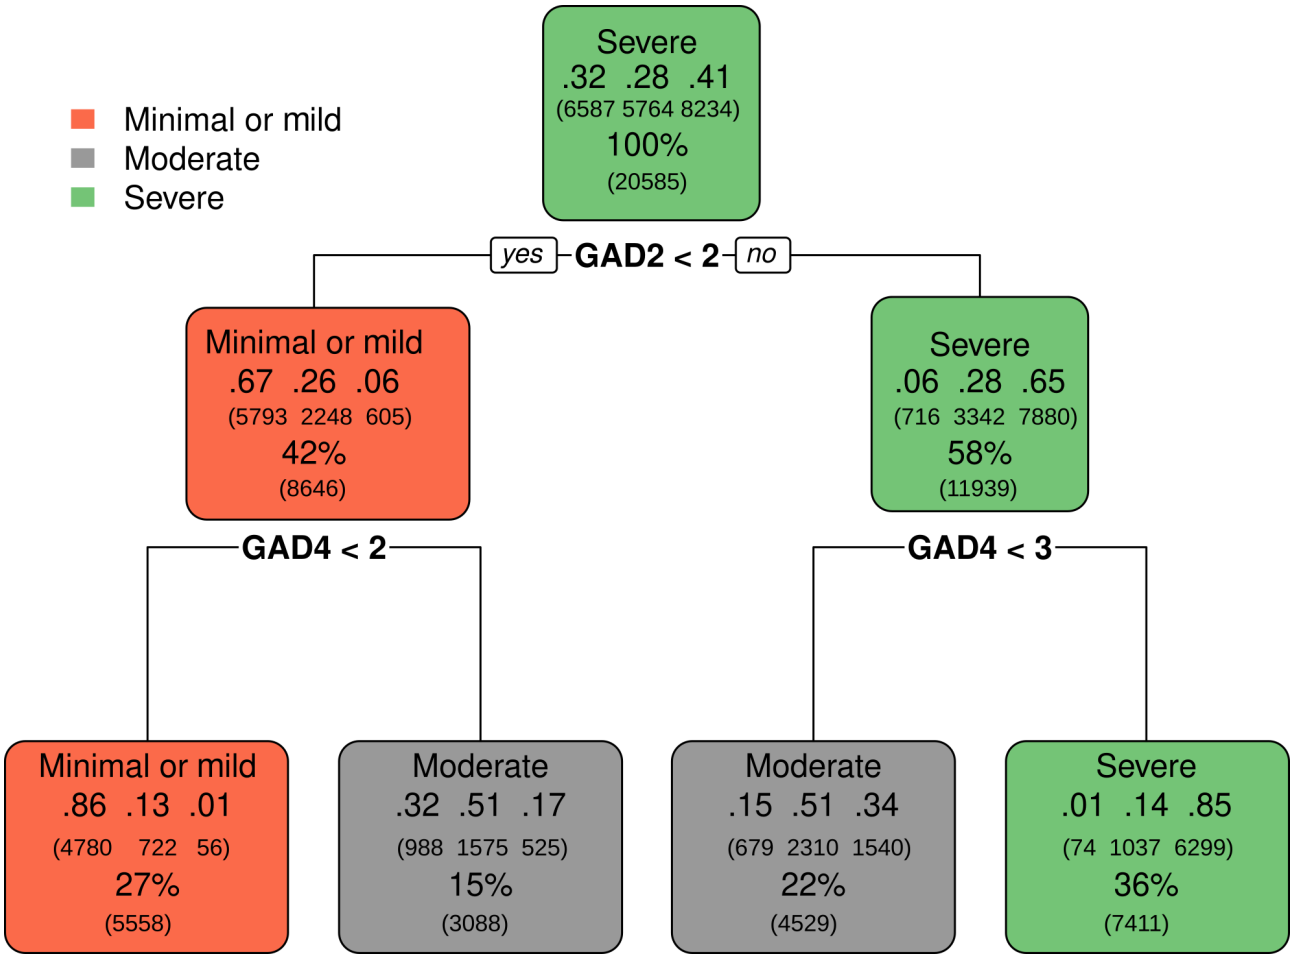

Figure 2. ROC curves for the most frequent decision tree rules classifying GAD-7 severity levels in a cross-sectional study of Brazilian adults (n=20,585), 2024. Each ROC curve represents the classification performance of the most frequently repeated decision tree rule for a given GAD-7 severity level (minimal, mild, moderate, or severe). The colored ribbons around the curves indicate the SD across 45,000 bootstrapped replications. GAD-7: Generalized Anxiety Disorder scale; ROC: receiver operating characteristic.

The most frequently repeated schematic rules for each GAD-7 class as prototypical decision trees are illustrated in Figure 3. These include the "minimal or mild" level and are characterized by the rule "GAD2<2 and GAD4<2." This means that a person who scored 0 or 1 in GAD2 ("not being able to stop or control worrying") and GAD4 ("trouble relaxing") was correctly classified as having "minimal or mild" level anxiety in 86% (0.86) of the cases, within a total of 27% of cases that matched with this class. Of the 27% classified as "minimal or mild," 13% were misclassified as "moderate" (0.13) and almost none as "severe" (0.01).

XSL•FO
RenderX

Figure 3. Prototypical decision trees representing the most frequently repeated classification rules for each severity level of the GAD-7 scale in a cross-sectional study of Brazilian adults (n=20,585), 2024. Each node displays the classification output of a decision rule for a specific GAD-7 severity level (minimal or mild, moderate, and severe). The middle line of each rectangle shows decimal values representing the proportion of participants in each true severity class, ordered left to right: minimal or mild, moderate, and severe. These values indicate the actual distribution of GAD-7 scores among those classified by the rule. The percentage on the bottom line indicates the proportion of the total sample that followed the corresponding decision path. GAD-7: Generalized Anxiety Disorder scale.

The rules were similar for cases from moderate severity levels or positive cases at any level up to significant anxiety symptoms. For example, to classify the "severe" level, the rule was "GAD2≥2 and GAD4=3." Of the participants scoring more than or equal to 2 in GAD2, 58% were included in the "severe" level, with 65% (.65) correctly classified. By adding GAD4 equal to 3, the percentage of cases classified as "severe" reduced to 36%, but the proportion of correctly classified cases increased to 85% (.85), with almost no cases misclassified as "minimal or mild" (.01). This means that the additional item reduced false-positive cases while increasing the accuracy level. The "moderate" levels showed 2 rules and 2 paths, implying more complexity: (a) "GAD2<2 and GAD4≥2," with 15% of total cases, of which 51% (.51) were correctly classified and (b) "GAD2≥2 and GAD4<3" with 22% of the total cases, of which 51% (.51) were correctly classified through the other path.

Beyond statistical performance, the clinical interpretation of these decision rules offers valuable insights. For the "minimal or mild" anxiety level, the rule "GAD2<2 and GAD4<2" suggests that individuals who report "not being able to stop or control worrying" (GAD2) and "trouble relaxing" (GAD4) "not at all" or "several days" (scores of 0 or 1) are highly likely to be correctly classified as having minimal or mild anxiety. By contrast, for the "severe" anxiety level, the rule "GAD2 ≥2 and GAD4=3" indicates that individuals who report "not being able to stop or control worrying" "more than half the days" or "nearly every day" (GAD2 score ≥2) and "trouble relaxing" "nearly every day" (GAD4 score=3) are highly indicative of severe anxiety. This specific combination underscores a significant and pervasive functional impairment related to anxiety symptoms, where both cognitive (worry) and somatic/behavioral (relaxation) aspects are severely affected. The addition of GAD4=3 to the rule for severe cases importantly reduces false positives, indicating that a high level of trouble relaxing is a critical differentiating factor for severe anxiety.

Patient Health Questionnaire-9

The decision trees for the PHQ-9 scores also demonstrated satisfactory accuracy, with a mean of 0.757 and "minimal or mild" and "severe" levels close to 0.800. In total, 126 distinct rules were identified and repeated 230,630 times across the trees. Similar to the GAD-7, no demographic variable appeared as part of any rule. The most repeated rules for each PHQ-9 class (Table 3) accounted for more than 51% of all rule repetitions. Table 3 presents such rules for each PHQ-9 severity class and the classification performance metrics. The "minimal or mild" and "severe" severity levels of the PHQ-9 also

XSL•FO
RenderX

exhibited the highest performance across the estimated metrics. The fit was lower in the "moderate level," although with acceptable indicators. Figure 4 displays the ROC curves for all rule repetitions.

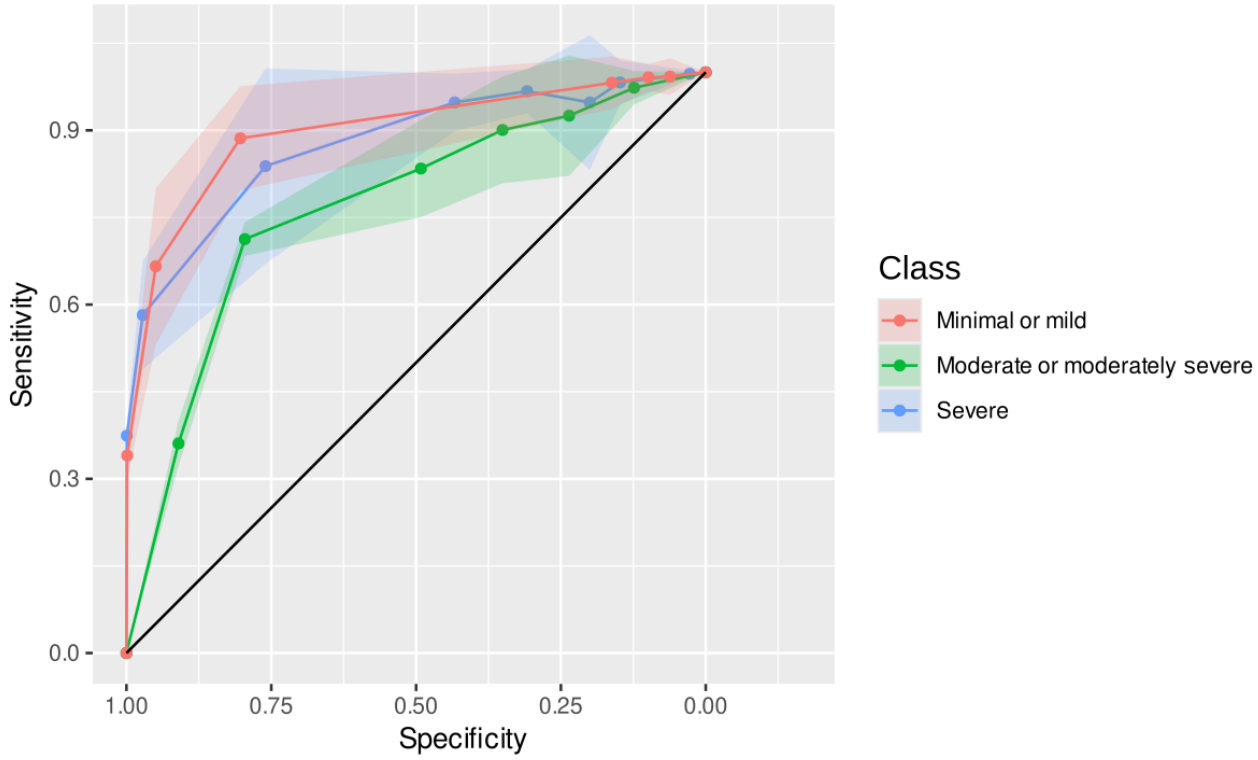

Table . Performance metrics for the most frequently repeated decision tree rules for each severity level of the PHQ-9 scale in a cross-sectional study of Brazilian adults (n=20,585), 2024.[a]

Class	Rule	Repetition	Accuracy	Sensitivity	Specificity	Precision	F1-score	AUC
Minimal or mild	PHQ2<2 and PHQ4<2	28740	0.817 (0.004)	0.767 (0.008)	0.930 (0.003)	0.817 (0.007)	0.792 (0.006)	0.921 (0.011)
Moderate or moderately severe	PHQ2≥2 and PHQ8<2	32125	0.669 (0.004)	0.783 (0.041)	0.723 (0.023)	0.677 (0.012)	0.725 (0.016)	0.776 (0.029)
	PHQ2<2 and PHQ4≥2	29680	0.688 (0.005)	0.761 (0.039)	0.733 (0.032)	0.679 (0.019)	0.717 (0.011)	0.776 (0.029)
Severe	PHQ2≥2 and PHQ8≥2	26405	0.788 (0.003)	0.700 (0.041)	0.921 (0.010)	0.782 (0.012)	0.738 (0.017)	0.903 (0.011)

[a]Values for accuracy, sensitivity, specificity, precision, F1-score, and AUC are reported as mean (SD) across 45,000 bootstrapped decision tree models. Precision, F1-score, and AUC are reported as mean (SD) across 45,000 bootstrapped decision tree models.

[b]AUC: area under the curve.

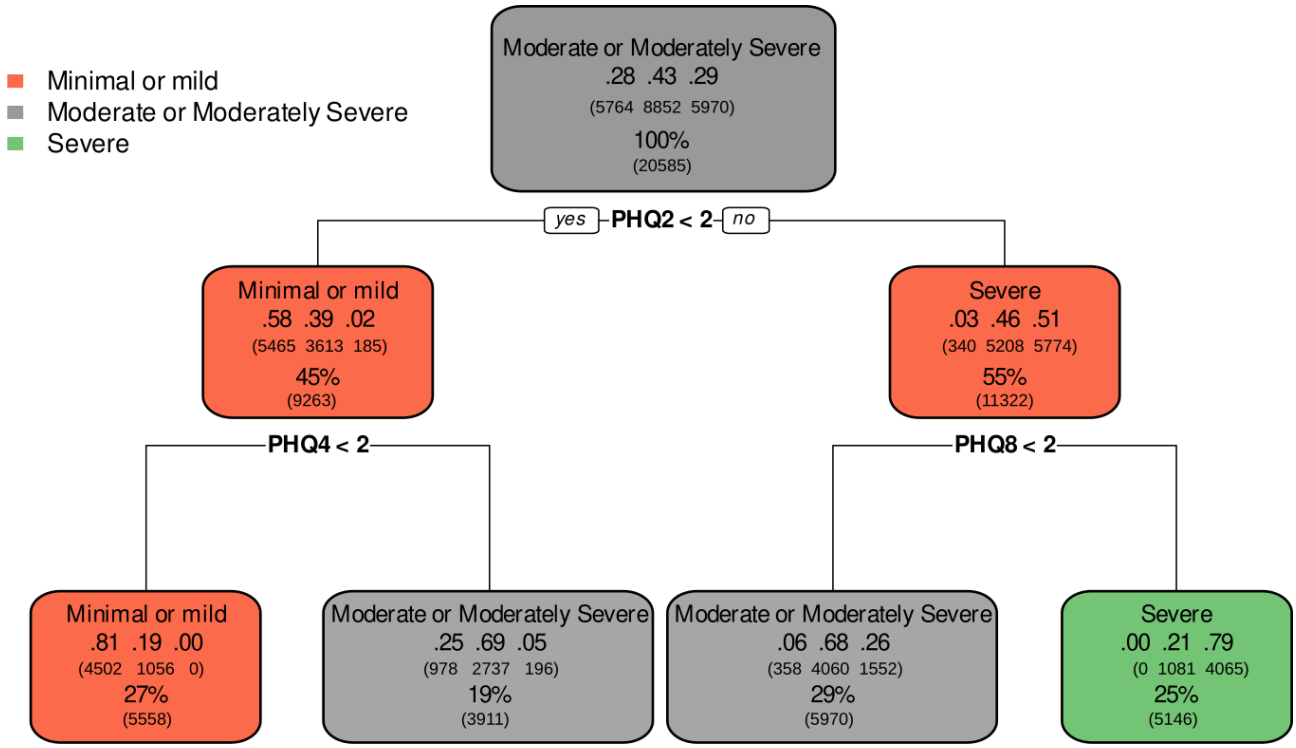

Figure 4. ROC curves for the most frequent decision tree rules classifying PHQ-9 severity levels in a cross-sectional study of Brazilian adults (n=20,585), 2024. Each ROC curve represents the classification performance of the most frequently repeated decision tree rule for a given PHQ-9 severity level (minimal, mild, moderate, moderately severe, or severe). The colored ribbons around the curves indicate the SD across 45,000 bootstrapped replications. PHQ-9: Patient Health Questionnaire-9; ROC: receiver operating characteristic.

The highest repeated rules for each PHQ-9 class are illustrated as prototypical decision trees in Figure 5. The "minimal or mild" level was characterized by the rule "PHQ2<2 and PHQ4<2," which means that a person who scored 0 or 1 on PHQ2 ("feeling down, depressed, or hopeless") and PHQ4 ("feeling tired or having little energy") was correctly classified as having a "minimal or mild" level depression in 81% (.81) of the 27% total cases that fit within this class. Concerning misclassifications, 10% were misclassified as "moderate or moderately severe" (.10) and none as "severe" (.0).

XSL•FO
RenderX

Figure 5. Prototypical decision trees representing the most frequently repeated classification rules for each severity level of the PHQ-9 scale in a cross-sectional study of Brazilian adults (n=20,585), 2024. Each node shows the classification output of a decision rule for a specific PHQ-9 severity level (minimal or mild, moderate or moderately severe, and severe). The decimal values on the middle line of each rectangle represent the proportion of participants in each true severity class, ordered from left to right: minimal or mild, moderate or moderately severe, and severe. These values indicate the actual distribution of PHQ-9 scores among participants classified by the rule. The percentage on the bottom line indicates the proportion of the total sample that followed the corresponding decision path. PHQ-9=Patient Health Questionnaire-9.

Considering only the "moderate" level, which can imply positive cases at some level to significant depression symptoms, the rules were based on a few items. For instance, to classify the "severe" level, the rule was "PHQ2≥2 and PHQ8≥2." Considering the response higher or equal to 2 in PHQ2, 55% of the cases were at the severe level, with 51% (0.51) correctly classified. When the PHQ8 item ("moving or speaking so slowly that other people could have noticed. Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual") greater than or equal to 2 was added, the proportion of cases classified as "severe" decreased to 25%; however, the proportion of correctly classified cases increased to 79% (0.79), with none as "minimal or mild" (0.0). The "moderate or moderately severe" level showed 2 rules, indicating a more complex classification: (a) "PHQ2≥2 and PHQ8<2" with 29% of total cases and shared some fit with the "minimal or mild" (0.06) and "severe" levels (0.26), although 68% (0.68) of them were correctly classified and (b) "PHQ2<2 and PHQ4≥2," with 19% of total cases, of which 69% (0.69) were correctly classified in the other route, which shared some fit with "minimal or mild" and "severe" cases (0.25 and 0.05, respectively). Finally, item 9, which addresses suicidal ideation, did not align with the final rules for the PHQ9 scale.

The clinical interpretation of the PHQ-9 decision paths reveals key depressive symptom profiles. For the "minimal or mild" depression level, the rule "PHQ2<2 and PHQ4<2" suggests that individuals reporting "feeling down, depressed, or hopeless" (PHQ2) and "feeling tired or having little energy" (PHQ4) "not at all" or "several days" (scores of 0 or 1, respectively) were accurately classified as having minimal or mild depression. This highlights that the absence of frequent anhedonia/hopelessness and fatigue is a strong indicator of lower severity. For the "severe" level, the rule "PHQ2≥2 and PHQ8≥2" was particularly revealing. It indicated that individuals experiencing "feeling down, depressed, or hopeless" "more than half the days" or "nearly every day" (PHQ2≥2) and significant psychomotor agitation or retardation ("moving or speaking so slowly.or being so fidgety or restless." [PHQ8≥2]) are highly indicative of severe depression. The inclusion of PHQ8 points to a clinically significant functional impairment often associated with severe depressive episodes, with observable changes in motor activity.

External Validation

When applied to the independent datasets, the rules identified in the main analyses showed consistent performance across both instruments. For the GAD-7, the rules showed high accuracy (range=0.852 - 0.902, M=0.875, SD=0.025), sensitivity (0.792 - 0.903, M=0.847, SD=0.047), specificity (0.916 - 0.951, M=0.937, SD=0.015), precision (0.925 - 0.983, M=0.961, SD=0.033), and F1-score (0.853 - 0.942, M=0.900, SD=0.036) for the minimal anxiety class. For the severe class, the results were also satisfactory, with accuracy (0.865 - 0.969, M=0.919, SD=0.055), sensitivity (0.585 - 0.797, M=0.722, SD=0.094), specificity (0.929 - 0.986, M=0.965, SD=0.025), precision (0.687 - 0.859, M=0.788, SD=0.073), and F1-score (0.673 - 0.793, M=0.745, SD=0.053). The moderate class, however, presented somewhat lower performance, with accuracy (0.761 - 0.877, M=0.816, SD=0.055), sensitivity (0.676 - 0.829, M=0.758, SD=0.071), specificity (0.788 - 0.898, M=0.828,

XSL•FO
RenderX

SD=0.047), precision (0.449 - 0.546, M=0.485, SD=0.046), and F1-score (0.549 - 0.646, M=0.588, SD=0.*041)*.

For the PHQ-9, the rules showed balanced performance across severity levels. For the minimal depression class, the results were as follows: accuracy (range=0.803-0.927, M=0.859, SD=0.051), sensitivity (0.711-0.804, M=0.769, SD=0.044), specificity (0.916-0.981, M=0.939, SD=0.030), precision (0.878-0.935, M=0.899, SD=0.027), and F1-score (0.808-0.839, M=0.828, SD=0.014). Performance for the severe class was also balanced, with accuracy (0.862-0.889, M=0.879, SD=0.012), sensitivity (0.513-0.724, M=0.668, SD=0.104), specificity (0.945-0.958, M=0.948, SD=0.006), precision (0.598-0.864, M=0.752, SD=0.111), and F1-score (0.552-0.782, M=0.707, SD=0.105). The moderate/moderately severe class also showed reasonable performance, with accuracy (0.730-0.808, M=0.768, SD=0.031), sensitivity (0.749-0.892, M=0.803, SD=0.068), specificity (0.677-0.778, M=0.741, SD=0.048), precision (0.591-0.752, M=0.665, SD=0.066), and F1-score (0.688-0.816, M=0.726, SD= 0.059).

Overall, the PHQ-9 rules demonstrated more uniform performance across severity classes, whereas the GAD-7 rules performed strongly for minimal and severe cases but less so for moderate cases. The performance metrics obtained from the validation datasets were consistently aligned with those observed during model training (see Tables 2 and 3, as well as Supplementary Tables 2 and 3 in Multimedia Appendix 1).

Discussion

Principal Findings

This study investigated whether CART models could generate simplified yet accurate decision rules for stratifying anxiety and depression severity using GAD-7 and PHQ-9 items. The findings confirmed that a small number of items—2 for anxiety and 3 for depression—could produce high-performing rules, particularly for identifying minimal/mild and severe cases. Using bootstrapped resampling and cross-validation on a large nonclinical sample, we identified consistent and robust classification patterns, which were also reproduced in an independent dataset collected in Brazil with the same recruitment strategy, and also other four datasets in international contexts and different samples, providing evidence of external validity in relation to the target population. The resulting decision tree rules provided concise symptom pathways with strong performance across multiple metrics, supporting previous findings regarding simplified assessment methods [42]. The most frequent and best-performing rules involved only 2 or 3 items per scale, with no sociodemographic variable contributing to the classification. These findings underscore the potential of brief, rule-based models to enhance screening efficiency while maintaining classification accuracy [53,54].

These findings can be compared with those of other studies that used decision trees to analyze PHQ-9 and GAD-7 [43-46]. However, the models used in this study had the advantage of being less complex and using a large sample size. For example, in two studies that administered PHQ-9 to 2830 Japanese participants, the final model comprised all scale items and more than 20 rules [44,45], while this study had 4 rules. Another study that also applied PHQ-9 to 10,179 participants in Hong Kong found a final model with 8 items and more than 8 rules [43]. Furthermore, some studies with decision tree models included the total GAD-7 and PHQ-9 scores [46], with no straightforward severity stratification. To the best of our knowledge, this study combines the largest sample size with the simplest model. The findings suggest that abbreviated paths could optimize strategies for large-scale healthcare management [41].

Innovative approaches, such as logical rules for the GAD-7 and PHQ-9, as seen in this study, may serve as “shortcuts” for interpreting score combinations, enhancing the precision of large-scale screenings and targeted interventions. The approach leveraged ML models to identify adaptive conditional pathways within the full GAD-7 and PHQ-9 scales. This method preserved the comprehensiveness of the full symptom set while creating shortened, symptom-specific paths—similar to the GAD-2 and PHQ-2—but with the added ability to integrate other symptoms and severity levels in classifications. This approach balances respondent burden with a more nuanced and individualized evaluation of anxiety and depression symptoms, enhancing both screening precision and clinical utility [42]. By identifying the key items and logical rules, these results can support the development of scalable, cost-effective mental health screening models, addressing critical gaps in public health care, particularly in resource-limited settings.

The decision rules identified in this study offer a practical framework for rapid mental health screening, particularly in low-resource settings. By reducing the number of items needed for severity classification, the models allow nonspecialists to quickly identify minimal/mild, moderate, or severe cases. This can support timely decisions in primary care, schools, and community programs—settings where time and training are limited. The high performance for classifying extreme severity levels enables confident triage, guiding decisions from basic psychoeducation to referral for specialized care. These rules are also well-suited for integration into digital tools, expanding access to scalable and efficient assessment.

The current proposal offers significant advantages over GAD-2 and PHQ-2. First, the established ML rules enable the screening of symptom presence or absence and identification of severity levels, while providing detailed information on specific symptoms or sets of symptoms across the full scales. This approach moves beyond the fixed focus on 2 predetermined items in each scale. Second, through such rules, instruments as concise as the GAD-2 and PHQ-2 could be used while retaining the ability to detect other relevant symptoms, facilitating intervention design. The adaptiveness of these rules—the algorithms—allows for replication in diverse contexts, accommodating cultural and local specificities and facilitating the tracking of specific symptom trajectories across various scenarios. This adaptability is important as mental health expressions and symptomatology can vary significantly across cultural backgrounds (eg, [64-66]). Third, the rules can function as a preliminary screening step using if/else conditionals, reducing the length of the full scales, minimizing respondent burden, and lowering associated costs. Finally, it enables tailored

XSL•FO
RenderX

interventions focused on specific symptoms and severity levels. For example, different strategies could be used for addressing PHQ-9 item 4 (fatigue) at minimal or mild versus moderate severity levels.

Our results demonstrated robustness when the procedure was repeated with different cutoff values for the scale scores, consistently identifying rules based on the same scale items. For example, in the PHQ-9 classifications, items 2 and 8 were most relevant for characterizing "severe" cases, whereas items 2 and 4 were most relevant for characterizing "minimal or mild" cases. However, a combination of these 3 items can show the path to the "moderate" levels: more related to the "minimal or mild" class while being closer to the "severe" level. GAD-7 findings could be interpreted similarly, where the moderate level shared some overlapping with "minimum or mild" and "severe" cases. Moreover, common limitations of decision trees, such as overfitting and instability, were not detected in this study [67]. Overfitting, often characterized by overly complex rules [54], was avoided as no rules contained more than 3 elements. Similarly, instability, which refers to changes in the tree structure due to variations in training data, was mitigated by identifying consistent patterns through resampling [68].

The decision tree rules demonstrated robust classification performance for the "minimal or mild" and "severe" categories; however, noticeably lower accuracy was observed for the "moderate" severity class (GAD-7: 51%; PHQ-9: 67%). This finding suggests that the symptom profiles for moderate anxiety and depression may be inherently more nuanced and overlapping with those of minimal/mild and severe cases, leading to increased classification complexity. As illustrated by the prototypical decision trees, the "moderate" levels often required more complex rules and paths compared to the more distinct "minimal or mild" and "severe" levels, indicating a less clear-cut symptomatic boundary. This partial overlap with other severity levels points to an area for future methodological refinement. Future studies can improve the mid-severity level classification using alternative ML approaches. For instance, ensemble models (eg, random forests, gradient boosting machines), which combine multiple decision trees to reduce overfitting and enhance predictive accuracy, might be more adept at capturing the subtle distinctions within moderate symptom presentations. Additionally, exploring probabilistic thresholds rather than strict categorical cutoffs, or incorporating a fuzzy logic approach to severity classification, could provide a more nuanced and potentially more accurate assignment to the moderate range.

While the introduction highlighted the potential for decision trees to incorporate additional variables for adaptive and personalized analyses, the specific analyses revealed that sociodemographic factors (sex/gender, age, education level, and self-reported skin color/ethnicity) had minimal predictive value and did not emerge as part of any of the most frequently repeated classification rules for either the GAD-7 or PHQ-9. This suggests that within the context of our CART models and the specific severity stratification, the core symptom items were overwhelmingly more influential in classification. Consequently, detailed subgroup analyses based on these sociodemographic characteristics were not the most impactful predictive features for streamlined screening. Future research, perhaps using different ML approaches or focusing on distinct research questions, could more thoroughly investigate the interplay between sociodemographic factors and symptom presentation. By contrast, the lower impact of sociodemographic variables reinforces the principle that a broad approach to mental health literacy—including brief, self-guided interventions—can be directed at the general population with a reasonable margin of safety in reaching the intended audience. In other words, it offers a cost-effective strategy by enabling a concise and focused implementation to support scalable public policies.

These findings have significant practical implications for public mental health. The concise, rule-based models derived from the GAD-7 and PHQ-9 can be efficient "shortcuts" for large-scale mental health screening, particularly in resource-limited settings where extensive assessments are often impractical. For instance, in primary care settings, these simplified rules can empower health professionals, including nonspecialists, to rapidly identify disorders at varying risk levels (minimal/mild, moderate, and severe). This rapid stratification can facilitate tailored interventions, ranging from basic psychoeducation and self-guided resources for minimal/mild cases to immediate referral for more intensive support (eg, in-person appointments, specialized care) for moderate and severe cases. This directly supports the development of scalable and cost-effective mental health policies, enabling more efficient allocation of resources and improved access to care for a wider population.

While previous research has used similar methodologies to examine the PHQ-9 and GAD-7 scales using decision trees [43-46], our approach provides several key advantages, warranting a more critical comparison. For instance, some studies [44,45] are focused on individual PHQ-9 items; however, they often used different hyperparameters and, in some cases, dichotomized PHQ-9 scores, leading to substantially more complex decision trees with over 20 rules. By contrast, our study achieved highly accurate classifications with a significantly smaller set of rules (4 for PHQ-9), demonstrating a superior level of parsimony. Furthermore, some prior work [46] used total PHQ-9 and GAD-7 scores and incorporated sociodemographic variables directly into their models but, unlike our study, did not aim for severity stratification based on minimal item sets.

A critical advantage of our study lies in its large sample size, encompassing more than 20,000 participants from across all Brazilian states. This extensive and geographically diverse dataset significantly enhances the external validity and generalizability of our findings compared to those of previous studies with smaller cohorts. This large sample also allowed us to rigorously use bootstrapping and cross-validation, enabling robust estimation of rule performance and providing valuable dispersion measures that attest to the stability of the identified rules. While digital convenience sampling presents a limitation regarding full representativeness of the general population and potential selection bias toward individuals with digital access, the sheer scale and geographic breadth offer a substantial improvement in sample diversity compared to that in several previous studies in this domain. Thus, our work represents a significant advancement in optimizing mental health screening by combining the largest known sample size with the

XSL•FO
RenderX

development of the most parsimonious and highly accurate decision tree models for GAD-7 and PHQ-9 severity classification.

Unlike fixed short scales such as the GAD-2 and PHQ-2, which rely on 2 specific symptoms and offer only binary outcomes, our models generate brief but adaptive rules that capture severity levels across a wider symptom range. While prior decision tree studies often retained most items and many rules, our models achieved high accuracy using only 2 - 3 items and 4 rules per scale. These findings combine the simplicity of ultra-brief tools with the precision of full assessments, offering a more scalable and clinically informative alternative for public mental health applications.

The models identified in this study are concise and can be implemented in primary care by training health professionals in basic psychological care and developing specific intervention tools (eg, self-guided booklets, telephone consultations, and remote support) to manage "minimal or mild" symptoms. For moderate and severe cases, they serve as pathways for the rapid identification of individuals requiring more intensive support, such as in-person appointments, home visits, outpatient care, or even higher-level interventions such as inpatient treatment (eg, day hospitals or long-term hospitalization) [14,69,70]. These initiatives may be more feasible with straightforward instruments for evaluation and decision-making, improving the cost-benefit ratio and adding value to low-cost solutions for most demanding realities, such as mental health care in LMICs [8,40,71-75]. Thus, this study is aligned with the principles of a precision approach in the mental health field [76-78]—specifically, a precision health psychology approach.

Limitations

This study has some limitations. First, the sample presented unbalanced sociodemographic characteristics, with more than 90% of participants identifying as female and an uneven distribution of skin color/ethnicity and education levels. Although variable importance analysis showed that sociodemographic factors—including sex/gender—contributed little to the final classification models (as none appeared in the most frequent rules), this representation pattern may limit the generalizability of the decision rules, particularly for male populations. Future studies should aim for a more balanced sample, especially with respect to sex/gender, which remains a persistent challenge across research contexts [79,80]. Although the CART models prioritized symptomatic items, it is possible that gender-specific symptom expressions or reporting styles may affect rule performance in different demographic contexts.

Second, although the dataset was large and included individuals from both rural and urban areas across Brazil, it is not representative of the general population. The recruitment was based on digital convenience sampling, using social media and electronic invitations, which may have introduced selection bias. Participants with limited internet access or low digital literacy may be underrepresented. Future studies should consider alternative recruitment methods to increase sample heterogeneity and representativeness.

Third, although robustness was supported by cross-validation, bootstrapping, and reproducibility in an independent national dataset, the reliance on digital convenience sampling may still limit representativeness. Future studies should extend external validation to different recruitment strategies and other nonclinical and clinical populations to strengthen generalizability. In addition, the choice of CART models was based on their interpretability and feasibility for large-scale use, but other machine learning techniques—such as ensemble models or deep learning—may offer alternative trade-offs between performance and complexity. Comparative studies could support future applications, especially in resource-limited settings.

Conclusions

This study applied machine learning techniques—specifically decision trees combined with bootstrapping and cross-validation—to improve the classification of anxiety and depression severity based on GAD-7 and PHQ-9 items. Our findings show that just 2 items for anxiety and 3 for depression could generate highly accurate rules for identifying individuals with minimal or severe symptoms. Although the models performed well in distinguishing the extremes, their accuracy was lower for moderate cases, likely due to overlapping symptom patterns. These results suggest that caution is warranted when interpreting classifications in the middle severity ranges.

Simplified, rule-based models like those tested here can contribute to more efficient mental health care strategies. By using fewer items without compromising accuracy, they allow for faster assessments, better allocation of clinical resources, and quicker identification of cases requiring closer attention. In large-scale settings, this may support early interventions for mild cases and timely referrals for individuals showing more severe symptoms. Reducing the length and complexity of screening tools can also ease the burden of national data collection efforts, making it easier to integrate screening into population-based initiatives. Personalized guidance can then be offered based on specific symptom patterns—from psychoeducational materials and mental health literacy to behavioral interventions and clinical support. In this way, simple algorithms may support scalable and adaptive mental health surveillance strategies.

Further research should test these models in more diverse populations, using broader recruitment strategies beyond digital outreach to improve generalizability. While decision trees offer transparency and efficiency, comparative studies involving other machine learning methods—such as ensemble models or deep learning—could shed light on different cost-benefit trade-offs, especially in resource-limited settings. Longitudinal studies are also needed to evaluate the stability of these simplified models over time and their potential to monitor symptom progression or support personalized care. Finally, integrating these tools into digital health platforms or mobile applications could further enhance their accessibility and usefulness in real-world settings.

Abstract

Background: Avoidable hospitalizations (AHs) have been widely used in high-income countries as a proxy indicator for the quality of primary care. However, it is rarely evaluated in low- and middle-income countries such as China. Studies examining changes in AHs before and during the COVID-19 pandemic are also limited. The appropriateness of AHs as an indicator measuring primary care quality under pandemic conditions has not been well discussed.

Objective: This study aims to describe trends in AHs in Beijing, China, during both the prepandemic (2016-2019) and pandemic (2020-2021) periods and examine factors associated with AH rates.

Methods: We used hospital discharge data of Beijing residents between January 1, 2016, and December 31, 2021. We identified AH cases from all discharge cases and calculated AH rates each year, adjusting for population structure changes. We performed regression analyses to explore factors associated with AH rates, where the COVID-19 outbreak, health care resources, and socioeconomic characteristics were used as the main explanatory variables.

Results: Before the COVID-19 pandemic, the total number of hospital discharges in Beijing increased steadily from 2016 to 2019 but decreased sharply in 2020 and partially rebounded in 2021. The sex- and age-standardized AH rate per 100,000 population rose from 514.7 (95% CI 511.4 - 517.9) in 2016 to 552.8 (95% CI 549.4 - 556.1) in 2019. Then it declined to 331.2 (95% CI 328.6 - 333.8) in 2020 and rebounded to 465.1 (95% CI 462.1 - 468.1) in 2021, which was still below the prepandemic level. Regression analyses show that the presence of newly confirmed COVID-19 cases was significantly associated with a lower AH rate. As for other factors, higher densities of primary physicians were linked to lower AH rates. Moreover, AH rates were also associated with population structure, the level of economic development, and demographic variables.

Conclusions: The AH rate in Beijing exhibited a consistent upward trend before the pandemic and remained higher than in many high-income countries. These characteristics suggest a potential overuse of tertiary care and highlight the necessity for health care system reforms in Beijing, particularly a transition from the hospital-centered model to a primary care–focused delivery system. In addition, the observed associations between AH rates and factors, such as pandemic shock and socioeconomic variables, indicate that AH should be interpreted with appropriate controls when it is used as an indicator of primary care performance.

KEYWORDS

avoidable hospitalization; COVID-19; primary care; accessibility; quality of care

Introduction

In the past 2 decades, improving access to high-quality primary or ambulatory care has been a global policy priority [1]. It has been regarded as a means to improve population health and control health expenditures. One key measure that policy makers and researchers use to evaluate the accessibility to high-quality primary care is hospitalizations related to ambulatory care sensitive conditions (ACSCs), as they could be potentially avoided with timely and effective health care management [2,3]. These ACSCs-related hospitalizations are often referred to as avoidable hospitalizations (AHs) that may impose substantial burdens on individuals, the health care system, and the whole society.

AHs have been widely used to evaluate primary care performance in high-income countries, such as the United States,

XSL•FO
RenderX

Europe, Australia, and South Korea [4-9]. A series of studies have also identified factors associated with AHs in high-income countries, such as access to primary care, organizational arrangements, and individual socioeconomic status [10-12]. However, to the best of our knowledge, few studies have investigated the trends in AHs and their associated factors in low- and middle-income countries [13,14], where health care resources are generally insufficient and the quality of care is usually unsatisfactory. More evidence on AHs from low-income countries contributes to a better understanding of their health care system performance through international comparisons.

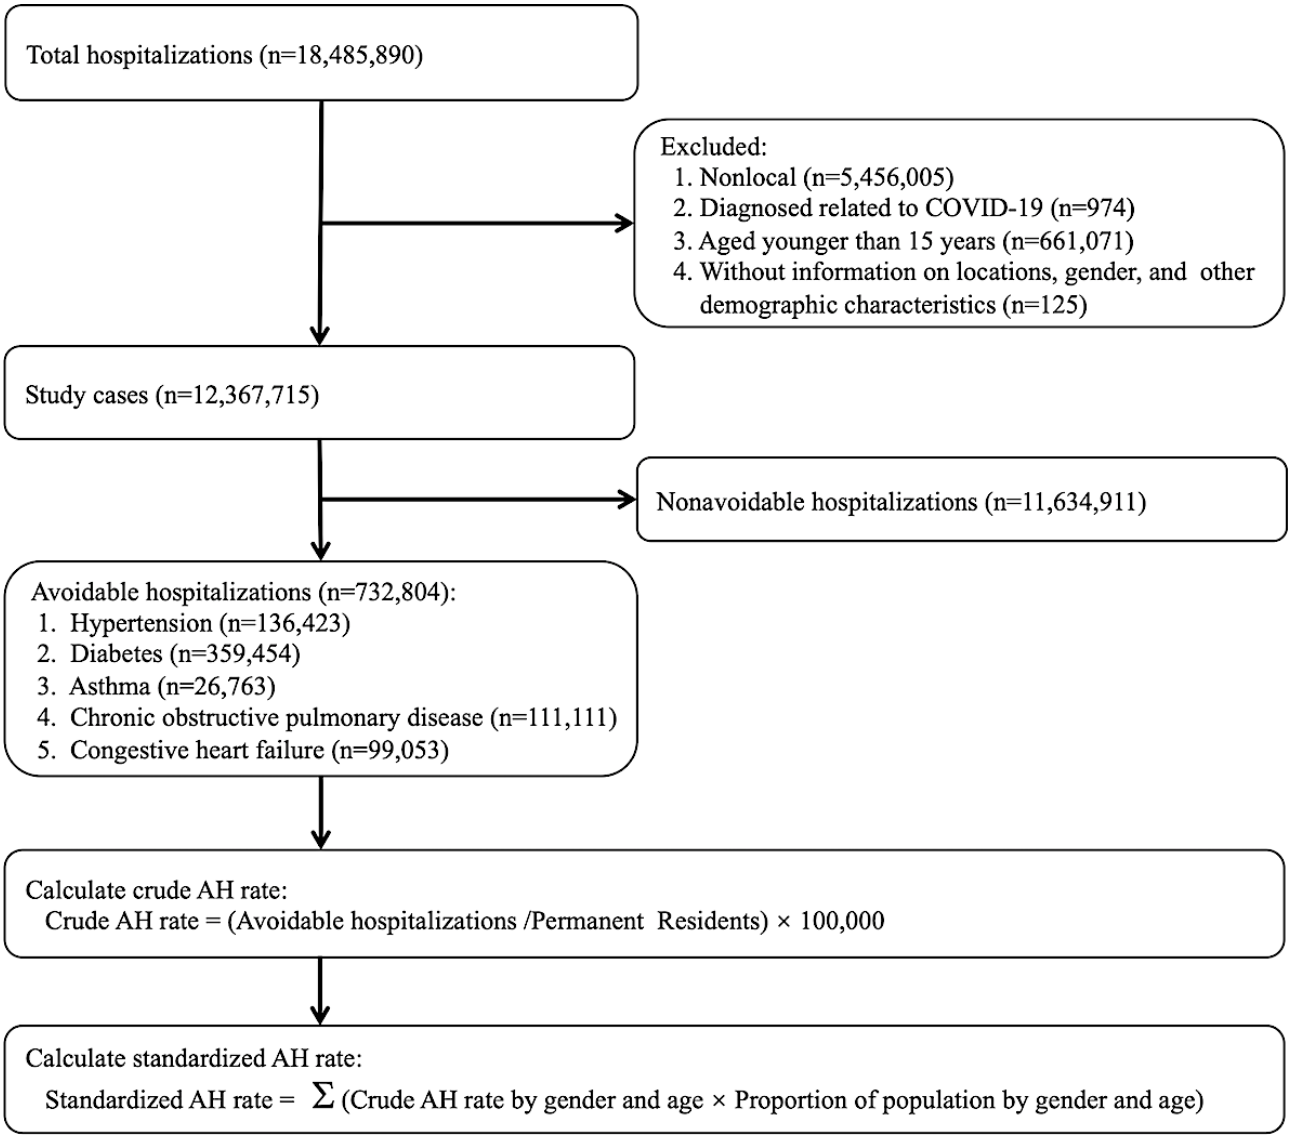
Furthermore, our understanding of trends in AHs during the COVID-19 pandemic is limited, especially in low-income countries. A series of studies on high-income countries have shown the impacts of the COVID-19 pandemic on disrupting access to non–COVID-19–related medical services, such as decreasing hospitalizations and preventive service usage [15-17]. However, little is known about changes in AHs in low- and middle-income countries before and during the pandemic, although existing studies have found substantial declines in outpatient visits and hospital admissions [18-20]. A few studies have also examined changes in admissions for ACSCs during the pandemic but results have been inconsistent [21-24]. On the one hand, lockdown policies during the pandemic may reduce hospitalizations related to ACSCs, resulting in a decrease in the AH rate. On the other hand, delayed health care usage may exacerbate ACSCs, leading to an increased AH rate.

In this study, we aim to use Beijing as an example to examine AHs in the setting of the Chinese health care system. We used hospital discharge data from Beijing between 2016 and 2021 to describe trends in AHs, which cover periods prior to and during the COVID-19 outbreak. We also performed regression analysis to explore the factors influencing AH rates, with COVID-19 cases and socioeconomic characteristics as the main explanatory variables. As the capital of China, Beijing leads in socioeconomic development and population health in China. It is the medical hub of North China with abundant medical resources. The social health insurance schemes in Beijing, especially in the coverage of outpatient care, are more generous than those in most other Chinese cities. The hospital discharge rate among Beijing's local residents in 2019 was approximately 11.1% (2,431,274/21,901,000), which was lower than both the national average in China (18.6%) and the average across 35 Organisation for Economic Cooperation and Development (OECD) countries (14.9%) [25,26]. However, similar to other Chinese cities, Beijing has a profit-driven, hospital-centered health care system with weak primary care [27-29]. In 2019, more than 50.0% of the medical revenues of public hospitals in Beijing came from pharmaceuticals and diagnostic tests, while less than 25.0% were from medical services [30]. Approximately 172.1 million outpatient visits were provided by hospitals, while primary care institutions accounted for only 68.3 million visits [31]. Moreover, 62.6% of total health expenditures went to hospitals, while only 10.2% were allocated to primary health care institutions [32]. All these figures suggested the system's heavy reliance on hospital-based care. Due to low perceived quality, patients do not trust primary care facilities much and often bypass the primary care system. Consequently, they often seek care at tertiary hospitals for simple conditions, leading to overcrowded tertiary hospitals and rising health expenditures. Therefore, results about AHs in Beijing not only inform us of the health system performance in Beijing but also provide implications for the challenges in the Chinese health care system.

One of the prominent events during our study period was the outbreak of COVID-19 pandemic, which may profoundly affect the trend and level of AHs. After the outbreak of the COVID-19 pandemic in January 2020, the Beijing municipal government took strict measures to control the viral transmission, including restrictions on human mobility, body temperature monitoring, and contact tracing [33]. Although there were only sporadic outbreaks and a small number of confirmed cases in the following 2 years (as shown in Figures S1 and S2 in Multimedia Appendix 1), these strict measures may generate substantial effects on people's daily lives, including consumption behaviors, willingness to work from home, investment decisions, and health care usage [34-37]. As some studies have already examined the complex drivers of AHs (eg, primary care quality, socioeconomic conditions, hospital admission policy, and health insurance types) and questioned the appropriateness of AHs in measuring the quality of primary care [38,39], trends in AHs before and during the COVID-19 pandemic could provide important implications for the effectiveness and limitations of the usage of AH as a proxy for access and quality of primary care, given that large shocks to both the demand and supply sides of health care services were caused by the COVID-19 pandemic.

Methods

Study Population and Data Source



In this study, we mainly used hospital discharge data in Beijing between January 1, 2016, and December 31, 2021, to investigate trends in AHs. This dataset was acquired from the Beijing Municipal Health Big Data and Policy Research Center. The dataset included all hospital discharge records in 267 hospitals in Beijing, except for 13 military hospitals. It contained extensive information on medical diagnoses (the *ICD-10* [*International Statistical Classification of Diseases, Tenth Revision*] code), procedures (the *ICD-9-CM-3* [Volume 3 of the *International Classification of Diseases, Ninth Revision, Clinical Modification*] code), length of stay, health expenditures, health insurance types, and patient demographic characteristics [40]. As this dataset encompassed both the prepandemic and pandemic periods, it allowed us to scrutinize how the COVID-19 pandemic affected health care usage among residents in Beijing.

According to the Health Care Quality Indicator Definitions proposed by the OECD [41], discharges with a principle of *ICD-10-CM* (*International Classification of Diseases, Tenth Revision, Clinical Modification*) code for any 1 of the following 6 ACSCs were identified as AHs: hypertension, diabetes, asthma, chronic obstructive pulmonary disease (COPD), congestive heart failure (CHF), and diabetes-related lower limb amputation. Because of their small volume (less than 200 cases per year) and the overlap with diabetes cases, diabetes-related lower limb amputations were merged into the scope of diabetes

XSL•FO
RenderX

for analysis. This classification allowed us to compare our results with international studies as well as some other China-specific findings [13,42,43]. As depicted in Figure 1, we identified a total of 732,804 cases of AHs, adhering to the specific inclusion and exclusion criteria outlined in Table S1 in Multimedia Appendix 1. Among these AHs, there were 136,423 cases of hypertension, 359,454 cases of diabetes, 26,763 cases of asthma, 111,111 cases of COPD, and 99,053 cases of CHF.

Figure 1. Flowchart for identifying AHs and calculating AH rates. The initial dataset contained 18,485,890 discharge cases during the period between 2016 and 2021. Then, we narrowed our sample to local patients because this study aimed to examine AHs among permanent residents in Beijing. Beijing is the largest medical hub in China, serving a large share of inpatient cases from various provinces nationwide. Since these nonlocal inpatients' conditions tend to be more severe and are not related to primary care in Beijing, nonlocal inpatients were excluded to avoid biasing the estimation of AH rates. We also excluded inpatient cases related to COVID-19, cases related to age less than 15 years [41], and cases lacking information on residential locations, sex, and other demographic characteristics. Finally, we obtained a sample of 12,367,715 cases for our analysis. AH: Avoidable hospitalization.

Variables

In this study, we defined key, dependent variables at both case and district levels. At the case level, the dependent variable is a binary indicator denoting whether a given hospital admission was an AH. At the district level, the dependent variable is the monthly AH rate for each district. As shown in Figure 1, we conducted calculations by dividing the count of AHs by the total resident population and then multiplied the result by 100,000 to derive the crude AH rates per 100,000 population. In addition, we calculated sex- and age-standardized AH rates, referencing the population structure of Beijing in 2010, to examine the consistency and stability of our findings.

Regarding independent variables, we also collected data at both the individual and district levels. First, we extracted demographic and clinical characteristics from hospital discharge records, including sex, age, marital status, health insurance types, and the Charlson Comorbidity Index (CCI) score. Second, we collected data on socioeconomic and health resources at the district level to examine the associated factors of AH rates. These variables included densities of hospital physicians (ie, the number of hospital physicians per 1000 population), primary physicians (ie, the number of primary physicians per 1000

XSL•FO
RenderX

population), proportion of males, proportion of the population aged older than 65 years, education level, and economic development, which were calculated based on information from the Beijing annual reports of medical institutions and Beijing statistical yearbooks. Finally, we obtained data on the daily confirmed COVID-19 cases in Beijing from the Chinese Center for Disease Control and Prevention to construct 2 dummy variables to indicate the presence of the COVID-19 pandemic in the current month or the previous month within each district of Beijing. Table S2 in Multimedia Appendix 1 shows the definitions of all variables used in this study.

Statistical Analysis

We first conducted descriptive analyses. Categorical variables are described with numbers and percentages, and continuous variables are described with means and SDs. We reported crude and standardized AH rates with 95% CIs for years between 2016 and 2021 and used chi-square tests to examine the statistical significance of differences between different years. In addition, we calculated AH rates across various districts in Beijing to show geographic variations. There are 16 administrative districts in Beijing, consisting of 6 urban districts located at the center of the city and 10 suburban districts. Compared with the suburban districts, the central districts have better socioeconomic developments, higher population density, and more abundant medical resources.

Furthermore, we performed linear regressions with robust SEs to explore the associated factors of AHs. First, we used district-level AH data to explore the association between AHs and the COVID-19 outbreak, health care resources, and socioeconomic characteristics. The model can be written as follows:

$$(1) Yit=\beta 0+\beta 1COVIDit+\beta 2Resourceit+\beta 3Controlsit+\lambda year+ it$$

where the subscript i denotes the district in Beijing and t denotes each month from January 2016 to December 2021. The dependent variable Y_{it} is the crude or standardized monthly AH rate for each district. The independent variable $COVID_{it}$ is a dummy variable that takes 1 if the district experienced 1 or more newly confirmed COVID-19 cases in the current month. Otherwise, it equals 0. $Resource_{it}$ denotes variables measuring the density of medical resources at the district level, including the number of hospital physicians per 1000 population and the number of primary physicians per 1000 population. Because of collinearity, other variables measuring the density of medical resources, such as hospital beds per 1000 population, are not included in the analysis. $Controls_{it}$ are a series of socioeconomic variables, including population structure, average education level, and economic developments. λ_{year} denotes the year fixed effects to control unobservable variables that change over time but are constant over districts. $_{it}$ denotes the robust error term.

In addition, we used individual-level data to perform logistic regressions to explore individual-level factors associated with AHs. The model can be written as follows:

$$(2) Pr(Yijst=1)=11+e-(\beta 0+\beta 1COVIDjst+\beta 2Xijst+\beta 3Hospitalj+\beta 4Districtst+\lambda t)$$

where the subscript i denotes the hospitalized case, j denotes the hospital, s denotes the district in Beijing, and t indicates the year. The dependent variable Y_{ijst} is a binary indicator that takes 1 if the hospitalized patient case i who resides in district s was admitted to hospital j in year t for ACSCs, and 0 if the admission was due to other conditions. The independent variable $COVID_{ijst}$ is a dummy variable that takes 1 if the district where the patient lived had 1 or more new confirmed COVID-19 cases within a period before the patient was admitted. Otherwise, it equals 0. X_{ijst} denotes a series of individual-level variables, including sex, age, marital status, CCI score, and health insurance types. $Hospital_{jt}$ denotes the ranking of the hospital, which is classified into 3 groups: primary, secondary, or tertiary hospitals. $District_{st}$ denotes variables measuring the density of medical resources in the district where the patient lived, including the number of hospital physicians per 1000 population, the number of primary physicians per 1000 population, and other socioeconomic variables. λ_t denotes the year fixed effects to control for unobservable variables that change over time but are constant over the patient. Robust SEs are clustered at the district level. All statistical analyses were carried out in Stata 17.0 (StataCorp LLC). All P values were from 2-sided tests and results were deemed statistically significant at $P<.1$.

Ethical Considerations

This study was approved as a secondary use of administrative data with a waiver of informed consent by the Peking University institutional review board. All data used in the study were deidentified prior to analysis to protect participants' privacy and confidentiality. The study was conducted in accordance with institutional ethical standards and followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guideline for cross-sectional studies.

Results

Summary Statistics

Table 1 shows the summary statistics for variables in the discharge data. From 2016 to 2019, the number of discharge cases for local inpatients aged older than 15 years increased from 1,931,230 to 2,303,308, while it decreased to 1,697,228 in 2020 and rebounded to 2,282,250 in 2021. The proportion of females was consistently higher than that of males and it decreased modestly over the years. The share of inpatients older than 60 years increased from 46.0% (887,617/1,931,230) in 2016 to 50.5% (1,151,718/2,282,250) in 2021. The share of inpatients without comorbidities as measured by the CCI (Table S3 in Multimedia Appendix 1) decreased by about 6 percentage points during this period. Patients receiving treatment at tertiary hospitals took a larger share after 2020, which implies a significant change in the patient composition during the COVID-19 pandemic. Additionally, these findings were in line with rising expenditures per admission after 2020, compared with those between 2016 and 2019.

Tables S4 and S5 in Multimedia Appendix 1 show the summary statistics for AHs and non-AHs, respectively. Similar to the trends in all inpatient cases, both the numbers of AHs and non-AHs experienced large declines during the pandemic. However, the reduction in AHs (38.4%, 54,499/141,811) in 2020 was markedly greater than that in non-AHs (25.5%,

XSL•FO
RenderX

555,581/2,161,497). More than half of AHs were males, contrary to the sex share among non-AHs. The proportion of AHs aged older than 60 years was consistently larger than that of non-AHs during our study period. Most AHs had comorbidities and the group of AHs had much higher CCI scores than non-AHs. However, the average expenditures for AHs were consistently lower than those for non-AHs.

[a]Categorical variables are described with numbers and percentages (%), and continuous variables are described with means and SDs.

[b]AHs: avoidable hospitalizations.

[c]Unmarried status includes never married, widowed, and divorced.

[d]CCI score: the Charlson Comorbidity Index score. It was included to measure the severity of comorbidities, which was calculated for each case based on the information from the hospital discharge data (Table S3 in Multimedia Appendix 1). It was further categorized into 4 subgroups (0, 1 - 2, 3 - 4, and ≥5) [44].

[e]UEBMI: urban employee basic medical insurance.

[f]URBMI: urban resident basic medical insurance.

[g]NCRMS: new rural cooperative medical system. URBMI and NCRMS, mainly provided for minors and unemployed persons, were put together for

XSL•FO
RenderX

analysis because they had been merged since 2018.

[h]Other types of health insurance schemes include commercial medical insurance, other social insurance, poverty relief, public free health, and without insurance coverage.

[i]All expenditures are reported in Chinese yuan (CNY). The average exchange rate in 2021 was 6.4515 CNY to 1 USD.

[j]LoS: length of stay.

Trends in AHs

The first row of Table 2 shows crude changes in overall AHs in Beijing between 2016 and 2021, suggesting that the COVID-19 pandemic had significant impacts on AHs. Before the pandemic (2016-2019), the overall crude AH rate per 100,000 population exhibited a consistent upward trend, rising annually from the lowest of 633.4 (95% CI 629.8 - 637.0) in 2016 to the highest of 740.0 (95% CI 736.2 - 743.8) in 2019. The difference in the crude AH rate between 2016 and 2019 was statistically significant (difference=106.6; P<.001). However, during the pandemic, the crude AH rate experienced a sharp decline to 452.4 (95% CI 449.4 - 455.4) in 2020 and rebounded to 639.3 (95% CI 635.8 - 642.9) in 2021, but the crude AH rate in 2021 was still lower than the average level in the prepandemic period. Sex- and age-standardized AH rates followed a similar trend to crude AH rates before and during the pandemic. As for regional differences, Figure S3 and Table S6 in Multimedia Appendix 1 report AH rates at the district level from 2016 to 2021. Overall, suburban districts consistently have higher AH rates than central districts, showing similar trends. Figure S4 in Multimedia Appendix 1 also illustrates trends in mean expenditure and length of stay for avoidable hospitalizations from 2016 to 2021.

[a]AH: avoidable hospitalization.

[b]Chi-square tests were used to test the statistical significance of differences between different survey years.

[c]COPD: chronic obstructive pulmonary disease.

[d]CHF: congestive heart failure.

[e]Standardized AH rates were standardized by the sex and age population structure of Beijing in 2010.

Impact of the COVID-19 Pandemic and Associated Factors of AHs

Table 3 reports linear regression results that investigated the impact of the COVID-19 pandemic on the monthly AH rates for each district as well as associated factors of AH rates at the district level. In these regression analyses, we included the key variables $COVID_{this\ month}$ and $COVID_{last\ month}$, representing the existence of newly confirmed COVID-19 cases in the district for the current month and the previous month, respectively. We also included variables related to medical resources, population structure, and other control variables. In column 1 of Table 3, results show that the existence of the COVID-19 pandemic in the current month was significantly associated with a decrease in the crude AH rate for that month. Considering that the existence of the COVID-19 pandemic in the previous month

XSL•FO
RenderX

might influence the change in AHs in the current month, we further included $COVID_{last\ month}$ to examine the impact of the pandemic on AHs. In column 2, it is evident that the existence of the COVID-19 pandemic was correlated with a significant decrease in the AH rate in the following month. The magnitude of change caused by the pandemic in the last month was larger than that in the current month. Regarding district-level medical resources, a higher density of hospital physicians was positively associated with AH rates. In contrast, a higher density of primary physicians was associated with lower AH rates. To account for demographic changes in Beijing, we changed the dependent variable from the crude AH rate to the standardized AH rate by the Beijing reference population. As shown in columns 3 and 4 of Table 3, the coefficients for various variables remained largely unchanged when using the standardized AH rate as the dependent variable. When we controlled for month-year fixed effects, our results remained largely robust, as shown in Table S8 in Multimedia Appendix 1.

We performed logistic regression analyses using individual-level data to further test the robustness of our findings. As shown in the first 2 columns of Table S7 in Multimedia Appendix 1, the presence of newly confirmed COVID-19 cases within 14 days or 1 month before hospital admission, as well as a greater number of primary care physicians in the patient's residential district, was associated with a decreased likelihood of the hospitalization being classified as an AH. These results are consistent with the findings based on district-level data. In terms of individual-level factors, hospitalized patients who were male, older, and had comorbid conditions had a higher probability of being classified as AH cases than their female, younger, and noncomorbid counterparts. Inpatients covered by urban resident basic medical insurance or new rural cooperative medical scheme were more likely to be AHs than those covered by urban employee basic medical insurance. Additionally, patients admitted to primary hospitals were more likely to be AHs than those treated in secondary or tertiary hospitals. Table S7 in Multimedia Appendix 1 also shows regression results using expenditure and length of stay as dependent variables to examine potential changes in case composition.

[a]AH: avoidable hospitalization.

[b]Crude AH rate in models (1) and (2) indicates the monthly crude AH rate of each district.

[c]Standardized AH rate in models (3) and (4) indicates the standardized monthly AH rate of each district according to the population structure of Beijing in 2010.

[d]RSE: robust standard error.

[e]Key variables $COVID_{this\ month}$ and $COVID_{last\ month}$ indicate whether new COVID-19 cases were recognized in the district this or last month.

[f]Not included in this model.

Discussion

Principal Findings

Using discharge data from Beijing, this study found that both the crude and the sex- and age-standardized AH rates in Beijing displayed an upward trend before the COVID-19 pandemic (2016 - 2019) and experienced a sharp decline after the outbreak of the pandemic. This trend suggests substantial impacts of the COVID-19 pandemic on health care usage among residents in Beijing. Moreover, regression results showed that AHs were significantly associated with multiple factors, including pandemic shocks, densities of health care resources, socioeconomic variables, and various demographic characteristics.

We found that both the crude and the sex- and age-standardized AH rates in Beijing displayed an upward trend before the COVID-19 pandemic (2016 - 2019) and experienced a sharp decline after the outbreak of the pandemic. This trend suggests substantial impacts of the COVID-19 pandemic on health care usage among residents in Beijing.

Based on the results regarding trends in AHs before and during the COVID-19 pandemic, we further compared the AH rate in Beijing with that in some high-income countries, including the United States, the United Kingdom, France, Canada, and Korea, by calculating sex- and age-standardized AH rates based on the OECD 2015 reference population [45]. As shown in Table 4, the overall sex- and age-standardized AH rate per 100,000 population in Beijing was 904.1 in 2019, higher than that in the United Kingdom (530.5 in 2019), France (636.0 in 2015), Canada (537.3 in 2019), and Korea (641.0 in 2019), but slightly lower than that in the United States (961.0 in 2019). This comparison suggests that it is necessary for Beijing to strengthen its primary care system and restructure its hospital-centered delivery system.

In terms of specific diseases, the sex- and age-standardized AH rates for hypertension and diabetes in Beijing were much higher than those in all comparison countries. That finding may be due to the relatively low awareness and control rates of these conditions among the Chinese population [29], which often results in delayed diagnosis and more severe symptoms requiring hospitalization. In addition, medical insurance policies in China provide higher reimbursement rates for inpatient care than for outpatient care, which may incentivize hospitalization over outpatient care. By contrast, the standardized AH rates for asthma, COPD, and CHF in Beijing were at a relatively low level, compared with those in other countries. Given the high proportion of hypertension and diabetes among all AHs in Beijing, more attention should be paid to the prevention and control of hypertension and diabetes.

Moreover, this study showed that relatively high-income districts with abundant primary care medical resources generally had lower AH rates than suburban districts. This was consistent with the regression result that a higher density of primary physicians was associated with a lower AH rate. It also implied that the AH rate could at least partially reflect the accessibility to primary care. In addition, we found that the AH rate was significantly associated with demographic and socioeconomic variables, such as population structure and economic development. These supported the previous finding that AHs should be interpreted in conjunction with metrics of demographic composition and the level of economic development [39,46].

More importantly, we found that the COVID-19 pandemic was associated with the reduction of the AH rates in Beijing. This association remained robust across alternative regression specifications, including using various definitions of the COVID-19 pandemic, changing the dependent variable from crude rates to standardized rates, and using data at the individual level. These results highlight that we cannot interpret solely the reduction in AH rates as the result of the changing performance of primary health care, as the pandemic has caused many changes in health care providers' and patients' behaviors that could be related to the AH rates. During the COVID-19 pandemic, many countries took large-scale public health measures such as stay-at-home orders, closing schools, cancellation of mass gatherings, and even lockdowns of endemic areas [20,47-50]. In Beijing, despite low COVID-19 mortality and a limited number of confirmed cases, the government implemented a stringent "zero-COVID" policy, including movement restrictions, community lockdowns, testing mandates, and hospital visitor bans. These measures created substantial barriers to hospital access for patients with no COVID-19 cases. Compared to non-AHs, AH patients typically present with milder symptoms and some of them seek hospitalization primarily because the reimbursement rate for inpatient care is higher than for outpatient care in the nonpandemic period. As a result, during the pandemic period, AH patients became more sensitive to the demand-side factors (eg, patients with ACSC avoiding hospitals unless their symptoms became severe) and the supply-side factors (eg, providers restricting admissions for mild cases to prevent in-hospital viral transmission), which collectively contributed to the larger reductions in AHs.

Taken together, our findings highlight the complexity of using AH as a proxy for access to primary care, especially when there are systemwide changes. The determinants of AHs are multifactorial, including factors at the patient level, regional level, and national system level. These factors may not be independent but intertwined, especially when there are changes that simultaneously occur in both the demand and supply for

XSL•FO
RenderX

medical care. As a result, when we observe a change in AH rates, it may be inappropriate and inaccurate to interpret them solely as the consequence of changes in the accessibility and quality of primary health care or outpatient care.

Table . International comparisons of sex- and age-standardized avoidable hospitalization rate[a].

Variables	Beijing (2019)	United States[b] (2019)	United Kingdom[b] (2019)	France[b] (2015)	Canada[b] (2019)	Korea[b] (2019)
Total AHs[c]	904.1	961.0	530.5	636.0	537.3	641.0
Hypertension	167.5	60.6	18.7	34.8	14.6	79.2
Diabetes	405.1	248.5	81.7	155.6	98.9	237.3
Asthma	29.4	37.3	74.9	29.8	13.9	68.5
COPD[d]	153.5	186.8	239.2	128.8	229.5	161.5
CHF[e]	148.5	427.8	116.0	287.0	180.4	94.5

[a]All the sex- and age-standardized AH rates per 100,000 population were standardized by the OECD (Organisation for Economic Co-operation and Development) 2015 reference population.

[b]These countries' sex- and age-standardized AH rates were obtained from the OECD website.

[c]AHs: avoidable hospitalizations.

[d]COPD: chronic obstructive pulmonary disease.

[e]CHF: congestive heart failure.

Limitations

There are several limitations to this study. First, we can only roughly measure the impact of primary health care access but not directly measure the effect of primary health care quality on AHs due to data availability. Second, we cannot evaluate the gains in social welfare from reductions in AHs during the pandemic. We also cannot clearly identify the mechanisms through which the pandemic significantly reduced the AH rate. Third, we used the definition of ACSCs proposed by OECD, which might not fully capture China's epidemiological features and health system characteristics [51]. Finally, due to the limited time span of the data, we were unable to explore long-term changes in AH rates after the COVID-19 pandemic, which may help us better understand the long-lasting effects of pandemic-related disruptions in health care usage. These limitations should be addressed in future research.

Conclusions

Using administrative discharge data, we found that Beijing had a relatively high AH rate compared with other high-income countries. Trend analysis showed that the overall AH rate in Beijing displayed an upward trend between 2016 and 2019 but experienced a sharp decrease in 2020. The increasing AH rates in Beijing before the pandemic highlight the necessity to strengthen its primary care system and restructure its hospital-centered delivery system in Beijing. Potential strategies include improving the capacity of primary care physicians, creating incentives for health care providers to provide preventive and primary care, and expanding the benefit coverage of health insurance schemes for outpatient services. Regression results showed that AHs were significantly associated with multiple factors, including the COVID-19 pandemic shocks, the regional density of health care resources, and demographic variables. These results imply that changes in AHs cannot solely be interpreted as changes in access and quality of primary care. Appropriate controls accounting for the multifactorial drivers of all hospital admissions are needed when we use this indicator as a tool to monitor health care system performance, especially when there are system-wide changes such as the COVID-19 pandemic.

Abstract

Background: The maintenance of public health behaviors stands as a critical issue within the realm of public health. COVID-19, a major global emergency, has profoundly impacted the sustainability of public health behaviors. However, there is currently a gap of empirical studies examining the status and influencing mechanisms of public health behavior maintenance after the pandemic, especially those adopting a multifactorial and integrated approach.

Objective: This study aims to investigate the current status of public health behavior maintenance in China after the COVID-19 pandemic. It integrates the complementary advantages of the Multi-Theory Model (MTM) and the Protective Action Decision Model (PADM) to conduct a comprehensive analysis of the multi-factorial mechanisms influencing the maintenance of public health behaviors. The findings are expected to provide empirical evidence and strategic recommendations for the formulation of public health policies and the promotion of national health.

Methods: An integrated model was developed based on the MTM and the PADM. Data were collected from the Chinese public between October and November 2023 via the online survey panel Sojump (Changsha Ranxing Information Technology Co., Ltd.). The questionnaire included items on health behavior maintenance, variables from the MTM and the PADM, sociodemographic and personal disease, and health characteristics. Univariate analysis, correlation analysis, multivariate regression analysis, and structural equation modeling were performed to explore the determinants of health behavior maintenance.

Results: This study collected 1216 valid samples, including 726 females and 490 males, with an average age of 27.38 (SD 8.52) years, and most of them had been infected with COVID-19 at least once (1054/1216, 86.68%). The public maintenance of health behaviors was at a fairly low level (Mean 2.88, SD 0.45). Multivariate regression analysis revealed that those with high monthly incomes, married individuals, and who were more concerned about their health after the COVID-19 pandemic had higher levels of health behavior maintenance. These variables, along with others from the MTM and the PADM, accounted for 45.5% of the variance in health behavior maintenance. Structural equation modeling indicated that efficacy perception had the most significant positive influence on health behavior maintenance (β=.386, *P*<.001), followed by emotional transformation and practical changes (both β=.213, *P*<.001). Risk perception had a slightly negative effect on health behavior maintenance (β=−.099, *P*=.013). Variables such as social cues, warning messages, and information sources also indirectly influenced the public maintenance of health behaviors.

Conclusions: This study indicates a slight decline in public health behavior maintenance following the COVID-19 pandemic, and our analysis has explored some of its influencing factors. Attention should be given to broadening information channels and appropriately explaining the risks of unhealthy behaviors. In addition, integrating external support and bolstering the public's efficacy in maintaining health behaviors can promote sustainable healthy practices.

Introduction

Health behaviors have a direct impact on an individual's health status and are crucial for maintaining health and prolonging life. Gochman defines health behaviors as patterns, actions, and habits related to health maintenance, recovery, and improvement [1]. However, many health-promoting behaviors need to be practiced consistently over time to significantly affect health [2]. This leads to the important concept of health behavior maintenance, which refers to the sustained adoption of health behaviors to maintain overall health and well-being [3]. Engaging in long-term health behaviors, such as regular physical activity and a healthy diet, can greatly reduce the risk of severe acute infectious diseases and chronic noncommunicable conditions, including coronary heart disease, type 2 diabetes mellitus, and cancer [4,5]. Large-scale and sustained health behavior practices are vital as they help mitigate future pandemic risks and enhance preparedness [6].

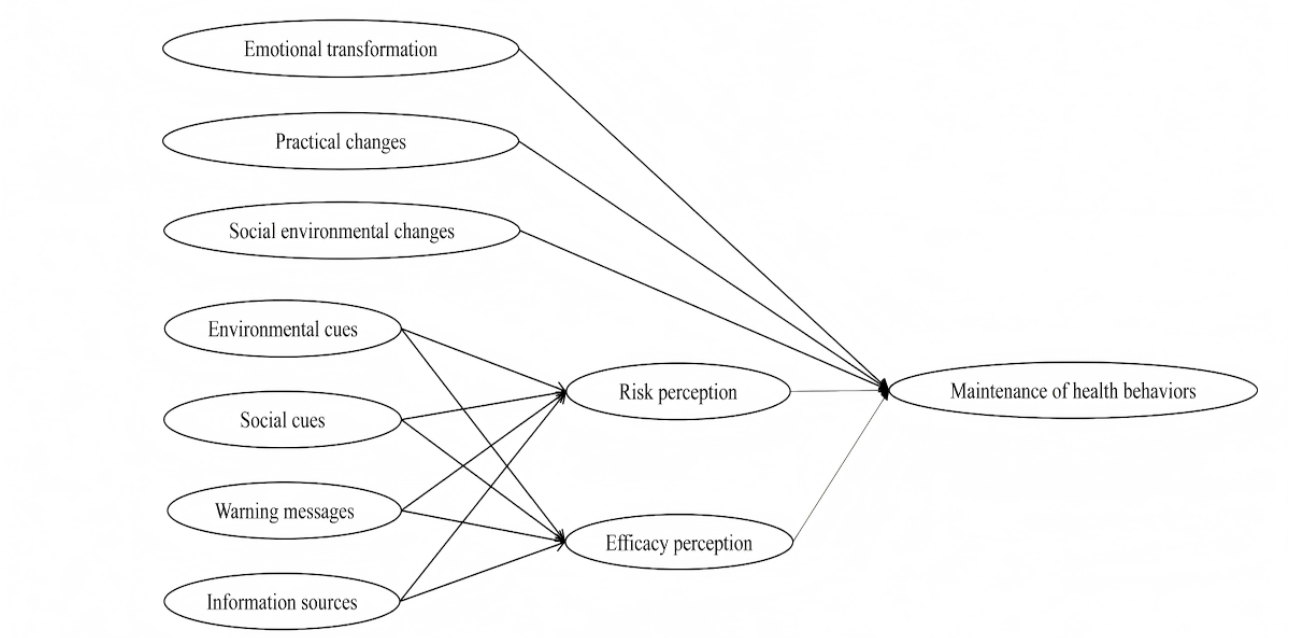
The COVID-19 pandemic, as a global public health emergency, has exerted significant changes in public health awareness, behavioral patterns, and social support mechanisms, impacting the maintenance of public health behaviors. Studies reveal a divergence of health behaviors caused by the pandemic: some individuals persistently adopt protective measures, such as mask-wearing, due to heightened risk perception [7], while others exhibit behavioral relaxation attributed to "pandemic fatigue" or socioeconomic pressures [8]. Psychological traits, such as conspiracy beliefs, have been found to significantly influence compliance with protective behaviors [9], whereas social trust and cultural values, such as collectivism, regulate the sustainability of behaviors through group identity [10]. Although existing studies in China have addressed the impact of pandemic-related knowledge and anxiety on health behaviors [11,12], and there have also been studies on changes in health behaviors before and during the pandemic in European countries [13], there remains a notable gap in theoretical exploration regarding the dynamic mechanisms of health behavior maintenance and multifactorial interactions.

Numerous studies have explored health behaviors, but most existing studies mainly focus on the static characteristics of health behaviors rather than their continuity [14]. Current studies often concentrate on changes in specific types of health behaviors, such as dietary habits or disease prevention measures, with less attention given to integrating a variety of health-related behaviors. In addition, while psychological and cognitive factors, such as risk perception and efficacy perception, have been emphasized, there has been insufficient comprehensive analysis that incorporates both internal and external factors, such as health-related message and peer support [15]. Based on theories of health behavior change, some studies have been conducted on health education and promotion interventions for patients with chronic disease [16]. Although these studies have identified factors related to the maintenance of health behaviors within the context of interventions, whether health behaviors can be sustained after removing external interventions is worthy of further study.

Studies on health behavior change have typically relied on single theoretical frameworks, such as the Theory of Planned Behavior or the Protection Motivation Theory, often overlooking social and environmental factors and behavioral continuity [17]. These approaches struggle to fully explain the complexity of maintaining health behaviors. In contrast, the Multi-Theory Model (MTM) proposed by Sharma integrates behavioral intention, practical skills, and environmental changes to predict the dynamic maintenance of health behaviors [18,19]. The Protective Action Decision Model (PADM) proposed by Lindell and Perry [20] emphasizes the interaction between risk perception, resource assessment, and adaptive decision-making, which is suitable for analyzing postcrisis behavior adaptation [21]. The MTM helps understand the impact of an individual's emotional and behavioral reactions on behavior maintenance, while the PADM focuses on behaviors in risk environments and complements the perceived factors not addressed in the MTM. The combination of these 2 models can provide a more comprehensive analytical framework for postpandemic health behavior study.

In conclusion, maintaining health behaviors is crucial for enhancing individual well-being amid the pandemic-driven public health challenges, and these challenges also provide a natural opportunity for us to investigate the maintenance of public health behaviors after the pandemic. However, public health behaviors may change due to personal psychological perceptions and external social factors after the pandemic, a topic that has not been systematically and comprehensively explored. Therefore, this study aims to investigate the status of public health behavior maintenance in the postpandemic era. By integrating the MTM and the PADM, we seek to uncover the key factors and mechanisms that influence the maintenance of public health behaviors. This study stands to enrich health behavior knowledge, and the strategies and recommendations proposed based on the findings may offer a theoretical foundation for policy implementation, inform effective public health interventions, and help build a more resilient and health-conscious society after the pandemic.

Methods



Framework of the Study

In reference to the study by Atanasova et al [22], this study combined 2 models to explore the key factors and mechanisms influencing the maintenance of public health behaviors after the COVID-19 pandemic. Based on the previous context, these 2 models are the MTM and the PADM, both widely used to explain and predict behaviors, and in our case, we target public maintenance of health behaviors. The MTM posits that 3 factors—emotional transformation, practical changes, and social environmental changes—influence long-term behavioral maintenance [18]. Meanwhile, the PADM emphasizes that environmental cues, social cues, warning messages, and information sources trigger core perceptions, including risk perception and efficacy perception, driving protective behavioral responses [20]. In the context of health behavior maintenance after the pandemic, the MTM helps predict the continuation of these behaviors, while the PADM aids in understanding how

XSL•FO
RenderX

people adapt their decisions in response to evolving risks and available resources. Combining these 2 models offers a comprehensive analysis of the factors influencing behavior maintenance from cognitive, motivational, and environmental perspectives as pandemic risks decline (Figure 1).

Figure 1. Framework of predictors for public maintenance of health behaviors based on the MTM and the PADM. MTM: Multi-Theory Model; PADM: Protective Action Decision Model.

Study Setting and Participants

A cross-sectional survey was conducted. From October to November 2023, we recruited participants from the general population in China using convenience sampling. The survey was conducted anonymously via the Sojump platform, a widely used online survey tool in China with a national user base. The eligibility criteria for participants were (1) voluntary completion of the questionnaire and informed consent to participate and (2) proficiency in using electronic devices.

The sample size was calculated using a formula guided by the Cochran technique [23], which is effective for large-population studies [24]. The calculation variables were n (sample size), z=1.96 (for a 95% confidence level), p=50% (the probability of selecting a choice, suitable for highly dispersed population), q=(1–p), and d=3.272% (allowed error percentage). According to the calculation, a sample size of 898 was determined.

$$n=z2pqd=1.962\times0.5\times(1-0.5)0.032722=897.0684\approx898$$

Recruitment Procedures

We distributed the survey links and recruitment advertisements on social media via our research team members, using the Sojump to provide survey links and widely invite eligible participants who met the inclusion criteria. To ensure data quality, all questionnaire items were set as mandatory, and each IP address, device, and account was restricted to one submission only. Also, a time limit was imposed to exclude respondents finishing the survey in less than 2 minutes. To encourage participation, those who successfully completed the survey were rewarded with 3 - 5 RMB (US$ 0.42-0.70). Ultimately, 1216 valid data were obtained.

Measurement Instruments

Dependent Variable

In consideration of the fact that there is currently no mature scale for assessing the maintenance of health behaviors, we adopted the Health Lifestyle and Personal Control Questionnaire developed by Darviri et al [25] to evaluate the public maintenance of health behaviors. This questionnaire comprises 26 items across 5 dimensions: healthy eating behaviors, unhealthy eating behaviors, daily life behaviors, organized physical exercise, and social and psychological balance. Respondents self-reported their sustained engagement in these behaviors during and after the COVID-19 pandemic. The scoring was as follows: “1” indicated the lowest level of maintenance (health behaviors never taken), “2” indicated a lower level of maintenance (behaviors adopted less frequently after the pandemic), “3” indicated unchanged maintenance, and “4” indicated a significant improvement in maintenance (behaviors adopted more frequently after the pandemic). Confirmatory factor analysis (CFA) indicated that the standardized factor loadings for each dimension ranged from 0.684 to 0.772, except for the second dimension (unhealthy eating behaviors) at −0.228. However, as eating behavior is also an important aspect of health behaviors, this dimension was retained. The Cronbach’s alpha (α=0.89) of this questionnaire demonstrated good internal consistency.

Independent Variables

Referring to the study by Li and Wang [26], environmental cues were assessed using 4 items with “yes” or “no” responses, scored as 1 for “no” and 2 for “yes.” A higher score indicated a stronger public perception of external environmental cues.

XSL•FO
RenderX

Based on Saghafi-Asl et al's study [27], social cues were evaluated using 5 items rated on a 5-point scale from 1 (strongly disagree) to 5 (strongly agree). A higher score suggested that the public received more social cues about maintenance of health behaviors. These items showed good internal consistency (α=0.88) with standardized factor loadings ranging from 0.596 to 0.773.

Following Sun et al [28] and Wang et al [29], information sources were measured with 8 items on a 5-point Likert scale (1=never, 2=rarely, 3=sometimes, 4=often, 5=very often). A higher score indicated that the public would obtain more information about health behaviors. The CFA revealed standardized factor loadings between 0.662 and 0.775, and Cronbach's α=0.86 demonstrated good internal consistency.

Warning messages were assessed through 3 items on the same 5-point Likert scale as for information sources, which were developed by Guo et al [21]. A higher score implied that the public received more information prompting them to engage in health behaviors. The CFA showed good validity (standardized factor loadings ranged from 0.837 to 0.853), and the Cronbach's α=0.83 demonstrated good internal consistency.

Referring to the study by Liu et al [30], risk perception was measured with 4 items. A higher score denoted a greater perceived risk associated with unhealthy behaviors. The CFA revealed standardized factor loadings from 0.781 to 0.832. The Cronbach's α=0.81 indicated good internal consistency.

Efficacy perception was assessed using a revised 5-item scale based on the study by Witte [31]. A higher score suggested a greater perception of the benefits of maintaining health behaviors. The CFA showed standardized factor loadings between 0.805 and 0.882, and Cronbach's α=0.85 demonstrated good internal consistency.

According to the study by Sharma et al [19], emotional transformation, practical changes, and social environmental changes in the MTM were evaluated using 3, 2, and 3 items, respectively. Higher scores in each variable indicated a greater likelihood of maintaining health behaviors. The CFA revealed standardized factor loadings ranging from 0.746 to 0.800 for emotional transformation, 0.784 to 0.832 for practical changes, and 0.709 to 0.767 for social environmental changes. The Cronbach's α values 0.81, 0.79, 0.78, respectively demonstrated acceptable internal consistency. These measurements, based on 5 variables, were consistent with the 5-point Likert scale used for social cues.

Control Variables

The maintenance of health behaviors is influenced by multiple factors. Based on previous literature review, we have summarized the following additional factors related to the public that may influence health behavior maintenance: (1) sociodemographic characteristics: gender, age, education, career, average monthly income, settlement type, marital status, and living condition. (2) Personal disease and health characteristics: whether they have a chronic disease, times that they have been infected with the COVID-19, self-assessment of health status, and whether they are more concerned about health after the COVID-19 pandemic.

Statistical Analysis

The data analysis was performed using R Studio (R 4.2.3; R Core Team). The CFA was used to test the validity of the measurements, with standardized factor loadings and average variance extracted as indicators of convergent validity. The reliability of the measurements was examined using Cronbach's α and composite reliability. Results of validity and reliability of measurements are shown in the Multimedia Appendix 1. Categorical variables were presented as frequency and proportion, and continuous variables were expressed as mean and SD. In the univariate analysis, normally distributed data were analyzed using *t* tests or ANOVA, and non-normally distributed data were analyzed using Wilcoxon rank-sum tests or rank correlation tests. Spearman correlation analysis was conducted to explore relationships between variables. Multivariate regression analysis was applied to examine impacts of demographic characteristics and key factors on the maintenance level of health behaviors. Structural equation modeling (SEM) was used to analyze pathways of factors influencing the public maintenance of health behaviors. A 2-sided *P* value below .05 was considered statistically significant.

Ethical Considerations

During the data collection, it was clearly stated to ensure that the survey is anonymous and all personal information would remain confidential. Participants were informed that their involvement is voluntary and they can withdraw from the study at any time. This study was approved by the Ethics Committee of Southern Medical University in Guangzhou (approval number: [2022] no. 65) and was conducted in accordance with the ethical principles outlined in the World Medical Association's Declaration of Helsinki for medical research involving human subjects. Participants who successfully completed the survey were rewarded with 3 - 5 RMB (US $0.42–0.70).

Results

Characteristics of Participants

A total of 726 females and 490 males participated in this survey, with an average age of 27.38 (SD 8.52) years. Among the participants, 12.83% (156/1216) reported having a chronic disease, and most of them had been infected with COVID-19 at least once (1054/1216, 86.68%). Over half rated their health as good (746/1216, 61.35%) and 73.27% (891/1216) indicated an increased concern for their health after the COVID-19 pandemic. Details are presented in Table 1.

Univariate Analysis and Correlation Among Variables

For all participants, the overall maintenance score of health behaviors was 2.88 (SD 0.45) (Table 2). Factors such as age, education, career, average monthly income, marital status, living condition, whether one has a chronic illness, self-assessed health status, and the level of attention to personal health after the COVID-19 pandemic showed statistically significant associations with the public maintenance of health behaviors. Specifically, the factors of settlement type and time of COVID-19 infection showed no statistical differences with the public maintenance of health behaviors (Table 1). The results of the correlation analysis between variables reveal that all correlation coefficients were statistically significant, and the specific values of the correlation coefficients are shown in Table 3.

Multivariate Regression Analysis

The demographic factors found to be statistically significant in the univariate analysis, along with core study variables, were sequentially incorporated into the multivariate regression analysis using a stepwise forward method. Specifically, the inclusion order prioritized (1) statistically significant demographic factors identified in univariate analysis, (2) variables from the MTM, and (3) variables from the PADM. By the way, 2-tailed t test for a regression coefficient was conducted and the degrees of freedom was 1175. The results indicated that average monthly income, marital status, increased health concern after the COVID-19, emotional transformation, practical changes, information sources, warning messages, and efficacy perception influenced the public maintenance of health behaviors, with an adjusted R^2 of 0.455 (Table 4).

Structural Equation Modeling and Hypothesis Testing

In the SEM, the path coefficients could reflect the strength and direction of causality between variables. Compared with regression coefficients, path coefficients capture the net effect of one variable on another after controlling variables [32]. Standardized path coefficients convert these into a unitless value for direct comparison [33]. All standardized path coefficients in this study were within the normal range, as shown in Table 5. The modified model shows good overall fit to the actual sample data, with χ^2/df of 4.92 (χ^2_{353}=1737.201) and the goodness-of-fit index, comparative fit index, standardized root mean square residual, and root mean square error of approximation of 0.894, 0.923, 0.055, and 0.057, respectively. All indicators meet the requiremexcept for thet for goodness-of-fit index, which is slightly below 0.90.

XSL•FO
RenderX

Table . Path coefficients of variables in the SEM.

Hypothesis	Unstandardized coefficient	SE	*z*	*P* value	Standardized coefficient
Maintenance of health behaviors ← emotional transformation	0.296	0.045	6.635	<.001	0.213
Maintenance of health behaviors ← practical changes	0.296	0.045	6.635	<.001	0.213
Maintenance of health behaviors ← social environmental changes	0.036	0.087	0.418	.676	0.026
Maintenance of health behaviors ← efficacy perception	0.313	0.038	8.320	<.001	0.386
Maintenance of health behaviors ← risk perception	–0.095	0.038	–2.484	.013	–0.099
Risk perception ← environmental cues	0.015	0.043	0.356	.721	0.009
Risk perception ← social cues	1.130	0.081	13.939	<.001	0.789
Risk perception ← warning messages	–0.091	0.032	–2.859	.004	–0.064
Risk perception ← information sources	–0.091	0.032	–2.859	.004	–0.064
Efficacy perception ← environmental cues	–0.007	0.044	–0.149	.882	–0.003
Efficacy perception ← social cues	1.334	0.092	14.562	<.001	0.782
Efficacy perception ← warning messages	0.038	0.032	1.184	.236	0.022
Efficacy perception ← information sources	0.038	0.032	1.184	.236	0.022

The analysis shows that social cues have a positive influence on efficacy perception (β=.782, *P*<.001), which in turn has the most significant effect on the maintenance of public health behaviors (β=.386, *P*<.001). Emotional transformation and practical changes from the MTM also positively affect public health behavior maintenance (both β=.213, *P*<.001). Risk perception is found to have a negative impact on public health behaviors (β=−.099, *P*=.013). Social cues are the most influential factor for risk perception with a positive effect (β=.789, *P*<.001), while warning messages and information sources are negatively associated with risk perception (both β=−.064, *P*=.004).

Discussion

Principal Findings

This study found that the public maintenance of health behaviors was at a fairly low level (mean 2.88, SD 0.45) after the COVID-19 pandemic. Similar to the study of Wang and Gago [34], children exhibited health behavior maintenance issues after the pandemic, such as poor sleep, increased screen time, and changed daily activities. When examining the dimensions of health behavior maintenance, the public surveyed in this study maintained relatively stable social and psychological balance, daily life behaviors, and organized physical exercise. However, the maintenance of dietary behaviors showed significant fluctuation. This echoes the study by van Reekum et al [35], which highlighted the difficulty in sustaining dietary patterns formed during the pandemic once normal life resumed. Moreover, as the pandemic progressed, pandemic fatigue set in, leading to a decline in health behaviors due to the sustained high level of vigilance required [36]. Even a short-term decrease in health behavior maintenance may adversely affect health. Therefore, it is crucial to focus on public health behavior maintenance and its influencing factors after the pandemic and to implement effective and timely interventions.

In this study, factors such as average monthly income, marital status, and personal health concern after the COVID-19 pandemic were found to be associated with the public maintenance of health behaviors. Wambiya et al [37] similarly found that low-income groups, burdened by economic hardships and work demands, may neglect the role of health behaviors in promoting physical health. Meanwhile, spousal encouragement,

XSL•FO
RenderX

support, and supervision can aid in maintaining health behaviors [38]. In addition, individuals with higher health concerns tend to have better health cognition, enabling them to practice health behaviors more effectively [39]. Notably, this study found no correlation between settlement type or whether individuals have been infected with COVID-19 and public health behavior maintenance. This is inconsistent with the study of Wollast et al [40]. The discrepancy may arise because most participants surveyed in this study had been infected with COVID-19 (86.68%). With frequent social interactions and population movements between urban and rural areas, resulting in widespread COVID-19 infections [41], which led to no significant differences in population distribution.

This study confirms that emotional transformation and practical changes in the MTM are positive predictors of health behavior maintenance, aligning with prior study [42]. Emotional transformation emphasizes redirecting negative emotions associated with health behaviors, such as reluctance and resistance, toward the goal of maintaining health behaviors [43]. Practical changes focus on identifying and correcting barriers and incorrect practices in implementing health behaviors through recording or reflection [44]. Throughout these 2 processes, individuals typically combine intrinsic self-motivation with extrinsic emotional support, seeking solutions that use both internal and external resources to overcome psychological barriers in maintaining health behaviors.

This study reveals that warning messages and information sources in the PADM negatively impact risk perception, which in turn undermines the public maintenance of health behaviors. This contradicts Cao and Liu's [45] findings in their study on internet users. Generally, access to public health information is positively correlated with health behaviors [46]. However, in this study, the public might have encountered an abundance of conflicting and dubious health information, resulting in confusion, information overload, and distrust [47]. This aligns with Pedro et al's [48] study, which could diminish sensitivity to health risks. Some studies point out that risk perception is a positive predictor of health behaviors [49,50], but excessive risk perception may trigger impatience or rebelliousness, decreasing individuals' willingness and frequency of action [51]. Therefore, the bidirectional effects of information reception and risk perception on behavior warrant further exploration.

This study indicates a positive correlation between efficacy perception and the public maintenance of health behaviors, consistent with existing studies [52,53]. Individuals with stronger beliefs in their ability to maintain health behaviors exhibit higher self-control and willingness, highlighting the beneficial role of confidence and motivation in adhering to health practices [54]. Moreover, a greater perception of health behavior effects strengthens their belief in maintaining these behaviors [55]. However, this study found that information sources and warning messages do not influence health behavior maintenance through efficacy perception, conflicting with the hypothesis in the PADM [20]. This might be due to asymmetric information transmitted through these channels, leading to varying efficacy perceptions. When individuals perceive insufficient benefits, they tend to adopt a conservative behavior pattern and are less likely to persist in health behaviors [56].

This study found that social cues positively influence risk perception and efficacy perception, in turn affecting public health behavior maintenance, consistent with the PADM [20]. Individuals with greater exposure to social cues show heightened awareness of potential behavioral risks [57] and acquire more health-related information. This increased awareness and information boost their confidence in maintaining health behaviors and motivate them to sustain these behaviors. However, unlike previous studies [58,59], no statistical link was found between environmental cues and health behavior maintenance through risk and efficacy perception, nor any impact of social environmental changes on health behavior maintenance. This might be because most participants had COVID-19–related experiences during the study period. Due to frequent social interactions and population movements, people's sensitivity to environmental cues and social environmental changes decreased compared to the pandemic period. Similar to a "gray rhino" event, individuals tend to overlook health risk warnings when they are accustomed to a situation [60].

Strengths and Limitations

The MTM and the PADM are both useful for studying behavior change mechanisms. The MTM focuses on individual psychology and emotional shifts, while the PADM emphasizes external environmental information. Despite their different focal points, they have not been integrated into previous studies. This study combines their strengths to analyze factors influencing public health behavior maintenance. It takes into account the public real-time health risk-benefit perception and behavioral responses after the pandemic, offering a new perspective on health behavior study and providing references for promoting public health behavior maintenance.

This study offers initial insights into the health behavior maintenance and its influencing factors among the Chinese public, but it has limitations that need further exploration. The results of this study rely on self-reporting by the participants, which may be prone to recall bias. Future research could use smart wearable devices to collect objective data on health behavior maintenance, such as daily step counts and sleep duration. In addition, the online survey with convenience sampling leans toward younger participants who are more tech-savvy, while they can provide unique perspectives on this study. To enhance data representativeness, future studies can combine online and offline recruitment channels, with regional stratified sampling to recruit more diverse participants, and embrace a longitudinal design to better establish causal relationships between factors.

Implications

Drawing on this study, we propose the following suggestions to enhance public health behavior maintenance. First, government, health departments, and medical institutions should be actively engaged as authoritative sources to promote public health behaviors, leveraging their authority and credibility. Second, integrate traditional, online, and social media to broaden information-sharing channels, innovate dissemination methods, and embed health concepts into public daily life. While propagandizing the benefits of health behaviors, it is also

XSL•FO
RenderX

necessary to educate the public about the dangers of unhealthy behaviors and corresponding health warning messages. It is crucial to avoid false information and exaggerated information. Finally, enhance family and social support to help individuals manage negative emotions related to health behavior maintenance and encouraging self-motivation for effective health behavior management.

Conclusions

This study, integrating the MTM and the PADM, explores the status and influencing mechanisms of public health behavior maintenance after the COVID-19 pandemic. Our findings indicate that enhancing emotional transformation, practical changes, social cues, and warning messages can boost health behavior maintenance. However, attention should be given to pandemic-related fatigue, and the risk information should be communicated properly. Also, external support should be integrated to boost the public's sense of efficacy in maintaining health behaviors. This study attempts to integrate the MTM and the PADM within the Chinese cultural context and offers perspectives on health behavior studies. It provides some strategies and recommendations for promoting the public maintenance of health behaviors.

Abstract

Background: The prevalence of stress factors in urban settings has increased, with significant potential impact on health outcomes.

Objective: This study aimed to explore the effect of perceived unfairness, uncertainty, and life stress on self-reported health status, short-term illness, and noncommunicable chronic diseases (NCDs).

Methods: A cross-sectional study using multistage stratified sampling was carried out in Xi'an, Hangzhou, Guangzhou, and Guiyang in China in July 2021, and 2851 participants were included in data analysis. Self-reported health status, short-term illness, and NCDs were assessed using self-administered questionnaires. Perceived life stress, unfairness stress, and uncertainty stress were measured using a standard scale. Descriptive statistics were used to analyze participants' demographic characteristics, and chi-square tests clarified statistical differences in self-reported health status, short-term illness, and NCDs based on these characteristics. Multiple logistic regression models were constructed to measure the effects of perceived unfairness stress, uncertainty stress, and life stress on self-reported health status, short-term illness, and NCDs.

Results: Severe uncertainty stress (odds ratio [OR] 1.230, 95% CI 1.007-1.503) and severe life stress (OR 1.728, 95% CI 1.411-2.118) were associated with a higher likelihood of poor self-reported health status. Severe uncertainty stress (OR 1.565, 95% CI 1.270-1.929) and severe life stress (OR 1.404, 95% CI 1.136-1.731) increased the odds of short-term illness. In addition, severe unfairness stress (OR 1.306, 95% CI 1.053-1.620), severe uncertainty stress (OR 1.542, 95% CI 1.248-1.905), and severe life stress (OR 1.344, 95% CI 1.084-1.667) were linked to a higher prevalence of NCDs.

Conclusions: To conclude, severe uncertainty and life stress were both associated with increased odds of poor health outcomes (self-reported health status, short-term illness, and NCDs), while severe unfairness only affected NCDs. The findings of this study may serve as an empirical reference for the improvement of self-reported illness among Chinese urban residents.

KEYWORDS

self-reported illness; self-reported health status; short-term illness; noncommunicable chronic diseases; unfairness stress; uncertainty stress; life stress

Introduction

Stressors typically arise from an imbalance between an individual's perceived needs and their ability to meet those needs. Consequently, stress occurs when individuals are unable to effectively manage or regulate these demands [1,2]. Increasing evidence suggests that stress levels among populations have reached unprecedented heights during natural disasters [3] and the COVID-19 pandemic [4], driven primarily by stressors such as a sharp economic downturn, widespread unemployment, and geopolitical instability [5].

Current research examining the relationship between stress and health has faced criticism on several fronts. According to the stress-diathesis theory, further classifications of general stress are necessary, as different types of stress exert distinct effects on health [6]; however, many studies have yet to differentiate between various forms of stress. Life stress is defined as persistent daily worries, such as poor living conditions and strained personal relationships [7,8]. These stressors have been

XSL•FO
RenderX

shown to negatively affect health. A review article highlighted that life stress, especially stress arising from adverse social environments, serves as a key indicator of aging [9]. Previous studies have also demonstrated a positive association between life stress and conditions such as insomnia and depression [10,11]. Furthermore, life stress has been linked to physical health issues, including hypertension and respiratory illness [12-14].

Perceived unfairness has been identified as a significant source of stress, encompassing violations of rights or psychological infringements linked to group membership or personal experiences [15]. As a psychological construct shaped by social dynamics, perceived unfairness has profound implications for physical health. According to the perceived unfairness model, perceived injustice triggers stress responses, which can be detrimental to physical well-being [16]. Specifically, perceived unfairness contributes to anxiety and insecurity, and prolonged exposure to such psychological challenges can severely damage individuals' social lives and well-being, ultimately impacting their overall health [17]. Substantial evidence supports the adverse effects of unfairness on various health indicators [18,19]. For instance, a study among multiethnic adults shown that perceived unfairness was related to self-reported history of depression and high blood pressure [20], Similarly, another study identified unfairness as a risk factor for metabolic syndrome and its components [21].

Uncertainty stress is a subjective experience stemming from perceptions of unpredictability and ambiguity [22]. Early studies have confirmed that uncertainty stress is a significant stressor in the context of illness and hospitalization [23], and uncertainty stress has been linked to the exacerbation of health conditions, with individuals facing health-related uncertainties reporting greater symptom severity and functional limitations [24]. Experimental research has further demonstrated that exposure to uncertainty stress leads to increases in both systolic and diastolic blood pressure [25]. Besides, chronic exposure to daily uncertainty has also been associated with a poorer quality of life and reduced well-being [26]. Given the pervasive nature of uncertainty in modern society, recent studies have shifted their focus to uncertainty stress in broader social contexts, particularly social change uncertainty and social value uncertainty [22], which reflect deeper societal and cultural transformations that shape individuals' stress responses and health outcomes. Research has found that uncertainty stress is linked to a range of adverse health outcomes and unhealthy behaviors, including unintentional injuries [27], deliberate self-harm [28], suicidal ideation [29], problematic alcohol use [30], and poorer self-rated health [31,32]. Following the outbreak of COVID-19 pandemic, studies have demonstrated that uncertainty stress is positively associated with disease-related fear [33], depression, and anxiety symptoms [34]. However, few studies have specifically examined the relationship between uncertainty stress and different types of illnesses, highlighting a critical gap in the literature.

The novelty of this study lies in 2 key aspects. First, most previous studies on this topic have been conducted outside of China, with limited research addressing the unique characteristics of the Chinese population. Despite profound societal changes following the Reform and Opening-up, including a widening income gap and increasing disparities in resource distribution the overall perception of inequity among China's residents appears relatively weak, with a high level of acceptance [35]. This context underscores the urgency of exploring whether perceived unfairness is still associated with adverse health outcomes and identifying the specific health outcomes involved. Second, this study uniquely explores the effects of 3 distinct stressors on health outcomes. It is critical to examine whether perceived uncertainty stress and perceived unfairness stress remain associated with health outcomes, even after controlling for life stressors. The results would be crucial for the development of future stress management strategy.

To conclude, very few studies have examined the relationship between perceived unfairness, uncertainty, and life stress in terms of urban residents' health among the Chinese population. The aim of this study was to examine the effect of perceived unfairness, uncertainty, and life stress on urban residents' health among the Chinese population, including self-reported illness, short-term illness, and noncommunicable chronic diseases (NCDs).

Methods

Participants

A cross-sectional study was conducted across 4 provincial capital cities in China—Hangzhou (East China), Xi'an (Northwest China), Guangzhou (South China), and Guiyang (West China)—in July 2021. A multistage stratified sampling approach was used. In the first stage, 4 provincial capital cities were selected to represent different geographical regions of China. In the second stage, 2 districts in the main urban area were randomly selected within each city. In the third stage, 4 communities in each selected district were chosen randomly. In the fourth stage, due to the restriction caused by the COVID-19 epidemic, convenience sampling was used within communities to recruit participants. Urban residents aged ≥18 years were eligible to enroll, and a total of 2851 participants completed the survey and were included in data analysis. Informed consent was obtained from all participants before their inclusion in the study.

Assessment and Measurements

Self-Reported Health Status

Self-reported health status was measured by the item "What do you think about your health status when compared with your majority of colleagues/classmates?" The response was recoded dichotomously, with responses as excellent or good=0 and fair, poor, or bad=1 during data analysis [36].

Short-Term Illness

Short-term illness was assessed by the question "Have you experienced short-term illnesses such as diarrhea, colds and others at least three times in the last 6 months?" The answer was coded as "yes=1" and "no=0" [37].

XSL•FO
RenderX

NCDs

NCDs were assessed by the question "Are you suffering from any chronic diseases, such as digestive trouble, hypertension, other cardiovascular diseases, and others," with the responses coded as "yes=1" and "no=0."

Perceived Life Stress

Perceived life stress was measured through standard questionnaires designed by Yang and colleagues [38]: life stress from (1) unstable work and income, lack of security in life; (2) high work pressure, heavy tasks, and a fast pace; (3) tension with leaders or coworkers; (4) friction between family members; (5) difficulty in children's education or employment; and (6) poor health of family members or oneself. These questions were measured by a 5-point Likert scale ranging from 1 (no stress) to 5 (severe stress). The average score of >3 was classified as severe life stress.

Perceived Unfairness Stress

Perceived unfairness stress was measured by 7 dimensions: income unfairness, education unfairness, promotion unfairness, health care unfairness, workplace benefit unfairness, pension unfairness, and other unfairness. Responses were recorded on a 5-point Likert scale from 1 to 5: never, rarely, sometimes, often, and very often. An average score more than 3 was classified as severe perceived unfairness stress.

Perceived Uncertainty Stress

Perceived uncertainty stress was assessed by standard questionnaires designed by Yang and colleagues [38]. The perceived uncertainty items included the following: life is unstable and cannot be controlled, uncertain about what will happen in the future, uncertain about how to achieve goals, and cannot follow social values. The score was based on a 5-point scale (very low, low, medium, high, and very high). The higher the total score, the higher the perceived uncertainty stress. An average score greater than 3 was classified as severe uncertainty stress. Previous studies have illustrated the good reliability and validity of the scale [29,30,39].

Sociodemographic Information

Sociodemographic characteristics of participants were measured by the following items: hukou (urban and rural; a population management policy in China), district (Xi'an, Hangzhou, Guangzhou, and Guiyang), sex (male and female), age (<25, 25 - 34, 35 - 44, 45 - 54, >55 years), ethnicity (Han and minority), marital status (never married, married and living together, married without living together or divorced, or widowed), education (junior high school and below, senior high school, university, and postgraduate or above), occupation (government agencies, public institutions, or state-owned enterprises; private enterprise; self-employed people; freelance work; unemployed, student, or retired), average household income (1 RMB=US $0.15 at the time of the study; <50,000 RMB, 50,001 - 100,000 RMB, 100,001 - 150,000 RMB, 150,001 - 200,000 RMB, and >200,000 RMB).

Statistical Analysis

Descriptive statistics were used to analyze the demographic characteristics of the participants. Chi-square test was used to clarify the statistical differences of self-reported health status, short-term illness, and NCDs in terms of demographic characteristics, respectively. Multiple logistic regression models were constructed to examine the effects of perceived unfairness, uncertainty, and life stress on self-reported health status, short-term illness, and NCDs. Variables that showed statistical significance in chi-square tests were selected and then simultaneously entered into the model using the "Enter" method in SPSS (IBM Corp).

Ethical Considerations

The study was approved by the Ethics Committee at the Zhejiang Chinese Medical University Medical Center (approval number 20210622 - 3). The procedures followed were in accordance with the Declaration of Helsinki. Verbal consent was obtained from all participants before data collection, and each participant received a small gift valued at 3 yuan (1 RMB=US $0.15 at the time of the study). The study ensured that all participant data were anonymized and deidentified to protect privacy. The data were securely stored and accessible only to the research team.

Results

As shown in Table 1, the study included 2851 participants, with a balanced representation of rural and urban hukou, a nearly equal gender distribution, and a predominance of Han ethnicity. The largest age group was participants aged <25 years (771/2851, 27.1%) and over half (1622/2851, 56.9%) were married or living together. University-educated individuals account for 46.8% (1334/2851), and 34.9% (994/2851) of them were unemployed, students, or retired. Household income levels varied, with the most common range being 150,001 - 200,000 RMB (1 RMB=US $0.15 at the time of the study) per year. Notable disparities in health outcomes were observed across different sociodemographic participants. Rural hukou individuals reported poorer self-reported health status (485/1382, 35.1%) compared to urban hukou individuals (420/1469, 28.6%), while urban hukou individuals exhibited a slightly higher prevalence of NCDs. Significant regional differences were also noted, with Xi'an reporting the highest prevalence of both poor self-reported health status and NCDs. Age was a strong determinant, with older participants (>55 y) showing higher prevalence of poor self-reported health status and NCDs. Other factors, such as ethnicity, education level, and employment status, were similarly associated with variations in health outcomes.

As shown in Table 2, multiple logistic regression models were constructed to estimate the odds ratios (ORs) for self-reported health status, adjusting for unfairness stress, uncertainty stress, and life stress, as well as a full model including all variables. Key findings revealed that rural hukou individuals had higher odds of poor self-reported health compared to urban hukou individuals. Significant regional differences were also observed, with Hangzhou and Guangzhou showing higher odds of poor health compared to Xi'an, while the difference between Guiyang and Xi'an was not statistically significant. Age was also a significant factor, with individuals aged >55 years having the highest odds of poor health. Sociodemographic factors, such as ethnicity, marital status, education level, occupation, and income, also played critical roles.

[e]Not applicable.

Stress factors were important determinants, and individuals who were at severe uncertainty stress and life stress had significantly higher the odds of poor health. Both were statistically significant.

Multiple logistic regression models (short-term illness) were constructed to estimate the ORs, adjusting for unfairness stress, uncertainty stress, life stress, and a full model incorporating all factors. As shown in Table 3, key findings highlighted that rural hukou individuals had slightly higher odds (OR 1.206, 95% CI 0.996-1.460) of short-term illness compared to urban hukou individuals, and regional disparities were evident. Compared to Xi'an, Hangzhou showed lower odds of short-term illness, while Guangzhou and Guiyang exhibited little to no difference. Sociodemographic factors such as age, ethnicity, marital status, education, and income also played roles.

Individuals experiencing severe uncertainty stress had a 56.5% higher odds of reporting short-term illness compared to those with low uncertainty stress. Individuals experiencing severe life stress had 40.4% higher odds of reporting short-term illness compared to those with low life stress. Both were statistically significant.

Multiple logistic regression models (NCD) were constructed to estimate ORs, adjusting for unfairness stress, uncertainty stress, life stress, and a full model incorporating all factors.

Illustrated in Table 4, key findings showed that rural hukou individuals had a slightly lower odds of NCDs compared with urban hukou individuals. Significant regional differences were observed, with Hangzhou reporting higher odds (OR 1.290, 95% CI 0.994 - 1.674) of NCDs compared to Xi'an, while Guiyang showed lower odds. Age was also a significant factor, with older participants, especially those over 55 years old, having the highest OR of NCDs. Other sociodemographic variables like ethnicity, marital status, education level, occupation, and income also influenced outcomes.

Individuals experiencing severe unfairness stress had 30.6% higher odds of developing NCDs compared to those with low uncertainty stress. Those with severe uncertainty stress had 54.2% higher odds and those with severe life stress had 34.4% higher odds. All findings were statistically significant.

Discussion

Principal Findings

The study provided valuable insights into self-reported illness among urban residents in China, particularly concerning perceptions of unfairness, uncertainty, and life stress. Furthermore, this research pioneered an exploration of how perceived unfairness, uncertainty, and life stress relate to self-reported illness, encompassing health conditions such as short-term illness and NCDs.

The Effect of Perceived Unfairness, Uncertainty, and Life Stress on Health Status

Individuals experiencing severe uncertainty (OR 1.230, 95% CI 1.007-1.503) and life stress (OR 1.728, 95% CI 1.411-2.118) were more likely to report health problems, due to the physiological and psychological impacts of prolonged stress [40]. Uncertainty intensified anxiety levels, impeding effective coping strategies and exacerbating stress responses [41]. Chronic life stress contributed to dysregulation of the hypothalamic-pituitary-adrenal axis [42], leading to prolonged secretion of stress hormones like cortisol, increase vulnerability to illnesses [43], contributing to poor self-reported health. Moreover, prolonged stress could disrupt sleep patterns [44], appetite regulation [45], and cardiovascular health [46], further compromising overall well-being.

The Effect of Perceived Unfairness, Uncertainty, and Life Stress on Short-Term Illness

Individuals experiencing severe uncertainty stress (OR 1.565, 95% CI 1.270-1.929) and life stress (OR 1.404, 95% CI 1.136-1.731) were more likely to report higher odds of short-term illness. Uncertainty stress significantly elevated anxiety, disrupted coping mechanisms, and impaired immune function. The heightened stress led to prolonged activation of the hypothalamic-pituitary-adrenal axis [42], resulting in elevated cortisol levels, then altering the gut microbiota composition, weakening the gut barrier and increasing the risk of infections. Furthermore, chronic life stress could exacerbate gut inflammation [47], dysbiosis [48], and disrupt gut motility and transit time, all of these were associated with short-term illness.

The Effect of Perceived Unfairness, Uncertainty, and Life Stress on NCDs

Individuals experiencing severe unfairness (OR 1.306, 95% CI 1.053-1.620), uncertainty (OR 1.542, 95% CI 1.248-1.905), and life stress (OR 1.344, 95% CI 1.084-1.667) exhibited significantly higher odds of NCDs. These stressors contributed to the development of NCDs through a variety of physiological and psychological mechanisms [49]. Unfairness stress could trigger chronic systemic inflammation by activating the release of pro-inflammatory cytokines, which were implicated in the pathogenesis of conditions like cardiovascular disease and diabetes [50]. Moreover, unfairness stress could disrupt metabolic homeostasis, leading to dysregulated glucose metabolism and insulin resistance, further predisposing individuals to diabetes and metabolic syndrome [51].

XSL•FO
RenderX

Uncertainty stress would lead to prolonged stress response: it not only impaired immune function but also promoted oxidative stress and inflammation, contributing to the development of NCDs. Dysregulation of the immune system under uncertainty stress could also impair immune surveillance against cancer cells and increase susceptibility to infections [52], potentially influencing the onset and progression of various NCDs. Additionally, chronic stress disrupted sleep patterns [44] and might lead to unhealthy coping behaviors [53], such as poor diet choices, physical inactivity, and substance abuse, all of which are risk factors for NCDs.

Although some public health professionals and members of the public recognize that perceived stress is associated with adverse health outcomes [54,55], few studies have specifically examined the impact of different stressors on various types of illness. A key finding of this study is that even after controlling for life stress and perceived uncertainty stress, perceived unfairness stress remains significantly associated with a higher prevalence of NCDs. We believe this is closely linked to China's unique sociocultural context. Hofstede's cultural dimension theory identifies China as one of the nations with the highest power distance indices globally [56]. In such a culture, the unequal distribution of power and resources is often regarded as natural and legitimate, leading individuals to internalize power disparities and normalize unfair social relations [57]. It is reported that Chinese residents tend to have a limited perception of unfairness and a high level of acceptance [35]. However, despite this apparent adaptation to unfairness, such dignitary harm [58] threatens the fundamental basis of social respect [59]. Living in a society with low levels of fairness negatively affects psychological well-being by diminishing feelings of social justice, reducing social trust, and weakening reciprocity [60]. As a result, individuals face greater constraints in accessing coping resources, which, according to Conservation of Resources theory, may lead to chronic and long-term harm to physical health [61].

Implications

First, implement programs that provide psychosocial support tailored to address perceived unfairness, uncertainty, and life stress among urban residents, include counseling services, stress management workshops, and community support groups to enhance mental resilience. Second, encourage employers to establish stress management initiatives in workplaces, focusing on mitigating factors such as perceived unfairness and uncertainty, like promoting work-life balance, improving communication channels, and offering employee assistance programs to support mental well-being. Third, community mental health programs should address uncertainty stress through targeted interventions, such as digital and online resources, public awareness campaigns, tailored interventions targeting high-risk groups, as well as crisis helplines.

Limitations

First, this study was a cross-sectional study, and could not clearly indicate the causal relationship between the variables. However, this study was large-scale, and results could provide some implications regarding the important associations between different types of stress and urban residents' health. Second, in this study, an important outcome variable was "Are you suffering from chronic diseases?" No in-depth research was conducted to investigate the type and severity of NCDs, but the data collected still offered a general overview of the prevalence of chronic conditions among the surveyed population, offering valuable insights for policy makers and contributing to a better understanding of the health outcomes of stress. Third, as this study focused on specific urban residents in China, the results might not fully capture the experiences or health outcomes of other regions, which would limit the broader applicability of the conclusions, but it is still useful for other countries at a similar stage of development as China. Finally, the reliance on self-reported health outcomes, which were not validated using clinical measures, may introduce reporting bias due to participants' subjective interpretations or recall errors; however, the use of self-reported data is a widely used method in public health research for capturing individual health awareness and perceived well-being.

Conclusions

In summary, the cross-sectional study clarified the effect of perceived unfairness, uncertainty, and life stress on self-reported illness among Chinese urban residents. The study found significant associations between several stress factors and self-reported health status. Severe uncertainty and life stress were both associated with increased odds of poor health outcomes, while severe unfairness was only associated with NCDs. Future longitudinal research is needed to better understand the temporal dynamics and causal pathways underlying these associations and to further inform effective interventions that decrease stress and promote well-being in urban populations. The findings of this study emphasize the importance of policies that strive for a fairer society, with a great focus on well-being, and may serve as an empirical reference for improving population health among Chinese urban residents.

Abstract

Background: Breast cancer (BC) is the most commonly diagnosed cancer and the leading cause of cancer-related deaths among women globally. Despite the significance of mammography screening rate for early BC detection among Jordanian women, it remains low, mainly due to various cognitive, psychosocial, and behavioral barriers. Understanding these factors is essential for developing effective interventions.

Objective: This study aims to assess the BC knowledge and beliefs about mammography screening among Jordanian women aged 40 years and older based on the Health Belief Model (HBM) as a theoretical framework.

Methods: A cross-sectional design was used with a convenience sample of eligible women from a Jordanian public hospital. Data were collected through face-to-face interviews using a validated Arabic structured questionnaire consisting of 3 sections: sociodemographic data, knowledge about BC, and health beliefs about mammography. Descriptive statistics and multivariate analysis of variance (MANOVA) were conducted using IBM SPSS version 28.

Results: A total of 405 women completed the study, with an average (SD) age of 52.4 (8.57) years. Findings revealed a notably low knowledge level, as participants scored an average (SD) of 5.80 (2.64) out of 12. The average (SD) scores for the health beliefs section (out of 5) were also low: perceived benefits, 2.59 (0.59); perceived barriers, 2.48 (0.71); and health motivation, 2.51 (0.71). Significant associations (P<.001) with medium to large effect sizes (ηp^2>0.06) were observed between participants' age and education level in relation to BC knowledge and health beliefs regarding mammography screening. Participants cited several reasons for their reluctance to undergo mammography, including a lack of knowledge (72.8%), cultural beliefs (63%), and religious factors (29.4%).

Conclusions: A significant gap exists in BC knowledge and beliefs about mammography among Jordanian women aged 40 years and older. Policy makers and health care providers should prioritize the development of tailored strategies and context-specific, sensitive educational interventions. These efforts should address the unique needs, cultural beliefs, and awareness levels of this population to improve mammogram screening practices in Jordan.

Introduction

Background

Cancer has become a significant global public health concern, surpassing cardiovascular diseases as the leading cause of death in many high-income countries [1]. Breast cancer (BC) is the most diagnosed, with around 2.3 million new cases and 670,000 deaths in 2022 [2-4], making it the leading cause of cancer-related death among women globally [3,4]. Although the incidence of BC is lower in high-income countries, it is often diagnosed at advanced stages, leading to higher mortality rates [5].

XSL•FO
RenderX

As a low-income country, the World Bank classifies Jordan as a lower-middle-income country (LMIC) [6]. It confronts substantial health care resource management challenges, particularly for noncommunicable diseases like cancer [5,7]. BC is the most common cancer among women in Jordan, accounting for 39.2% of female cancer cases in 2022. The age-standardized rate (ASR) of BC is 60 per 100,000 population, which is higher than in some neighboring Arab countries but lower than in Western countries. The global ASR average is 46.8 [2,8,9]. The rising incidence of BC in LMICs is linked to increased life expectancy, improved health care services, and increased health insurance coverage. In addition, the adoption of Western lifestyles and changes in reproductive behaviors, such as delayed childbirth and shorter breastfeeding durations, have also contributed to this trend [10,11].

The American College of Radiology (ACR) recommends that all women at average risk of BC should begin annual mammograms at the age of 40 years. Moreover, women who are at higher-than-average risk due to various factors are recommended to undergo more intensive screening [12]. Ultimately, mammography screening can reduce BC mortality by 40% or more in women aged 40 years and older [12]. Early detection of BC through mammography can lead to significantly improved survival rates [12,13]. In response to this, Jordan established the Jordan Cancer Registry in 1996, the King Hussein Cancer Foundation and Center in 2001, and the Jordan Breast Cancer Program (JBCP) in 2007 to coordinate detection efforts, provide screening, and raise public awareness [11]. It also recommends that women begin mammogram screenings at the age of 40 years [9,14].

Despite these national initiatives, participation in mammography screening remains low. According to the Jordan Cancer Registry, only 18.6% of women aged 40-69 years have undergone mammographic screening in the past 2 years [15]. Another survey indicated that just 14% of women aged 40-49 years have ever had a mammogram [16]. These rates are comparable to those in neighboring countries, such as Qatar (22.5%) and Saudi Arabia (27.7%) [17,18]. However, they are still significantly lower than the rates reported in high-income countries, such as France (48.5%) and the United States (61%) [19,20]. This low participation persists despite the expansion of screening services and public awareness campaigns, indicating ongoing barriers to preventive care [7,11,14].

One of the main challenges and barriers is that many Jordanian women are unaware of their eligibility for screening due to a lack of awareness, absence of health problems, fear of diagnosis, and the influence of cultural and religious beliefs [16,21]. Although educational interventions have been implemented, evidence suggests that simply increasing awareness is insufficient to effect meaningful change in screening behaviors [21-23]. Deeply rooted beliefs and attitudes, shaped by cultural and individual factors, continue to hinder adherence to breast cancer screening (BCS) guidelines [24,25]. Furthermore, health beliefs regarding mammography among this age group in Jordan are underresearched [26,27].

To address these gaps, this study aims to investigate how knowledge and health beliefs about mammography screening practices based on the Health Belief Model (HBM) among Jordanian women aged 40 years and older. The study also seeks to identify the sociodemographic characteristics that influence knowledge and beliefs regarding screening.

Theoretical Framework

This study is guided by the HBM, a theoretical framework that explains preventive health behaviors in various contexts, such as vaccination and smoking [28,29]. The HBM suggests that individuals' actions are influenced by their perceptions of susceptibility, severity, benefits, barriers, cues for action, and self-efficacy [28-30].

Victoria Champion developed the Champion Health Belief Model (CHBM) as an adaptation of the original HBM to better understand and predict women's participation in BCS behaviors [31,32]. Champion initially created separate scales to measure constructs such as perceived susceptibility, benefits, and barriers related to BCS [31,32]. These scales were later combined and revised to form the Champion Health Belief Model Scale (CHBMS) [33,34]. This comprehensive instrument emphasizes health motivation and self-efficacy in women's decisions to participate in BCS, while also taking into account cultural factors [33,34]. The CHBMS has been adapted and validated in various cultural contexts to assess the beliefs and attitudes that influence BCS behaviors [22,26,34,35].

In this study, we used 3 constructs of the CHBMS: perceived benefits, barriers, and health motivation. These constructs were selected based on the study conducted by Petro-Nustas [26], who revised these specific aspects of the CHBMS [22,33]. This psychometrically validated tool has been used to assess the beliefs of Jordanian women regarding mammography.

Methods

Study Design

This study implemented a cross-sectional design to assess the knowledge and beliefs about BC and mammography among Jordanian women aged 40 years and older. It adhered to the Strengthening of the Reporting of Observational Studies in Epidemiology (STROBE) guidelines (Checklist 1) [36]. The HBM served as the theoretical framework for this study, as it has been identified as the most frequently used and suitable theoretical health behavior model in previous studies that explain women's BCS practices [37,38].

Study Setting

This study was conducted at Albashir Hospital in Amman, Jordan, the largest public medical complex in the country. It is a national referral center comprising multiple specialized hospitals and centers. The sample included women from different socioeconomic and clinical backgrounds. In 2022, the hospital's outpatient clinics received a total of 632,352 patients who visited the hospital and the outpatient clinics. Participant recruitment and data collection took place from women attending various outpatient clinics between May and July 2024 during regular clinic hours (8:00 AM to 4:00 PM, Sunday through Thursday).

XSL•FO
RenderX

Participants

Eligibility Criteria

Women of Jordanian nationality who are 40 years of age and older were eligible to participate in this study, provided they met specific criteria. Participants were required to demonstrate sufficient literacy in Arabic, have not received mammography screening within the previous 12 months, and be free from any physical or mental disabilities that could impede independent participation or reliable self-reporting. To maintain the study's focus on screening behaviors, individuals with a personal history of BC or those who have a first-degree relative (parent, sibling, or child) diagnosed with BC were excluded from participation.

Selection and Recruitment

A convenience sampling strategy was used, with a multiphase approach to uphold ethical standards, ensure participant privacy, and maintain methodological rigor. Before the recruitment process began, all health care providers involved in the recruitment and data collection team participated in a 3-day training in May 2024. This training addressed the study's methodology, objectives, questionnaire elements, and ethical considerations to ensure consistent data collection and minimize interviewer bias.

Each morning, the appointment schedules at the various outpatient clinics were reviewed to identify women eligible for the study, thereby ensuring a diverse population and minimizing selection bias. Team members approached these women in the waiting areas, explaining the research and inviting them to participate while ensuring that they minimized any disruption to their time. Interested women were then escorted to a private meeting room, where they received detailed information and reassurances that their participation would not impact their health care.

Women had the right to decline or provide written consent if they agreed to participate. After obtaining consent, face-to-face interviews were conducted by the same team member who initiated recruitment, ensuring consistency and rapport with the participants. To support women with low literacy levels, each interview followed a structured questionnaire format. The interviewer offered additional clarification and read the questions aloud as needed, ensuring that all participants, regardless of their literacy level, could fully understand and answer each item. The interviews, conducted in Arabic, typically lasted between 10 and 15 minutes to reduce information bias.

Data Sources and Measurement

The variables of interest in this study—sociodemographic data, knowledge of BC, and health beliefs about mammography screening—were clearly defined and systematically measured. Data for all variables were collected using a questionnaire. The questionnaire consisted of 3 sections: sociodemographic characteristics, knowledge about BC, and health beliefs, measured using 3 constructs from the CHBMS.

The sociodemographic data section included questions about participants' age, education, marital status, health insurance status, and mammography screening history in the past 12 months (these questions were used to assess participants' eligibility). In addition, participants were asked an open-ended question to provide up to 4 reasons for not having a mammogram, offering qualitative insight into the barriers to screening, with no specific order required.

The knowledge section featured 12 true, false, or do not know questions about BC, with 7 correct answers marked as "true" and 5 as "false." Participants scored 1 point for each correct answer and zero for each incorrect or "do not know" answer. The maximum possible score was 12, indicating excellent knowledge, while a score of zero indicated limited knowledge.

The health belief section consisted of 3 constructs from the CHBMS, comprising 18 statements: 6 related to perceived benefits, 5 to perceived barriers, and 7 to health motivation. The scale is positively associated with screening behaviors, except for perceived barriers, which are negatively associated. Each statement was rated on a 5-point Likert scale (1=strongly disagree to 5=strongly agree), with reversed scoring applied to the barriers. Scores ranged from 18 (highly negative beliefs) to 90 (highly positive beliefs).

In the previous section on health beliefs, we used a culturally adapted Arabic version of the CHBMS (Multimedia Appendix 1), initially translated and validated for BCS among Jordanian women by Mikhail and Petro-Nustas in 2001 [35]. Petro-Nustas later revised and validated the entire questionnaire to better reflect the health beliefs of Jordanian women regarding mammography, focusing on 3 constructs from the CHBMS: perceived benefits, perceived barriers, and health motivation [22]. Our study followed this methodology and obtained permission from Petro-Nustas and Champion to use the questionnaire (Multimedia Appendix 2).

Study Size

The study size was determined based on previous relevant studies [14,24,27] 2727 and calculated using the Raosoft sample size calculator (Raosoft, Inc) [39]. The target population consisted of Jordanian women aged 40 years or older, totaling approximately 1,460,300 in 2023. Based on a 95% confidence level, a 5% margin of error, and a response distribution of 50%, the minimum required sample size was determined to be 384 participants. A total of 405 women were recruited to mitigate potential nonresponses, attrition, and data exclusion while preserving statistical power.

Statistical Analysis

Descriptive statistics were calculated, including the mean and SD for continuous data and frequencies and percentages for categorical data. A Multivariate Analysis of Variance (MANOVA) was conducted to examine the association between sociodemographic independent variables: age, educational level, marital status, and health insurance, and the dependent variables: knowledge and health beliefs based on the HBM, specifically in terms of perceived benefits, perceived barriers, and health motivation. Following significant results from the MANOVA (P<.05), indicating an association between the dependent and independent variables, Bonferroni post hoc tests were conducted to determine which specific groups within each dependent variable showed statistically significant differences (P<.001); to quantify the magnitude of effects beyond statistical

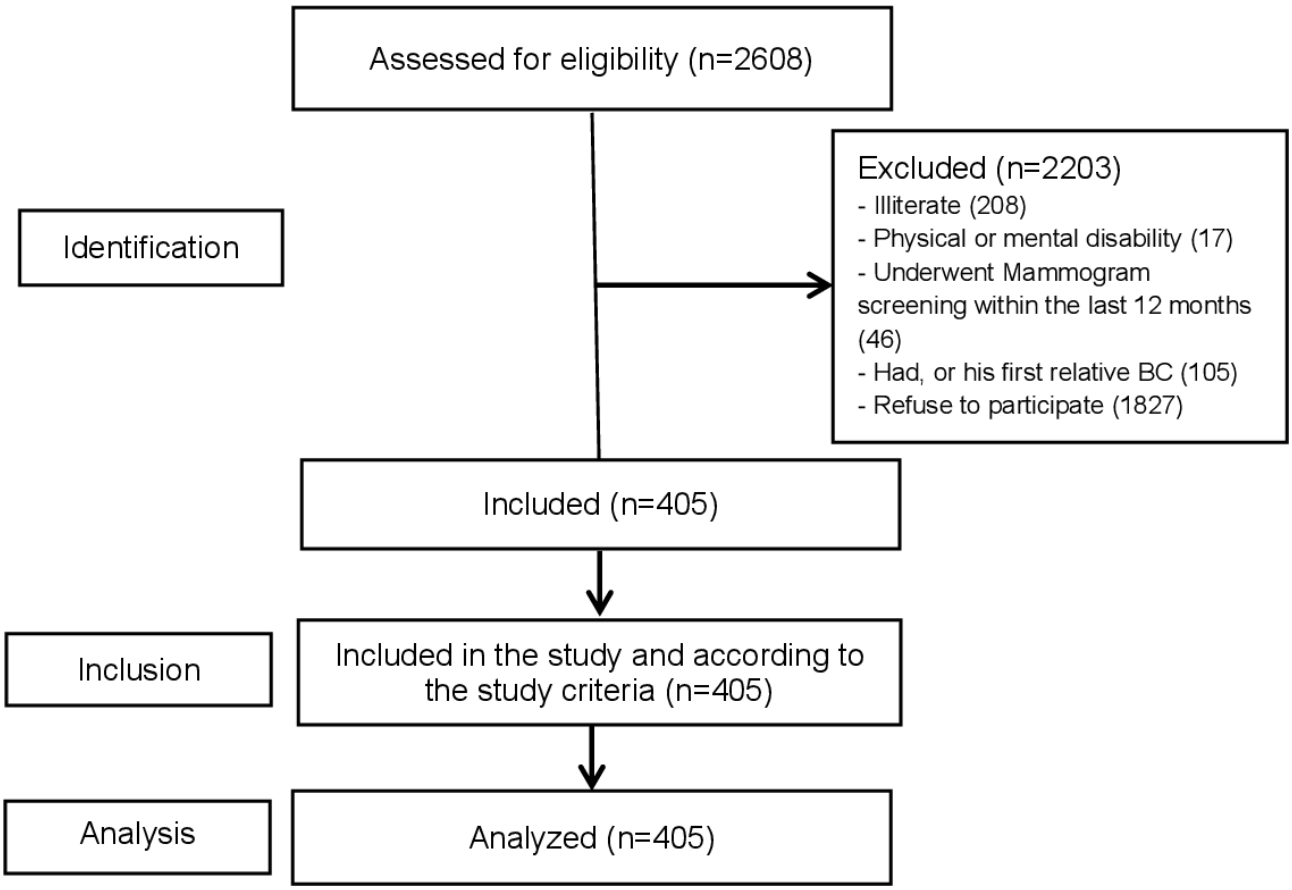
significance, partial eta-squared (ηp^2) values were calculated for each independent and dependent variable relationship. All statistical analyses were performed using IBM SPSS version 28 [40].

Ethical Considerations



This study was conducted in accordance with the ethical principles outlined in the Declaration of Helsinki. Ethical approval was obtained from the Institutional Review Board (IRB) of the Ministry of Health and Albashir Hospital in Jordan (IRB-7790) in May 2024 (Multimedia Appendix 3). Written consent was obtained from all participants before their participation (Multimedia Appendix 4). They were provided with detailed information about the study's aims and significance, as well as their right to withdraw at any time without any obligations. To ensure privacy, no personal identifiers were used; participants were assigned unique code numbers to maintain confidentiality. No financial compensation or incentives were provided to participants.

Results

Overview

Out of 2608 women screened at Albashir Hospital outpatient clinics, 376 were excluded, and 1827 refused to participate, resulting in 405 eligible participants who consented and completed the study. This process is outlined in the STROBE flow diagram [36] as shown in Figure 1.

Figure 1. Strengthening the Reporting of Observational studies in Epidemiology flow diagram

Sociodemographic Characteristics

A total of 405 Jordanian women participated in the study, aged 40-76 years. The vast majority, 187 (46.2%), fell within the 40 - 49 years age group, 173 (42.7%) completed secondary education, 213 (52.6%) were married, 372 (91.9%) reported having health insurance, and none had undergone mammogram screening in the past 12 months (Table 1).

XSL•FO
RenderX

Table . Sociodemographic characteristics of the study participants (N=405).

Variables	Frequency, n (%)
Age groups	
40 - 49 years	187 (46.2)
50 - 59 years	140 (34.6)
60 years and older	78 (19.2)
Education level	
Primary	123 (30.4)
Secondary	173 (42.7)
University	109 (26.9)
Marital status	
Single	104 (25.7)
Married	213 (52.6)
Divorced	37 (9.1)
Widowed	51 (12.6)
Do you have any health insurance?	
Yes	372 (91.9)
No	33 (8.1)
Mammogram screening within the last 12 months	
Yes	0 (0)
No	405 (100)

The participants' responses to the open-ended questions were analyzed and categorized into 8 main reasons that may negatively impact screening practices. An example of the main reasons reported among the 405 participants was a lack of knowledge, cited by 72.8% (295). This was followed by fear of results, reported by 66.4% (269), cultural beliefs at 63% (255), and religious reasons, mentioned by 29.4% (119) (Multimedia Appendix 5).

Knowledge About Breast Cancer

Table 2 shows that the overall knowledge score about BC was relatively low (48.3%), with a mean (SD) score of 5.80 (2.64). Regarding knowledge aspects, approximately out of 405, three-quarters of the sample, 74.3% (301), correctly recognized that BC is the most common cancer among women. In addition, half of the sample, 206 (50.9%), identified excess weight and having a first child after age 30 years as risk factors for BC. In contrast, only 145 (35.8%) correctly identified that most breast tumors are not cancerous.

XSL•FO
RenderX

Table . Breast cancer knowledge questions with correct answers (N=405).

Item	Correct answer	Correct answer, n (%)
Myths and misconceptions		
A strong blow to the chest can cause breast cancer after a period of time.	False	192 (47.4)
The constant discomfort of a tight bra may cause breast cancer after a period of time.	False	176 (43.5)
Some types of fibrous sacs in the breast (noncancerous tumors) increase the risk of breast cancer.	False	176 (43.5)
Women over the age of 70 rarely have breast cancer.	False	186 (45.9)
Most breast tumors are cancerous.	False	145 (35.8)
Risk factors		
Excess weight may cause breast cancer to some women.	True	195 (48.1%)
A woman who conceives her first child after the age of thirty is more likely to have breast cancer than a woman who conceives her first child before the age of thirty.	True	206 (50.9%)
Women in the United States are more likely to have breast cancer than Asian or African women.	True	167 (41.2)
Breast cancer is more common among women at age 65 than at age 40.	True	188 (46.4)
The most common cancer among women is breast cancer.	True	301 (74.3)
Physical exercises reduce the risk of breast cancer.	True	202 (49.9)
Diet affects the risk of breast cancer.	True	214 (52.8)

Beliefs About Mammography

Scores for each construct and question within the CHBM scale ranged from 1 to 5. The perceived benefits of mammography had a relatively low mean (SD) score of 2.59 (0.59). Among the perceived benefits, women identified that mammography helps in the early detection of lumps, with a mean (SD0 score of 2.62 (1.08). The perception that mammography decreases the chances of dying from BC had a mean (SD0 score of 2.60 (1.13). Furthermore, the item related to reducing worry about BC was rated the lowest, with a mean (SD) score of 2.45 (1.19) (Table 3).

XSL•FO
RenderX

Table . Breast cancer knowledge and health beliefs scores based on the Champion Health Belief Model scale.

Items	Mean (SD)
Knowledge	5.80[a] (2.64)
CHBM[b] construct	
Perceived benefits	2.59[c] (0.59)
When I get a recommended mammogram, I feel good about myself.	2.62 (1.10)
When I get a mammogram, I don't worry as much about breast cancer.	2.45 (1.19)
Having a mammogram of the breast will help me find lumps early.	2.62 (1.08)
Having a mammogram of the breast will decrease my chances of dying from breast cancer.	2.60 (1.13)
Having a mammogram of the breast will decrease my chances of requiring radical or disfiguring surgery if breast cancer occurs.	2.60 (1.14)
Having a mammogram will help me find a lump before it can be felt by myself or a health care professional.	2.62 (1.03)
Perceived barriers[d]	2.48 (0.71)
Having a routine mammogram of the breast would make me worry about breast cancer.	2.52 (0.92)
Having a mammogram of the breast would be embarrassing.	2.38 (1.00)
Having a mammogram of the breast would take too much time.	2.49 (0.96)
Having a mammogram of the breast would be painful.	2.48 (1.02)
Having a mammogram of the breast would cost too much money.	2.54 (1.05)
Health Motivation	2.51 (0.71)
I want to discover health problems early.	2.64 (1.09)
Maintaining good health is extremely important to me.	2.62 (1.12)
I search for new information to improve my health.	2.64 (1.12)
I feel it is important to carry out activities which will improve my health.	2.63 (1.12)
I eat well-balanced meals.	2.61 (1.13)
I exercise at least 3 times a week.	2.31 (0.95)
I have regular health check-ups, even when I'm not sick.	2.11 (1.08)

[a]Mean score for the knowledge item out of 12.

[b]CHBM: Champion Health Belief Model

[c]Mean score for all items of perceived benefits, barriers, and health motivation out of 5.

[d]Reversed score: a lower score indicates higher perceived barriers.

The perceived barriers to undergoing mammograms were assessed with a mean (SD) score of 2.48 (0.71), indicating that women have various concerns about this procedure. Worries related to BC (item 7) had a mean (SD) score of 2.52 (0.92), while fears of pain had a mean (SD) score of 2.48 (1.02). Item 8, "Having a mammogram of the breast would be embarrassing," was the highest perceived barrier, with a mean (SD) score of 2.38 (1.00).

Participants reported a low health motivation score regarding mammography, with a mean (SD) of 2.51 (0.71). Among the health motivation items, the desire to detect health problems early (item 12) had the highest mean (SD) score of 2.64 (1.09). In contrast, lower scores were observed for exercising 3 times a week (item 17), with a mean (SD0 of 2.31 (0.95), and for undergoing regular health check-ups even when not sick (item 18), with a mean (SD) of 2.11 (1.08).

Knowledge and Beliefs Regarding BC and Mammography Across Sociodemographic Characteristics

The statistical analysis, conducted using MANOVA, revealed that age and educational level had a significant influence on knowledge and beliefs, as measured by the CHBM scale (P<.05 for all). Moreover, the Bonferroni post hoc tests for age groups and educational levels revealed that women aged 60 years and older with primary or secondary education demonstrated lower levels of knowledge, perceived benefits, and health motivation. In addition, they reported higher perceived barriers compared with women in the 40 - 49 years and 50 - 59 years age groups who had a university education (P<.001). In contrast, marital status and health insurance had no significant effect on the variables related to BC and mammography (P>.05 for all) (Table 4).

[a]Reversed score: a lower score indicates higher perceived barriers.

[b]MANOVA test. A *P* value less than .05 was considered significant.

[c]Partial eta square (ηp²): ηp²<0.01:Negligible, 0.01≤ηp²<0.06:Small, 0.06≤η²<0.14:Medium, ηp²≥0.14: Large.

The results showed that age significantly influenced knowledge (F_{2402}=22.44; *P*<.001). Participants aged 40 - 49 years had a mean (SD) score of 6.43 (2.70), while those aged 50 - 59 years had a mean (SD) score of 5.86 (2.44). These groups had significantly higher mean scores than participants aged 60 years and older, who had a mean (SD) score of 4.17 (2.13, *P*<.001). In addition, the educational level also significantly influenced knowledge (F_{2402}=179.05; *P*<.001). Participants with a university education had mean (SD) scores of 8.19 (2.15), which were higher than those with secondary education, 5.98 (1.92), and primary education, 3.42 (1.69), *P*<.001. In addition, the partial eta squared (ηp²) results for age showed a medium effect size for knowledge (ηp²=0.10), while education level displayed a large effect size for knowledge (ηp²=0.471).

Similarly, perceived benefits were significantly influenced by age (F_{2402}=27.82; *P*<.001), and had a medium effect size (ηp²=0.122). The mean (SD) score for the participants aged 40 - 49 years was 2.86 (0.97), and for those aged 50 - 59 years, it was 2.54 (0.70). Both mean scores were higher than those of participants aged 60 years and older, who had a mean (SD) score of 2.02 (0.68), *P*<.001. In addition, the educational level significantly influenced perceived benefits (F_{2402}=203.11; *P*<.001), and had a medium effect size (ηp²=0.503). Participants with a university education had higher mean (SD) scores of 3.44 (0.81) compared with those with secondary education, 2.63 (0.60), and primary education, 1.77 (0.47), *P*<.001.

Moreover, the perceived barriers were significantly influenced by age (F_{2402}=19.32; *P*<.001) with a medium effect size (ηp²=0.088). Participants aged 60 years and older displayed significantly higher barrier scores, with a mean (SD) score of 2.08 (0.64), compared with those in the 40 - 49 years age group, 2.65 (0.73), and the 50 - 59 years age group, 2.48 (0.63),

XSL•FO
RenderX

P<.001. In addition, the educational level had a significant influence (F_{2402}=45.24; P<.001), and a large effect size (ηp^2=0.184). Participants with primary education had higher barrier mean (SD) scores of 2.09 (0.66) compared to those with secondary education, 2.50 (0.60), and university education, 2.89 (0.69), P<.001.

Ultimately, health motivation was significantly influenced by age (F_{2402}=17.53; P<.001). The participants' mean (SD) score for both ages 40 - 49 years was 2.68 (0.77), and that for 50 - 59 years was 2.49 (0.62), which was higher than those of participants 60 years and older, 2.14 (0.57), P<.001. The educational level also had a significant influence (F_{2402}=118.54; P<.001), with women holding a university education 3.08 (0.64) scoring higher than those with secondary education 2.56 (0.58) and primary education 1.94 (0.47), P<.001. Furthermore, the partial eta squared results for age revealed a medium effect size for health motivation (ηp^2=0.080). The effect size was large for both educational level and health motivation (ηp^2=0.371).

Regarding marital status, the effect sizes were small or negligible for all dependent variables: knowledge (ηp^2=0.019), perceived benefits (ηp^2=0.005), perceived barriers (ηp^2=0.007), and health motivation (ηp^2=0.003). Finally, there was no effect (ηp^2=0.000) on any dependent variables for health insurance status.

Discussion

Principal Findings

This cross-sectional study examines the knowledge and beliefs of Jordanian women aged 40 years and older regarding BC and mammography, using the HBM as a theoretical framework. The findings offer valuable insights into the knowledge, perceived benefits, barriers, and health motivations that influence mammogram screening practices among this population.

Participants in this study reported several barriers that adversely affected their participation in screening practices, such as cost, fear of results, pain, cultural beliefs, and religious factors. These findings were consistent with those observed by Abu-Helalah et al in Jordan [14], which identified the main reasons for avoiding screening as fear of results (63.8%), lack of support (59.7%), cost (53.4%), and religious beliefs (51.1%). Another study conducted by AlAbdulKader et al [41] in Saudi Arabia found that the main barriers to receiving BCS include feeling that it is unnecessary (24.2%), believing it to be painful (22.1%), and fearing abnormal results (18.6%). In addition, other regional and global studies support these findings, highlighting fear of pain and fear of diagnosis as common reasons for avoiding BCS [42,43].

Furthermore, the prevalence of cultural beliefs (63%) and religious factors (29.4%) is a significant barrier to mammography screening, as observed in our study and supported by Albadawi et al [44], who found that these beliefs influence BCS behaviors among women in Jordan. Similarly, Taha et al [45] and Salman et al [46] revealed through qualitative interviews that many Jordanian women hold fatalistic views shaped by the religious concept of "Qadaa Wa Qadar" (predestination).

These beliefs lead many to view BC as "from Allah (God)" and thus unavoidable, reducing their perceived benefits of early detection. This religious fatalism, as highlighted in studies by Petro-Nustas et al and Donnelly et al [22,47], serves as a significant barrier to adopting preventive health behaviors. Moreover, Taha et al [45] also discussed this in a study conducted in Jordan, where men viewed BC as an unavoidable act of God, detached from their families. This belief is linked to notions of improper behavior and a readiness to confront the cultural stigma of Eib (shame) [48]. In addition, research by Al-Naggar and Bobryshev [49] found that religious beliefs accounted for 42.5% of screening avoidance among Malaysian Muslim women, closely aligning with our finding of 37.5%. Their study also emphasized that support from religious leaders can boost participation rates, a factor worth exploring in the Jordanian context.

We observed a significant lack of knowledge about BC among the participants in this study, with a low average score of 5.80 out of 12. Furthermore, 72.8% of participants indicated that their lack of knowledge was the primary reason for not undergoing mammogram screenings. This finding aligns with Kawar's study [50], which emphasized the importance of health care advice in improving awareness and encouraging participation in screenings. In addition, a 2023 national survey conducted among Palestinian women revealed that 53.2% believed the idea of "having a physical trauma" was a myth associated with BC, while 19.4% regarded "wearing a tight bra" as a misconception [51]. In contrast, our study found that only 43.5% of participants understood that not all fibrous sacs increase the risk of BC, and only 35.8% recognized that not all breast tumors are cancerous. These findings suggest a substantial gap in understanding breast abnormalities, which is similar to the health literacy deficiencies commonly observed in low-resource settings, where limited access to accurate health information contributes to poor health literacy [7,52,53].

The findings from the CHBM scale in this study revealed that perceived barriers had the lowest mean (SD) score of 2.48 (0.71) out of 5, followed by health motivation at 2.51 (0.59) out of 5 and perceived benefits at 2.59 (0.71) out of 5. This finding is consistent with previous studies that have identified perceived barriers as the most significant predictor of mammogram screening [27,33,37]. Participants in our study showed a negative perception regarding the benefits of mammography, as evidenced by their lower scores on statements such as: "When I get a mammogram, I do not worry as much about BC" and "Having a mammogram will decrease my chances of dying from BC." These results were compatible with findings from other studies [22,33], as reported by Al-Naggar and Bobryshev [49], which indicated that Malaysian women with a limited understanding of the benefits of mammography were less likely to participate in regular screenings; only 15% had ever undergone a mammogram. Together, these findings underscore the importance of educational interventions in addressing misconceptions and promoting awareness of the benefits of mammography [54].

XSL•FO
RenderX

In our study, participants reported higher perceived barriers to mammogram screening, such as the belief that "having a mammogram would be embarrassing" or "having a mammogram would be painful." Previous studies support these findings, as Amin et al [55] found that embarrassment and anxiety about pain significantly deterred Bangladeshi women from mammography screening, especially where modesty is prioritized. In addition, Al-Mousa et al [56] found that Jordanian women often avoid mammography due to feelings of embarrassment and fear of the results, as they believe they do not need a mammogram if they have no family history of BC, which is deeply rooted in cultural beliefs. These studies emphasize the need for culturally sensitive interventions to increase the screening rate.

Moreover, participants in our study had a negative perception of health motivation, with low mean scores for attending regular check-ups, maintaining a balanced diet, and exercising regularly. These findings suggest that targeted health interventions should increase awareness about the importance of routine check-ups, provide accessible and culturally appropriate dietary guidance, and promote exercise through structured programs to foster sustained engagement in preventive health behaviors [22,23,56]. The motivation for health and awareness was significantly associated with screening behavior [27].

Our study's findings, related to the association between sociodemographic characteristics and knowledge and beliefs regarding BC and mammography, reveal that participants' age and education have a significant influence on their knowledge and beliefs. Older and less educated women showed lower awareness and more negative perceptions regarding the screening. These results align with previous studies and underscore the significant influence of age and education on shaping women's perspectives toward mammography screening [23,27,56,57].

Specifically, our study's findings revealed a significant association between knowledge and beliefs, as measured by the CHBMS, and the ages and educational levels of the participants (P<.05). Participants aged 40 - 49 years and 50 - 59 years scored higher on knowledge, perceived benefits, and health motivation compared with those aged 60 years and older (P<.001). This was consistent with previous studies suggesting that younger women have better access to health information, are more exposed to BC awareness campaigns, and benefit from higher literacy rates and greater access to digital platforms [58,59]. Younger women appreciate early detection, which is influenced by targeted screening and health care recommendations. Moreover, older women may underestimate the benefits of mammography, possibly due to rooted cultural beliefs, as found by Mah et al [60] that older women felt less vulnerable to BC than younger women and were less positive about screening. This suggests that motivation declines with age due to health priorities and misconceptions about the effectiveness of screening in older adults [61,62].

Similarly, women with a university education scored higher on knowledge, perceived benefits, and health motivation compared to those with secondary and primary education (P<.001). This supports the notion that individuals with higher education are more proactive about their health and preventive care and are more likely to follow medical advice [63]. This suggests that highly educated women are more likely to recognize the value of early detection and preventive care [64]. This suggests a more substantial health motivation for the importance of screening among women with higher levels of education [63,64].

Conversely, the perceived barriers were significantly more negative among participants aged 60 years and older compared with those aged 40 - 49 years and 50 - 59 years (P<.001), aligning with the logistical and psychological challenges faced by older women and their traditional beliefs [65,66]. Furthermore, participants with primary education reported more barriers than those with secondary and university education (P<.001), suggesting that lower education is associated with higher perceived obstacles, such as lack of knowledge, fear, embarrassment, financial concerns, and cultural beliefs [67,68].

Neither marital status nor health insurance had a significant impact on knowledge and beliefs (P>.05). This finding contrasts with studies suggesting that married women benefit from spousal support for mammography [69,70]. While health insurance facilitates access to screening, its impact may diminish in areas with few financial barriers [71,72].

Limitations

The study has several limitations. Its cross-sectional design uses convenience sampling, which prevents the determination of causal relationships between beliefs and screening behaviors and limits the generalizability of the results. The reliance on self-reported data may introduce information bias. Recruiting participants from a single hospital through convenience sampling may limit the generalizability of the findings to all Jordanian women aged 40 years and older, as it will not encompass all Jordanian women from different geographical locations, particularly those from rural areas. Furthermore, excluding women who had a mammogram within the last 12 months, as well as those with personal or family histories of BC, may introduce selection bias and limit insights into the influence of hereditary factors on screening behaviors.

Implications for Practice

Developing effective educational interventions for Jordanian women requires a multifaceted approach that addresses both individual and systemic barriers. These interventions must account for varying levels of awareness, health beliefs, and the influence of religious factors, such as fatalism, which affect screening behaviors. Involving religious and community leaders in program content can boost motivation and reduce participation barriers.

Educational initiatives should include different community activities, such as workshops, home visits, and outreach sessions with community leaders, religious figures, and BC survivors. This approach fosters trust and delivers culturally appropriate information. Expanding mobile mammography units and organizing workplace screening campaigns are crucial, especially for underserved rural populations.

Public health officials and health care providers need ongoing training in culturally competent communication and patient

XSL•FO
RenderX

counseling to ensure sensitive and supportive care. To improve accessibility, financial barriers can be addressed by offering free or subsidized mammograms for low-income women and advocating for broader insurance coverage.

Delivery methods should use digital health tools, such as mobile apps and SMS text messaging reminders, which can enhance personalized education and appointment alerts. In addition, providing culturally appropriate support services, including flexible scheduling and female-only environments, is important for addressing concerns about modesty and privacy.

These interventions should be integrated within a robust policy framework that updates national screening guidelines and incorporates educational efforts into a national registry and monitoring system. By tackling awareness levels, health beliefs, and religious perspectives, Jordan can implement effective interventions to improve BCS and outcomes for women nationwide. Ultimately, ongoing research to monitor screening trends is crucial for evaluating and enhancing health initiatives, providing valuable insights to inform future policies and programs.

Conclusion

This study contributes to the growing body of research on BCS in Jordan and similar contexts. It highlights significant barriers to mammogram screening among Jordanian women aged 40 years and older, including a lack of knowledge, cultural beliefs, and psychological and financial challenges. The study emphasizes the importance of establishing a solid foundation for culturally appropriate and sensitive interventions that are tailored to the local context and targeted to improve health awareness, accessibility, and policy reforms. Health care providers and policy makers can adopt an evidence-based approach to enhance early detection, reduce BC mortality rates, and promote a healthier future. Future research should focus on assessing the long-term effects of these initiatives.

Acknowledgments

We gratefully acknowledge Karolinska Institute for funding the Article Processing Charge (APC) and Albashir Hospital in Jordan for their invaluable administrative and resource assistance. We greatly appreciate Dr. Mohammad Al-Share's technical assistance and contributions to the data collection process. Finally, we acknowledge all participants whose engagement was essential to the success of this study.

The authors declare that the publication fees for this research article were covered under the national open-access agreement between Karolinska Institutet, as a member of Sweden's academic consortium Bibsam, and JMIR journals.

Data Availability

The datasets generated or analyzed during this study are not publicly available due to ethical and privacy considerations, but are available from the corresponding author on reasonable request.

Authors' Contributions

AA contributed to conceptualization, data curation, formal analysis, investigation, methodology, visualization, writing of the original draft, and review and editing of the manuscript. HT contributed to methodology, formal analysis, funding acquisition, supervision, and writing – review and editing. LGV contributed to methodology, formal analysis, supervision, and writing – review and editing. MA contributed to data curation and investigation. HA contributed to investigation. CAP contributed to methodology, formal analysis, project administration, and writing – review and editing.

Conflicts of Interest

The Karolinska Institute funded the Article publication charge (APC) for this article. Still, it was not involved in the study's design, data collection, analysis, interpretation, writing, or the decision to submit it for publication. Additionally, Dr. Hana Taha, one of the study's authors, serves as an editor for the JMIR Public Health and Surveillance journal.

Abstract

Background: Health indicators can facilitate the assessment of individual and population health status and are valuable in health care and public health settings. However, it is challenging to collect all measures at once. There is no single, objective, comprehensive, accurate, easy-to-use measure for individual health status yet, and we aim to develop one. We identified 29 health indicators via literature review and ranked their importance through public ratings to start the effort.

Objective: This study aims to explore the effects of 4 demographic variables (age, sex, professional group, and educational level) on the importance ratings of the 29 indicators.

Methods: This was a cross-sectional study. Online surveys were administered on 2 US college campuses and through ResearchMatch, an online platform specialized in finding clinical research participants. Only individuals 18 years or older were considered for inclusion as respondents. A 4-way multivariate analysis of variance (MANOVA) with post hoc testing was conducted to determine the effects of 4 demographic factors on the 29 health indicators. Descriptive statistics and bivariate correlation analysis were reported, along with the results of MANOVA with post hoc testing.

Results: The study included 1153 participants from the United States of America with 1144 complete responses. Our study found significant correlations among the 29 health indicators. Age, education, sex, and professional groups showed correlations with multiple health indicators. Correlation analysis indicated that age was correlated with 16 of the 29 health indicators, followed by education (9 indicators), sex (8 indicators), and professional group (7 indicators). MANOVA modeling revealed that age (partial eta squared=0.058; $P<.001$), sex (partial eta squared=0.05; $P<.001$), professional group (partial eta squared=0.049; $P<.001$), and educational levels (partial eta squared=0.047; $P<.001$), as well as the interactions between sex and professional group (partial eta squared=0.044; $P<.001$) and sex and age (partial eta squared=0.041; $P<.001$), showed significant effects on the combination of the 29 health indicators. In general, female participants provided significantly higher ratings on 10 health indicators than male participants ($P<.05$), whereas older participants provided significantly higher ratings on 20 health indicators than younger participants ($P<.05$).

Conclusions: Age emerged as a critical factor influencing the ratings of the 29 health indicators and showed the largest effect size along with sex, professional group, and educational level. These findings can be used as a quantitative foundation for the development of an objective measure for individual health status, for grouping health indicators, for conducting demographic factor adjustments during data analysis, for designing customized behavioral intervention studies based on demographic factors, or for health policy-making or program development.

Introduction

Contexts for Health Indicators

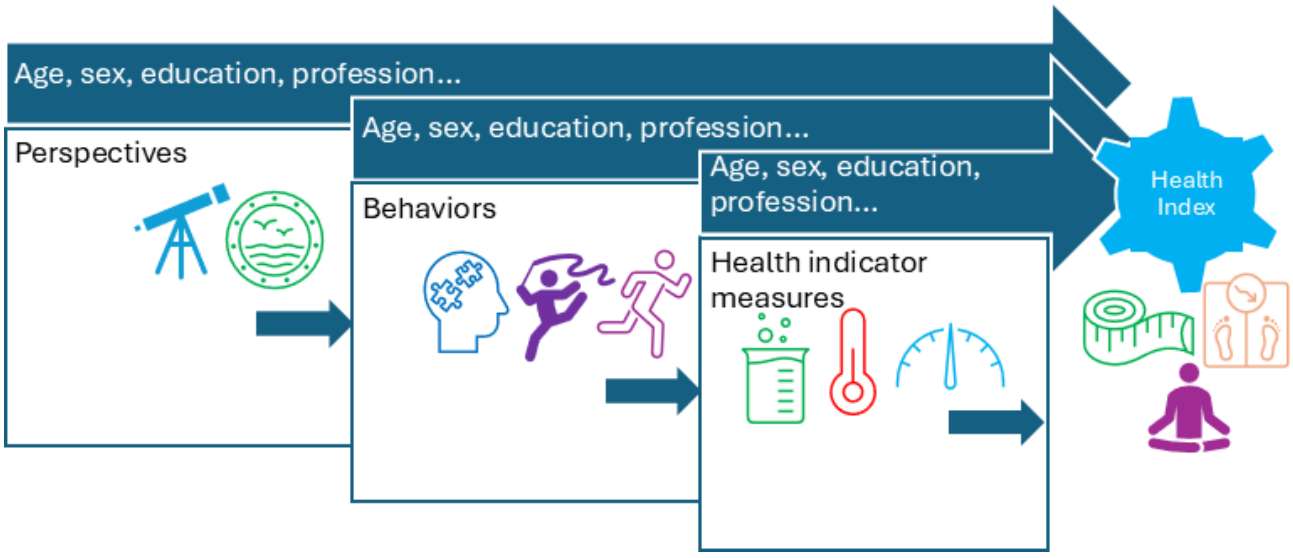
Health indicators can be used in various health care scenarios and public health settings, for example, measuring individual health status [1], measuring population health, community health, tracking longitudinal changes in individual or population health [2-4], tracking the outcomes of preventive services or programs over time, evaluating outcomes of interventions implemented, and comparing health statuses among more homogeneous subgroups [2,5-7]. The importance of health indicators has been recognized and studied since 1972 [8]. However, most of the effort has focused on group or population level measurements, for example, life expectancy and mortality [3,4,9,10]. Disease stages (eg, different stages of cancer) have long been used to help physicians determine more appropriate treatment plans and establish relatively more homogeneous patient groups for better comparability. For example, the Charlson Comorbidity Index (CCI), a comprehensive measurement that predicts long-term mortality, is one of the landmark tools used broadly to help stratify patients with chronic conditions into more homogeneous subgroups for better comparability and more accurate analysis [11,12].

Limitations of the Current Health Indicators

The most used measurement of overall individual health status is self-rated health status, which has been shown to have good validity among the US population [5,13,14]. Although this measure had initially been used to predict mortality among older adults, published studies show its use in measuring outcomes of primary care [15], people with chronic conditions [16], and general adults [17]. Self-rated health status has also been broadly used by the World Health Organization (WHO) and the Organisation for Economic Co-operation and Development (OECD). Nevertheless, given the lack of clear criteria for rating each level of self-rated health status, the obtained ratings may be considered subjective. This subjectivity has been recognized as a potential limitation that could affect comparisons among different populations [5]. Numerous economists have focused on well-being studies and their measurements [18], using gross domestic product (GDP), GDP per capita, life expectancy, or mortality [19] as measures. Meanwhile, some researchers have focused on population health and socioeconomic determinants [18]. However, a literature search suggests the lack of a comprehensive, objective, and consistent measurement for healthy individuals or populations, that is, a counterpart of the CCI, albeit for healthy individuals instead of patients with chronic conditions, the primary target of the CCI.

Needs of a Single, Objective, Comprehensive, and Easy-to-Use Health Indicator

Although life expectancy, morbidity, and mortality have long been used to measure and compare group health outcomes [20] within and among individual countries by the United Nations or WHO, more objective, comprehensive, and accurate methods for measuring a healthy individual's health status are certainly needed, given the lack of existing measures. Some individual health indicators, such as BMI, blood pressure, drug and substance abuse, alcohol abuse, smoking, and tobacco use, may not be obtained easily all at once. Measurement of individual health status could provide important evidence to stratify the healthy population into more homogeneous subgroups, which can make comparisons meaningful.



Our Previous Studies on Current Health Indicators

We started by conducting a literature review [1,5,21-25] to compile 29 health indicators [26] measuring an individual's health status, including mental, physical, and social well-being. These health indicators include (in descending order based on public perceived importance rating): drug or substance abuse, smoking and tobacco use, alcohol abuse, major depression, diet and nutrition, blood sugar level, physical inactivity, immunization and vaccination, hypertension screening, low-density lipoprotein (LDL) cholesterol, blood triglycerides, high-density lipoprotein (HDL) cholesterol, having a sense of purpose in one's life, cancer screening detection, total cholesterol, health literacy rate, personal care needs, air quality index > 100, family history of cancer, self-rated health status, HIV testing, insurance coverage, BMI, supply of dentists, sun protection, unemployed individual, engagement in life, high school diploma as a health indicator, and race and ethnicity [26].

Thereafter, we examined 4 commercial electronic health record (EHR) systems, and the results showed that none of the systems included all 29 health indicators [27]. Practically, collecting all 29 health indicators can be burdensome for EHR users [28]. Then we conducted a survey wherein the public was invited to rate the importance of each health indicator. Such ratings may correspondingly impact their behaviors, though not necessarily consciously. Literature has documented people's risk perception and its core impact on one's health behavior [29,30]. The initial analysis of the importance ratings showed that the respondents agreed most on 13 of the 29 health indicators [26]. Figure 1 presents a conceptual framework illustrating the relationship between perspectives, health behaviors, health indicator measures, and associated factors, such as age, sex, education, and profession. This paper is a follow-up and in-depth analysis of the same survey results, focusing on the relationship between importance ratings and demographic information (respondents' age, sex, education level, and professional group).

Methods

Study Design and Period

This was a cross-sectional study via 3 online surveys administered (Multimedia Appendix 1) at Ohio University (2017), ResearchMatch (2018), and Clemson University (2020). No compensation was provided to any respondents.

Study Population

The only inclusion criterion in this study was that the survey respondents were required to be 18 years or older. The survey was administered via 2 public universities and ResearchMatch [31], which is an online platform for recruiting clinical research participants. Among the 1153 participants who responded, 1144 who provided complete responses for all question items were included as the final total sample.

Data Collection Instrument

The survey was developed via different stages of testing and validation. The health indicators were grouped into 5 categories in the survey to provide a better experience for participants: health risks and behaviors (8 indicators), health care (3 indicators), health care provider supply (3 indicators), blood tests in physical exams (5 indicators), and others (10 indicators) [26]. The survey requested the respondents to rate the importance of 29 health indicators, with each health indicator being defined in the survey. The details related to the survey (see Multimedia Appendix 1) and definitions of each health indicator have all been published [26].

Recruitment and Data Collection Procedures

Qualtrics surveys were used to administer the survey at Ohio University and Clemson University. The importance of each health indicator was rated from 1 (least important) to 10 (most important). The ResearchMatch survey was administered via REDCap (Research Electronic Data Capture; Vanderbilt University), with the ratings ranging from 1 (least important) to 100 (most important). The rating scale was converted into a 1 to 10 scale during the analysis.

The survey link was anonymous, and we explicitly stated in the invitations that the participants were welcome to share the link with others. Multimedia Appendix 2 shows the invitation email used in all 3 settings. All participants consented to the study electronically before they responded to the survey. At Ohio University and Clemson University, the survey was shared via an email broadcast. In ResearchMatch, the survey invitation was sent out randomly. All respondents were volunteers.

Research Question for This Analysis

The following research question was used for this analysis: “What are the effects of age, sex, profession, and education on the perceived importance of 29 health indicators, individually or in combination, among the public?”

Statistical Analysis Plan

This analysis examined all 29 health indicators according to age, sex, educational level, and professional group. Our analysis did not include race or ethnicity, mainly due to imbalanced data [26]. Descriptive statistics were reported to present the demographic profile of the participants (see Table 1).

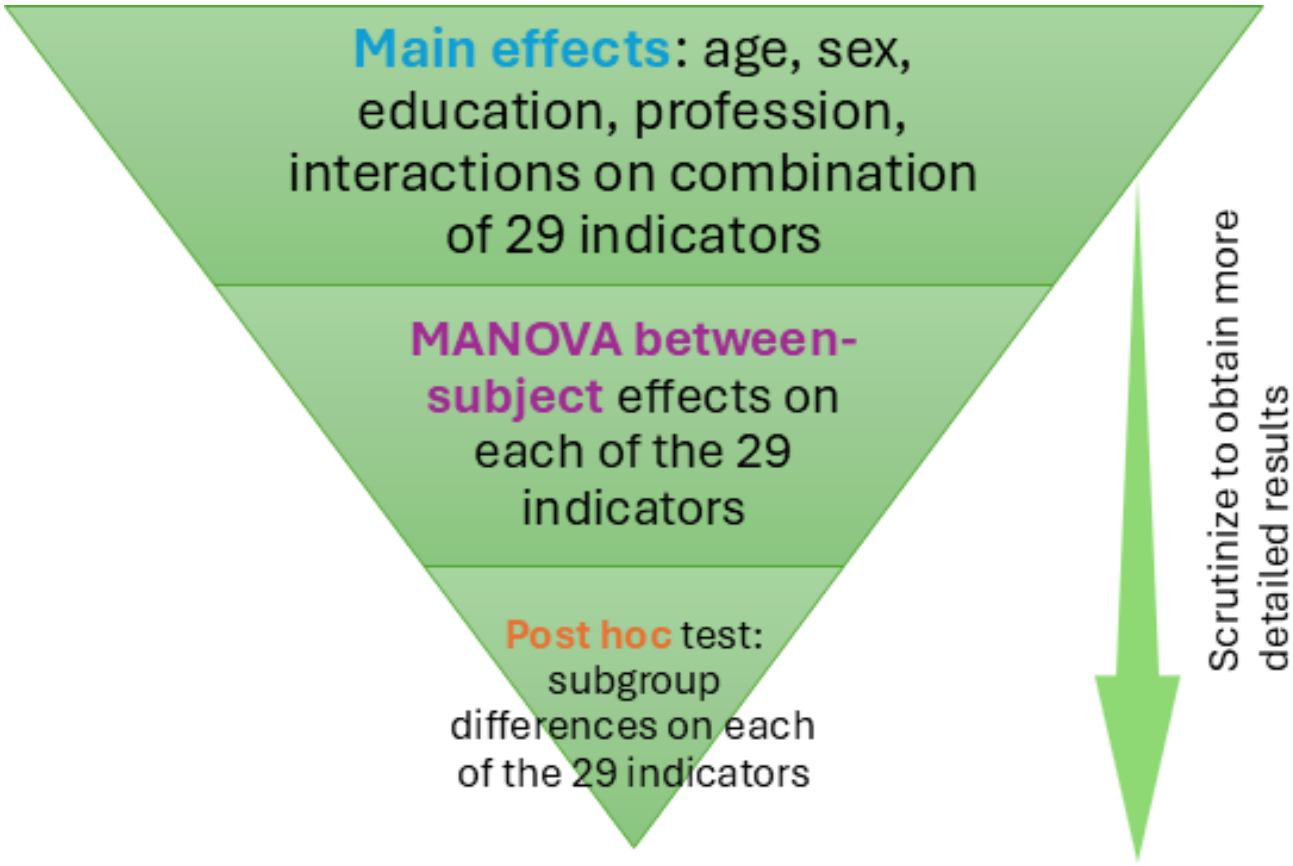
Health care providers	227 (19.84)
Public health professional	70 (6.12)
Researcher who uses health indicator data	78 (6.82)
Other researchers	203 (17.74)
Other professional groups, specify	566 (49.48)
Educational qualification	
High school	216 (18.88)
Associate degree	95 (8.3)
College degree	364 (31.82)
Master's degree	325 (28.41)
Doctoral degree	144 (12.59)

Specifically, to examine bivariate relationships among all variables, a correlation analysis was conducted among the 4 demographic factors and the 29 health indicators. To examine group mean differences, a complete multivariate analysis of variance (MANOVA) with the 4 demographic factors as the independent variables (IVs) and the 29 health indicators as the dependent variables (DVs) was performed. MANOVA was selected to test 29 health indicators simultaneously because it can test the combined effect of all IVs and all DVs at once rather than running separate tests. MANOVA helps control multiplicity by addressing the inflated type 1 error, and it is powerful for detecting multivariate patterns by considering the covariance structure of the 29 dependent variables.

Before we ran MANOVA, we tested the assumptions of normality and homogeneity of variances. Both assumptions were violated. The Box test results indicated significance. Levene test results for 13 of 29 dependent variables were significant. To address the violation of homogeneity, we used Pillai trace values and proceeded with Games-Howell post hoc testing. Regarding the violation of normality, we used MANOVA with no concerns because it is robust to violations of normality when the sample size is large (n=1144). For a sample size larger than 30, the central limit theorem says that the sample mean vectors are approximately multivariate normally distributed, even if the individual observations are not.

The null hypothesis of MANOVA was that a combination of the ratings for the 29 health indicators would have no significant mean difference between the groups. The alpha level for the 4-way MANOVA analysis was set as .05. As such, we identified significant 2-way interaction effects of age by sex and sex by professional group. Therefore, the final MANOVA model included 4 main effects of age, sex, education, professional group, and 2 interaction effects (ie, age by sex and sex by professional group). All statistical analyses were conducted via SPSS (version 29; IBM Corp).

Ethical Considerations



This study was approved by the Ohio University Institutional Review Board (IRB; 17-X-142) and Clemson University IRB (IRB2019-441). All participants completed the consent form remotely before responding to the online survey. This study only uses aggregated results during analysis and in the communication of results; no identifiable information was used in any analysis or publication. The online survey is purely voluntary; no incentives were used except for a warm invitation email.

Results

Figure 2 organizes the results, excluding the participants' profiles and the bivariate correlation results, to help readers navigate the Results section.

Figure 2. Organizational overview of the multivariate analysis results. MANOVA: multivariate analysis of variance.

Respondent Profile

Table 1 summarizes the percentages and numbers of all 4 independent variables (ie, age, sex, profession, and education) and their respective levels (ie, subgroups) to provide a basic profile of the survey respondents.

Bivariate Correlations Between Demographic Factors and the 29 Health Indicators

The bivariate correlation analysis for age, sex, professional group, and education level, and the 29 health indicators (DV) indicated that all the dependent variables were significantly correlated with each other (Pearson correlation coefficient, r=0.058-0.838). The independent variable, age, was correlated with 21 of the dependent variables, except for the following 8 indicators: diet and nutrition, health literacy, high school diploma, HIV testing, immunization, insurance coverage, personal care needs, and total cholesterol level. Sex was correlated with 20 of the DVs, except for the following 9 indicators: air quality index >100, cancer screening, having a sense of purpose, immunization, high school diploma, insurance coverage, hypertension screening, personal care needs, and unemployment. Education level was correlated with these 11 health indicators, namely alcohol abuse, BMI, drug or substance abuse, physical inactivity, smoking, cancer screening, HIV testing, total cholesterol, engaged people, race and ethnicity, and unemployment. The professional group was correlated with 8 health indicators, namely diet and nutrition, engaged people, having a sense of purpose, high school diploma, personal care needs, physical inactivity, total cholesterol levels, and unemployment. The complete correlation matrix is provided in Multimedia Appendix 3.

Main Effects of Demographic Factors on the Combination of the 29 Health Indicators

MANOVA modeling indicated that age, sex, professional group, and education level had significant main effects on the combination of 29 health indicators after controlling for other predictor effects. In addition, significant interaction effects between sex and professional group, as well as sex and age group, were observed on the 29 dependent variables after controlling for other predictor effects. The age group had a relatively increased effect size (ie, partial eta squared=0.058), whereas the interaction between sex and age group had a relatively small effect size (ie, partial eta squared=0.041).

Table 2 details the MANOVA results, including Pillai trace value, df, F, P values, and partial eta squared values. Only statistically significant interactions are presented in Table 2.

Sex and professional group	0.352	1.731 (232)	<.001	0.044
Sex and age group	0.248	1.616 (174)	<.001	0.041

Significant MANOVA Results for Between-Subject Effects

Four-way MANOVA with post hoc testing (Games-Howell) was conducted to examine group mean differences in the 29 health indicators according to the 4 demographic variables (age, sex, professional group, and education level). Table 3 presents the significant results of MANOVA modeling for between-subject effects. Accordingly, age showed significant effects on 16 health indicators, educational level on 9 health indicators, sex on 8 health indicators, and professional group on 7 health indicators. Meanwhile, the interactions between sex and age showed significant effects on 7 health indicators, whereas the interactions between sex and professional group showed significant effects on 5 health indicators.

Table 3 details all significant MANOVA results for between-subject effects. The complete set of the MANOVA testing results of between-subject effects, including both significant and insignificant results, can be found in Multimedia Appendix 4.

Post Hoc Testing Results

Of the 29 health indicators, 13 of them did not have homogenous variances. Due to this violation of the MANOVA assumption, we ran Games-Howell post hoc testing for each of them using ANOVA in SPSS. The other 16 indicators that met the equal variances assumption were tested using Bonferroni post hoc in SPSS. A close examination beyond the main effects of demographic factors on health indicator ratings through post hoc analysis revealed some interesting findings. More specifically, the MANOVA results for between-subject effects indicated significant differences in ratings between female and male respondents on the 10 health indicators (see Table 4, post hoc results and sex). All mean differences between these 10 health indicators showed that female ratings were higher than male ratings. The full set of post hoc testing results is available upon request.

Regarding age, post hoc testing results showed that the ratings for the following 20 health indicators all showed a similar trend of significantly higher ratings among older participants than among younger participants: self-rated health status, air quality index >100, dentist supply, blood sugar level, blood triglycerides, HDL, LDL, alcohol abuse, BMI, drug or substance abuse, family history of cancer, physical inactivity, smoking, sun protection, hypertension screening, engaged people, major depression, having a sense of purpose, race and ethnicity, and unemployment (see Table 4, post hoc results and age).

Post hoc testing results also showed that health care providers rated 3 health indicators significantly higher than other professional groups: physical inactivity, engaged people, and having a sense of purpose in life (see Table 4, post hoc results, and profession). Meanwhile, public health professionals rated 2 health indicators significantly higher than other professional groups: insurance coverage and race and ethnicity. More complete results are presented in Table 4.

Post hoc testing results showed that participants with higher educational levels provided significantly and consistently higher

XSL•FO
RenderX

ratings for the following 7 health indicators than those with lower educational levels: alcohol abuse, drug and substance abuse, physical inactivity, smoking, engaged people, race and ethnicity, and unemployment (see Table 4, post hoc results and education). Meanwhile, participants with high school education rated significantly higher for HIV testing than those with Master's or Doctoral degrees.

Overlapping Results According to Different Approaches

The left part of Table 4 (see Main effects and interaction effects) presents an alternative view of a portion of the results in Table 3. The left side of Table 4 also combines the results when the same approach was used, but only examined the 13 more consistent health indicators per our previous publication [26] (Table 4). After considering the results from all 29 health indicators and the 13 more consistently rated health indicators, we found that age apparently showed consistent and significant effects on the ratings of the following 15 health indicators: blood sugar level, alcohol abuse, BMI, drug and substance abuse, physical inactivity, smoking, engaged people, having a sense of purpose in life, self-rated health status, air quality index >100, dentist supply, LDL, family history of cancer, sun protection, and hypertension screening. In other words, older participants provided higher ratings for these indicators than did younger participants. Meanwhile, the educational level also showed a significant effect on the ratings of HIV testing (inversely), alcohol abuse, physical inactivity, smoking, engaged people, race and ethnicity, and unemployment. Except for HIV testing, all 6 other health indicators were observed such that participants with higher educational levels provided higher ratings for them.

In addition, we also noticed the following interesting findings from Table 4:

1. After examining all 29 health indicators, we found that 5 indicators did not show any significant effects according to demographic factors or their interactions: immunization, health literacy rate, HDL, total cholesterol, and major depression (see Table 4).
2. Meanwhile, there are 3 health indicators showing the significant effects of 4 or 5 demographic factors and their interactions: smoking (5), physical inactivity (4), and race and ethnicity (4).
3. Among the 29 indicators, 13 that received more consistent ratings showed much fewer significant effects according to demographic factors and their interactions:
    - A total of 12 significant effects for 13 indicators versus 40 significant effects for the rest of the 16 indicators, that is, the "Main effects and interaction effects" in Table 4.
    - A total of 11 significant post hoc results for 13 indicators versus 34 significant post hoc results for the rest of 16 indicators, that is, the "Post hoc results" in Table 4.

Discussion

Interpretation of Results

In summary, female participants rated 10 health indicators higher than male participants, and older participants rated 20 health indicators higher than younger participants, based on an overlap analysis of different statistical methods. The demographic factors showed the least significant effects on these 5 health indicators: immunization, health literacy rate, HDL, total cholesterol, and major depression. Meanwhile, demographic factors show significant impacts on ratings of smoking, physical activity, and race and ethnicity.

An alternative presentation of the MANOVA analysis is provided in Table 4 (ie, the "Main effects and interaction effects" from Table 3, whereas the "Post hoc results" details the significant results from post hoc testing); we also noticed the following points. First, the main effects may not be significant when significant post hoc test results were obtained, possibly due to cancellation effects. Second, post hoc results are always necessary when using a complicated MANOVA model for comparisons among subgroups, which cannot be demonstrated via the main effects. Third, among the 29 health indicators, 13 that showed more consistent importance ratings had much fewer main effects and fewer significant post hoc test results than did the remaining 16 health indicators. This third point validates the results across different analytic strategies.

Significance of the Work

This study has endeavored to prioritize the 29 commonly used health indicators via public perspective surveys, thereby providing a foundation for the prioritization of these 29 health indicators, 13 of which received relatively consistent ratings across all 3 samples. The detailed results can be used to determine which health indicators should be included in EHR or PHR systems, given the burden associated with collecting all 29 health indicators. The survey results [26] and further analysis presented in this study provide a foundation for developing a comprehensive health indicator formula that can measure individual health and outcomes of preventive medicine services over time [21,32-34]. Preventive services have been recognized as important for controlling the increasing costs of health care [35,36]. However, the accurate measurement of such services can be challenging given the complexity of measuring most of their outcomes within a short time period.

This paper further explored demographic factors, namely age, sex, educational level, and professional group, and their effects on public ratings of these 29 health indicators. Our results showed that age was a critical factor, with older participants rating 20 health indicators significantly higher than younger ones, indicating the wisdom accumulated based on experience and time. However, more carefully designed experiments are required to determine the actual relationship between age and importance ratings of the 20 health indicators, which is beyond the scope of this paper. However, our results can provide quantitative evidence for age-based adjustments during health indicator-related data analysis.

XSL•FO
RenderX

Sex also played a critical role in ratings of 10 health indicators, with female participants providing significantly higher ratings than male participants. Considering the longer life expectancy among females than males in many countries (5.4 y difference in the United States) [37] and the relationship between perception and health behavior, our public perspective results in the importance ratings of the 10 health indicators aligning well with the life expectancy difference between females and males. Our understanding is that females may pay more attention to their health in general, as evidenced by more female participants in our study and in other studies, higher ratings of health indicators, more female participants in fitness group exercises, and longer life expectancies. However, the actual and accurate relationship may not be as linear, given that females perceived these health indicators to be more important than males, which could lead to healthier behaviors and, eventually, a longer life expectancy. Nonetheless, the observed data points seemingly demonstrate a trend. In addition, we also believe that this point validates our public perspective survey results. Regardless of whether such gender-related differences have physiological roots or purely sociocultural effects [38,39], similar observations were documented between females and males. Our results could be used in making health-related policy, especially in the public health field, for example, conducting more intensive campaigns focusing on males or promoting healthy lifestyles among males. Perhaps new ways of delivering health-related information need to be explored to better engage males during their lifespan.

The detailed comparisons and results presented in this paper can be used as a quantitative foundation to develop a more objective and comprehensive measure of individual health status. In addition, our results can be used as a foundation for designing future health behavioral studies, considering the published demonstration of relationships between perceptions and health behavior [29,30]. The public's perspectives on the studied health indicators have been assumed to be influenced by their health-related awareness or behaviors, either consciously or subconsciously. Our study results could shed some light on the adjustment of demographic-related factors during data analysis or modeling of health-related factors.

Comparison With Other Similar Measures to Provide Context for Our Results

County Health Ranking & Roadmaps, a typical population-level program established by the University of Wisconsin Population Health Institute and supported by the Robert Wood Johnson Foundation [40], compares 2 categories (health outcomes and health factors), 5 classes (health outcomes, health behaviors, clinical care, social & economic factors, and physical environment), and 15 measures and demographic information for each county in the United States [40]. Several similarities in the measures used have been noted between our study (to measure individual health status) and the mentioned program. In fact, a comparison showed a 60% (9/15) overlap in the measures used, which provides a sense of validation and methodological alignment for our study, considering County Health Ranking & Roadmaps is an established and well-respected project, and their results were used and cited broadly in developing population-level health programs and policies. Meanwhile, we also noticed that the main differences were that County Health Rankings used more measures in the social and economic factors, such as income, housing, family and social support, and community safety, whereas our study used more individual-level measures, such as blood sugar level and total cholesterol. Considering that focused groups vary quite significantly (ie, individuals versus county-level populations), the difference in measurement selection is understandable despite similarly attempting to measure health. Our study and results provide a complementary role to the County Health Ranking & Roadmaps, which focuses on the health and comparison between counties, a basic unit, while our study focuses on individuals' health. Considering our different application purposes, we think our study and County Ranking & Roadmaps can be used in complementary ways to study individual or their collective health status.

The UK Health Index, which consists of 3 categories, namely healthy people, healthy lives, and healthy places, has been used to track changes over time and compare the health of residents across different areas of England [2,6,41]. The healthy lives category is very similar to many of our health indicators, also referred to as modifiable risk factors, at the individual level. The healthy people category measures health at the population level, whereas the healthy places category measures health at the system level or beyond individual control (eg, air quality) [42].

A closer comparison of the UK Health Index [6,41] and our 29 health indicators [26] showed a large overlap in 15 health indicators between the two. Over half of the health indicators used in our study were also used by the UK Health Index, which provides additional validity for these health indicators, considering that the UK Health Index is a government-funded project.

However, after closely examining the methodology used in developing the UK Health Index, we noticed the following differences between our project and the UK Health Index project. First, the UK Health Index was developed to measure a nation's health status at both the population and individual levels, whereas our health indicators were used to measure individual health status only. Collectively, however, such indicators can be aggregated to compare health outcomes across different groups or track changes over time. Second, in terms of the long-term objectives, our goal was to use the survey results, analysis results, and real-world data to develop a formula that could calculate a more objective, data-driven health indicator to measure an individual's overall health status. The UK Health Index project used factor analysis to group health indicators and determine the weight of each health indicator. Third, as a next-stage effort, our project will focus on formula development and validation of health indicators, whereas the UK Health Index project uses existing and available data sources and already provides Health Index comparisons among various areas in England, as well as comparisons for the same area over time. Although the references provided by the UK Health Index project are exceedingly helpful [42,43], our study's focus and trajectory differ from that of the UK Health Index project. Fourth, given our initial goal of measuring individual health status, measurement is our core focus, which will be necessary

XSL•FO
RenderX

for the long-term use of our study within EHR or PHR systems. The UK Health Index, however, focuses on the availability and continuity of data sources and compares the same or various locations across different time points.

Strengths and Weaknesses of the Study

Our study explores strategies for measuring individual health more objectively, accurately, and comprehensively. Currently, an objective and accurate measure of individual health status is missing. Such a measure can track the performance of health care systems, preventive services, or intervention programs for individuals, as well as the health and outcomes of the population over time. In addition, such measures can be used to establish more comparable and homogeneous subgroups for conducting epidemiological or health service studies. Although our study constitutes the first step in the development of a larger project, its direction is critical for improving the health of the whole population and the use and promotion of preventive care services. In addition, we used multiple statistical methods during the results analysis, and we emphasized the overlap results across different methods, which provides additional confidence in the results. We feel this is an important step to mitigate the potential limitations of observational studies like ours.

Our work is in the preliminary stages, which is the main limitation of our study. Although our survey included a validation question and only included complete and valid responses in the analysis, this analysis was based on public perspectives. Despite this reality, we believe that our deep analysis of the demographic variables of individual respondents and their effects on and interactions with the rating results are nevertheless helpful for thoroughly understanding the public's perspectives on the 29 health indicators. In addition, our analysis and results can provide insights and quantitative evidence for the future development of a comprehensive individual health index.

Another limitation was that our results were derived from survey results. Despite the relatively large sample sizes and in-depth analysis, our study is an observational study. Nonetheless, our results can shed light on the correlations between various demographic subgroups and ratings. However, given that they are not as convincing as those from a hypothesis-driven randomized controlled study, we urge readers to interpret the results within context. In addition, other factors, such as pain or sleep, had not been considered in our study [10]. Meanwhile, we acknowledge that, due to the voluntary nature of the survey, the respondents have a higher percentage of female participants with relatively higher educational levels compared to the general public. Therefore, users need to put the results into these contexts. In addition, the use of different scales (1 - 10 in Qualtrics and 1 - 100 in REDCap) may also lead to unintended effects in ratings.

Potential Future Developments

Our next step is to explore longitudinal individual health data, possibly through EHR, to establish comparable cohorts to develop, refine, and validate the new individual health measure. All of Us, a National Institutes of Health—initiated project, can be a potential platform and data source to develop and validate the measure [44,45]. Despite numerous studies exploring a measure of health status for decades [8,9,46-49], no consensus has yet been reached regarding such a measure. In addition, others can use our results during data analysis, especially when they need to conduct age- or sex-based adjustments. Meanwhile, our results can also be used as evidence to develop more customized public health programs or interventional studies related to the demographic factors we analyzed in this study. In addition, designing further studies to understand how demographic factors affect the importance ratings of health indicators is certainly worthwhile to explore.

Conclusion

Our analysis showed that all 29 health indicators were significantly intercorrelated. The MANOVA modeling results indicated that age, sex, professional group, educational level, and the interaction between sex and professional group and sex and age had significant main effects on the combination of 29 health indicators. Our findings could provide a quantitative foundation for (1) developing a formula for an overall health index, (2) providing evidence to guide the design of customized behavioral interventional studies for subgroups of the public, and (3) providing evidence for demographic factor-related adjustments during data analysis, modeling, policy making, and program development.

Acknowledgments

We sincerely thank all participants for their responses and for sharing their perceptions with us. Without their participation, none of the work would be possible. Authors have not used generative AI tools in preparing any part of the manuscript at any stage of the writing process. Only Grammarly was used to check and correct grammar errors during writing and revision.

Data Availability

The data sets, statistical analysis strategies, codes, and full sets of testing results for this paper are available upon request from the corresponding author.

Authors' Contributions

XJ, TS, FL, and SD contributed to the initial conceptualization and design of the project. XJ and YZ determined the initial analytic strategies. YZ conducted data analysis and drafted the Methods and Results sections. TS, XJ, and YZ drafted the initial manuscript, and TS revised it significantly. TS cleaned the data and organized it for better usability, with guidance from YZ and XJ. XJ, TS,

Abstract

Background: Increased aging and accelerated urbanization have led to the migration of older adults within China. Migrant older adults (MOAs) may experience physical and psychological discomfort in influx cities, and they are a vulnerable group that has emerged in the course of fast urbanization. Previous studies have confirmed the association between oral health and loneliness as well as the relationship between social support and loneliness; however, no research has been done to clarify the underlying mechanisms and the migrant-local difference between oral health, social support, and loneliness.

Objective: This study aimed to test the association between oral health, social support, and loneliness among Chinese older adults, as well as the migrant-local difference on the above relationship.

Methods: Multistage cluster random sampling was used to enroll a total of 1205 participants, including 613 MOAs and 592 local older adults (LOAs). Loneliness was assessed by the 6-item short-form UCLA Loneliness Scale; oral health was measured via the Chinese version Geriatric Oral Health Assessment Index (GOHAI); social support was evaluated by the Social Support Rating Scale (SSRS). Descriptive analysis, χ^2 tests, and *t* tests were conducted. Multigroup structural equation modeling (SEM) was employed to clarify the migrant-local difference on the association between oral health, social support, and loneliness among MOAs and LOAs.

Results: The mean score of loneliness was 8.58 (SD 3.032) for MOAs and 8.00 (SD 2.790) for LOAs. Oral health and social support were found to be negatively related to loneliness among MOAs and LOAs; the standardized direct effects for MOAs were −0.168 and −0.444 (*P*<.001), and they were −0.243 and −0.392 (*P*<.001) for LOAs, respectively. Oral health generated a direct positive effect on social support, and the direct effect was 0.186 for MOAs (*P*<.001) and 0.247 for LOAs (*P*<.001).

Conclusions: Loneliness was fairly low among older adults in Weifang, China, while MOAs showed higher loneliness than LOAs. Oral health had both direct and indirect negative effects on loneliness among MOAs and LOAs, with no significant path differences between MOAs and LOAs. Social support was found to be negatively associated with loneliness for both MOA and LOA, while the association was stronger among MOAs than LOAs. Oral health exerted a significantly positive effect on social support for both MOAs and LOAs, while no significant difference existed between them. Measures should be taken by the government, society, and families to increase social support, improve oral health, and further reduce loneliness among MOAs and LOAs.

Introduction

China has one of the fastest growing aging populations in the world [1]. According to the data of China's Seventh National Census, the number of people aged 60 years or above was 264.02 million, accounting for 18.70% (the number of people aged 65 years or above was 190.64 million, accounting for 13.50%). Compared with 2010, the proportion of people aged 60 years or above increased by 5.44% [2]. As the population ages, concern regarding older adults' health status has also increased.

In the past few decades, China has experienced a rapid increase in economic level and an acceleration of urbanization, which also caused an economic gap across different cities and may further lead to population migration. Due to the traditional Chinese culture, which highlights the family union, more and more older adults move to live with their adult children. Existing studies refer to the older adults who leave their hometown to migrate with their children as migrant older adults (MOAs) [3]. Previous studies found that MOAs had difficulties in developing social networks and social integration, which would further affect their mental health [4,5], life satisfaction [6], and quality of life [7]. Based on "adaptive theory" [8] and "social support buffering model" [9], MOAs face increased adaptation stress and social isolation, which may lead to higher reliance on social support networks to cope with the challenges posed by migration. Thus, it is also important to pay more attention to the health status of MOAs, in addition to that of local older adults (LOAs).

Loneliness is defined by Weiss [10] as a subjective feeling formed when individuals perceive that they lack satisfying interpersonal relationships and there is a gap between their desire to connect and the actual situation of connection. Donovan et al [11] found that 17.6% of US older adults felt lonely much of the time during the preceding week. Guo et al's [12] nationwide study found that 24.3% of older people reported they were lonely in China. Another study found that nearly one-fourth of Chinese older adult participants felt lonely [13]. In terms of MOAs, one longitudinal study showed that migrants from non–English-speaking countries reported higher levels of loneliness, as compared with the native-born, non-Indigenous Australians [14]. Some studies indicated that loneliness was associated with some negative health outcomes [15,16], such as poor physical health [17] and poor mental health [18,19]. Moreover, another national study in China clarified that a high degree of loneliness could further reduce the life satisfaction of older adults [20]. A cohort study from northern and southern Europe showed that loneliness was associated with a decreased quality of life among older adults [21]. Therefore, it is important to pay more attention to older adults' loneliness and find possible ways to reduce their loneliness.

Oral health has been defined by the World Health Organization (WHO) as a state of being free from chronic mouth and facial pain, oral and throat cancer, oral infection and sores, periodontal (gum) disease, tooth decay, tooth loss, and other diseases and disorders that limit an individual's capacity in biting, chewing, smiling, speaking, and psychosocial well-being [22]. The Fourth Chinese Oral Health Epidemiological Survey Report demonstrated that the prevalence of dental caries in older adults' permanent teeth was fairly high, implying serious oral health conditions [23]. Oral health, as a part of general health, is an important determinant of loneliness. One study examined the relationship between oral health and mental health issues and found that oral health was negatively associated with depression [24]. However, few studies have examined the association between oral health and loneliness. A study among English older adults demonstrated that oral health–related quality of life was identified as an independent risk factor for loneliness both cross-sectionally and longitudinally, and older adults with oral impacts had a significantly higher risk of being lonely than their counterparts without any oral impacts [25]. A previous study also found that the fewer number of teeth, the more likely both Japanese and British older adults were to report social isolation or loneliness [26]. Studies also clarified that the degenerative changes of oral function could lead to eating difficulties and imbalanced nutritional intake, which in turn affects physical and mental health and may increase the loneliness of older adults [27,28]. Thus, it is important to test the empirical association between oral health and loneliness among older adults.

Social support refers to the material and moral help provided by various parties in society, including family, relatives, friends, colleagues, organizations, and trade unions [29]. A meta-analysis has pointed out that increased social support would be supportive of successful aging among older adults [30]. Existing research also found that social support could not only provide the necessary resources (such as financial help and emotional help) for older adults to cope with challenges, but also had a huge positive impact on their physical and mental health [30,31]. Conversely, previous studies clarified that a lack of social support would cause adverse outcomes, such as limitations on activities of daily living [32] and poor quality of life [33]. The association between social support and loneliness has been widely explored. A previous study pointed out that social support was negatively associated with loneliness among older adults [34]. Chung and Kim [35] found that social support was critical in lowering loneliness in middle-aged and older adults. Studies from different countries indicated that the changes in older people's social networks and social support resulted in a significant onset of loneliness during the COVID-19 pandemic [36,37].

A previous study indicated that social support was related to older adults' oral health [38]. A nationwide study in Britain demonstrated social support was associated with the oral health status and oral health behavior of older people [39]. A study conducted in Germany clarified that impaired oral health–related quality of life was positively correlated with lower social support among older seniors [40]. A study had shown that oral condition was closely related to facial appearance, which can affect social image and confidence and negatively affect relationships [41]. A cross-national comparative study found that oral health was strongly associated with social isolation, with poorer oral health accelerating social isolation and thus reducing individuals' perceived social support [26]. Therefore, oral health has a critical impact on social support in older adults, and it is essential to study the effects of both in MOAs and LOAs.

XSL•FO
RenderX

Based on the above literature review, no study was found that determined the association between oral health, social support, and loneliness, and no study has ever compared the difference between MOAs and LOAs regarding the above relationship. Thus, this study aimed to (1) clarify the association between oral health, social support, and loneliness and (2) test whether a statistically significant difference exists for the above relationship.

Methods

Sample Collection

The data were collected in Weifang City, Shandong Province, China in August 2021. The gross domestic product of Weifang City was 701.06 billion Chinese yuan in 2021 (US $96.9 billion at 2025 conversion rate) [42]. Weifang governed 10 districts and 2 counties (59 subdistricts and 59 towns) until July 2020 [43]. The total population of Weifang City was 9.3 million by the end of 2020 according to the Seventh National Census. In 2020, nearly 2.38 million of its whole population constituted migrants from other counties, cities, or provinces, with a variety of sociodemographic and cultural backgrounds [44]. Thus, two groups of older adults were recruited in this study. For MOAs, the inclusion criteria were: (1) aged ≥60 years; (2) their Hukou is not in the present place (Hukou is one of China's oldest tools for population control; it is essentially a household registration permit, similar to an internal passport, which defines where people are registered, not where they currently reside [45]); and (3) an ability and willingness to communicate with surveyors. For LOAs, the inclusion criteria were (1) and (3) from the previous list.

Multistage cluster random sampling was conducted to select the samples of MOAs and LOAs. In the first stage, 4 of 12 districts were selected as the primary sampling units (PSUs), considering the economic development and geographic location. In the second stage, 1 subdistrict was selected from each district (PSU), and a total of 4 subdistricts were taken as the secondary sampling units (SSUs). In the last stage, 4 communities were chosen from the SSUs as the tertiary sampling units (TSUs); that is, 1 community was selected from each of the subdistricts chosen previously. All the MOAs as well as the LOAs who met the above criteria constituted the total study sample. Initially, 616 MOAs and 592 LOAs were selected for interviews. However, 3 MOAs were excluded for answering the questionnaire incorrectly or incompletely. Ultimately, 613 MOAs and 592 LOAs were included in the database. The detailed sample selection process is shown in Multimedia Appendix 1.

Measurement

Sociodemographic Characteristics

The section on sociodemographic characteristic traits included the following: gender (man, woman); age group (60 - 64, 65 - 69, 70 - 74, 75 - 79, ≥80 years); Hukou (rural, urban); marital status (married, single); education level (illiterate, primary school, junior high school, high school and above); pension (Yes, No).

Oral Health

The Chinese version of the Geriatric Oral Assessment Index (GOHAI) was used to measure participants' oral health status. This tool is primarily used to assess the self-reported oral health of older adults and is widely used in China [46]. The Chinese version of the GOHAI is divided into 12 items and 3 subdimensions designed to assess different aspects of oral health: (1) physical functioning (four items), (2) psychosocial functioning (five items), and (3) pain or discomfort (three items). GOHAI scores could be divided into the following 3 categories: (1) 50 and below are defined as low oral health, (2) 51 - 56 as fair-to-moderate oral health, and (3) 57 - 60 as high oral health. In the previous study, the GOHAI scores also had good reliability and validity [47]. In this study, the Cronbach α coefficient was 0.853, indicating that the scale had good reliability.

Social Support

The Social Support Rating Scale (SSRS) was used to measure the social support of MOAs and LOAs, including 10 types of support: friends, residents, neighbors, colleagues, family members, financial, comfort, conversation, help, and activities [48]. The social support scale has 10 items, including 3 dimensions of objective support (3 items), subjective support (4 items), and utilization of social support (3 items). The range of the total score of the scale is 12 - 66. A higher total social support score means the subject received more social support. The SSRS has been proven to have good reliability and validity in practice and has been widely used in China [49,50]. The Cronbach α coefficient was 0.822, implying this scale had good reliability.

Loneliness

The 6-item version of the UCLA Loneliness Scale (ULS-6) was used to assess the loneliness of participants, which excluded 2 reverse-scored items from the 8-item UCLA Loneliness Scale. The scale measures loneliness caused by the discrepancy between the level of desired social engagement and that which is actually experienced. The options are on a Likert scale: l=never, 2=rarely, 3=sometimes, and 4=always, with a total score ranging from 6 - 24. Previous studies have demonstrated good reliability and validity in a Chinese population [51,52]. In this study, the Cronbach α coefficient of the ULS-6 was 0.82, indicating the scale had good reliability.

Statistical Analysis

This study used SPSS (version 24.0; IBM Corp) and AMOS (version 24.0; IBM Corp) to perform the data analysis.

The samples' sociodemographic characteristics in this study were characterized by using descriptive statistics, including frequency (%) and mean (SD). The difference between sociodemographic characteristics of MOAs and LOAs was determined using the χ^2 test, while the *t* test was used to explore the difference in oral health (3 dimensions), life satisfaction (5 items), and loneliness (6 questions) of MOAs and LOAs. *P* values less than .05 were considered statistically significant. The above analyses were performed using SPSS (version 24.0; IBM Corp).

XSL•FO
RenderX

A hypothesized structural equation model was set to analyze the relationship between oral health, social support, and loneliness among MOAs and LOAs in Shandong Province. The maximum likelihood estimation method was used to evaluate the hypothesized model's fit. The structural equation modeling (SEM) process model consisted of 2 categories of variables: latent variables and observed variables. The latent variables were oral health, life satisfaction, and loneliness. The 3 observed variables of oral health included physical functioning, psychosocial functioning, and pain and discomfort. The 3 observed variables of social support were objective support, subjective support, and utilization of social support. The 6 observed variables of loneliness were the 6 items of the ULS-6. All SEM analyses were performed using AMOS (version 24.0; IBM Corp).

The following model fitness indexes were used to judge the fit of the hypothesized model: CMIN (Chi-square value, χ^2), degrees of freedom (*df*), *P* value of the χ^2 test, root mean square error of approximation (RMSEA), the goodness-of-fit index (GFI), the adjusted goodness-of-fit index (AGFI), and the comparative fit index (CFI). In this study, the models would be regarded to be well-fitted when *P*>.05, GFI>0.90, AGFI>0.90, and RMSEA<0.05 [53]. *P* value is easily influenced by sample size under many conditions, so it was only demonstrated in this study and not used as a criterion for judgment [54].

In the multigroup analysis, various parameters are restricted to find the most suitable path model. Five models were displayed in this study, namely M1 (MOA model), M2 (LOA model), M3 (unconstrained model), M4 (measurement weights model), and M5 (structural weights model). M1 and M2 were models fitted based on the sample data of two groups, and M3-M5 were obtained by adding conditions gradually restricted from the initial unconstrained model [55]. The multigroup model invariance was determined before the discussion of the MOA and LOA difference in the structural model of SEM. The change in CFI (ΔCFI) and the change in RMSEA (ΔRMSEA) were used to assess the measurement invariance between unconstrained and constrained multigroup analyses [55]. ΔCFI is independent of both model complexity and sample size, as well as the overall fit measurements. ΔCFI<0.010 indicates that we obtained measurement invariance across groups [56]. For the ΔRMSEA, with more than 300 samples, ΔRMSEA less than 0.015 implies that measurement invariance has been successfully established [57]. After the multigroup model invariance test was passed, we determined whether there were path differences between the different groups based on the model outputs, and paths with an absolute value of the critical ratio greater than 1.96 indicate a significant difference in the coefficients between the two groups (*P*<.05) [58].

Ethical Considerations

The research program was reviewed and approved by the ethical committee of Shandong University (number 20180225). For the original data collected, all participants had given informed consent to our study and were well aware of their right to withdraw from the study at any time. Our data have been completely anonymized and there is no information to identify the participants.

Results

Sample Characteristics

Table 1 shows the demographic characteristics of the participants, with a total of 1205 older adults included in the data analysis, of which 613 were MOAs and 592 were LOAs. Overall, 885 (73.4%) of the total sample were women while 320 (26.6%) were men; more than half (64.7%) of participants belonged to the 60 - 69 year old group; nearly half of older adults had a rural Hukou; 971 of 1205 participants (80.6%) were married; approximately four-fifths of older adults (n=975, 80.6%) were educated; and 785 (65.1%) older adults have a pension.

Pension					106.504 (1)	<.001
	Yes	785 (65.1)	314 (51.2)	471 (79.6)		
	No	420 (34.9)	299 (48.8)	121 (20.4)		

[a]MOAs: migrant older adults.

[b]LOAs: local older adults.

The disparity between MOAs and LOAs was statically significant for age (*P*<.001), Hukou (*P*<.001), marital status (*P*<.001), education level (*P*<.001), and pension (*P*<.001). Specifically, nearly four-fifths of MOA participants (486/613, 79.3%) were aged 60 - 69 years, while less than 50% (294/592, 48.9%) of LOAs were in that age group. In total, 525 (85.6%) of MOAs were rural Hukou while 468 (79.1%) of LOAs were urban Hukou; in addition, there were more than twice as many single LOAs than single MOAs (n=160, 27% vs n=74, 12.1%); over one-fourth of MOAs (n=161, 26.2%) were illiterate, while approximately one-tenth of LOAs (n=69, 11.7%) were illiterate. Finally, 471 (79.6%) LOAs had a pension while only 121 (51.2%) MOAs had one.

Oral Health, Social Support, and Loneliness of the Participants

Table 2 illustrates the general characteristics of participants' oral health, life satisfaction, and loneliness, and the difference between MOAs and LOAs for the above variables. The total scores of GOHAI, SSRS, and ULS-6 for MOAs were 54.95 (SD 6.469), 38.89 (SD 6.629), 8.58 (SD 3.032), and 54.40 (SD 7.024), 39.51 (SD 6.856), and 8.00 (SD 2.790) for LOAs. Statistical differences between MOAs and LOAs were found in total ULS-6 score (t_{1203}=3.442, *P*=.001), SSRS score (objective support*:* t_{1203}=4.545, *P*<.001; subjective support*:* t_{1203}=−3.608, *P*<.001), and GOHAI score (psychosocial function*:* t_{1203}=2.028, *P*=.04). It is noted that there were no statistically significant differences in Q4 (t_{1203}=1.760, *P*=.08) and Q6 (t_{1203}=1.265, *P*=.21) of the total score of loneliness between MOAs and LOAs.

Structural Equation Model

Measurement Invariance Across Migration Status

Table 3 shows 5 selected models, which revealed related fit statistics of the measurement invariance across migration status and the fitness indexes. The fitness indexes of MOAs and LOAs should be compared to check whether the variable "migration state" was suitable for the group comparison.

In this study, χ^2, *df*, *P* value, GFI, AGFI, CFI, and RMSEA were the fitness indexes. As shown in Table 3, the fitness indexes of the MOAs were GFI=0.969, AGFI=0.952, CFI=0.971, and RMSEA=0.045 (M1), while for the LOAs, they were GFI=0.964, AGFI=0.944, CFI=0.940, and RMSEA=0.051 (M2). All fitness indexes showed values over 0.90 and very slight differences between the MOA and LOA groups, implying that we could further compare the differences between the MOA and LOA groups with the other models. Although the RMSEA value of M2 was more than 0.05, these variables were mainly used to calculate the change of RMSEA, not to assess the model's fitness. Then, the ΔCFI and ΔRMSEA between M3 (unconstrained model), M4 (measurement weights model), and M5 (structural weights model) were used to evaluate the measurement invariance. The M3 did not restrict any coefficient in the model, the M4 assumed the indicator loadings for the corresponding construct of each group are equal, and the M5 constrained the indicator loadings of the corresponding construct and the structural coefficients between the groups.

As seen in Table 3, the ΔCFI between M4 and M3 was 0.002; between M5 and M4, it was 0. All of the ΔCFI values were less than 0.010, indicating that measurement invariance was established between the models of M1, M2, M3, M4, and M5 between the MOA and LOA groups. The ΔRMSEA between M4 and M3 was 0.001, and it was 0 between M5 and M4. All of the ΔRMSEA values were less than 0.015, also indicating that measurement invariance was established between the models of M1, M2, M3, M4, and M5 across the MOA and LOA groups.

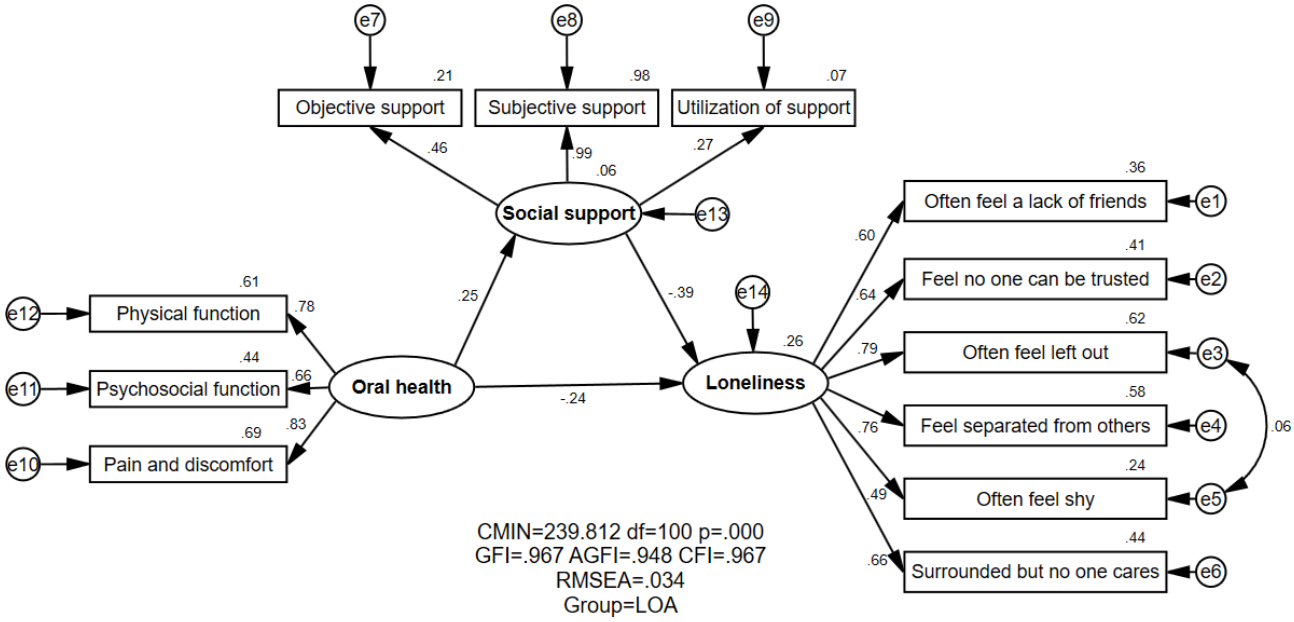
Model Fitness Indexes



Figures 1 and 2 show the proposed models for MOAs and LOAs, respectively, which contained 3 variables: oral health, social support, and loneliness. Table 3 demonstrates the model fitness indexes for variable models (M1=MOA, M2=LOA). The MOA and LOA groups both had the same estimated value for model fitness: GFI=0.967, AGFI=0.948, CFI=0.967, and RMSEA=0.034. All fitness indexes implied that the theoretical model perfectly matched the empirical data for both the MOA and LOA groups.

All parameter estimates were statistically significant (*P*<.05).

Relationship Between Oral Health, Social Support, and Loneliness Assessed by SEM

Association Between Oral Health and Loneliness of Participants

The association between oral health, social support, and loneliness was shown in Figures 1 and 2 and Table 4. A negative and direct association was observed between oral health and loneliness among the MOAs (standardized direct effect=−0.168) and LOAs (standardized direct effect=−0.243). Moreover, oral health could exert a negative effect on loneliness indirectly via social support (standardized indirect effect=−0.083 for MOAs; standardized indirect effect=−0.097 for LOAs). It is noted that oral health was negatively associated with loneliness, which meant that MOAs and LOAs with higher oral health would generally have lower loneliness. A statistically significant relationship between oral health and loneliness was found in both the MOA and LOA groups.

Table . Standardized effects between oral health, social support, and loneliness among MOAs[a] and LOAs[b].

Path	Direct effect		Indirect effect		Total effect		Difference (critical ratio)
	MOA	LOA	MOA	LOA	MOA	LOA	
Oral health → Loneliness	−0.168[c]	−0.243[c]	−0.083[c]	−0.097[c]	−0.251[c]	−0.340[c]	−0.538
Oral health → Social support	0.186[c]	0.247[c]	—[d]	—	0.186[c]	0.247[c]	1.145
Social support → Loneliness	−0.444[c]	−0.392[c]	—	—	−0.444[c]	−0.392[c]	2.741[e]

[a]MOAs: migrant older adults.

[b]LOAs: local older adults.

[c]*P*<.001.

[d]Not applicable.

[e]*P*<.01.

Association Between Social Support and Loneliness of Participants

As for the relationship between social support and loneliness, a negative and direct effect was demonstrated among both MOAs (standardized direct effect=−0.444) and LOAs (standardized direct effect=−0.392), which meant less social support among both MOAs and LOAs would generally indicate higher loneliness. Concerning the group difference, a significantly negative correlation was slightly stronger in the MOA group than in the LOA group (critical ratio=2.741, *P*<.01).

Association Between Oral Health and Social Support of Participants

Oral health had a positive and direct effect on social support for both MOAs and LOAs (standardized direct effect=0.186 for MOAs; standardized direct effect=0.247 for LOAs), indicating that the higher the oral health of MOAs and LOAs, the higher

XSL•FO
RenderX

their social support. It was found that a statistically significant relationship existed between oral health and social support among MOAs and LOAs.

Discussion

Principal Findings

This study examined the severity of loneliness as well as the association between social support, oral health, and loneliness among older adults in Weifang. The results further showed a statistical difference in loneliness between MOAs and LOAs; the empirical associations between oral health, social support, and loneliness (including the local-migrant difference) were also clarified.

Loneliness Among MOAs and LOAs

The mean score of loneliness among MOAs (8.58) and LOAs (8.00) was lower than in a previous study conducted among rural empty-nest older adults in China (16.19) [51], indicating a lower level of loneliness among the MOAs and LOAs in this study. Moreover, this study found loneliness in MOAs was higher than in LOAs, which was similar to a study that showed that immigrant groups were lonelier than older adults born in Canada [59]. This may be due to the fact that, because of MOAs' migration, they need more time to adapt to their new environment while LOA have been in a familiar environment for a long time.

Association Between Oral Health and Loneliness

A negative association between oral health and loneliness was found among both MOAs and LOAs, which was similar to one existing study, which reported that older people who had a poor oral health status had higher odds of experiencing loneliness [60]. Ma and Chen [27] found that masticatory function, swallowing function, tooth loss, tooth function, and toothache were the influencing factors of loneliness among Chinese older people in the community. Another cross-sectional study in Indonesia showed similar findings, where older adults who had a poor oral status had a higher chance of feeling lonely [61]. Some studies pointed out that poor oral health increases psychological stress in communication among older adults, consequently limiting social interaction with others and causing loneliness [62,63]. However, the results showed that the effect of oral health on loneliness was not statistically different between MOAs and LOAs. This may be due to the fact that the relationship between oral health and loneliness is generalizable across older populations [25]. Another possible reason is that when facing oral health problems, both MOAs and LOAs will adopt different coping styles to decrease their loneliness. Some studies suggested that people with higher socioeconomic status and health literacy tend to proactively utilize medical resources to mitigate the negative impacts of oral problems [64]. In contrast, MOAs had poorer oral health services in their hometowns [65] and have experienced and adapted to more oral problems, which were more common and socially acceptable in their lives [66]. These further result in fewer psychological changes and lower loneliness even though oral problems occurred in the inflow cities.

Association Between Social Support and Loneliness

A negative relationship between social support and loneliness was found among both MOAs and LOAs, indicating that older adults with higher social support could reduce their loneliness. This was consistent with a previous nationwide cohort study, which also showed that social support decreased the odds of loneliness incidence among older adults in China [67]. The effect of social support on loneliness could be explained through the interaction theory, which views loneliness as a response to a lack of satisfying social networks and attachment partners [68]. Moreover, this study showed that the negative association between social support and loneliness was stronger among the MOAs than the LOAs. The economic development gap between urban and rural areas led to higher medical and education services in urban areas, which further resulted in population mobility mainly from rural to urban areas in China [69,70]. As for the MOAs, their migration may lead to a decline in the quantity and quality of social connections [71], which may further result in higher levels of loneliness among them than in the LOAs.

Association Between Oral Health and Social Support

The SEM results illustrated that oral health and social support were positively correlated, implying the better the oral health status, the higher the social support. This was consistent with previous findings, which suggested the experience of oral pain was associated with physical discomfort [72] and social barriers [73]. In addition, people with poor oral health may face additional mental health challenges due to problems such as halitosis, creating social anxiety and exacerbating barriers to interaction [74]. The results also noted that no significant difference was found between LOAs and MOAs when examining the impact of oral health on loneliness. This meant that the gradual loss of teeth and changes in facial morphology in older adults as they age, whether migrating or not, could lead to similar social limitations and increased psychological stress, which can affect their social participation and social support.

Implications

In order to reduce older adults' loneliness, the following measures should be taken. First, this study found that MOAs had higher loneliness than LOAs. Hence, strengthening social integration and promoting equality may be beneficial for reducing the loneliness of MOAs. Second, the results indicated that loneliness was negatively correlated with oral health; thus, it is important to aid older adults in maintaining their oral health. The government could speed up the process of including oral health services in health insurance reimbursements for older patients and enhance oral health education for them. Third, the findings showed that high social support would also reduce the loneliness of older adults. In particular, for MOAs, their social networks will be affected and they may face challenges such as language barriers and cultural differences after migration, making it more urgent for them to implement effective measures to alleviate their loneliness. Therefore, there is a need to enhance social support through the efforts of family members, communities, and the government. For instance, the government could implement policies to support young people whose families include older adults since older adults may receive

XSL•FO
RenderX

financial and emotional support from their children. It is necessary to promote the equalization of social security and welfare benefits for older adults who migrate with their families and further enhance their belonging in the inflow city.

Limitations

Some limitations existed in this study and should be addressed in future research. First, this study used cross-sectional data, therefore causal relationships could not be made and a longitudinal design is needed for follow-up research. Second, oral health status was assessed by a self-report scale with a lack of clinical evidence. In the future, clinical oral health examinations could be used to evaluate the oral health of older adults. Third, in addition to social support, there may be other variables that exert an indirect effect on loneliness among older adults and the variables used in this study may also be influenced by other confounding factors; therefore, more research is needed to verify their association.

Conclusion

Loneliness levels were fairly low among older adults in Weifang, China, while MOAs showed higher loneliness than LOAs. Oral health had both direct and indirect negative effects on loneliness among MOAs and LOAs, with no significant path differences between MOAs and LOAs. Social support was found to be negatively associated with loneliness for both MOAs and LOAs, while the association was stronger among MOAs than LOAs. Oral health exerted a significantly positive effect on social support for both MOAs and LOAs, while no significant difference existed between LOAs and MOAs.

Acknowledgments

The research team greatly appreciates the funding support obtained and thanks the research participants for their cooperation and support. This study was supported and funded by the National Natural Science Foundation of China (number 71804094), China Postdoctoral Science Foundation (number 2016M592161), Natural Science Foundation of Shandong Province (number ZR2016GB02), Postdoctoral Science Foundation of Shandong Province (number 201603021), and Fundamental Research Funds of Shandong University (number 2015HW002, number 2018JC055).

Data Availability

Under reasonable requirements, the data and material of this study can be obtained from the corresponding author. The data are not publicly available due to privacy restrictions.

Authors' Contributions

HL and JW conceptualized and designed the study; analyzed the data; and wrote the first draft of the manuscript. RC, XX, and MP contributed to surveys, data curation, and software and methodology usage. KF, BL, QL, ZQ, and SY contributed to data curation and visualization and validation of results. NIZ provided several valuable comments on the draft and corrected some issues related to grammar, vocabulary, and other aspects. FK applied for the funding used to support this study; designed the study; completed the questionnaire design; supervised and combined the data collected; instructed the writing, statistical analysis, and data processing; and provided comments on the modification of the manuscript; FK also polished the manuscript. All authors read and approved the final manuscript.

Abstract

Background: The World Health Organization (WHO) has made significant efforts to promote age-friendly community initiatives (AFCI) to address the challenges of population aging. Previous studies have discussed the construction of age-friendly communities (AFC) in urban cities, evaluating AFCs often rooted in the WHO's Checklist and focused on a single group, namely older adults, overlooking the role of other age groups in community development.

Objective: This study aims to evaluate AFCs from multidimensional aspects, particularly the positive living experiences of older adults, summarize the deficiencies in both hardware and software aspects in the process of constructing AFCs in China, and provide some recommendations to promote AFCIs worldwide.

Methods: Using a multistage sampling strategy, 470 community residents from urban and suburban areas participated in this study. A self-designed questionnaire was designed to use a standardized method to evaluate older adults' living experiences across five dimensions, including the degree of age-friendliness in the community, social support, sense of gain, sense of happiness, and sense of security. Respondents rated each dimension on a 10-point scale. This study defined community residents into 3 groups: residents younger than 45 years(Group 1: youth), those aged 45-59 years (Group 2: middle-aged), and those aged ≥60 years (Group 3: old-age).

Results: In this study, 382 (81.3%) community residents were unaware of the relevant concepts of AFCs. Most participants highlighted the importance of community support and health services, followed by respect and social inclusion, and outdoor spaces and buildings. The findings showed that the highest-rated dimension was the sense of security. The mean scores for the degree of the sense of security in urban and suburban areas were 7.88 (SD 1.776) and 7.73 (SD 1.853), respectively. For Group 2, the mean scores were 7.60 (SD 2.070) and 8.03 (SD 1.662), while Group 3 had mean scores of 7.34 (SD 2.004) and 7.91 (SD 1.940). The lowest-rated dimension was social support; the mean scores for Group 1 for the degree of social support in urban and suburban areas were 7.63 (SD 1.835) and 7.48 (SD 1.918), respectively. For Group 2, the mean scores were 6.94 (SD 2.087) and 7.36 (SD 2.228), while those for Group 3 were 6.37 (SD 2.299) and 6.84 (SD 2.062). Further, there were significant differences in the scores of residents among different age groups in urban areas regarding age-friendliness (P<.001), social support, (P<.001), and sense of gain (P=.01).

Conclusions: China is in the early stages of developing AFCs. We further highlight the importance of continued research on the collaboration and participation among multiple stakeholders. These outcomes have a direct and positive impact on the well‐being of older adults.

Introduction

The History and Imperative of Implementing Age-Friendly Communities

Population aging is poised to become one of the most significant problems in the 21st century, impeding the development of many countries globally. Data from *World Populations Prospects* [1] predicated that the number of persons aged ≥65 years in countries and areas with populations that have already peaked is projected to reach 409 million by 2027, surpassing the number of children under 18. The number of persons aged ≥80 years is increasing at an even faster rate and is likely to triple, from 85 million in 2024 to approximately 267 million by 2100. With the increasing trend of population aging, health issues in older adults have become a major concern for scholars and policymakers worldwide. As people age, many experience a myriad of changes impacting their health and functional ability to manage independent living in their homes and communities [2]. Meanwhile, age-related changes such as physiological and cognitive decline may lead to negative health outcomes such as frailty, mobility limitations, and disability. Moreover, many social and physical environmental factors also affect the health status and quality of life of older adults [3,4]. Therefore, finding accessible and affordable measures to help older adults live longer and healthier will be crucial.

To address the challenges of population aging and achieve the goal of healthy aging, the World Health Organization(WHO) has made significant efforts to promote age-friendly community initiatives (AFCI). The concept of age-friendly communities (AFCs) originated from the Ecology Theory of Aging in 1973 [5,6], which indicated that aging was a dynamic process at both the individual and community levels, revealing that a positive surrounding environment can promote well-being among older adults. In 2000, the American Association of Retired Persons first defined AFCs as communities with affordable housing, adequate infrastructure and services, and diverse options of transportation. Based on the report *A Guide: Global Age-Friendly Cities* [7], the AFCs incorporated three aspects and eight key domains. Three aspects included service support, space environment, social and humanistic environment [8], and the eight key domains consisted of outdoor spaces and buildings, transportation, housing, social participation, respect and social inclusion, civic participation and employment, communication and information, and community and health services [9,10]. In the current conceptualization of AFCs, the importance of social environment and physical environment are placed equally as the determinants of health and older adults are considered to be effective social resources involved in community construction [11]. The AFCs are designed to account for the wide diversity among older people and promote their autonomy, inclusion, and contributions in all areas of community life [12].

Meanwhile, the implementation of aging-in-place policies highlights the imperative for AFCIs [13]. Supporting older adults to continue living safely and comfortably within their communities is a shared vision of many governments and international organizations. Due to their continuous efforts, the WHO Global Network for AFCIs currently includes 1705 cities and communities across 60 countries, covering over 330 million people worldwide. However, the lack of measurability of the actual age-friendliness of AFCs has been a major weakness in moving AFCIs forward. As age-friendliness is a complex, dynamic, multidimensional, and highly context-dependent concept, it does not easily lend itself to standardization of measurement [14-16].

Evaluating the Age-Friendliness of Communities

While constructing AFCs, it is crucial to evaluate the age-friendliness of communities [17]. The previous studies have mainly focused on measuring the age-friendliness of a city or community in which older adults live, based on the WHO's Checklist [18]. Jo-Ying Huang et al [19] developed indicators of age-friendliness for communities in Taiwan province that conform to international standards by referring to the WHO's Checklist and Taiwan's existing indicators. Yu, Wong, and Woo [20] examined the relationships between perceptions of neighborhood environment, sense of community, and self-rated health by relying on the WHO Checklist. Wood et al [21] conducted a systematic scoping review of 23 articles using citizen science or participatory approaches. An inductive and deductive thematic analysis was performed to identify local urban barriers and facilitators and map them against the WHO's Checklist. Kim et al [22] used data from the American Association of Retired Persons AFC surveys to evaluate the reliability and concurrent validity of AFC assessment tools. They found that higher levels of perceived availability of community and health services were associated with worse health outcomes.

Additionally, the Age Friendly Cities and Communities Questionnaire (AFCCQ) is designed by Dikken for measuring age-friendliness. Compared with WHO's Checklist, the Age Friendly Cities and Communities Questionnaire only has 23 items, covers eight domains of the WHO's AFC model, and has an additional ninth domain of financial situation [23]. In addition to the above-mentioned measurement tools of age-friendliness, sets of priority indicators, frameworks, and conceptual surveys are proposed by other studies. Jiravanichkul et al [24] identified minimum standard indicators and explored the development of a well-being environment and AFC assessment criteria by using the analytic hierarchy process. Ide et al [17] developed a community-level AFC indicator based on the WHO AFC guidelines by incorporating dementia-friendly elements and tested its validity and reliability.

Beijing as a Case Example

Beijing is the capital of China, and a municipality directly governed by the Central Government. It is famous as China's political, cultural, international communication, and science and technology innovation center. Beijing currently has entered a moderately aging society. By the end of 2023, the permanent resident population aged 60 years and above was 4.948 million, accounting for 22.6% of the total permanent resident population. The resident population aged 65 years and above was 3.469 million, accounting for 15.9% of the total resident population [25]. To enhance older adults' sense of gain, happiness, and security in communities, the National Health Commission (National Office for the Elderly, 2020) launched an initiative

XSL•FO
RenderX

to construct AFCs across the country. By the end of 2023, a total of 93 communities in Beijing had been named " National Model AFCs," which were at the forefront of AFC development nationwide.

Focus of the Current Study

Although many scholars have attempted to evaluate the age-friendliness of communities in various ways, there is limited research emphasizing the positive aspects of health, such as the sense of gain, happiness, and security that older adults experience in their communities. Additionally, most studies have focused on the construction of AFCs in urban cities [26,27], and evaluating the age-friendliness of communities was only based on assessments from older adults [22,28], which overlooked the perspectives of other community residents. Therefore, the current evaluation of constructing AFCs may lack objectivity and accuracy.

This study aims to explore the cognition of AFCs among the different aged communities' residents in Beijing, evaluate AFCs from multidimensional aspects, especially the positive living experience of older adults, summarize the deficiencies in hardware and software infrastructure in the process of constructing AFCs in Beijing, and provide a reference for promoting AFCIs across the world.

Methods

Study Design

This is a cross-sectional study, designed to understand the awareness and perception of AFCs among different aged community residents, explore deficiencies in the process of constructing AFCs, and propose recommendations for improvement.

Study Setting and Sample

Considering the level of economic development and construction status of AFCs among 16 districts in Beijing, a cross-sectional quantitative survey was conducted on community residents between urban and suburban areas. This study adopted a multistage sampling strategy [29,30]. In the first stage, Xicheng District, Fengtai District, Daxing District, and Huairou District were selected based on the functional orientation of the 16 districts in Beijing and the current situation of constructing AFCs. To implement urban strategic positioning, promoting sustainable development, and considering the practical needs of the historical pattern of the ancient capital, Beijing issued the Beijing Urban Master Plan in 2017. According to the Beijing Urban Master Plan, there are six central urban areas (including Dongcheng District, Xicheng District, Chaoyang District, Haidian District, Fengtai District, and Shijingshan District), five new towns in plain areas (including Shunyi District, Daxing District, Yizhuang District, Fangshan District, and Changping District), and six ecological conservation areas (including Mentougou District, Pinggu District, Huairou District, Miyun District, and Yanqing District). For this study, plain new towns and ecological conservation areas were unified as suburban areas, while the central urban areas were unified as urban areas. Among the 16 districts, Xicheng District, Fengtai District, Daxing District, and Huairou Districts ranked second, third, fifth, and eighth, respectively. In the second stage, 3 - 5 communities were randomly picked from each district, amounting to 15 communities in the list. In the last stage, trained investigators visited each sampling community to randomly invite community residents to participate in our investigation. Potential participants were recruited via the invitation of the investigators, and we sought to balance the sample based on population characteristics such as gender, age, education, and region. To better understand the construction of AFCs, our goal was to recruit residents who lived in the communities and who could freely and voluntarily express their insights.

Measures

A self-designed questionnaire was developed to use a standardized method for assessing the residents' living experience and their community's age-friendliness in Beijing. It was designed in consultation with a group of AFC experts [31].

To explore the cognition of community residents regarding the concept of AFCs, the questionnaire included questions such as whether they had heard of or learned about AFCs. Based on our literature review and WHO guidelines, we asked residents to choose the most important domain among the eight domains (outdoor spaces and buildings, transportation, housing, social participation, respect and social inclusion, civic participation and employment, communication and information, and community and health services) in the process of constructing AFCs.

The positive living experience of older adults that was obtained within their community was measured across five dimensions: (1) the degree of age-friendliness in the community, (2) the level of social support for older adults, (3) the sense of gain in community, (4) the sense of happiness in the community, and (5) the sense of security in the community. Respondents rated each dimension on a 10-point scale (0 - 1: does not exist, 2 - 3: poor, 4 - 5: fair, 6 - 7: good, 8 - 9: very good, 10: excellent).

To understand the shortcomings in the current process of constructing AFCs, the deficiencies were categorized into hardware and software aspects. Hardware aspects included increasing the green spaces and beautiful buildings, building more nursing institutions and medical institutions for older adults, building more leisure and entertainment places, installing more age-friendly facilities for older adults, and expanding traffic roads, among others. Software aspects consisted of conducting more abundant recreational activities, creating an age-friendly atmosphere, providing personalized elderly care services and community and neighborhood support, providing community volunteer services, and more personalized medical services. Participants were asked to choose the items that required urgent improvement in their communities.

Data Analysis

Based on the latest WHO age definition criteria [32], this study defined community residents into three age groups: (1) Group 1 as youth (younger than 45 years) (2) Group 2 as middle-aged adults (45-59 years), and (3) Group 3 as old-aged adults (above 60 years).

XSL•FO
RenderX

All the gleaned data were recorded into EpiData software (version 3.1; EpiData Association) and analyzed by SPSS software (version 21.0; IBM Corp). The mean and standard deviation were used to describe continuous data, while the categorical data were presented by composition ratio, frequency distributions, and parity arrangement. Frequency and rank analyses were used to summarize the quantitative data of community residents including demographic characteristics such as gender, age, region, and education level. The rank-sum test was used to analyze the most important domains of AFCs and deficiencies in the construction of the AFCs. One-way ANOVA was used to explore the five dimensions of the community living experiences of older adults.

Ethical Considerations

The study was approved by the Medical Ethics Committee of Capital Medical University, Beijing, China (Reference number Z2023SY048). All participants provided informed consent for the collection, handling, and storage of their personal and health data. All procedures were performed in accordance with relevant guidelines and regulations. All participants joined the study voluntarily, and no compensation was provided to them. All data were kept confidential, deidentified, and anonymous.

Results

A total of 477 residents voluntarily agreed to participate in our survey. We collected 470 valid questionnaires were collected, resulting in a validity rate of 98.53%. Table 1 presents the demographic characteristics of community residents. Among the 470 community residents in our survey, the majority were female (n=339, 72.1%). Approximately 44.5% (n=209) of the participants were younger than 44 years, and the average age of the 470 community residents was 46.74 (SD 18.63) years. A total of 259 (55.1%) community residents were from urban areas. Additionally, 113 participants (24%) had lived in their current community for more than 30 years and 178 (37.9%) participants had obtained a bachelor's degree.

Table . Demographic characteristics of community residents.

Items	Surveys (N=470), n (%)
Gender	
Male	131 (27.9)
Female	339 (72.1)
Age (years)	
≤44	209 (44.5)
45-59	132 (28.1)
≥60	129 (27.4)
Regions	
Urban areas	259 (55.1)
Suburban areas	211 (44.9)
Length of residence (years)	
≤10	157 (33.4)
11-30	200 (42.6)
31-50	53 (11.3)
51-70	42 (8.9)
≥71	18 (3.8)
Education	
Junior high school or below	129 (27.4)
High school or Junior college	99 (21.1)
Bachelor's degree	178 (37.9)
Master's degree or above	64 (13.6)

Table 2 shows community residents' cognition of AFCs. Almost 81.3% of the community residents were not aware of the concept of AFCs; only 88 (18.7%) community residents had heard of AFCs.

Not know	382 (81.3)
The most important domain of the Age-Friendly Communities from the perspective of community residents, total points[a] (rank)	
Outdoor spaces and buildings	453 (3)
Transportation	260 (6)
Housing	293 (5)
Social participation	364 (4)
Respect and social inclusion	559 (2)
Job opportunities and civic participation	84 (8)
Communication and information	135 (7)
Community support and health services	666 (1)

[a]Note: total points: number of people selected for the first important domain ×3 + number of people selected for the second important domain ×2 +number of people selected for the third important domain ×1.

With regard to the eight important domains of creating an AFC, community support and health services were the most important domains from the perspective of residents when they lived in the community, followed by respect and social inclusion, and outdoor spaces and buildings. Job opportunities and civic participation were considered relatively less important for residents when they lived in the community.

Table 3 displays an evaluation of the living experiences of older adults, categorized by different aged community residents. Among the five dimensions of older adults' living experience, the scores of the sense of security in the community were relatively high, whereas the scores for the degree of social support for older adults were relatively low. There were significant differences in the scores of residents between different age groups in urban areas in terms of age-friendliness (P<.001), social support (P<.001), and sense of gain (P=.01), whereas no significant differences were found in terms of happiness and security. In the evaluation of age-friendliness, there were significant differences between young and middle-aged residents, and between young residents and elderly residents. In the evaluation of the degree of social support, there were significant differences between young residents and middle-aged residents, and between young residents and elderly residents. Additionally, the sense of gain differed significantly between young residents and elderly residents.

Table 4 presents the shortcomings in the current process of constructing AFCs. Regarding the aspects of community hardware facilities, most residents expressed the need for building more nursing institutions for older adults, followed by building additional medical institutions and installing more suitable age-friendly facilities. Expanding traffic roads was an aspect that concerned fewer people. Regarding the community software facilities, creating an age-friendly atmosphere was most commonly reported by many community residents, followed by providing personalized elderly care services, more personalized medical services, and more recreational activities.

Table . The shortcomings in the current process of constructing age-friendly communities.

Items	Frequency	Rank
The aspects of community hardware facilities that should be improved		
Increase the green area and beautiful buildings	217	5
Build more nursing institutions for older adults	319	1
Build more medical institutions for older adults	257	2
Build more leisure and entertainment places	221	4
Install more suitable facilities for older adults	252	3
Expand traffic roads	78	6
Others	11	7
The aspects of community software facilities that should be improved		
Hold more abundant recreational activities	207	4
Create an age-friendly atmosphere	323	1
Provide personalized elderly care services	317	2
Provide community and neighborhood support	117	6
Provide community volunteer services	170	5
Provide more intimate medical services	241	3
Others	13	7

Discussion

Principal Findings

This study is the first to comprehensively evaluate AFCs from multidimensional aspects in China. It particularly examines the positive living experiences that residents derive from their communities, compares the cognition and perception of AFCs among different aged community residents in urban and suburban areas, and explores the deficiencies in the process of constructing AFCs from both hardware and software perspectives. The community residents' suggestions for improvement for constructing AFCs reflect the needs and interests of older adults and other age groups, providing a direction for constructing AFCs in the future.

Increasing Age-Friendly Awareness and Sense of Belonging Among Community Residents

China has only recently begun promoting AFCIs; compared to other developed countries, there remains significant progress to be made. Consequently, the public is not aware of the concepts of AFCs, which is consistent with our findings as only 88 (18.7%) residents were aware of AFCs. Recognizing the age-friendliness of communities is the premise to engage residents in the construction of AFCs. Relevant studies show that perceived age-friendliness of the community is positively associated with a sense of belonging to the community [33,34]. However, a gap exists between family belonging and community belonging. Given the changes in China's economic and social structures, the sense of community belonging has been weakened [35], which may have led to a lack of initiative and consciousness among residents in the process of creating AFCs. Therefore, it is vital to improve the consciousness of

XSL•FO
RenderX

age-friendliness and strengthen the sense of belonging among community residents in the process of constructing AFCs.

Establishing an Age-Friendly Atmosphere and Improving Communities' Software Facilities

Previous studies have shown that constructing AFCs mainly focuses on eight domains, based on the WHO guideline [14,36]; however, little is known about which domains are considered most important for community residents. In our study, most participants highlighted the importance of community support and health services; they wish to build more medical institutions and provide more personalized medical services in their communities, which reflects the high demand for medical services by community residents in Beijing. However, a major challenge faced by both high-income and low-income countries today is inequitable access to health care resources [37-39]. For example, in suburban or medically underprivileged communities, residents may often be unable to access desired health care services. Telemedicine in China has been improving the dissemination of high-quality health care resources from urban cities to remote suburban areas, providing services such as teleconsultations and specialist diagnoses [37]. Meanwhile, respect and social inclusion are also key components for promoting AFCIs. Many community residents identified that creating an age-friendly atmosphere was the most important step in the process of AFCs to improve the aspects of community software facilities, which is consistent with other studies. Lui et al [13] noted that a supportive environment characterized by positive relations, engagement, and inclusion is a core prerequisite for aging well. Rémillard et al [40] have explored eleven case studies of AFCs worldwide and reported that the need to shift perception, change mindsets, and promote a more positive view of aging were identified as key priorities. Respect and promoting social participation of older adults is also seen as a way to challenge ageism. In addition, the range of recreational activities and social support for community residents within their communities should be increased. Some studies found a positive association between employment, social participation, and healthy aging [41]. These observations could be due to the potential of these activities to enhance individuals' social status, promote psychological well-being, and foster a sense of dignity.

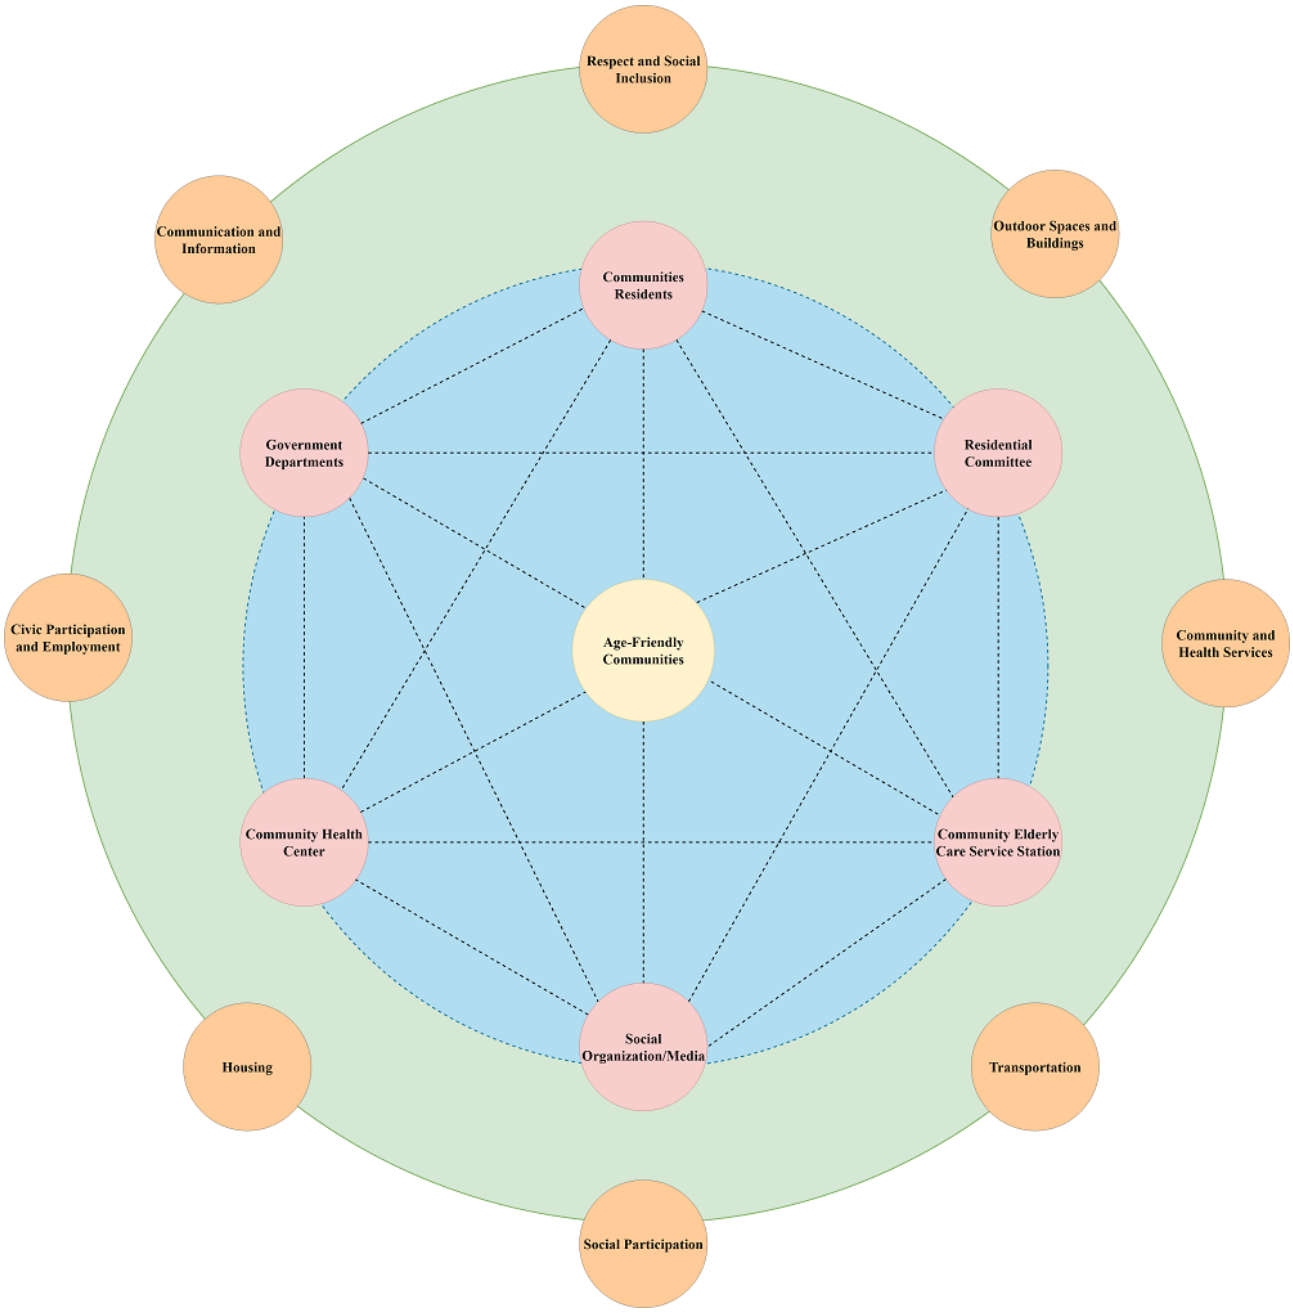
Improving the Living Environment and Strengthening Communities' Hardware Facilities

Our results indicate that many community residents wish to improve the physical infrastructure of their communities; outdoor spaces and buildings were the third most important domain of AFCs. This finding is in line with the reality of communities' infrastructure in China. Most older communities in Beijing lack elevators, which causes major inconvenience for older adults when going out. In addition, there is limited public space for residents to participate in activities and exercise. A common phenomenon in many old communities is that public spaces meant for residents' activities are occupied by parked cars. As shown in Figure 1, limited public space, scarcity of age-appropriate fitness equipment, and the absence of elevators are key physical environment factors that may hinder older adults from participating in community activities.

XSL•FO
RenderX

Figure 1. Overview of hardware facilities in a surveyed community in the Daxing District, showing limited public space, scarcity of age-appropriate fitness equipment, and no elevators.

Actively Participating in Community Activities to Enhance Community Residents' Happiness



In the process of constructing AFCs, the notion of healthy aging should be considered the final goal. Older adults in good health can continue to be vital societal resources, experience greater job satisfaction and independence in their lives, and engage more actively as community residents. This study aimed to evaluate the positive living experiences that older adults obtained in their communities. Our findings show that among the five dimensions assessed, the sense of security scored the highest, while social support scored the lowest, particularly among urban older adults. Social support is a well-recognized social determinant of health, and it is obvious that obtaining social support from others is crucial throughout life, including old age [42]. Most older adults consistently prefer aging in place, which requires a high level of social support in the process of constructing AFCs [11]. Therefore, improving the degree of social support for older adults should be a key focus while constructing AFCs in the future. Further, there were significant differences in the evaluation of older adults' living experiences among different aged community residents in urban areas. Young residents rated the degree of social support, age-friendliness, sense of gain, and happiness significantly higher than older adults' self-evaluations. This disparity may stem from younger residents having greater physical capacity and healthier habits, which enables them to afford expenses related to transportation, health care, and retirement [41]. Consequently, they have more energy and capacity to actively engage in paid work, social participation, and environmental preservation, thereby fostering their sense of happiness and sense of gain. Besides, elderly residents in suburban areas have the highest scores for the sense of happiness, which suggests that older adults in suburban communities experience higher levels of happiness compared to their urban elderly residents. These findings may be attributed to both the physical environment (eg, accessible public facilities) and the social environment (eg, active engagement in volunteer activities), providing sufficient support to older adults in suburban areas [41]. Suburban seniors typically lived in the rural society for a long time. At the heart of rural society lies a deep-rooted connection to the land. Life in these communities is often dictated by the cycles of nature, with agricultural activities and environmental stewardship forming the backbone of their livelihoods. Therefore, compared with urban elderly residents, suburban seniors may engage in agricultural activities within their capacity, establish trust-based relationships with neighbors, and be more likely to participate in communities' activities.

Participation of Multiple Stakeholders in the Promotion of Constructing AFCs

The task of constructing AFCs is complex, dynamic, and multistage, which involves multiple stakeholders' cooperation. To address the challenges of an aging population and promote AFCIs, collaboration is essential between government departments, residential committees, community health centers, community elderly care service stations, social organizations, media, and community residents (Figure 2).

Figure 2. Constructing age-friendly communities as a central goal involves collaboration and participation from multiple stakeholders, including government departments, residential committees, community health centers, community elderly care service stations, social organizations, media, and community residents. Effective cooperation among these stakeholders is necessary to expand the reach of constructing age-friendly communities across all eight domains.

Government departments should focus on constructing AFCs, by formulating and improving relevant laws and regulations on AFCs, designing scientific and accurate tools for evaluating AFCs, and establishing long-term supervision and feedback mechanisms. Residential committees should first design medium- and long-term plans for promoting AFCIs based on three overarching areas [43]: (1) physical infrastructure (eg, outdoor spaces and buildings, transportation, housing); (2) social opportunities (eg, civic participation, social participation, respect, and social inclusion); and (3) supportive services (eg, communication and information, community and health services). Residential committees should conduct a comprehensive assessment of their respective communities based on AFC policies and tools developed by the government, and identify deficiencies within communities. Our findings show that community residents have urgent needs for old-age care and medical services. Therefore, promoting continuous and integrated community care that combines medical and

XSL•FO
RenderX

old-age care is necessary. Additionally, residential committees should explore smart community care services with the help of information technology, treating the community as the basic unit. Besides, it is important to build a smart service platform that connects "Internet+community home care", with community health centers and elderly care service stations, that can establish a connection between the elderly needs and community service resources. Finally, residential committees should create an atmosphere of age-friendliness within the communities, build more spaces where different aged residents can interact together, and encourage more older adults to participate in the construction of AFCs. Social organizations should adopt age-friendly practices or provide more activities catering to the needs of older adults. Social media should strengthen public awareness of AFCs, ensuring more residents understand the concept of AFCs and their benefits and actively participate in the construction of AFCs. Community residents should also actively cooperate with the work of the communities, improve their cognition of AFCs, and make suggestions for the construction of AFCs.

Limitations

The findings generated from this study should be interpreted considering several limitations. First, our survey included healthy and cognitively intact older adults, while those who were suffering from disabilities or dementia were excluded. However, understanding the living experience of this excluded group would be vital to help construct AFCs. Second, the representativeness of our study was limited, since we surveyed only a sample from 4 out of 16 districts in Beijing. Future studies should consider conducting similar studies in smaller cities across China and including more related subjects. Finally, our study followed a voluntary participation principle when conducting the questionnaire survey. Female respondents showed more willingness to participate in the survey, resulting in the gender ratio of female respondents (over 70%). Additionally, many surveyed residents never left their living communities, and they did not have a deep understanding of other communities. Future work should further explore the influence of gender, education level, and length of residence on community residents' perceptions of AFCs.

Conclusions

China is in the early stages of becoming an age-friendly society. Findings from this study show that community residents in Beijing have a low level of cognition of AFCs, and face many barriers from the perspective of hardware facilities and software facilities. Therefore, it is imperative to take measures to (1) increase age-friendly awareness and sense of belonging among community residents; (2) establish an age-friendly atmosphere and improve communities' software facilities; (3) improve the living environment and strengthen communities' hardware facilities; (4) increase the active participation of older persons in the community to enhance their happiness; and (5) and promote AFCIs through joint efforts of multiple stakeholders, including government departments, residential committees, community health centers, community elderly care service stations, social organizations, media, and community residents. Our study provides suggestions for tangible central government policy and practice initiatives and resource allocation. These outcomes have a direct and positive impact on the well‐being of older adults.

Acknowledgments

The author would like to thank all the participants, experts, and researchers who participated in this study. This study was funded by the Beijing Social Science Foundation Project (Funding Number 22SRBO08). The funding organization had no further role in the study design, data collection and analysis, interpretation of the data, writing the paper, or the decision to submit the paper for publication.

Abstract

Background: The increasing incidence of precocious puberty is a major health challenge for Chinese children, while related risk factors remain less well explored. Exposure to ambient fine particulate matter ($PM_{2.5}$) is a leading environmental hazard in China. Although certain components of $PM_{2.5}$ have been reported to be endocrine disruptors for sex hormones, population-based evidence is still lacking on the association between $PM_{2.5}$ exposure and precocious puberty in China.

Objective: Based on a cross-sectional survey covering 30 cities in 2017 to 2019, this study was designed to explore the association between long-term exposure to $PM_{2.5}$ and its 5 major components with precocious puberty in China and to check the potential modifying effects of family-related and personal factors.

XSL•FO
RenderX

Methods: We included 34,105 children aged 6 to 9 years. We collected the 5-year average concentrations of $PM_{2.5}$ and its 5 major components (sulfate, nitrate, ammonium, organic matter, and black carbon) in the area (at a spatial resolution of 0.1° × 0.1°) where each school was located. We used mixed effect logistic regression to estimate the effect sizes of the total mass of $PM_{2.5}$ and each of its components on precocious puberty, and we examined the modifying effects of family-related and personal factors using an additional interactive term. A weighted quantile sum (WQS) regression model was applied to identify the weights of each component in explaining the effect size of the total mass of $PM_{2.5}$.

Results: We found that the odds ratio (OR) for precocious puberty per IQR increase in the concentration of total $PM_{2.5}$ mass was 1.27 (95% CI 0.92-1.75) for the whole population, 2.12 (95% CI 1.27-3.55) for girls, and 0.90 (95% CI 0.62-1.30) for boys. Similarly, the effect sizes of the 5 major components were all substantial for girls but minimal for boys. Results of the WQS analysis showed that organic matter could explain the highest proportion of the effect of $PM_{2.5}$, with the weight of its contribution being 0.71. Modification effects of family income and dietary habits were only observed in certain population subgroups.

Conclusions: Long-term exposure to total $PM_{2.5}$ mass was significantly associated with precocious puberty in girls, with organic matter identified as the major effect contributor. The results add evidence on the detrimental effects of $PM_{2.5}$ on children's development and growth.

Introduction

Precocious puberty is an endocrine and metabolic disorder that may promote the development of pathophysiological or psychosocial outcomes in childhood and later life, including stunted growth, obesity, hypertension, type 2 diabetes, ischemic heart disease, stroke, and breast cancer [1]. Over the past decades, there has been a notable increase in the incidence of precocious puberty across countries. For instance, in Denmark, the annual incidence of precocious puberty among girls younger than 8 years rose from 2.6 to 14.6 cases per 10,000 individuals between 1998 and 2017 [2]. Similar increasing trends have also been observed in a few other countries, such as South Korea, where the incidence among girls younger than 9 years rose 4.7 times between 2008 and 2014 [3], and Spain, where the incidence among girls younger than 8 years increased 16.7 times between 1997 and 2006 [4]. Among these countries, China stands out because the incidence is increasing even more rapidly and there is a larger population base [5]. This raises the urgent necessity of clarifying risk factors to facilitate efficient health promotion strategies. Certain factors or preexisting health conditions are speculated to explain the rising incidence of precocious puberty, including genetic predisposition, obesity, environmental exposures, and socioeconomic conditions [1,6-8]. However, specific risk factors involved in the pathogenesis of precocious puberty and their potential interactions still remain unclear and underexplored.

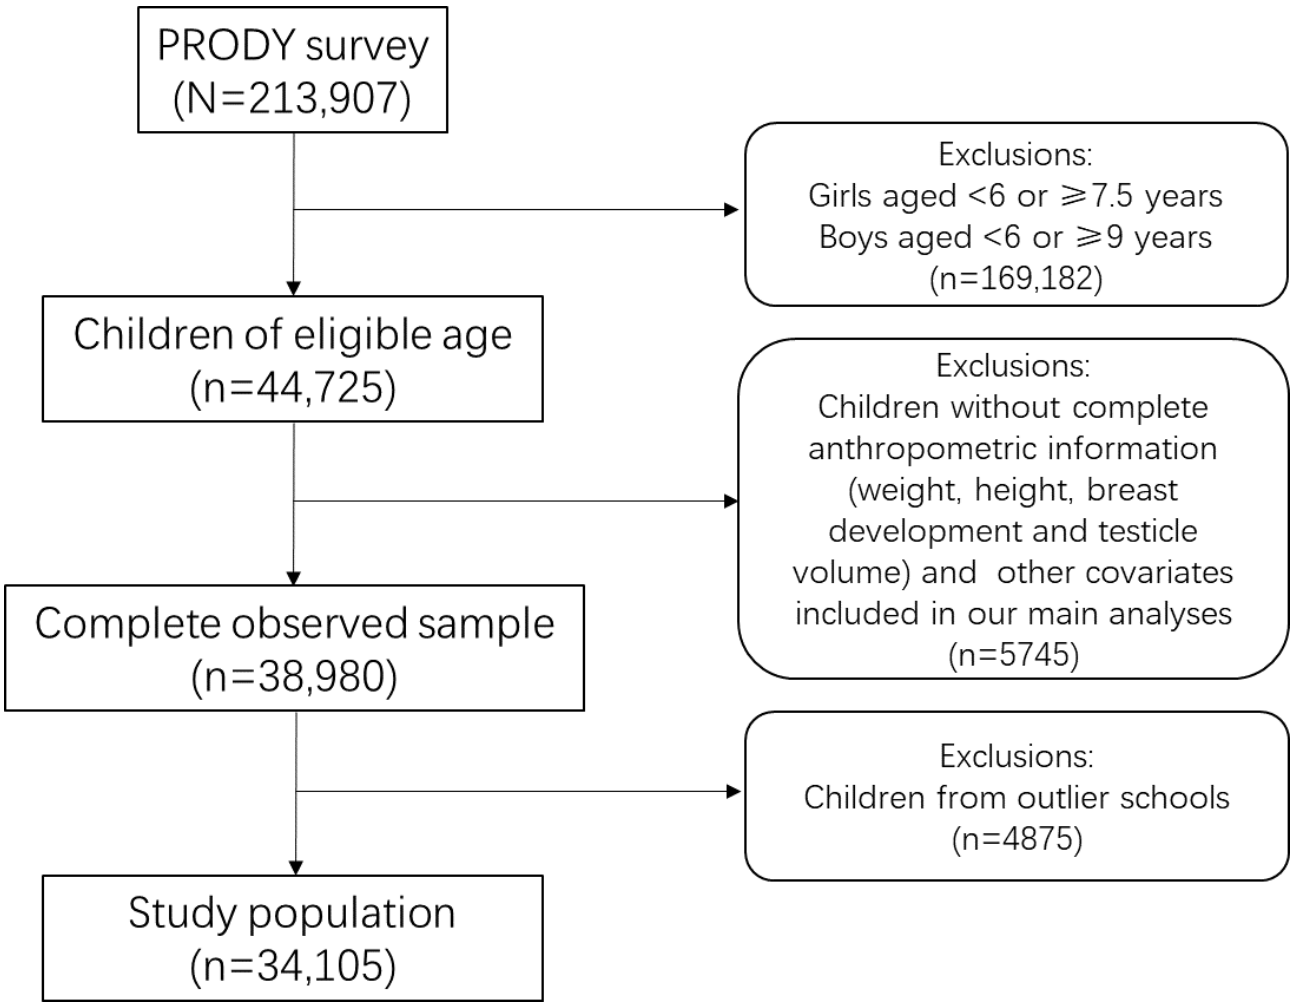
Air pollution is the second leading cause of global disease burden, and exposure to fine particulate matter ($PM_{2.5}$) could underlie most cases of air pollution–related disease, considering the complex toxicity of its components and the fact that over 90% of the world's population lives in highly polluted locations [9]. Some $PM_{2.5}$ components, such as phthalate, bisphenol analogs, and polycyclic aromatic hydrocarbons (PAHs), have been recognized as endocrine-disrupting chemicals (EDCs), affecting the normal production and signaling of sex hormones [10-12]. Some previous studies explored the association between long-term exposure to $PM_{2.5}$ and the risk of precocious puberty or related symptoms in children, but the conclusions remained inconsistent [7,13-15]. Explanations may be related to differing susceptibility across populations and the varied concentration of the essential components of $PM_{2.5}$ across countries and regions.

Ambient $PM_{2.5}$ pollution is a significant environmental hazard in China. Although air pollution has decreased dramatically in the past decade due to a series of new laws and advancements in environmental protection, the annual mean $PM_{2.5}$ concentration in 2023 was still 5 times higher than the recommended threshold of the World Health Organization (WHO) Air Quality Guidelines [9,16]. Considering the substantial number of children and the increasingly early age at onset of puberty, the adverse impact of $PM_{2.5}$ on precocious puberty, if it indeed exists, could stand out as a significant public health concern in China. However, to date, limited studies have clarified this research question.

Using data from a survey covering 30 cities of 11 provinces, our study aims to estimate the association between long-term exposure to $PM_{2.5}$ components and precocious puberty among school-aged children and to identify the components with the highest effect size in China. This will be indispensable for understanding the harmful effects of $PM_{2.5}$ and for health care promotion and environmental protection in this country.

Methods

Study Population



We analyzed data from eligible-aged children in the Prevalence and Risk Factors for Obesity and Diabetes in Youth (PRODY) study. A detailed profile of the PRODY data has been described previously [17]. Briefly, PRODY is a multicenter cross-sectional study conducted among children aged 3 to 18 years in China from 2017 to 2019. Participants were recruited using a stratified cluster random sampling strategy by considering their

XSL•FO
RenderX

geographic region, urbanization level, and economic level. Questionnaires and physical examinations were used to collect demographic characteristics, family information, dietary and behavioral habits, growth and development status, and other information, such as weight, height, parental educational level (low: high school or below; high: bachelor or higher), annual family income (first quartile [Q1]: <50,000 yuan [1 yuan=US $0.14]; Q2: 50,000 - 100,000 yuan; Q3: 100,000 - 200,000 yuan; Q4: >200,000 yuan), physical activity time (Q1:<90 min/week; Q2: 90 - 150 min/week; Q3:>150 min/week), frequency of consumption of dairy products, meat, fried foods, soy products, and junk foods (Q1:<1 times/month; Q2: 1 - 2 times/month; Q3: 3 - 4 times/month; Q4:>4 times/month), whole grains (Q1:<1 times/week; Q2: 1 - 2 times/week; Q3: 3 - 4 times/week; Q4:>4 times/week), and the consumption of sugary drinks, sweet fruit, and acidic fruit (yes or no). BMI (in kg/m^2) was calculated according to the growth reference of the WHO [18] and then categorized into 2 groups: low (normal weight or below) and high (overweight or obese).

This study initially included 213,907 participants across 11 provinces, autonomous regions, or municipalities in China (Xinjiang Uyghur Autonomous Region, Henan, Hubei, Guangdong, Guangxi Zhuang Autonomous Region, Zhejiang, Shanghai, Fujian, Jilin, Beijing, and Tianjin). Among the participants, 44,725 were at the eligible age for studying precocious puberty, and 38,980 of these (87.2%) accepted the related physical examination. Inclusion and exclusion criteria for the participants are shown in Figure 1. Briefly, based on previous studies and the diagnostic criteria for precocious puberty in China [5,19], we selected girls aged 6 to 7.5 years and boys aged 6 to 9 years as the study population. Children without complete anthropometric information or necessary covariates were excluded. To ensure the robustness of the analysis, schools were excluded as outliers if their prevalence rate of precocious puberty was 1.5 times greater or less than the IQR of the prevalence rates across all schools. The sample size for final analysis was 34,105. Differences in the main demographic characteristics of the study population and the original population were not statistically significant (Table S1 in Multimedia Appendix 1).

Figure 1. Flowchart of the inclusion and exclusion of study population. PRODY: Prevalence and Risk Factors for Obesity and Diabetes in Youth.

Ethical Considerations

This study protocol was approved by the Institutional Review Board of the Children's Hospital of Zhejiang University School of Medicine (approval number 2016-JRB-018). Written informed consent to participate in this study was provided by the participants' legal guardians or next of kin. We intended to use survey weights, but this possibility was denied by the data custodian due to data confidentiality concerns. All data used in this study were nonidentifiable.

XSL•FO

Outcome Measurements

The children's breast development, testicle volume, and pubic hair were measured by a well-trained endocrinologist. Pubertal stages were assessed following the 5-stage scale described by Marshall and Tanner [20]. Precocious puberty was defined as the initiation of secondary sexual characteristics, designated as Tanner stage 2, before the age of 7.5 years for girls and 9 years for boys [19]. Previous studies have demonstrated that over 98% of Chinese children younger than 6 years have not initiated pubertal development [5]. In line with previous studies, we confined the study population to girls aged 6 to 7.5 years and boys aged 6 to 9 years to improve modeling stability.

Exposure Measurements

Data on annual average concentrations of $PM_{2.5}$ and its 5 major components, sulfate (SO_4^{2-}), nitrate (NO_3^-), ammonium (NH_4^+), organic matter (OM), and black carbon (BC), were collected from the Tracking Air Pollution in China database [21] at a spatial resolution of 0.1° × 0.1° for the entire area of China for the period 2012 to 2019. The concentration at each school location was then calculated. Tracking Air Pollution developed a 2-stage machine learning model to predict daily $PM_{2.5}$ concentration using data from $PM_{2.5}$ measurements, satellite aerosol optical depth retrievals, online community multiscale air quality simulations, meteorological reanalysis data, land use information, and population distribution. Methodological details have been described elsewhere, with the data quality also warranted as high [22,23]. The 5-year average concentrations of $PM_{2.5}$ and its 5 major components, calculated as the average over the 0 to 4 years preceding the children's physical examinations, were assigned to each school address as a surrogate for personal exposure.

Statistical Methods

Single Exposure Model

Mixed-effects logistic regression was applied to quantify the association between $PM_{2.5}$ concentration and each of its 5 components with the binary status of precocious puberty, with the "province" indicator entered as the random intercept. Considering that certain dietary variables were correlated (Figure S1 in Multimedia Appendix 1), we used a least absolute shrinkage and selection operator regression model with the minimum mean squared error to select important dietary confounders related to precocious puberty (Table S2 in Multimedia Appendix 1). The main models were adjusted for gender, age, parental educational level, annual family income, physical activity time, BMI, and dietary habits, including frequency of consumption of dairy products, meat, fried food, and whole grains, as well as the intake of sugary drinks as a snack, fruit as a snack, sweet fruit, and acidic fruit. The results were described as odds ratios (ORs) for precocious puberty with the 95% CI per IQR increase in the concentration of each air pollutant. In this study, $PM_{2.5}$ and its 5 major components were not entered into a single model at the same time to avoid potential multicollinearity problems. The potential interaction effects were examined individually by adding an additional interaction term between $PM_{2.5}$ and each of these variables, including parental educational level, annual family income, physical activity time, BMI, and dietary habits.

Joint Exposure Model

Given the high correlations and uncertain relationships among the various components of $PM_{2.5}$, we used a weighted quantile sum (WQS) regression model to assess the joint exposure effects. The WQS model was used to construct a cumulative linear index by grouping $PM_{2.5}$ components into quartiles, with the corresponding weight of each component indicating its contribution to the overall index. WQS regression assumes that all exposures included in the index are associated with the outcome in the same direction. Therefore, we first evaluated the direction of the association between each pollutant and precocious puberty through the single exposure model. As suggested previously, the training and validation datasets were split 40% and 60%, and the bootstrap was set to 1000 times [24].

Sensitivity Analyses

A series of sensitivity analyses were conducted to examine the robustness of our main findings. First, the main models were expanded by additionally adjusting for other dietary variables selected from the literature that failed the selection procedure. Second, we modified the personal exposure from 0 - 4 years to 1 - 4 years and 0 - 2 years to explore whether the results might differ with exposure duration. Third, we further adjusted for gaseous pollutants, such as SO_2, CO_2, and O_3. The quantile-based g-computation (QGC) model was used for sensitivity analysis of the joint exposure model, as it allows for the evaluation of combined effects of exposure in different directions [25]. Meta regression was used to test the significance of differences in the results of the main analyses and sensitivity analyses.

R (version 4.3.0; R Foundation for Statistical Computing) was used for analyses. *P* values <.05 were considered statistically significant.

Results

Table 1 presents the demographic characteristics of the study participants. A total of 34,105 children (n=23,683, 69.44% boys) with an average age of 7.25 (SD 0.82) years were enrolled in this study. Among them, 62.39% (21,279/34,105) had an annual family income exceeding 100,000 yuan (US $14,327), 63.25% (21,570/34,105) had parents with a college degree or higher, and 26.01% (8872/34,105) were categorized as overweight or obese. A total of 401 of the 34,105 children (1.18%) were diagnosed with precocious puberty, of which 214 were boys (0.9%) and 187 were girls (1.79%). The average individual exposure over a 5-year period was 47.93 (SD 16.52) μg/m^3 for $PM_{2.5}$, 2.31 (SD 0.59) μg/m³ for BC, 6.34 (SD 2.25) μg/m³ for NH_4^+, 11.74 (SD 3.75) μg/m³ for OM, 9.52 (SD 3.95) μg/m³ for NO_3^- and 8.74 (SD 2.11) μg/m³ for SO_4^{2-}, respectively (Table S3 in Multimedia Appendix 1). A map of $PM_{2.5}$ concentration and the study population during the study period is shown in Figure S2 in Multimedia Appendix 1.

Variables	Precocious puberty (n=401)	Nonprecocious puberty (n=33,704)
Soy product frequency (times/day), mean (SD)	0.93 (0.88)	0.98 (0.89)

The analysis of the single exposure model indicated that the ORs for precocious puberty for the whole study population were 1.27 (95% CI 0.92-1.75) for total $PM_{2.5}$ mass, 1.42 (95% CI 1.03 - 1.97) for NH_4^+, 1.57 (95% CI 1.01 - 2.43) for NO_3^-, and 1.38 (95% CI 1.03 - 1.86) for SO_4^{2-} per IQR increase in their 5-year average concentrations (Figure 2). A clear gender variation in the effect size of $PM_{2.5}$ exposure was observed: per IQR increase in $PM_{2.5}$ mass, the ORs were 2.12 (95% CI 1.27 - 3.55) for girls and 0.90 (95% CI 0.62 - 1.30) for boys (P=.01). In addition, the effect sizes of all 5 $PM_{2.5}$ components were also only significant for girls.

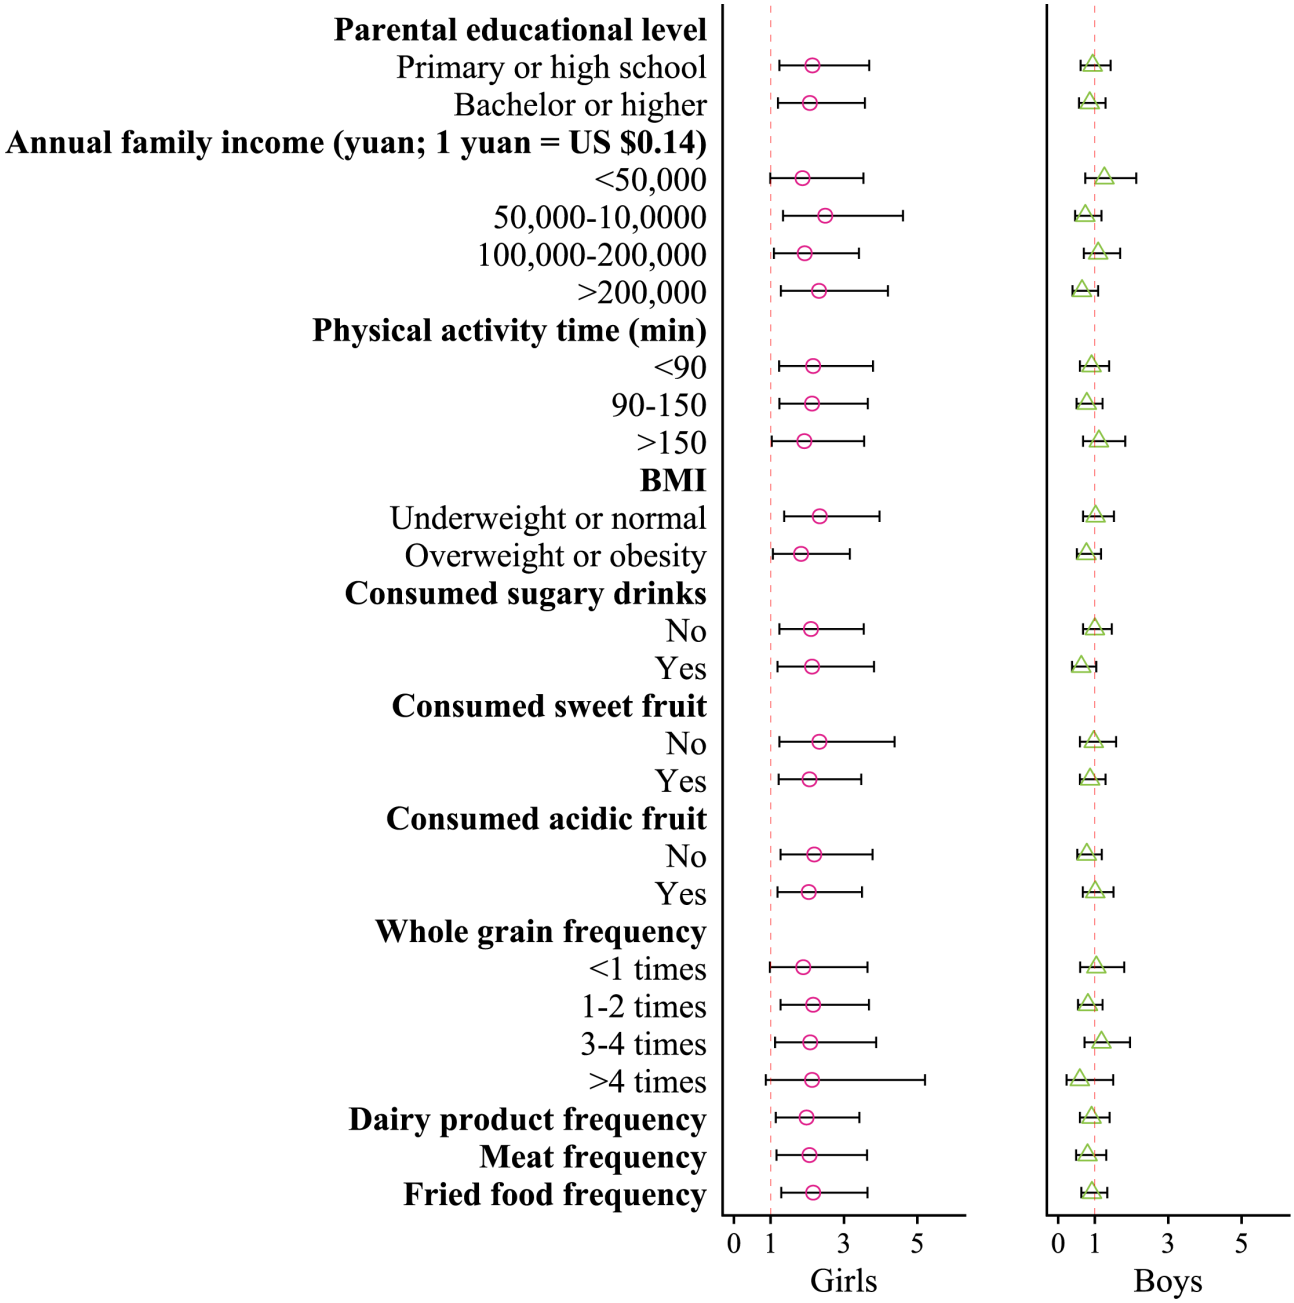

Figure 2. Odds ratio for precocious puberty per IQR increase in $PM_{2.5}$ mass and its 5 major components. $PM_{2.5}$:fine particulate matter; BC: black carbon; OM: organic matter; NO_3^-: nitrate; NH_4^+: ammonium; SO_4^{2-}: sulfate. Asterisks indicate the significance of differences between boys and girls: $^*P$<.05, $^{**}P$<.01, $^{***}P$<.001.

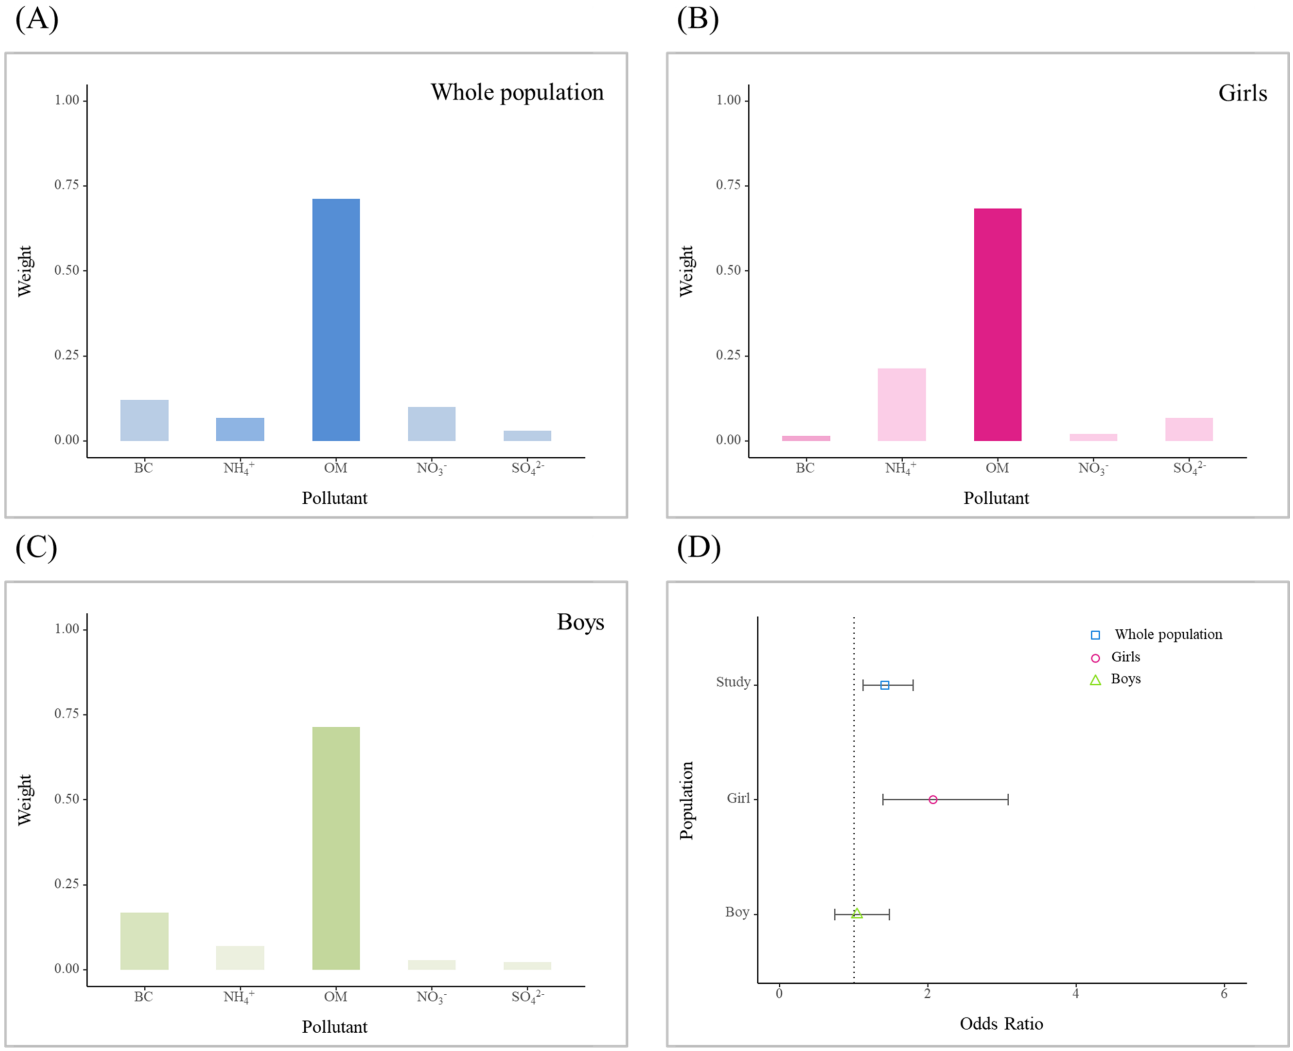
The effect size of $PM_{2.5}$ was nonsignificantly higher in groups with certain demographic characteristics, family information, and behavioral habits (Figure 3). For example, the OR for precocious puberty was 2.49 (95% CI 1.34 - 4.61) for girls with a family income at the Q2 level and 1.87 (95% CI 0.99 - 3.53) for those with family income at the Q1 level. Similarly, the ORs were 2.34 (95% CI 1.37 - 3.97) and 1.83 (95% CI 1.06 - 3.16) for groups with low BMI and high BMI, respectively. Certain modifying effects were observed in boys, such as family income (<50,000 yuan group vs >200,000 yuan group; P=.03) and sugary drink consumption (no vs yes; P=.03).

XSL•FO
RenderX

Figure 3. The modification effect of individual characteristics and dietary habits on the association between $PM_{2.5}$ exposure and precocious puberty.



As shown in Figure 4, the WQS index was significantly associated with precocious puberty (OR 1.42, 95% CI 1.12 - 1.80). The major contributors were OM, BC, and NO_3^-, with their weights in the overall effect size being 0.71, 0.12, and 0.10, respectively. After stratification by gender, a significant association was observed only in girls.

The strength of the association was stable after adjusting for additional covariables and gaseous pollutants or changing the exposure period in both the single-air-pollutant models and WQS models. The association between $PM_{2.5}$ components and precocious puberty remained unchanged in the QGC model, with OM continuing to be the major positive contributor to the overall effect of total $PM_{2.5}$ mass (Tables S4-5 in Multimedia Appendix 1).

XSL•FO
RenderX

Figure 4. Weights of the contributions of the 5 major components of fine particulate matter ($PM_{2.5}$) to its total effect size. Mean weights for (**A**) the whole study population; (**B**) girls; (**C**) boys. (**D**) Odds ratios for precocious puberty per IQR increase in the weighted quantile sum regression (WQS) index. WQS models were adjusted for gender; age; maximum level of parental education; annual family income; weekly physical activity time; BMI; consumption frequency of dairy products, meat, fried foods, and coarse food grain; intake of sugary drinks, sweet fruit, and acidic fruit; and province. BC: black carbon; OM: organic matter; NO_3^-: nitrate; NH_4^+: ammonium; SO_4^{2-}: sulfate.

Discussion

Principal Results

This study explored the association between exposure to $PM_{2.5}$ and its major components with precocious puberty based on a large survey of school-aged children in China. We observed that $PM_{2.5}$ mass was significantly associated with precocious puberty only in girls. OM was detected as the major effective component when the 5 major components of $PM_{2.5}$ were jointly exposed. Modification effects of certain factors at the individual or family levels were observed (eg, family income and sugary drink consumption), especially for boys.

Comparison With Prior Work

Recent evidence suggests that there is significant variation in the prevalence of precocious puberty across regions and study periods; the prevalence ranges from <0.05% to 2.53% in Denmark, Korea, and China [15,26,27]. To our knowledge, our PRODY study is to date the only large-scale survey on precocious puberty in China. We found that the prevalence in the study areas was 0.9% in boys and 1.79% in girls. Previously, only one study (the predecessor of PRODY) investigated precocious puberty in 5 Chinese provinces and reported a prevalence of 0.43% [26]. The differing prevalence across studies may be partly explained by differences in diagnostic criteria, population characteristics, the years of investigation, and certain limitations in sampling.

Previously, some studies have explored the effect of long-term $PM_{2.5}$ exposure on pubertal development or related sexual hormones and obtained inconsistent results. A cohort study in Poland revealed that children exposed to an average annual concentration of $PM_{2.5}$ exceeding 25 $\mu g/m^3$ were at high risk of menarche occurring before the age of 11 years [14]. Similarly, Jung et al [28] found that each 1 $\mu g/m^3$ increase in the 3-year average of annual mean PM_{10} concentration was associated with age acceleration at menarche by 0.031 years in 639 girls aged 13 to 17 years in South Korea. Additionally, a recent large-scale (n=1,205,784) nationwide retrospective cohort study reported that 4-year exposures to $PM_{2.5}$ and PM_{10} were

XSL•FO
RenderX

associated with precocious puberty in girls in South Korea [15]. By contrast, in Hong Kong's cohort of children born in 1997, Huang et al [7] found a nonsignificant association between childhood PM_{10} exposure and precocious puberty. A German study reported a weak association between $PM_{2.5}$ exposure and decreased estradiol level in girls in Munich [13].

There may be several explanations for the inconsistent findings across studies. For example, in comparison to the Hong Kong study, which used the age of 11 years as the diagnostic threshold for pubertal stage, our study applied a younger diagnostic age (<7.5 years for girls and <9 years for boys), following the latest official recommendation in mainland China. This lower threshold may more effectively capture the early onset of pubertal development in children and the related effect size of $PM_{2.5}$. In addition, the inconsistent results of these studies may also be attributed to the differences in study area, population characteristics, outcome definitions, and other potential confounders like socioeconomic status, as well as exposure period and levels. This study provides supporting evidence for the adverse effect of childhood $PM_{2.5}$ exposure on precocious puberty among a nationwide sample in China.

The potential mechanisms underpinning the adverse effect of $PM_{2.5}$ on precocious puberty have been rarely discussed. One suggested hypothesis is the endocrine disruption caused by $PM_{2.5}$. Certain EDCs, such as phthalates, bisphenol analogs, and PAHs, have been detected as $PM_{2.5}$ components in several major Chinese cities [29-31]. These chemicals may target the estrogen receptor or kisspeptin in the hypothalamic nuclei and exhibit estrogenic or antiandrogenic activity, thereby promoting hypothalamic maturation and consequently causing precocious puberty [8,32-34]. In addition, some heavy metals found in $PM_{2.5}$, especially lead and cadmium, have also been proven to disrupt estrogen levels in female individuals and influence pubertal development [35,36].

The health effects of $PM_{2.5}$ depend on its chemical components. An increasing number of epidemiological studies have paid attention to the association between $PM_{2.5}$ chemical components and a range of health outcomes, such as pregnancy disorders, lung function, mortality, and body weight [37-40]. To the best of our knowledge, our study is the first to report associations of $PM_{2.5}$ components with precocious puberty. We found that OM is the most important component of $PM_{2.5}$ associated with precocious puberty in China. OM is produced by the incomplete combustion of solid fuels, which have higher toxicity than noncombustion aerosols [41]. In China, OM is the primary component of $PM_{2.5}$ in several major cities [42], posing a significant health risk to the population. Although the differential impact of components of $PM_{2.5}$ on precocious puberty has not yet been adequately examined, some underlying mechanisms may explain the observed effects. As previously mentioned, the chemical components in $PM_{2.5}$ that exert endocrine-disrupting effects are predominantly OM, such as PAHs. In addition, OM has the potential to induce mutagenic, inflammatory, and lipid metabolic disturbances in vivo [43-45]. However, without data at the cellular and molecular levels, it is beyond the scope of this study to speculate further about the potential pathways mediating the impact of OM on pubertal development.

Previous studies have suggested that the effects of $PM_{2.5}$ on children's pubertal development may differ by gender [13,15]. Consistent with this, our study observed a more significant association between $PM_{2.5}$ and precocious puberty in girls than in boys. It has been speculated that gender differences are due to the varying effects of PM exposure on different hormone levels in vivo [46], as well as the fact that prepubertal girls are particularly sensitive to low levels of exogenous estrogens [47]. In addition, gender differences may be related to the criteria for measuring secondary sexual characteristics, which depend on physical examinations of breast development and pubic hair in girls and testicle volume and pubic hair in boys, rather than on sex hormones and gonad B-ultrasounds.

Significant modifying effects of family income and sugary drink consumption were observed. Previously, several studies explored potential modifiers of the adverse effect of long-term $PM_{2.5}$ exposure, although few have focused on pubertal development. For example, a large cohort study in Canada found that the impact of $PM_{2.5}$ on mortality was greater for low-income earners than for high-income earners [48]. A study in the United States indicated that the cardiovascular risks associated with $PM_{2.5}$ exposure were higher among low-income groups compared to high-income groups [49]. The inequalities in $PM_{2.5}$ exposure between high-income populations and low-income populations may partly explain the modifying effect of family income.

Pubertal timing is sensitive to nutritional regulation; for example, girls with the highest levels of dietary isoflavone intake may experience early onset of breast development [50]. Some animal studies have found that fructose diet–fed rats had lower plasma testosterone levels, which can lead to a high sensitivity of the pituitary-gonadal axis in Leydig cells [51]. It can be speculated that dietary factors may potentially involve pathways that overlap with $PM_{2.5}$ and promote or hinder the effects of $PM_{2.5}$ on precocious puberty. However, there is still a lack of evidence to explain why significant modifying effects of family income and sugary drink consumption were observed more prominently in boys than in girls. Due to the absence of detailed information, further exploration is not feasible. Future studies may be able to elucidate the underlying mechanisms.

Strengths and Limitations

This study has several strengths that can be mentioned. First, our findings came from a survey covering 30 cities in 11 provinces, improving the generalizability when compared to studies with a smaller geographical scale, such as a single city. Second, the PRODY survey incorporated measurements of breast development and testicle volume conducted by medical professionals, resulting in a more accurate diagnosis of precocious puberty compared to studies using self-reported or parent-reported data. Third, we analyzed the effects of joint exposure to $PM_{2.5}$ components on precocious puberty using WQS regression, which can identify major contributors and therefore provide targeted recommendations for air quality–related health improvement.

XSL•FO
RenderX

We acknowledge some limitations of our analysis. In this study, air pollutant concentrations at the school level may not fully reflect all sources of air pollution, such as indoor air pollution within households, potentially leading to exposure misclassification. Because of the large sample size in this study and the limitations imposed by survey costs, we were unable to measure children's air pollution exposure at a finer scale. Future studies are strongly encouraged to consider a more holistic approach by incorporating direct measurements of indoor air quality, possibly using portable air monitoring devices. Due to ethical considerations, only children willing to undergo physical examinations were included in the study, which might have introduced a certain sampling bias. Without access to data on appropriate survey weights, we were unable to evaluate the accurate generalization of our findings to the whole target population of the country, which warrants further exploration when data are available in the future. Due to the cross-sectional study design, the inference of causality was limited. Furthermore, owing to constraints in data availability, our study did not account for the adverse effects of some other toxic components (ie, heavy metals) or confounding variables such as parental history of precocious puberty, sleep patterns, and psychological status. We suggest that future research should include these additional variables to better understand their potential impacts on the results.

Conclusion

Our study suggests that OM may be a major contributor to the association between long-term exposure to $PM_{2.5}$ and precocious puberty. Our findings further endorse the call for reducing fossil fuel emissions, concurrently advocating the development of specific and effective strategies to protect children's developmental health.

Abstract

Background: Residual blood donor samples are commonly used in SARS-CoV-2 seroepidemiological studies; however their use may introduce bias due to the healthy donor effect, wherein blood donors are generally healthier than the general population. This potential bias is critical for accurately interpreting seroepidemiological data, as blood donors might not fully represent broader population-level infection rates. **Objective:** This study aims to assess the potential bias in SARS-CoV-2 seroprevalence estimates derived from blood donor samples in Japan by examining the association between blood donation history and COVID-19 diagnosis. By quantifying the healthy donor effect, we seek to refine the interpretation of SARS-CoV-2 seroepidemiological studies using residual blood donor samples. **Methods:** We conducted a web-based survey from December 14 to 28, 2023, recruiting 10,781 Japanese residents aged 16 - 69, stratified by demographic factors to match national representation. Participants provided information on demographics, socioeconomic status, COVID-19 vaccination history, comorbidities, and blood donation experience. A logistic regression model adjusting for confounders such as age, sex, education, occupation, comorbidities, and vaccination status, was used to estimate the odds of COVID-19 diagnosis among blood donors compared to nondonors. **Results:** Of the 10,781 participants, 3583 (33.2%) reported a history of COVID-19 diagnosis, and 5015 (46.5%) indicated they had donated blood at least once in their lifetime, and 1128 (10.5%) donated within the last year. Blood donors had mean of 13.5 (SD 43.6) donations and were older, with a mean age of 46.4 (SD 13.9) years, compared to 38.5 (SD 14.1) years for nondonors. Among blood donors, 39.9% had comorbidities (95% CI 38.5 - 41.2) compared to 27.9% (95% CI 26.7 - 29.0) of nondonors. Blood donors had 1.62 (95% CI: 1.48 - 1.78) times higher odds of COVID-19 diagnosis compared to nondonors. The higher diagnosis rate among blood donors likely reflects increased social interactions and health-seeking behaviors, a phenomenon we refer to as the inverse healthy donor effect. This suggests that blood donor samples could overestimate SARS-CoV-2 seroprevalence when generalized to the broader Japanese population. **Conclusions:** Higher COVID-19 diagnosis rates among blood donors may reflect increased community involvement and health-seeking behaviors, suggesting an inverse healthy donor effect. This pattern indicates that in terms of SARS-CoV-2 infection, blood donors might not represent the healthiest segment of the population. Consequently, seroprevalence studies using blood donor samples could overestimate SARS-CoV-2 infection rates in the general Japanese population. For more accurate public health surveillance, the development of statistical methods to adjust for this bias is recommended.

Introduction

The COVID-19 pandemic, triggered by the rapid dissemination of SARS-CoV-2, has highlighted the critical need for robust epidemiological surveillance to decipher the virus's transmission dynamics and shape effective public health strategies. As the pandemic intensified, the exponential increase in cases coupled with the presence of mild and asymptomatic infections strained traditional case-based surveillance systems. These systems primarily capture symptomatic cases seeking healthcare, leaving

XSL•FO
RenderX

a substantial proportion of the infected population—particularly those with mild or asymptomatic infections—undetected. This complication led to the adoption of seroprevalence studies, which estimate the extent of infection by measuring the presence of nucleocapsid or spike antibodies in populations to provide a broader estimation of infection spread, inclusive of undiagnosed cases.

While seroprevalence studies are invaluable for assessing SARS-CoV-2 exposure at the population level, they are subject to inherent biases [1,2]. For example, antibody levels can wane over time, and variations in assay sensitivity or specificity may underestimate or overestimate the seroprevalence. When residual blood samples from blood donors are used, an additional potential bias known as the healthy donor effect is introduced [3]. This effect arises because blood donors are typically healthier than the general population [4-7], potentially resulting in an underestimation of true seroprevalence. Although blood donor–based SARS-CoV-2 seroepidemiological studies have been widely conducted across various countries [8-11], these studies have not fully accounted for the extent of this effect. Recognizing and addressing such bias is critical to improving the reliability of seroprevalence estimates and their use in public health planning.

Despite recognition of the healthy donor effect, its quantitative impact on SARS-CoV-2 seroprevalence estimates remains largely unexplored, introducing uncertainty in interpreting findings derived from blood donor samples [12]. Our study addresses this gap by focusing on the quantification of the healthy donor effect within Japan's blood donor population, with the goal of improving the interpretation of SARS-CoV-2 seroprevalence estimates and providing a more accurate assessment of the population's exposure to SARS-CoV-2.

Methods

Study Participants and Questionnaire

The study surveyed Japanese residents aged 16 - 69 years—the age group eligible for blood donation in Japan—from all 47 prefectures who could respond in Japanese. The sample size was set at 10,829, based on an approximately 6.1% national blood donation rate reported in a 2022 Japanese Red Cross survey [13], with a 5% alpha error and 80% power. To ensure national representation, a quota-controlled sampling approach was applied, stratified by age, sex, and region, with quotas informed by the 2020 national census. Participants were recruited from Cross Marketing Inc.'s (Japan) panel of 5 million active and diverse members as of March 2024, who volunteered and were incentivized with point-based rewards redeemable for goods and services from affiliated businesses upon completion of the questionnaire. Panel members were accepted on a first-come-first-served basis until quotas for each age and prefecture category were met, ensuring coverage across all 47 prefectures, including both urban and rural populations. The survey was conducted from November 14 to 28, 2023, in alignment with a national seroepidemiological survey among blood donors in Japan. To ensure data completeness, respondents were requested to answer all questions.

The online questionnaire was developed based on a comprehensive literature review on blood donation and epidemiological surveys. For questions related to blood donation, we referenced validated items from governmental surveys [14]. The survey items were divided into three modules: (1) sociodemographic characteristics such as sex, age at the survey, residential prefecture, occupation, education level, and household income; (2) blood donation–related characteristics such as blood donation experience (yes or no) and the total number of blood donations; and (3) COVID-19-related and clinical questions such as the number and timing of prior COVID-19 infections, the number of COVID-19 vaccinations, and medical history. The definitions for COVID-19 vaccination, blood donation, and comorbidity are provided in Multimedia Appendix 1. A binary variable was created from medical history records to identify comorbidities that rendered participants ineligible for blood donation and medically unable to receive the COVID-19 vaccine (see Multimedia Appendix 2). These comorbidities included current treatment for periodontal disease or dental caries, a diagnosis of high blood pressure, diabetes, asthma, or chronic obstructive pulmonary disease, and a history of angina, myocardial infarction, stroke, or cancer.

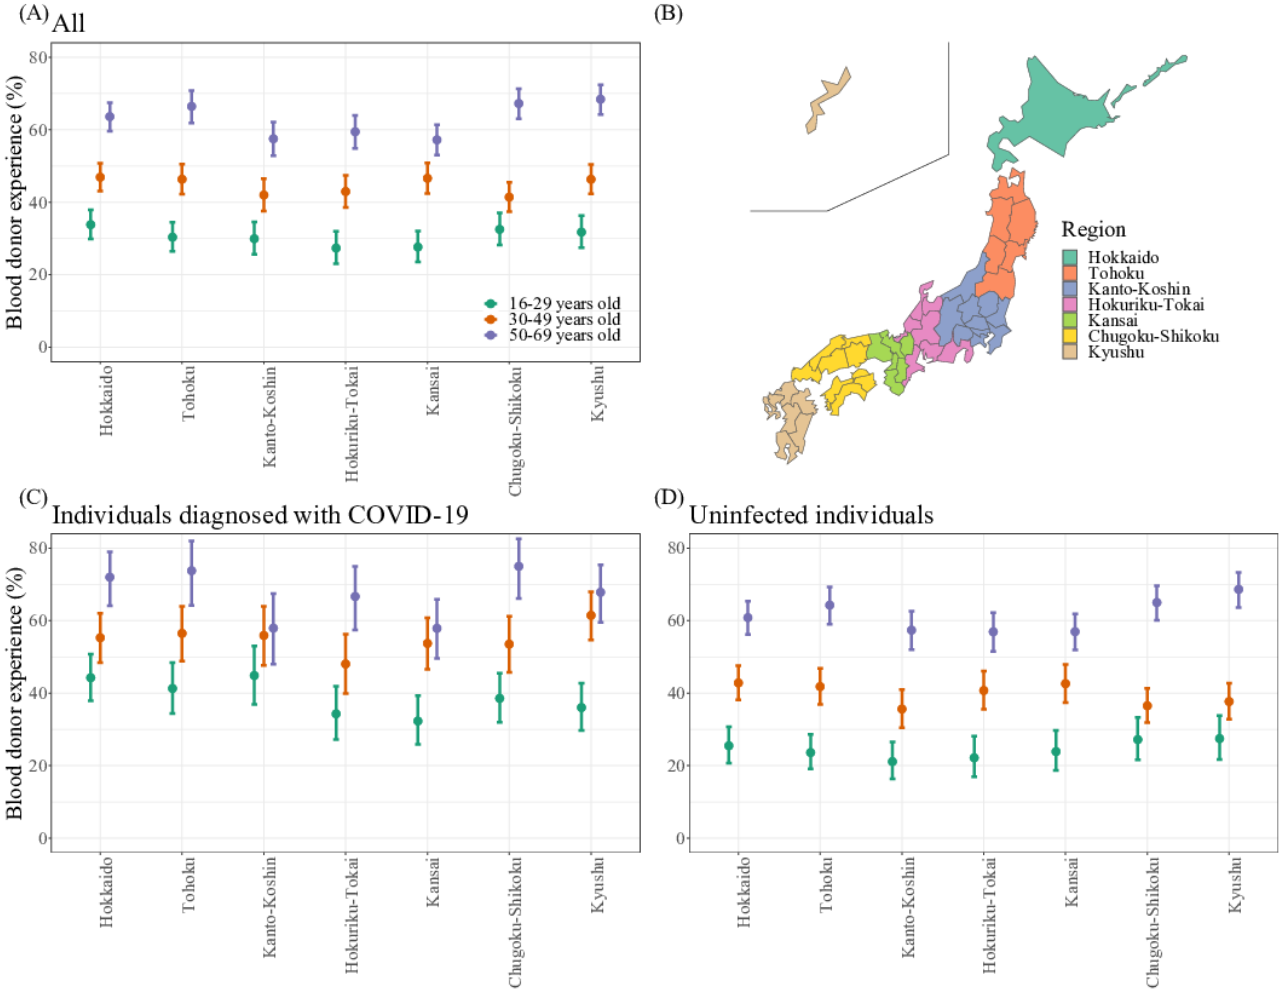
Statistical Analysis

First, sociodemographic data were tabulated separately for participants with and without blood donation experience to provide basic information on the study population. Continuous variables were analyzed using Mann-Whitney U test and categorical variables were analyzed using Fisher exact test. To estimate the association between COVID-19 infection and blood donation experience, a logistic regression model was used and the associated odds ratio was estimated. Based on a directed acyclic graph, these confounders were adjusted: age groups (16-29, 30-39, 40-49, 50-59, 60-69 years), sex, residential region, education level, occupation, number of blood donations, number of vaccinations, and comorbidities (Multimedia Appendix 3). As behavioral changes induced by vaccination are expected to differ by age group, an interaction term between age groups, and the number of vaccinations was also adjusted in the model. Further, to explore the model robustness, we conducted subgroup analyses using Firth logistic regression to account for potential bias due to small sample sizes or sparse data. Model performance was evaluated by calculating c-statistics, performing the Hosmer-Lemeshow test, and assessing multicollinearity using the adjusted generalized variance inflation factor (GVIF), where GVIF $^{1/(2\times df)}$, with *df* representing the degrees of freedom. All data analyses were conducted using R software (version 4.3.2; R Foundation for Statistical Computing).

Ethical Considerations

This study was reviewed and approved by the Institutional Review Board at the National Institute of Infectious Diseases (authorization no. 1579). Informed consent was obtained from all participants within the web survey, with only those providing consent allowed to proceed. All data used in the analysis were fully anonymized by Cross Marketing Inc. before being provided to the researchers. Participants received point-based rewards as

XSL•FO
RenderX



compensation for survey completion, in line with institutional review board–approved ethical guidelines.

Results

The main characteristics of the study participants are presented in Multimedia Appendix 4. A total of 10,781 participants were enrolled in Japan during the study period from December 14 to 28, 2023. Of these, 3583 (33.2%) had a history of COVID-19 diagnosis, and 5015 (46.5%) reported having donated blood at least once in their lifetime. Furthermore, 1128 (10.5%) had donated blood within the past year (Multimedia Appendix 5). Blood donors (defined as those with a history of blood donation) reported mean 13.5 (SD 43.6) donations. . Multimedia Appendix 6 shows the detailed distribution of blood donation frequency in our web survey. The mean age of blood donors was 46.4 (SD 13.9) years, whereas nondonors were younger, with a mean age of 38.5 (SD 14.1) years. Among blood donors, 39.9% (95%CI 38.5 - 41.2) had comorbidities, compared to 27.9% (95% CI 26.7 - 29.0) of nonblood donors (see Multimedia Appendix 7).

Figure 1A depicts the proportion of blood donors categorized by age group and geographic region in Japan. The corresponding geographic regions are illustrated in Figure 1B. In general, individuals who have been diagnosed with COVID-19 had a higher prevalence of prior blood donation compared to those without a history of diagnosis. The estimated results of the logistic regression model shown in Table 1. After excluding individuals with comorbidities that render them ineligible to donate blood or receive the COVID-19 vaccine, and after adjusting for potential confounders, we found that the odds of infection among blood donors were 1.62 times greater (95%CI 1.48 - 1.78) than nondonors. Overall, the positive odds ratio was similar across most subgroup analysis with different stratifications, with most results being statistically significant (see Multimedia Appendix 8). Model validation resulted in a c-statistic of 0.66, a Hosmer-Lemeshow test value of χ^2=6.78 (*P*=.56), and adjusted GVIF values below 5, with a mean of 1.34.

Figure 1. Proportion of blood donors and COVID-19 diagnosis status among Japanese residents aged 16 - 69 years, based on a web-based survey conducted across all 47 prefectures in Japan from December 14 to 28, 2023. (A) Overall proportion of participants with blood donation experience. (B) Map showing geographic regions represented in the study. (C) Proportion of blood donors among individuals diagnosed with COVID-19. (D) Proportion of blood donors among uninfected (undiagnosed) individuals.

Discussion

Our study showed a significant association between blood donation experience and COVID-19 diagnosis. However, the diagnosis rates did not increase with the frequency of donations, suggesting that the act of donating blood itself did not contribute to the transmission risk. Instead the higher incidence of COVID-19 among donors may be attributed to increased social interactions and greater health awareness, which could be characterized as an 'inverse' healthy donor effect [15]. Donors' community involvement could raise exposure risks, while their health vigilance could lead to more frequent SARS-CoV-2 testing, leading to higher COVID-19 diagnosis. Further studies are needed to understand the potential underlying mechanism behind this association.

We found that using blood donor samples could potentially bias seroprevalence estimates in Japan. The observed positive association suggests that these samples may overestimate the actual rates compared to the general population. Previous efforts to adjust for demographic variances, such as age, gender, and prefecture, have not completely resolved the bias inherent in using blood donor samples [11]. This highlights the need to measure the healthy donor effect for accurate SARS-CoV-2 seroprevalence interpretations and emphasizes the challenge of correctly determining incidence from donor data, underscoring the need for improved research methodologies. Development of a statistical method to adjust for this bias of blood donor samples in estimating the seroprevalence of the general population of Japan using blood donor samples remains an ongoing focus of our research group.

There are a few limitations to note. First, the identification of COVID-19 cases was based on clinical diagnoses rather than antibody-confirmed infection rates, suggesting that the study may reflect differences in health-seeking behavior rather than actual SARS-CoV-2 infection rates. Second, although we applied quota sampling based on demographic distributions from the national census to improve representation, the sample population may not fully represent the general population in Japan, as the study was conducted via a web-based survey. This approach may introduce potential selection bias, particularly excluding individuals without internet access or those less comfortable with technology. Third, the study relied on self-reported data, which may introduce recall bias or social desirability bias. Fourth, we may not have fully adjusted for residual confounding from variables that were not included in the survey. Fifth, the cross-sectional design has inherent limitations, including difficulty determining temporal relationships and tracking changes over time. Finally, our findings may be specific to the Japanese context and might not necessarily apply to other countries due to differences in demographics, healthcare systems, and social behavior. Further evaluation is needed to assess the external validity across different countries or regions.

In conclusion, our study has identified a potential bias in SARS-CoV-2 seroprevalence studies that use residual samples from blood donors. Quantifying the direction and magnitude of this bias is essential for accurately interpreting seroprevalence surveys, especially when these surveys are used to guide infectious disease surveillance.

Abstract

Background: Nonsuicidal self-injury (NSSI) is a major public health problem leading to psychological problems in adolescents and young adults, similar to disorders such as depression and anxiety.

Objective: The aims of this study were to investigate (1) the interaction between BMI and socioenvironmental factors (including chronotype and mental health) that contribute to NSSI, and (2) whether self-esteem plays a mediating role in this association.

Methods: From May to June 2022, the multistage cluster sampling method was used to sample college students in four grades, including freshmen and seniors. The baseline participants were followed up 6 months later, excluding those who did not qualify, and the participants included 1772 college students. Socioenvironmental factors (chronotype/mental health), self-esteem, and NSSI were measured using a questionnaire. Multivariate linear regression models and chi-square analysis were used to evaluate the linear relationship between BMI, socioenvironmental factors, and self-esteem and the NSSI status. We use a process approach (mediation-moderation analysis) to explore the complex relationships between these variables.

Results: The mean age of the participants was 20.53 (SD 1.65) years at baseline. A significant association was revealed, suggesting that a high BMI (β=.056, 95% CI 0.008 - 0.086, *P*=.018) was associated with a higher NSSI. There was also an interaction among BMI, socioenvironmental factors, and NSSI. Socioenvironmental factors played both moderating and mediating roles in the relationship between BMI and NSSI, whereas self-esteem only played a mediating role.

Conclusions: Paying attention to factors such as overweight and obesity is important for early BMI control to identify other potential risk factors for NSSI and to evaluate how self-esteem can be improved considering multiple perspectives to improve the effect of BMI on NSSI in adolescents.

Introduction

Nonsuicidal self-injury (NSSI) refers to physical harm, not the intention to commit suicide, and is not a socially recognized behavior [1]. NSSI, while being distinct from suicidal behavior, is a strong predictor of suicide and is also a significant mental health problem among adolescents worldwide [2]. NSSI is gradually increasing in the world; it seriously damages people's physical and mental health and is a psychopathological behavior, which has aroused people's attention and concern. The *DSM-5* identifies NSSI as a separate behavioral category and lists it as "an entry for further research" [3]. Adolescence and college years are important periods of psychological development and changes in life. In a meta-study, the reporting rate of NSSI was 22.5% (95% CI 17.2% - 28.9%) among adolescents [2]. The prevalence of NSSI ranged from 3.2% to 44.8% among

XSL•FO
RenderX

nonclinical populations [4]. For clinical populations, the incidence of NSSI in the past 12 months ranged from 5% to 16.4% [4]. The harm of NSSI goes far beyond that, and after the emergence of NSSI in adolescence, it has maintained a certain "trajectory" into adulthood, including a continuous increase or fluctuation between the increase and decrease of NSSI, as well as an increase in psychobehavioral problems that largely affect people's lives [5,6]. A systematic review and Bayesian meta-analysis concluded that in the entire developmental stage of adolescents, the NSSI frequency (but not the frequency of occurrence) in younger adolescents increased, that in middle adolescents remained stable, and that in older adolescents decreased [3]. On proceeding into the aftermath of the COVID-19 outbreak and trying to recover from its consequences, preventing NSSI and suicidal behaviors has continued to be a priority. In general, the current NSSI epidemic in China is serious [7], and it has become a major public health problem that severely endangers adolescents' physical and mental health. Being an ongoing social health problem, NSSI is a major concern for mental health and it deserves our attention.

With such a high incidence rate of NSSI that has not been effectively controlled thus far, it is important to explore the potential factors of and prevention measures for NSSI, including what factors affect NSSI, how they interact with each other, and what needs to be done to protect those with high NSSI frequency. The specific factors that affect NSSI are as follows: (1) individual psychological factors, including self-abasement, impulsivity, early traumatic experience, self-esteem, and other characteristics; (2) external environmental factors, including negative life events (events that individuals feel unpleasant); (3) neurobiological factors, including the influence of the metabolism of substances such as 5-hydroxytryptamine, glutamate, and dopamine, which may also be related to genetics; (4) family factors, including family environment, family atmosphere, and family economic conditions; and (5) school factors, including school environment, teacher-student relationship, and classmate relationship, which may also have an impact on children and adolescents' NSSI. The occurrence of NSSI behavior in adolescents is not the result of a single factor, but the result of the interaction of multiple factors. In addition, obesity has attracted considerable attention as a cause of many diseases, including physical diseases as well as psychological and behavioral problems [8]. Changes in BMI are correlated with suicide [9], and there is a significant association with suicide attempts in underweight and perceived overweight groups [10]. There is an association between psychological problems and NSSI [10,11]. A previous study demonstrated that while posttraumatic stress disorder leads to suicidal ideation, BMI plays a significant moderating role, indicating that the association between posttraumatic stress disorder and suicidal ideation is the strongest in individuals with high BMI values [11]. Another study has reported a correlation between obesity and NSSI and verified the correlation between BMI and major depressive disorder [12], but no precise research has explored the correlation between BMI and NSSI. NSSI is quite different from suicidal behavior in many aspects such as motivation, lethality, and manifestation; however, it remains a crucial risk factor for suicidal ideation and suicide attempts. This finding also suggests that psychological problems play an essential role in determining how BMI leads to NSSI.

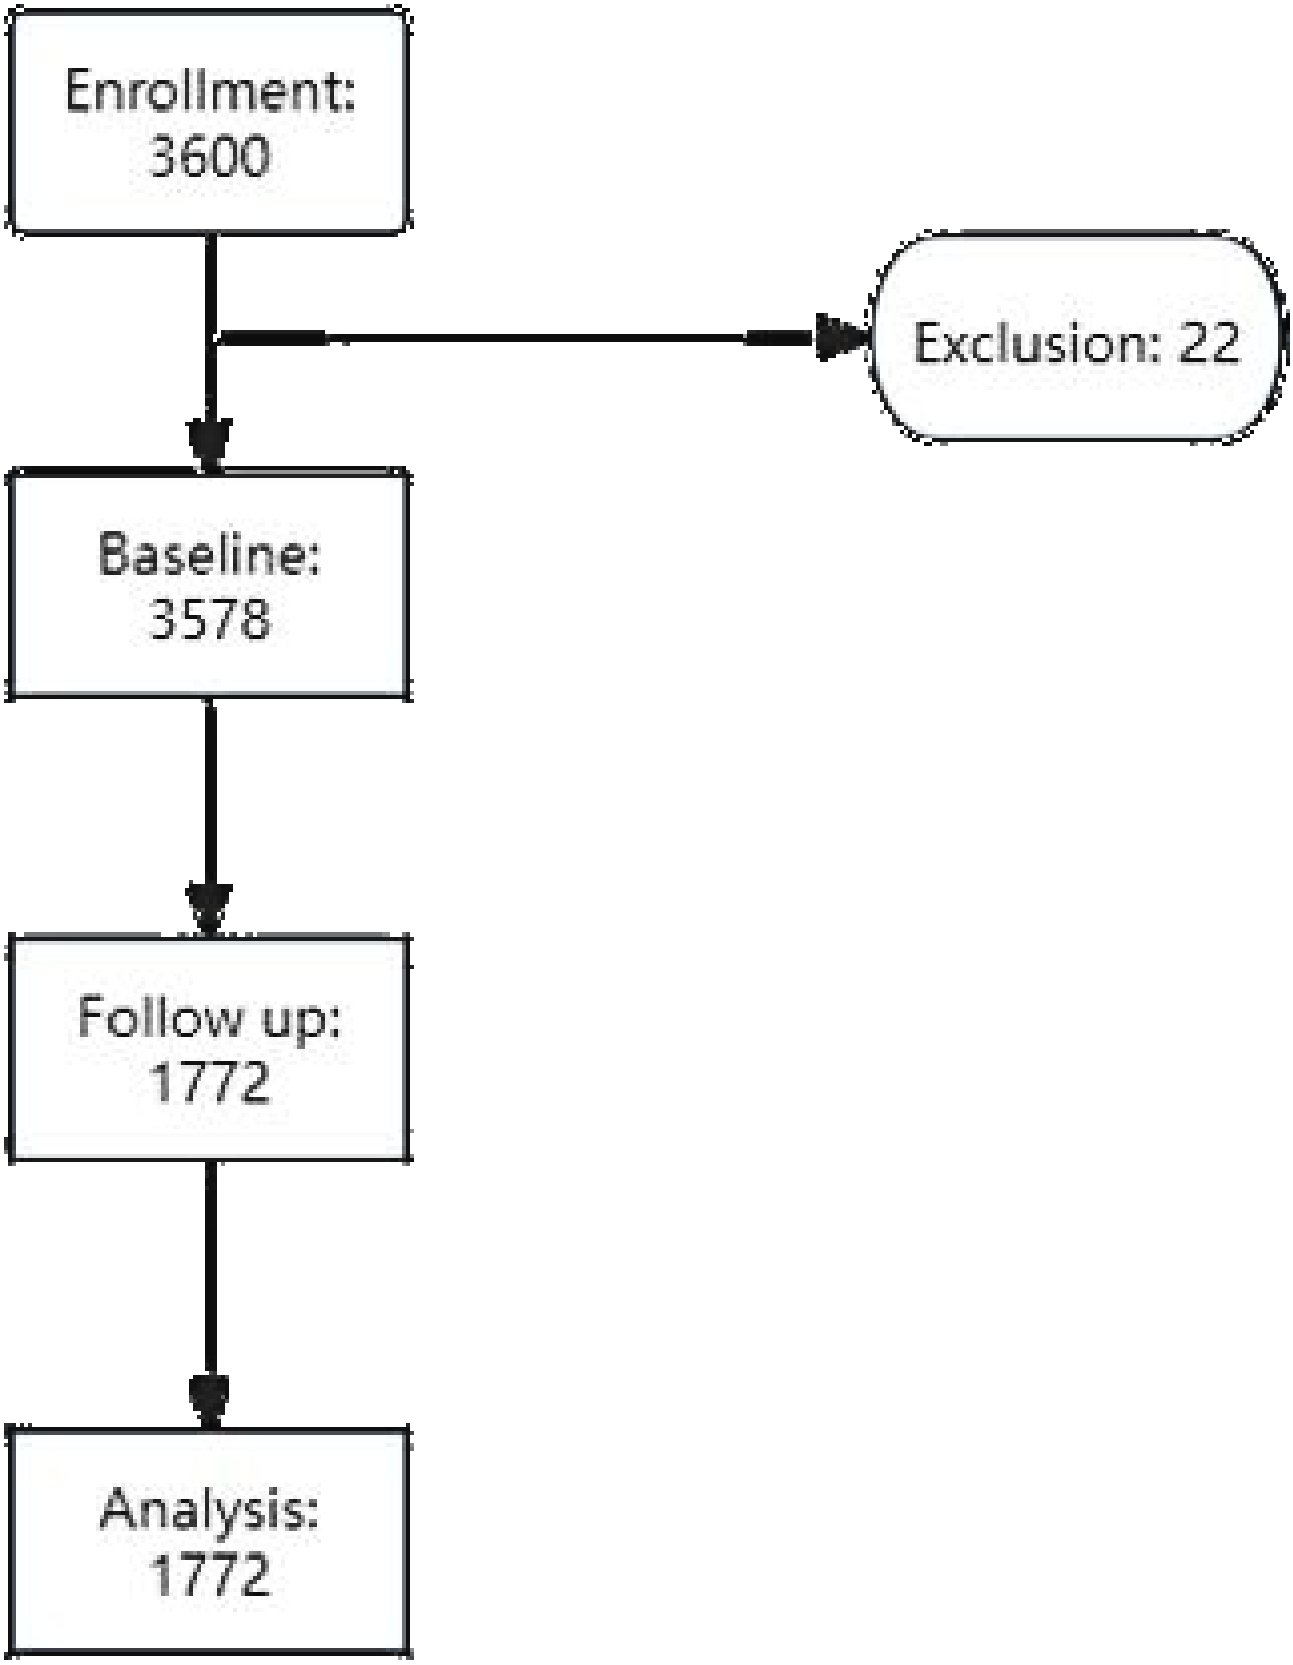
Although some studies identified BMI as a risk factor for self-injury or suicide, other studies have not found positive results, which means that not everyone with an increased BMI necessarily shows NSSI behavior [13], as other factors may also be at play. To identify other possible psychological mechanisms that support this relationship, it is necessary to understand complex associations and mechanisms beyond the current one. In addition to the association between BMI and NSSI, it is significant to understand the mediators and moderators of BMI and NSSI for public health prevention and clinical practice. Research on borderline personality disorder has revealed that sleep deprivation, disrupted sleep, and prolonged sleep duration are associated with suicidal behavior or NSSI [14]. Sleep occupies a very important position in the circadian rhythm, especially the lack of sleep; the circadian rhythm refers to the 24-hour physiological and behavioral rhythm of individuals, which is divided into endogenous rhythm and exogenous rhythm. When the endogenous rhythm and exogenous rhythm are "mismatched," circadian rhythms can be disrupted, which can lead to sleep disturbances [15]. Chronotype is a self-description of an individual's circadian preference, reflecting the differences in their daily activity pattern and sleep-wake cycle; it can be generally divided into three types: morning, intermediate, and evening [16]. Moreover, the evening type has been reported to be strongly associated with suicidal behavior [17].

These studies provide evidence that NSSI moderates the relationship between BMI and socioenvironmental factors. A higher BMI has been associated with a lower risk of suicide in a large prospective study [18]; however, the mechanisms underlying this link require elucidation. Some studies have verified the correlation between self-esteem and NSSI [17,19]. However, little is known about how self-esteem moderates the relationship between BMI and NSSI. Socioenvironmental factors underlying these associations also remain unclear. Moreover, only limited research has been conducted on the relationship between BMI and socioenvironmental factors, and the outcome of NSSI during adolescence. A systematic review and meta-analysis reported that treatment of childhood obesity resulted in increased self-esteem after intervention [19]. The results of studies evaluating the self-esteem and NSSI suggest that although low self-esteem and self-injury are associated with both clinical and nonclinical populations, there are many factors influencing this relationship [20]. Therefore, based on a previous study [19], we hypothesize that there was an association among SE, BMI, and NSSI.

From a management and prevention perspective, these modifiable risk factors are crucial, and how they interact with each other requires further exploration. This study aimed to investigate the influencing factors and possible mechanisms of NSSI in college students and to observe the influence of some possible factors on BMI that could result in NSSI. Therefore, this study aimed to (1) examine the correlation among BMI, socioenvironmental factors, self-esteem, and NSSI and (2) determine whether socioenvironmental factors and self-esteem

XSL•FO
RenderX

would play direct and indirect roles in the relationships between BMI and NSSI among Chinese college students.



Methods

Study Design and Study Setting for Recruitment

This was a longitudinal study, and the research methods have been described in previous studies [21,22]. The study setting for recruitment was as follows: we first selected a university in a city in the Anhui Province, and then selected college students in four consecutive grades according to the cluster sampling method. A total of 3600 college students were initially recruited using an anonymous electronic questionnaire survey about their health at baseline. The cluster sampling method was used for the schools surveyed, and most of the students from each grade were included in the study. The survey was conducted from May to June 2022. Some participants were excluded from the study owing to unwillingness to answer the questionnaire, absence from class, high levels of missing data (questionnaires with missing values greater than 5% were eliminated), or false responses [23-25] at baseline. The baseline group was followed up with a questionnaire after 6 months. Finally, a total of 1772 participants were included in the follow-up survey (Figure 1).

XSL•FO
RenderX

Figure 1. A flowchart for the enrollment and follow-up of participants.

Inclusion Criteria

Participants were included if (1) informed consent from them and their guardians were obtained, (2) they were college students aged 15 - 26 years, (3) they had no history of mental illness, and (4) they were attending the chosen school.

Exclusion Criteria

Participants were excluded if (1) their informed consent was not obtained, (2) they were junior and high school students, (3) they failed to submit the questionnaire, or (4) they had congenital or acquired immunodeficiency.

XSL•FO
RenderX

Exposure

Chronotype

The morningness-eveningness questionnaire is used to measure college students' sleep habits. According to the previous analysis results, personal sleep habits is classified into three types: morning, intermediate, and evening [26]. The suggested demarcations were further categorized as follows: sleeping from 4 AM to 7 AM is definitely eveningness, sleeping from 8 AM to 11 AM is medium eveningness, sleeping from 12 PM to 5 PM is intermediate type, sleeping from 6 PM to 9 PM is medium morningness, and sleeping from 10 PM to 12 AM is definitely morningness.

Self-Esteem

The self-esteem scale was first developed by Ronsenberg to evaluate an individual's overall feelings of self-worth and self-acceptance [27]. It was later translated and revised into Chinese by Ji Fuyi and Yu Xin [28]. There were 10 items on the scale: 5 items on self-denial and 5 items on self-affirmation. A 4-point Likert scale was used, ranging from 1 indicating "very inconsistent" to 4 indicating "very consistent." The 5 self-denial items were scored inversely. The higher the score, the higher the self-esteem.

Outcome

NSSI

One of the most important question in the questionnaire was "Have you intentionally hurt yourself in the past 12 months, but not for suicide?" The questionnaire also listed several NSSI methods: hit yourself with a fist or palm, pulled your hair, hit a hard object with your head or fist, pinched or scratched yourself, bit yourself, cut yourself, and stabbed yourself. Those who had an NSSI were asked about their NSSI frequency. The participants owning up to 5 or more methods were considered to be prone to NSSI [29].

Statistics Analysis

Conventional means and SDs were used for continuous variables. Univariate ANOVA was used to describe the association between independent and outcome variables. Frequency and percentage tests were used for categorical variables, and chi-square tests were used to explore the association between independent and outcome variables. The PROCESS method was used to conduct a mediation-moderation analysis to explore the relationships among BMI, chronotype, self-esteem, and NSSI [30]. The bootstrap method was used to resample 1000 samples, and the 95% CI was calculated. All data were analyzed using SPSS software (Windows version 23.0; IBM Corp).

Ethical Considerations

The current study is designed and reported according to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist. The design and data collection procedures were approved by the Ethics Committee of the First Affiliated Hospital of Anhui Medical University (review number PJ 2024-06-06). Written informed consent was obtained from the parents or guardians of all the students.

Results

General Demographic Characteristics

Table 1 presents the general distribution of the NSSI variables examined in this study considering the demographic characteristics, while Figure 2 is a directed acyclic graph showing the covariates. Among the 1772 participants included in the questionnaire analysis, 908 (51.1%) were male students; the mean age was 20.53 (SD 1.65) years at baseline; and 853 (48.1%) dwelled in rural areas, 548 (30.9%) in towns, and 371 (20.9%) in urban areas. The prevalence of NSSI was 5.6% (N=1772).

Figure 2. A directed acyclic graph showing the covariates. NSSI: nonsuicidal self-injury.

Association Between Independent Variables and Adolescent Psychological and Behavioral Problems

Table 2 presents the correlation between independent variables and depression symptoms through multilevel linear regression analyses. There was a significant relationship between different BMI and NSSI (β=.056); after controlling for covariates, these relationships were also significant. Furthermore, there was a significant relationship between self-esteem and NSSI (β=−.077); after controlling for covariates, this relationship was also significant. There was no significant correlation between chronotype and NSSI.

Table . Multilevel linear regression between independent variables and nonsuicidal self-injury (NSSI).

Impact of the Mediation Analysis Among BMI, Chronotype, and Self-Esteem on Adolescent NSSI

Mediation-moderation analyses were performed for BMI, self-esteem, chronotype, and NSSI scores. The results are listed in Tables 3 and 4. Among NSSI, findings have suggested the following: a positive association between BMI exposure and NSSI, chronotype was associated with NSSI, and chronotype played a moderating role in the increased risk of NSSI induced by BMI mediated by self-esteem.

Impact of Mediation Analysis Among BMI, Mental Health, and Self-Esteem on Adolescent NSSI

Mediation-moderation analyses were performed for BMI, self-esteem, mental health, and NSSI. The results are presented in Tables 5 and 6. In NSSI, results have suggested a positive association between BMI exposure and NSSI, where depression was associated with NSSI, and chronotype played a moderating role in the increased risk of NSSI induced by BMI and mediated by self-esteem (Tables 5 and 7). Similar results were obtained for stress and NSSI (Tables 6 and 8).

Discussion

Principal Findings

In our study, the prevalence of NSSI in a sample of college students was 5.6%. Here, we examined the combination of chronotype and mental health as well as the interaction effect among BMI, self-esteem, and NSSI. BMI was positively correlated with the development of NSSI during adolescence, that is, the higher the BMI, the higher was the incidence of NSSI. Consistent with our hypothesis, our study provided evidence that self-esteem mediates the relationship between BMI and NSSI; this relationship was also moderated by chronotype. The relationship among BMI, self-esteem, and NSSI is complex and may involve a moderating effect of chronotype. Therefore, this study developed and evaluated a mediation-moderation model to elucidate the role of multilevel factors, including BMI, self-esteem, and chronotype, in relation to NSSI [31].

Comparison With Other Studies

With the change in social living environment, adolescents are facing increasing pressure and challenges, and adolescent NSSI has become a problem that cannot be ignored. NSSI is a common mental health problem among adolescents [32]. In a college student–related survey, approximately 1 in 5 (20.4%) students reported lifelong NSSI, and the frequency of persistent NSSI was estimated at 56.4%, with 15.6% of students reporting high-frequency repeat patterns (≥5 times per year) [33]. This high prevalence is worth considering, and NSSI is not only associated with suicidal behavior but is also a specific risk factor for suicide. In addition to the burden on individuals and families, including NSSI and self-harm with suicidal intent, the increased incidence of NSSI requires significant health care and economic costs and can lead to death in severe cases, further emphasizing the need to study why people should be concerned about NSSI [34]. Therefore, it is necessary to pay attention to the factors that affect NSSI; some factors have been explored [35-38], such as adverse life events, stressful life events, negative coping styles, problematic internet use, sleep disorders, traumatic experiences, problematic parent-child relationships, and mental health issues. In the same way that obesity causes physical diseases (eg, cardiovascular disease and diabetes), obesity has a significant triggering effect on the number of times of suicide attempts [39]. However, a population-based telephone survey of US adults conducted by the Centers for Disease Control and Prevention found that traditional suicide risk factors do not show any correlation with BMI; therefore, there is unlikely to be any relationship between BMI and a lower risk of suicide [18]. That said, in some cases, it is not entirely the case that a higher BMI is associated with a greater number of risk factors. Further research into the relationship between BMI and suicide may lead to new modifiable risk factors that can result in or prevent this key cause of death [18]. This also encourages us to look beyond the known causes of suicidal behavior, as there are other factors at play in psychological research.

In the aforementioned research, individual factors are very important, and self-esteem is an important individual factor [20]. Such studies might shed light on how obesity interacts with chronotype factors and can affect self-esteem in people with NSSI [40]. Regarding the association between obesity and suicide-related variables, 3 out of 5 studies investigating these suicide attempts showed a positive association between these attempts and obesity, and this relationship may be related to the reduction in self-worth and self-esteem caused by obesity-related stigma, suggesting that self-esteem plays a key role in BMI-induced suicide attempts [20, 41]; the results suggest that although low self-esteem and NSSI are correlated in both clinical and nonclinical populations, many factors influencing this relationship still exist [20], which needs to be confirmed by further research. According to the developmental psychopathological model, individuals' negative understanding and evaluation of themselves will lead to the emergence of NSSI, so low self-esteem is an important variable that triggers NSSI. Therefore, another study demonstrated the mediating

XSL•FO
RenderX

role of self-esteem in the relationship between BMI and depression or suicidality, as well as the moderating role of sex in the mediated pathways [20], which also provides an effective theoretical basis for our research. It is noteworthy that self-esteem is a crucial factor given its significance in depression and NSSI. This study, thus, converges with the existing literature and extends it. Moreover, we noticed that chronotype patterns could moderate these relationships, and sleep deprivation itself could influence an increase in psychobehavioral problems [42]. Another review concluded that people with bipolar disorder are characterized by extreme mood swings, high rates of suicide, sleep problems, and dysfunction in psychological characteristics, such as self-esteem (a feeling ranked below depression and above mania), which further provides a theoretical basis for understanding the relationship between sleep, self-esteem, and metabolism [43]. The current findings highlight the importance of assessing self-esteem in mediating BMI and NSSI, perhaps targeting self-esteem to mitigate self-esteem–related mental health problems (eg, NSSI and suicide). We also considered the effect of the moderator mental health on BMI and NSSI. The stigma associated with being overweight has increased in recent decades, which may have exacerbated the harmful effects of being overweight on mental health [44], thereby further elevating the occurrence of NSSI.

Another study explored the relationship between adolescents' BMI and mental health issues, including social phobia, depression, suicidal tendencies, and low self-esteem, and the mediating role of sex in participation in bullying [45]. Therefore, this provides a theoretical basis for our study that BMI is closely related to self-esteem, mental health, and suicidal behavior, and the correlation among the variables is also affected by other variables. According to the US Health and Retirement Study, baseline BMI, BMI transition, and BMI trajectory play significant moderating roles in the positive association between adverse childhood experience with new-onset all-cause dementia and Alzheimer disease [46]. The possible mechanisms include increased insulin and glucagon levels in the plasma and cerebrospinal fluid [47]. Additionally, our findings highlight the need for a multidisciplinary, collaborative, and integrated approach to optimize patient care. Different mechanisms have been identified, including gut-brain mechanisms, inflammatory responses (changes in the neutrophil-lymphocyte ratio, monocyte-lymphocyte ratio, and platelet-lymphocyte ratio), and changes in cytokine levels (interferon-γ, interleukin-1β, interleukin-6, interleukin-8, monocyte chemoattractant protein-1, tumor necrosis factor-α, and transforming growth factor-β1) [48].

Clinical Practices

Overweight and obese adolescents often experience prejudice due to the surrounding environment, which causes them to have low self-esteem, depression, and other negative emotions; engage in bad behaviors; cause self-injury; and harbor suicidal thoughts. As sociality is an essential attribute of adolescents, overweight and obese adolescents should communicate with others and obtain support, thereby effectively reducing the occurrence of NSSI. By further exploring the two variables of chronotype and self-esteem, this study aimed to explore the sociological pathway of BMI leading to NSSI.

Strengths and Limitations

The strengths of this study are its longitudinal design and large number of participants. The purpose of mediating is to strengthen the quasi-causal inference about the mechanism by which independent variables influence outcomes, whereas the purpose of moderating is to examine variables that influence the strength and direction of the predictor-outcome relationship. The use of moderated mediation could help identify the interdependence between the BMI and chronotypes. We also explored the role of the processes between early BMI and NSSI later in life.

However, this study has some limitations. First, although this was a follow-up study, only one follow-up survey was conducted, and changes in BMI were not evaluated during this process. These data are self-reported survey data, which can inevitably produce potential recall bias; therefore, we will further correct for the bias caused by recall bias in the future. Second, the study examined results in only one city; it is not clear how representative this sample is. Therefore, follow-up surveys are needed with samples from different regions and cultures across the country. Third, although this study mainly focuses on the relationship between BMI and NSSI under the influence of different factors, biological indicators will be included for further discussion in the future. Finally, we must consider critical attitudes toward the potential mechanism. As only some variables were evaluated in this study, additional variables with psychosocial factors should be considered in the future [48].

Conclusion

In this study, there was a combination effect of BMI, self-esteem, and NSSI, as well as an interaction effect among BMI, self-esteem, and NSSI. NSSI prevention programs should focus on evidence-based approaches relevant to public health and address them in conjunction with relevant influencing factors, including a wide range of interventions such as self-help programs, education, policy change, and legislation. Stronger inferences about the role of BMI in the etiology of adolescent NSSI can be made by exploring sex and ameliorating unfavorable mental health in prospective cohort studies. Future studies should expand upon our small subset of measured variables to paint a broader picture of adolescent NSSI in response to early-life social, psychological, and environmental stimuli.

Acknowledgments

We would like to acknowledge all hospital action teams, the staff and participants from the participating hospitals, and our cooperators for assistance in data collection. Abstract

Background: Self-efficacy in mpox (formerly known as monkeypox) prevention plays a pivotal role in promoting preventive behaviors by fostering a sense of control and motivation, especially among men who have sex with men (MSM), the population most affected by mpox in many countries.

Objective: This study aims to assess the mpox prevention self-efficacy among MSM in China and identify factors influencing it, using a validated mpox prevention self-efficacy scale.

Methods: From October 2023 to March 2024, a nationwide cross-sectional study was conducted among MSM (aged ≥18 years) across 6 geographic regions in China using a snowball sampling method. The recruited participants (effective response rate=2403/2481, 96.9%) were asked to complete an anonymous questionnaire designed based on prior knowledge of mpox and social cognitive theory. The mpox prevention self-efficacy scale was evaluated for construct validity using exploratory factor analysis and confirmatory factor analysis, and its reliability was assessed using the Cronbach α coefficient. Univariate and multivariable logistic regression analyses were used to examine the factors associated with mpox prevention self-efficacy among MSM.

Results: A total of 2403 MSM participants were included, with a mean age of 29 (IQR 19 - 39) years. Of these, 1228 (51.1%) were aged 25 - 34 years, 1888 (78.6%) held a college degree or higher, and 2035 (84.7%) were unmarried. The median mpox prevention self-efficacy score was 23 (IQR 18 - 28). Exploratory factor analysis retained 6 items of the mpox prevention self-efficacy scale. Confirmatory factor analysis confirmed a strong model fit (χ^2 =32.1, n=1225; *P*<.001; comparative fit index=0.991; root mean square error of approximation=0.067; standardized root mean square residual=0.02; goodness-of-fit index=0.992; normed fit index=0.990; incremental fit index=0.991; Tucker-Lewis index=0.974), with all indices within acceptable ranges. The scale demonstrated good internal consistency, with a Cronbach α of 0.859. The positive factors associated with mpox prevention self-efficacy were mpox-related knowledge (OR 1.107, 95% CI 1.070 - 1.146), perceived risk awareness (OR 1.338, 95% CI 1.132 - 1.583), and mpox risk perception (OR 1.154, 95% CI 1.066 - 1.250), while the negative factor was age, with individuals aged 25 years and older exhibiting lower self-efficacy in mpox prevention (25 - 34 years: OR 0.789, 95% CI 0.642 - 0.970; 35 - 44 years: OR 0.572, 95% CI 0.444 - 0.736; 45 years and older: OR 0.569, 95% CI 0.394 - 0.823).

Conclusions: These findings highlight the critical role of targeted interventions to enhance mpox prevention self-efficacy, particularly through increasing knowledge, perceived risk awareness, and risk perception. Such interventions are especially important for middle-aged and older MSM, who may experience a decline in self-efficacy. Strengthening self-efficacy in these areas is essential for promoting sustained preventive behaviors, improving mental well-being, and contributing to more effective mpox prevention and control within the MSM community.

KEYWORDS

mpox; self-efficacy; men who have sex with men; MSM; monkeypox; cross-sectional study; mpox prevention self-efficacy scale

Introduction

Mpox (formerly known as monkeypox) is a viral illness caused by the *Monkeypox virus*, typically characterized by a skin rash or mucosal lesions lasting 2‐4 weeks. Other symptoms include headache, fever, back pain, muscle aches, fatigue, and swollen lymph nodes [1]. The World Health Organization declared the mpox outbreak a Public Health Emergency of International Concern twice: in July 2022 and again in August 2024 [2,3]. As of June 30, 2024, there were 99,176 confirmed cases and 208 deaths reported across 116 countries, including 2460 cases in China [4]. The outbreak predominantly affects men who have sex with men (MSM), who account for 85.8% of cases with known sexual behavior data [4,5]. China, with the world's largest MSM population—estimated at 8.3 million, nearly 1.8 times the size of the United States' MSM population—faces unique public health challenges in controlling mpox transmission [6]. In response, the National Disease Control Bureau of China, in collaboration with the National Health Commission, implemented a prevention and control strategy for mpox [7]. This includes educating high-risk populations, promoting self-protection among MSM, and encouraging timely medical consultations. Although the outbreak in China has been effectively controlled since September 2023, the high mobility and risk behaviors of the MSM population require continued vigilance and proactive measures [8].

According to social cognitive theory, self-efficacy, defined as the belief in one's ability to perform actions necessary to achieve desired outcomes [9], is a key factor in initiating and maintaining health-related behaviors [10]. Self-efficacy has been found to mediate the relationship between HIV self-testing provision and testing frequency among MSM [11], while it also directly influences the uptake of pre-exposure prophylaxis in this population [12], suggesting that enhancing self-efficacy may serve as an effective strategy to improve preventive health behaviors in at-risk populations. In the context of mpox prevention, self-efficacy is particularly critical for MSM, as it influences their confidence in adopting preventive measures, such as consistent condom use, vaccination, testing, and seeking timely medical care [13-16]. High self-efficacy has been associated with greater motivation to engage in mpox prevention behaviors and better adherence to preventive strategies, even among MSM who may continue to engage in high-risk behaviors despite awareness of mpox [17,18]. Given these findings, understanding mpox prevention self-efficacy in MSM is essential for informing targeted interventions and enhancing prevention strategies by identifying priority groups and potential barriers to mpox prevention and control.

A significant challenge in studying self-efficacy in mpox prevention is the lack of standardized measurement tools. Previous studies have primarily relied on single-item measures to assess the association between self-efficacy and mpox vaccination intentions [16,19] or used generalized instruments such as the General Self-Efficacy Scale or isolated questions [19,20]. Although these tools provide a general assessment, they fail to capture the nuanced dimensions of self-efficacy specific to mpox prevention. This limitation is particularly pronounced in the MSM population, where tailored assessments are essential to address unique behavioral and psychosocial factors. The lack of specificity and comprehensiveness in these existing measures not only undermines the validity of research findings, but also hampers the development of targeted interventions. Therefore, there is a clear need for tools specifically tailored to mpox prevention, integrating established scales with the unique characteristics of mpox.

Existing research indicates that the self-efficacy of MSM in preventing mpox may be influenced by multiple factors at various levels, including sociodemographic characteristics (eg, age, education level) [21], behavioral factors (eg, engagement in unsafe sexual practices) [22], and disease-related factors (eg, disease-related knowledge, risk perception) [23]. Research indicates that disease-related knowledge forms the basis for accurate health beliefs and enhances confidence in adopting safe sexual behaviors. A positive correlation has been observed between the level of disease-related knowledge and self-efficacy [24,25]. Additionally, mpox perceived risk awareness refers to individuals' recognition of the potential harm or likelihood of mpox in their surroundings [26,27], while risk perception pertains to the subjective judgment of one's personal susceptibility to mpox [28]. Evidence suggests that risk perception is a key trigger for both preventive awareness and action [29]. Along with disease-specific knowledge and awareness of environmental health risks, risk perception significantly influences mpox prevention awareness and behaviors [30]. However, the relationship between mpox perceived risk awareness, mpox risk perception, and self-efficacy, particularly among MSM, remains an underexplored area.

Given the critical role of self-efficacy in sustaining preventive motivation and goal-directed behavior among MSM, it is essential to assess it within the context of mpox prevention. While existing research on mpox prevention in MSM has primarily focused on vaccination willingness and testing behavior [15,31-33], there is a notable gap in understanding the self-efficacy of MSM in mpox prevention and the factors that influence it. Identifying these factors can help guide the development of targeted interventions. This study aims to evaluate mpox prevention self-efficacy among MSM in China, examining the impacts of sociodemographic characteristics, mpox-related knowledge, perceived risk awareness, and risk perception. By identifying these factors, the study seeks to provide a theoretical basis for designing more effective mpox prevention strategies tailored to this vulnerable population, while simultaneously contributing to improved behavioral outcomes and mental well-being within the MSM community.

Methods

Study Design

From October 2023 to March 2024, a nationwide cross-sectional study was conducted among MSM (age ≥18 years) across 6 geographic regions in China. Survey sites were located in the Northwest (Xinjiang Uyghur Autonomous Region), Northeast (Liaoning Province), Central (Shaanxi Province), Southwest (Yunnan Province), Southeast (Guangdong Province), and Eastern coastal region (Shanghai Municipality). Details of the program have been described previously [34].

Participant Recruitment and Data Collection

Eligibility criteria for participants included: (1) born male; (2) aged ≥18 years old; (3) have ever engaged in sex with men within the last six months; (4) primarily reside in one of the selected locations during the same period; and (5) agree to participate in the survey. Simultaneously, participants were excluded if they: (1) completed the questionnaire within 300 seconds; (2) failed the quality control questions (eg, Is Guangzhou, Shanghai, Beijing, or Shenzhen the capital city in China?); and (3) had an IP address indicating a location outside the target regions.

Participants were recruited from 6 cities in China with the assistance of local governmental centers for disease control and non-governmental organizations (NGOs), using a snowball sampling method. The NGOs routinely engaged with the MSM population in the region and were well-acquainted with local disease prevention and control initiatives. Initially, NGO staff, serving as primary investigators in each region, underwent training on recruitment procedures. They were tasked with recruiting 5‐10 "seed" participants (MSM individuals with good outreach potential) who met the inclusion criteria from each region. These seed participants were then asked to recruit additional participants from their social networks until the target sample size was achieved. Data collection was conducted entirely anonymously through an online survey. Participants accessed the electronic questionnaire via QR code scanning at designated survey locations. NGO staff assisted participants in completing the online survey, providing technical support and non-directive guidance as necessary, in accordance with the study protocol outlined previously [34].

After thorough verification, a total of 2481 questionnaires were collected, of which 2403 were deemed valid, yielding an effective response rate of 96.9%. The collected data underwent thorough cleaning and processing, including checks for missing data, outliers, and logical inconsistencies, with necessary adjustments and corrections made accordingly.

Ethical Considerations

The study was approved by Shanghai University of Medicine and Health Sciences (approval number 2023-MSMMPOX-22‐310222197604080237) on October 8, 2023. All participants signed electronic informed consent forms. Data collection was conducted anonymously using an electronic questionnaire administered through a secure, privacy-compliant platform (Wenjuanxing) via QR code scanning. To encourage participation, each individual who completed the survey and passed quality checks received Chinese yuan (CNY) 80 (about US $10.96). To ensure confidentiality, deidentified data were used for subsequent analysis.

Variables

Sociodemographic Characteristics

A range of sociodemographic characteristics (including age, education level, marital status, and monthly income) and disease diagnoses (including hypertension, diabetes, and hyperlipidemia) were assessed via self-report.

Mpox Prevention Self-Efficacy

Based on Bandura's self-efficacy theory and established scales [19], such as the HIV Prevention Self-Efficacy Scale [35] and the Self-Efficacy for HIV Prevention Behaviors Scale [36], we developed a 6-item mpox prevention self-efficacy scale tailored to the characteristics of MSM and mpox prevention. The scale aimed to assess individuals' confidence in their ability to effectively prevent mpox. Each item was rated on a 5-point Likert scale, ranging from "1 strongly disagree" to "5 strongly agree," as described in Table S1 in Multimedia Appendix 1. The composite variable was calculated by summing the scores of these items (range: 6‐30, Cronbach α=0.859), with a higher score indicating higher mpox prevention self-efficacy. A total score was categorized into 2 groups based on the median (median=23, skewness=−0.94): no/low self-efficacy (<23) and self-efficacy (≥23). When the independent variables are uncorrelated and exhibit a skewed distribution, the median is considered an effective tool for segmentation, which is the case for the variables in our study [37,38].

Mpox-Related Knowledge

Mpox-related knowledge included 12 yes/no questions designed to evaluate participants' understanding of mpox, covering various aspects such as pathogenesis (eg, "Mpox is a viral infectious disease"), epidemiological characteristics (eg, "Mpox can be transmitted through mucous membranes and broken skin"), clinical manifestations (eg, "The only symptom of mpox is a rash"), and preventive measures (eg, "Smallpox vaccination can be used to prevent mpox"). The overall score was calculated by counting the number of correct answers, with each correct response scoring 1 point. Higher scores indicated greater knowledge of mpox, with a possible range of 0‐12 (Cronbach α=0.80).

Mpox Perceived Risk Awareness

Perceived risk awareness, primarily utilized in public environmental health research, refers to the level of participants' attentiveness to potential risks in their environment [26,27]. We developed a composite variable for mpox perceived risk awareness based on 4 statements [28], each rated on a 5-point Likert scale (from "1=strongly agree" to "5=strongly disagree"). A composite scale score was calculated by summing the item scores, with higher scores indicating greater awareness of risks associated with mpox (range: 0‐20; Cronbach α=0.906). A total score was categorized into 2 groups based on the median: low perceived risk awareness (<17.00) and high perceived risk awareness (≥17.00).

XSL•FO
RenderX

Mpox Risk Perception

Risk perception refers to how people perceive the likelihood of experiencing harm or loss due to a disease and represents a subjective judgment of disease susceptibility [28]. It is a core construct in many health behavior theories, such as the Protection Motivation Theory and the Health Belief Model [39]. In the Health Belief Model, risk perception encompasses perceived susceptibility (belief in the likelihood of contracting a disease) and perceived severity (the perceived seriousness of the disease) [40]. In this study, considering the substantial variability in the clinical manifestations of mpox among individuals, mpox risk perception specifically focuses on participants' beliefs regarding the likelihood of contracting mpox. The statement "I believe I am someone who is likely to contract mpox" was used to assess personal mpox risk perception on a 5-point Likert scale, ranging from "strongly disagree" to "strongly agree" [28].

Statistical Analysis

First, descriptive statistics were used to characterize the distribution of the variables. Continuous variables, which were non-normally distributed, were presented as medians and IQRs, while categorical variables were described using frequencies and percentages. Second, the content validity of the questionnaire was evaluated using the critical ratio method and Spearman correlation coefficient (N=2403). The total scores of the mpox prevention self-efficacy scale were ranked from low to high, with the bottom 27% classified as the low-score group and the top 27% as the high-score group. The discrimination of each item was tested using an independent samples *t* test between these 2 groups. Additionally, the total sample was randomly split into 2 subsets using a random number method: one subset (n=1178) was used for exploratory factor analysis (EFA), and the other (n=1225) for confirmatory factor analysis (CFA), to cross-validate the scale. For EFA, the feasibility of factor analysis was assessed using the Kaiser-Meyer-Olkin test and Bartlett test of sphericity. For CFA, model fit was assessed using several fit indices: the chi-square goodness-of-fit (χ^2/df), goodness-of-fit index (GFI), root mean square error of approximation (RMSEA), standardized root mean square residual (SRMR), normed fit index (NFI), comparative fit index (CFI), Tucker-Lewis index (TLI), and incremental fit index (IFI). The average variance extracted and composite reliability were also computed to assess the scale's convergent and discriminant validity. Third, univariate logistic regression was employed to examine the crude associations between the outcome variable and the variables of interest (ie, mpox-related and demographic variables). Fourth, a multivariable logistic regression analysis was performed to identify factors associated with mpox prevention self-efficacy, using the Enter method. Odds ratios (OR) and 95% CIs were estimated. Variance inflation factors were calculated to ensure the independence of each variable in the model, as described in Table S2 in Multimedia Appendix 2. The Hosmer-Lemeshow test indicated a good model fit (χ^2_8=6.047, *P*=.642). Descriptive, univariate, and multivariable analyses were conducted using SPSS software (version 22.0; IBM Corp). The reliability and validity of the questionnaire were assessed using AMOS software (version 28.0; IBM Corp). Forest plots were generated using GraphPad Prism software (version 9.5; GraphPad Software Inc).

Results

Demographic Characteristics

The median age of participants was 29 (IQR 19 - 39) years old. In the 30-point self-efficacy score, the median mpox prevention self-efficacy score was 23 (IQR 18 - 28). The majority held a college degree or higher (n=1888, 78.6%), were unmarried (n=2035, 84.7%), and did not have diabetes (n=2334, 97.1%), hypertension (n=2248, 93.6%), or hyperlipidemia (n=2181, 90.8%). Among the participants, those with a college education or higher (1017/1888, 53.9%) and those who were divorced or widowed (62/113, 54.9%) demonstrated higher levels of mpox prevention self-efficacy (Table 1).

Reliability and Validity Assessment of the Mpox Prevention Self-Efficacy Scale

Content Validity of the Scale

The results of the independent samples *t* test revealed statistically significant differences between the high-score group (top 27%) and the low-score group (bottom 27%) across all items (*P*<.001), as described in Table S1 in Multimedia Appendix 1. The critical ratio was 65.957, indicating that the scale possesses strong discriminatory power. Furthermore, Pearson correlation analysis demonstrated that the correlation coefficients between the total questionnaire score and the scores of the 6 items ranged from 0.746 to 0.817 (*P*<.001), suggesting that each item is highly representative of the overall construct.

Construct Validity of the Scale

The Kaiser-Meyer-Olkin measure of sampling adequacy was 0.817, and the Bartlett test yielded a χ^2_{15} value of 3442.5 (*P*<.001), indicating that the data were suitable for factor analysis. EFA of the baseline data extracted a single factor with an eigenvalue greater than 1.00, accounting for 60.02% of the total variance. The factor loadings for each item on the common factor ranged from 0.630 to 0.799 (Table 2).

Table . Factor loadings of the mpox prevention self-efficacy scale for men who have sex with men (n=1225).

Path	Standardized factor loadings	SE	*P* value	CR[a]	AVE[b]
C1_1<--Self_efficacy	0.630			0.845	0.478
C1_2<--Self_efficacy	0.640	0.043	<.001		
C1_3<--Self_efficacy	0.645	0.070	<.001		
C1_4<--Self_efficacy	0.664	0.058	<.001		
C1_5<--Self_efficacy	0.752	0.056	<.001		
C1_6<--Self_efficacy	0.799	0.055	<.001		

[a]CR: composite reliability.

[b]AVE: average variance extracted.

We then conducted a CFA on the baseline data to evaluate the global model fit of the factor structure suggested by the EFA, as described in Figure S1 in Multimedia Appendix 3. The overall model fit was good (χ^2_5=32.1, n=1225; *P*<.001; CFI=0.991; RMSEA=0.067; SRMR=0.02; GFI=0.992; NFI=0.990; IFI=0.991; TLI =0.974). All indices were within acceptable ranges, indicating that the model was well-aligned with the data (Table 3).

Table . Model fit index of the mpox prevention self-efficacy scale for men who have sex with men (n=1225).

Model fitting index	Chi-square (*df*)[a]	RMSEA[b]	SRMR[c]	GFI[d]	CFI[e]	NFI[f]	TLI[g]	IFI[h]
Reference value	<3.000	<0.080	<0.050	>0.900	>0.900	>0.900	>0.900	>0.900
Model value	6.416	0.067	0.0184	0.992	0.991	0.990	0.974	0.991

[a]Chi-square (*df*): χ^2 goodness-of-fit.

[b]RMSEA: root mean square error of approximation.

[c]SRMR: standardized root mean square residual.

[d]GFI: goodness-of-fit index.

[e]CFI: comparative fit index.

[f]NFI: normed fit index.

[g]TLI: Tucker-Lewis index.

[h]IFI: incremental fit index.

Reliability Analysis of the Scale

The Cronbach α coefficient for the mpox prevention self-efficacy scale was 0.859, indicating good internal consistency (Cronbach α>0.80).

Factors Associated With Mpox Prevention Self-Efficacy

Univariate Logistic Regression Analysis

Univariate analysis revealed that higher levels of mpox-related knowledge, greater perceived risk awareness, and increased mpox risk perception were significantly associated with higher mpox prevention self-efficacy. Conversely, older MSM demonstrated lower self-efficacy in mpox prevention. All these differences were statistically significant (Table 4).

Multivariable Logistic Regression Analysis

Variables with statistically significant differences from the univariate analysis were included in the multivariable logistic regression model (Figure 1). In this analysis (Y: mpox prevention self-efficacy, 0=no/low self-efficacy, 1=self-efficacy), the positive factors associated with mpox prevention self-efficacy were mpox-related knowledge (OR 1.107, 95% CI 1.070 - 1.146), perceived risk awareness (OR 1.338, 95% CI 1.132 - 1.583), and mpox risk perception (OR 1.154, 95% CI 1.066 - 1.250). Individuals over the age of 25 years may exhibit lower self-efficacy in mpox prevention (25 - 34 years: OR 0.789, 95% CI 0.642 - 0.970; 35 - 44 years: OR 0.572, 95% CI 0.444 - 0.736; 45 years and older: OR 0.569, 95% CI 0.394 - 0.823).

Figure 1. Multivariable logistic regression analysis of mpox prevention self-efficacy among MSM in 6 Chinese cities (N=2403), from a survey conducted from October 2023 to March 2024. The categories "18 - 24 years old" and "low perceived risk awareness" were used as references in the model. MSM: men who have sex with men.

Discussion

Principal Findings

This study represents one of the earliest investigations into mpox prevention self-efficacy and its influencing factors among MSM. Given that the mpox outbreak was once again declared a Public Health Emergency of International Concern in 2024, concerns about the potential spread of the virus—particularly within the MSM community—have intensified. This highlights the critical need for effective preventive strategies tailored to this high-risk group. Considering the crucial role of self-efficacy in health behaviors and disease prevention, our findings offer valuable public health insights for managing mpox outbreaks and enhancing the psychological and behavioral well-being of the MSM population.

Comparison With Prior Work

The study found that the median mpox prevention self-efficacy score was 23 (IQR 18 - 28), with a negatively skewed distribution of self-efficacy scores. This suggests that most participants demonstrated relatively high self-efficacy scores in preventing mpox, though a small proportion reported lower self-efficacy levels. These results indicate that, while the MSM community generally exhibits strong preparedness for mpox prevention, targeted interventions may be necessary for individuals with lower self-efficacy. Establishing and reinforcing high levels of mpox prevention self-efficacy is essential, as it plays a critical role in identifying at-risk populations and implementing targeted interventions [41,42]. Strengthening self-efficacy, particularly among those with lower initial scores, can improve both individual and community-level responses to prevention efforts, thereby contributing to more effective mpox control strategies. Therefore, public health programs should prioritize efforts to improve self-efficacy, focusing on education and risk awareness to increase confidence in preventive actions.

The study found that MSM with an education level of junior high school or below exhibited lower levels of self-efficacy. These findings are consistent with the demographic characteristics observed in previous studies of MSM with mpox [43,44]. Higher education levels may be associated with increased awareness of self-protection measures, which may contribute to higher self-efficacy and a reduction in risky behaviors [45]. This underscores the potential effectiveness of educational interventions aimed at enhancing self-efficacy, particularly for individuals with lower education levels.

An interesting finding of this study is that the proportion of married MSM exhibiting high self-efficacy in mpox prevention was lower compared to their unmarried, divorced, or widowed counterparts, despite the lack of statistical significance (P>.05). This trend may be explained by the fact that unmarried, divorced, or widowed MSM tend to receive less familial support, which may drive them to be more proactive in seeking preventive and self-protective measures to avoid infection [46]. Previous studies have also shown that divorced or widowed MSM tend to have higher levels of mpox-related knowledge compared to married individuals [47], possibly because the latter may be less inclined to seek out information or self-protective behaviors related to mpox [48]. This observation warrants further exploration, as it may suggest that marital status could still influence self-efficacy in mpox prevention, albeit not significantly in this study.

Accurate measurement of self-efficacy is fundamental for developing effective mpox prevention strategies [49]. In this study, the mpox prevention self-efficacy scale was validated and demonstrated strong reliability, validity, and practical utility. Although the General Self-Efficacy Scale, originally developed by Schwarzer and Jerusalem [50], is widely used due to its excellent internal consistency and test-retest reliability, it lacks the specificity required for assessing self-efficacy in the MSM population and in the context of mpox prevention, limiting its applicability in this context. Previous research on mpox predominantly has largely relied on isolated questions to assess self-efficacy, without employing a comprehensive or systematic scale tailored to the MSM community [51]. To fill this gap, this

XSL•FO
RenderX

study designed and evaluated the mpox prevention self-efficacy scale specifically tailored for MSM. The scale offers a more precise tool for assessing self-efficacy and its related factors among MSM, providing valuable insights for future research and interventions aimed at improving mpox prevention strategies.

Univariate analysis revealed a significant negative association between age and mpox prevention self-efficacy, a relationship that remained significant in the multivariable regression model. These findings indicate that older MSM may exhibit lower levels of self-efficacy in mpox prevention compared to their younger counterparts (aged 18 - 24 years). This association may be partially attributed to older MSM having reduced access to mpox-related information. Age has been identified as a key determinant of mpox-related knowledge [52], with older individuals potentially having less exposure to relevant health information, which may contribute to lower awareness, confidence, and self-efficacy in preventing mpox. In contrast, younger MSM, being more familiar with using the internet, are more likely to access mpox-related information. Furthermore, previous studies have shown that older MSM are less willing to change their sexual behavior compared to their younger counterparts [37]. Specifically, older MSM are more likely to maintain risky sexual behaviors even after becoming aware of the health risks associated with mpox, highlighting the need for tailored interventions aimed at this population to enhance their self-efficacy in preventing mpox. Therefore, age-specific communication strategies should be considered in mpox prevention efforts, particularly targeting middle-aged and older MSM through effective media channels. Given that MSM extensively use the internet for socializing, seeking sexual partners, and accessing sexual health information [53,54], eHealth technologies have emerged as promising tools for delivering prevention interventions to this population [55]. Research has shown that enhanced behavioral interventions, such as tailored strategies, can lead to reductions in unprotected sex, while advanced eHealth technologies, including social media platforms, are associated with increased health screening in the MSM community [56]. Therefore, eHealth-based interventions, incorporating targeted communication strategies and educational tools, can be effectively implemented on widely used social platforms or websites to enhance mpox prevention self-efficacy, particularly in populations with lower levels of self-efficacy. Tailored interventions focusing on improving self-efficacy among older and less educated MSM may be particularly beneficial, as these groups tend to exhibit lower self-efficacy, which may increase their susceptibility to infection. These findings underscore the importance of demographic factors in informing targeted mpox prevention strategies, especially in guiding surveillance and health education practices.

This study found that mpox-related knowledge, perceived risk awareness, and risk perception were positively correlated with self-efficacy in mpox prevention. Previous research has demonstrated that attitudes towards a disease are closely linked to disease-related knowledge, suggesting that lower levels of knowledge among MSM are associated with more negative attitudes and decreased intentions to engage in mpox prevention behaviors [57]. Mpox perceived risk awareness reflects beliefs about the potential harm or likelihood of mpox in their surroundings, while risk perception represents a subjective judgment of personal susceptibility to the disease. According to social cognitive theory, individuals who recognize the severity of a negative health condition, believe that it can be avoided, maintain a positive attitude toward recommended actions, and have confidence in their ability to successfully execute these actions are more likely to engage in health-related behaviors [22,58]. Therefore, mpox prevention efforts among MSM should include further public health education and training to enhance perceived risk awareness, provide targeted risk communication, and ensure the privacy and confidentiality of services, which are crucial for effective mpox prevention within this population.

This research has several strengths. First, as one of the earliest studies in China examining mpox prevention self-efficacy among MSM, the findings carry significant public health implications for the prevention and control of mpox outbreaks in the country, while also enhancing the psychological and behavioral well-being of the MSM community. Furthermore, the study's multicenter design contributes to the generalizability of the results, as it incorporates a diverse sample from various regions across China.

Limitations

Despite the valuable insights provided by the study, several limitations must be acknowledged. First, participant recruitment was facilitated by government centers for disease control departments and NGOs using a snowball sampling method, which was used to improve the efficiency of identifying and recruiting members of the hidden MSM population [59]. Although this approach is effective for accessing hard-to-reach groups, it inherently introduces selection bias, as the sample composition is influenced by the characteristics of initial recruits (seeds) and the subsequent limited recruitment chains. Consequently, this may restrict the generalizability of our findings. Second, the sensitive nature of some inquiries, combined with self-reported data, may lead to information bias. Third, the cross-sectional design restricts the ability to infer causality, highlighting the need for future longitudinal studies to further explore the temporal relationships between mpox-related knowledge, perceived risk awareness, risk perception, and self-efficacy. Such prospective research could also evaluate the impact of targeted interventions aimed at enhancing self-efficacy in mpox prevention among MSM.

Conclusion

This study examined the mpox prevention self-efficacy of MSM and its influencing factors, based on the design and evaluation of the mpox prevention self-efficacy scale. The findings demonstrated significant associations between mpox prevention self-efficacy and sociodemographic characteristics, as well as mpox-related factors. These results underscore the importance of targeted interventions to enhance mpox prevention self-efficacy, particularly through efforts to increase mpox-related knowledge, perceived risk awareness, and risk perception. Special attention should be given to middle-aged and older MSM, who may experience a decline in self-efficacy. Future research should adopt longitudinal designs to better

XSL•FO
RenderX

understand the temporal relationships between self-efficacy and related factors, thereby providing more robust evidence to guide the development of effective mpox prevention strategies. Ultimately, these efforts are crucial for improving mpox prevention outcomes and promoting the overall health of the MSM community.

Acknowledgments

The authors would like to express their gratitude to Shanghai Qingai Health Center (Shanghai), Trans China (Yunnan), Consultation Center of AIDS Aid and Health Service (Liaoning), Xinjiang Rong'ai Health Consulting Co Ltd (Xinjiang), Lingnan Partners Community Support Center (Guangdong), and Xi'an Zhitong AIDS Prevention and Health Center (Shaanxi) for their contributions to data collection. We also extend our thanks to all the participants involved in this study. This study was funded by Key discipline projects of Shanghai Three-Year Action Plan for Public Health under Grant (GWVI-11.1-29), Public Health Research Project from Shanghai Disease Control and Prevention Administration (2024GKM30), Changning District Medical and Health Research Special Project (CNKW2022Y08), Tongren Hospital Talent Launch Project (TR2023rc11, TR2024RC10), Science and Technology Commission Shanghai Municipality (number 20JC1410204) for the Seroepidemiological Study of Novel Coronavirus Pneumonia in Key Populations, national health commission of the PRC (grant number Z155080000004), and the Research Fund of Shanghai Tongren Hospital, Shanghai Jiaotong University School of Medicine (TRYJ2024LC13, TRYJ2022LC10).

Data Availability

The datasets generated and analyzed during this study are not publicly available due to privacy and ethical considerations, but are available from the corresponding author on reasonable request.

Authors' Contributions

QG and SL performed the analyses, interpreted the data, and developed the manuscript; MT and HX conceptualized and validated data analyses; JZ and GX contributed to the data collection and provided critical insights into the methodology; JC reviewed and edited the manuscript; YC, FH, and YW designed and supervised this study, and reviewed and edited the manuscript. All authors have made a significant contribution to this study.

Abstract

Background: Achieving high vaccine coverage among clinicians is crucial to curb the spread of influenza. Traditional Chinese medicine (TCM), rooted in cultural symbols and concepts without direct parallels in modern Western medicine, may influence perspectives on vaccination. Therefore, understanding the preferences of TCM clinicians towards influenza vaccines is of great importance.

Objective: To understand preferences for features of influenza vaccination programs and identify the optimal influenza vaccination program among clinicians practicing TCM and Western medicine.

Methods: We conducted a discrete choice experiment with a national sample of 3085 Chinese clinicians from various hospital levels (n=1013 practicing TCM) from January to May 2022. Simulations from choice models using the experimental data generated the coefficients of preference and predicted the uptake rate of different influenza vaccination programs. Clinicians were grouped by vaccine preference classification through a latent class analysis.

Results: All included attributes significantly influenced clinicians' preferences for choosing an influenza vaccination program. An approximate hypothetical 60% increase of vaccine uptake could be obtained when the attitude of the workplace changed from "no notice" to "encouraging of vaccination"; there was an approximate hypothetical 35% increase of vaccine uptake when vaccination campaign strategies changed from "individual appointment" to "vaccination in a workplace setting." In the entire sample, about 30% (946/3085) of clinicians preferred free vaccinations, while 26.5% (819/3085) comprehensively considered all attributes, except vaccination campaign strategies, when making a decision about choosing an influenza vaccination program. Clinicians who practiced TCM, worked in tertiary hospital, or had at least a postgraduate degree exhibited a lower preference for free vaccinations. Clinicians who practiced Western medicine, worked in primary hospital, or had at most a bachelor's degree had a higher preference for vaccinations in workplace settings.

Conclusions: Offering a range of influenza vaccination programs targeting the preferred attributes of different clinician groups could potentially encourage more clinicians, including those practicing TCM, to participate in influenza vaccination programs.

Introduction

Annual seasonal influenza epidemics result in 290,000-650,000 deaths worldwide and over 88,000 preventable deaths in China annually [1,2]. During influenza seasons, health care workers (HCWs) are at a high risk of infection, leading to economic loss for the institutions they work for and potentially causing staff shortages [3]. HCWs may be asked or pressured to work despite having an influenza infection, contributing to clinic- or hospital-acquired influenza transmission [4]. Previous studies

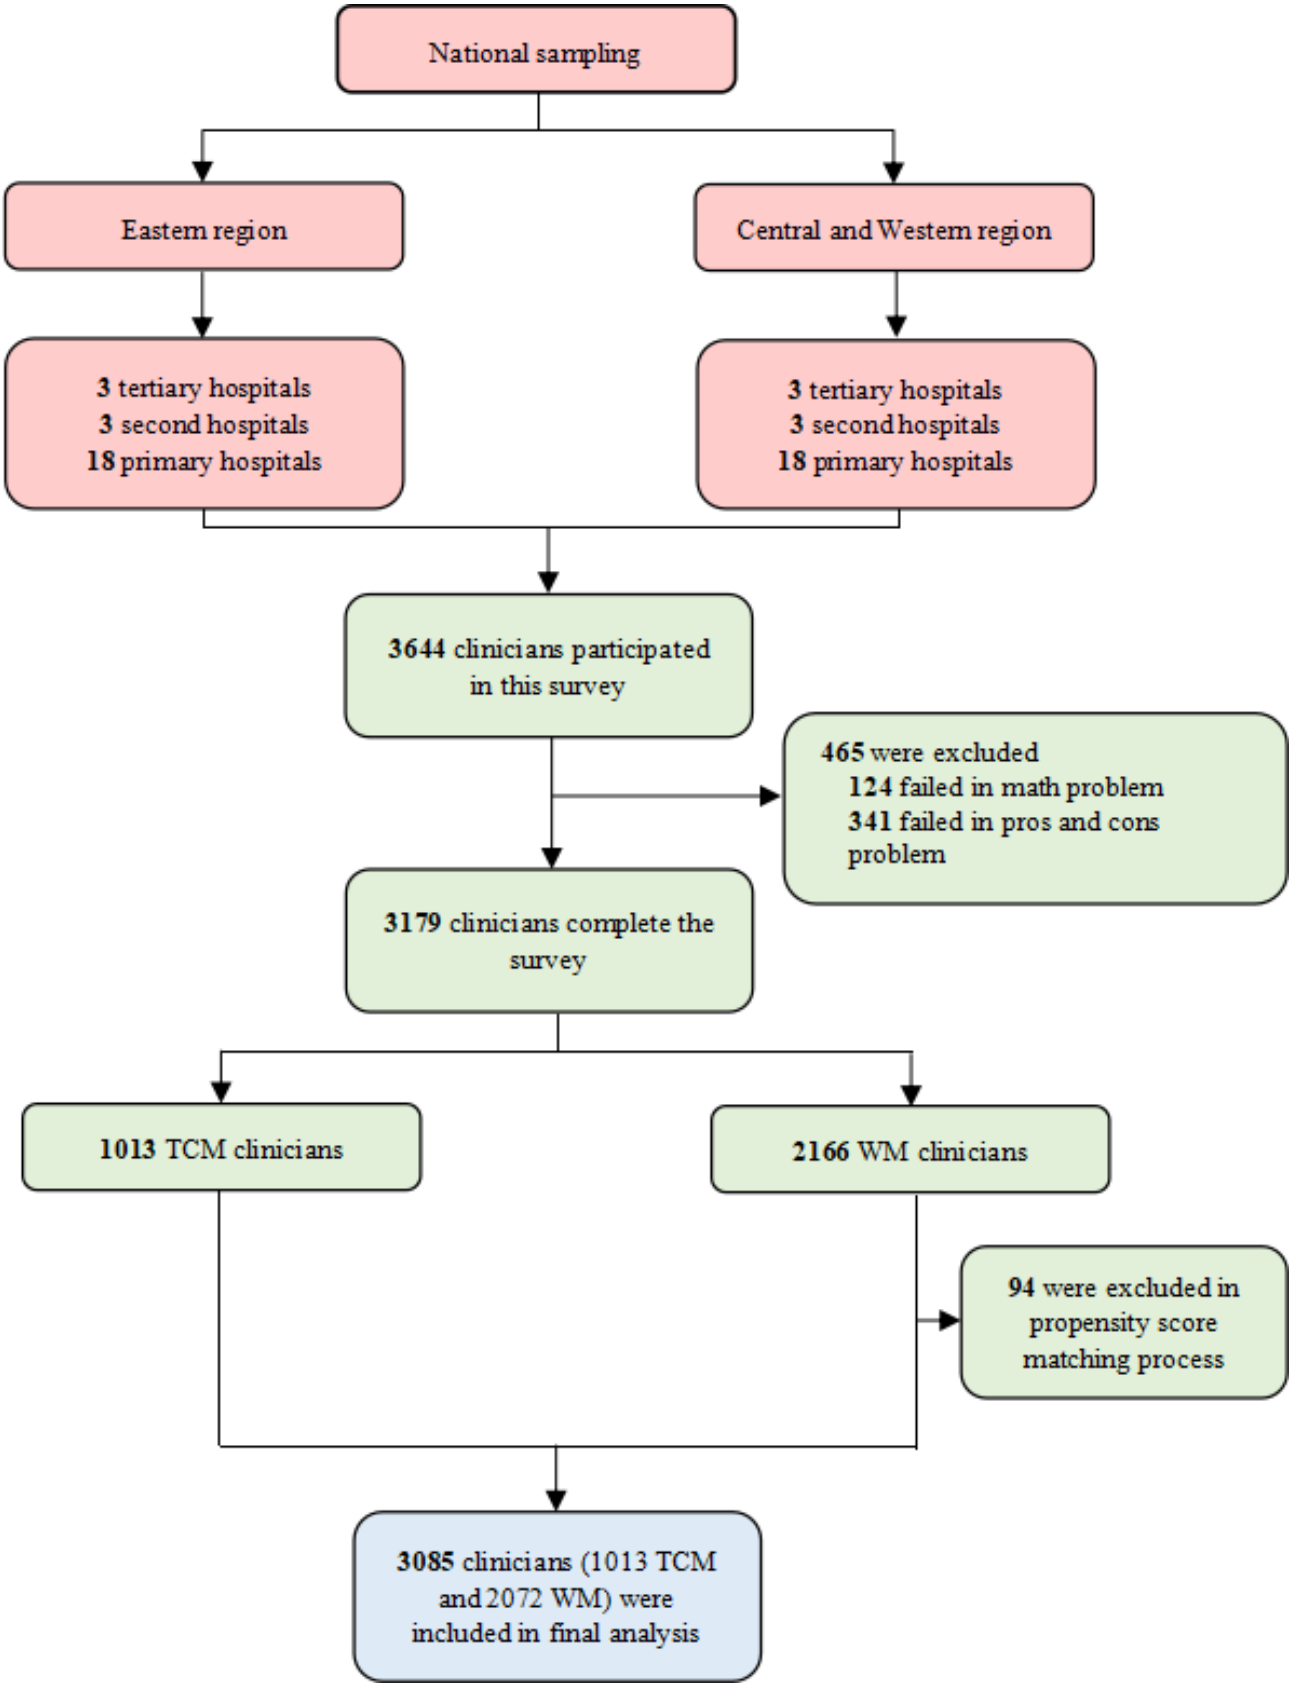
XSL•FO
RenderX

have indicated that clinicians play a crucial role in influencing vulnerable groups. Clinicians who were vaccinated were more likely to recommend vaccinations to their patients, highlighting the critical role of this group in improving vaccine uptake [5]. Influenza vaccination is the most cost-effective measure to protect high-risk groups against severe influenza-associated diseases and deaths, and the World Health Organization recommends the influenza vaccination in particular for specific target groups, including HCWs [6].

However, despite efforts to promote influenza vaccination among HCWs, uptake rates remain unsatisfactory in China. In the 2019-2020 season, only 61% of Chinese clinicians, who were recruited at a platform for respiratory medical professionals, received vaccines, which was lower than the 87.9% in Finland [7,8]. In the 2021-2022 season, the coverage was even higher in the United States, which had 91.3% clinicians who received vaccines [9]. Barriers to influenza vaccine uptake among HCWs in China include out-of-pocket costs and insufficient workplace regulations [7]. For example, workplaces did not require or encourage clinicians to get vaccinated before the flu season. Most importantly, previous studies have primarily treated Chinese clinicians as practitioners of modern medicine, overlooking the significant presence of clinicians practicing traditional Chinese medicine (TCM) in China [7,10].

Modern Western medicine, originating in Europe, dominates medical practices globally, including in China, and relies on biomedical science, genetics, and advanced medical technologies to diagnose, treat, and prevent illness [11]. In contrast, TCM, rooted in ancient China, follows a distinct philosophy with unique principles, like Yin-Yang and the Five Elements, and employs practices such as acupuncture and herbal remedies [12]. The theoretical and diagnostic foundation of TCM is difficult to interpret through the framework of Western medicine anatomy and physiology; it is based on the philosophy, logic, and beliefs of a distinct civilization, offering a view of health and disease that differs from modern scientific thinking [13]. Ancient texts such as *Huangdi Nei Jing* and *Shanghan Lun* remain core guides for TCM students today [14]. TCM was categorized as a kind of complementary and alternative medicine by the World Health Organization and has been adopted by over 100 countries [15]. In 2020, the United States had over 30,000 licensed acupuncturists, while Germany and Australia also had thriving TCM practitioner communities, with more than 3000 and 4000 practitioners, respectively [12]. In 2020, there were 682,770 registered TCM clinicians, accounting for 16.7% of all clinicians, in mainland China, who provided medical services for over 1 billion outpatients and 35 million hospitalizations [16]. Considering the massive medical work undertaken by TCM clinicians, it is important to understand their influenza vaccination preferences.

We conducted a nationwide survey using a discrete choice experiment (DCE) among both TCM and Western medicine clinicians from January to May 2022 in China, to capture their stated preferences regarding influenza vaccination programs. This study's objectives were: (1) to investigate how different characteristics of influenza vaccination programs influenced clinicians' vaccination decisions, including TCM and Western medicine clinicians; (2) to estimate the expected influenza vaccine coverage and identify the optimal influenza vaccination program among TCM and Western medicine clinicians; and (3) to identify different subgroups that share certain outward preferences using latent class analysis (LCA).



Methods

Participants

Clinicians (both TCM and Western medicine) holding a current practicing license in a hospital or community health service center, as of the date of survey administration, were included as potential participants. Data were collected through stratified cluster sampling between January 10 and May 10, 2022. In China, the coastal region (Eastern) and inland region (Central and Western) were stratified according to geographical location and socioeconomic development. Three tertiary hospitals, 3 secondary hospitals, and 18 primary hospitals were selected as survey spots in both the Eastern region and the Central and Western regions. The names and locations of these tertiary and secondary hospitals are listed in Table S1 in Multimedia Appendix 1. The primary hospitals were selected with the help of local health bureaus. They selected these hospitals through internal networks, and the name of each primary hospital was unknown to the researchers. We confirmed the location of primary hospital clinicians using their internet protocol address when they accessed the online questionnaire. The geographic distribution of all participants is presented in Figure S1 in Multimedia Appendix 1. Each hospital established a messaging group through WeChat (a free messaging and calling app) that included all the clinicians who worked in the hospital. Hospital administrative staff and local health bureaus delivered the online questionnaire link to these WeChat groups. We provided a brief statement for every participant before they answered the questionnaire to introduce the objective of our survey and to obtain informed consent. All participants were anonymized. Each WeChat account was allowed to submit only 1 online questionnaire. In China, real-name registration is required to apply for a phone number, and each phone number can be linked to only 1 WeChat account. Thus, we can reasonably assume that each individual could complete only 1 questionnaire. Participants who completed the questionnaire and correctly answered 2 quality control questions (a simple math problem and a pros-and-cons question where 1 choice is better than the other) were rewarded with a modest monetary incentive. Before the questionnaire was programmed, it was pilot tested by experts as well as 30 clinicians, who were contacted through our personal network, and adapted based on the feedback received. After sampling, we adjusted the Western medicine clinician sample using the propensity score matching method to ensure comparability between TCM clinicians and Western medicine clinicians (Figure 1).

Demographic Variables

We used a 2-part questionnaire with demographic questions and DCE options. The demographic variables assessed are listed in Textbox 1.

XSL•FO
RenderX

Textbox 1. Demographic variables assessed.

- Age in years, divided into groups (≤29, 30–39, 40–49, or ≥50 years)
- Sex (male or female)
- Educational level (junior college degree or lower, bachelor's degree, postgraduate degree, or doctorate)
- Medical license type (traditional Chinese medicine, Western medicine, or traditional Chinese medicine integrated with Western medicine)
- Annual personal income (CNY <¥100,000, ¥100,000-¥200,000, or >¥200,000; US <$13,649.18, $13,649.18-$27,298.35, or >$27,298.35, respectively)
- Length of time practicing medicine, in years (≤3 , 4-9, 10-19, 20-29, or ≥30 years)
- Professional (job) title (resident, fellow, or attending)
- Hospital level (primary, secondary, or tertiary)

Discrete Choice Experiment

A DCE is a technique used widely in the health care sector that elicits people's preferences by prompting them to make specific choices [17]. In this study, participants were asked to select a series of preferable vaccination programs. Each program was defined by a set of attributes, such as cost of the vaccine and risk of mild adverse events, and the variation in each attribute was referred to as a level. By making a series of choices between a vaccination program with one set of attribute levels and another with alternative attribute levels, participants implicitly revealed the degree to which each attribute is more important to them and the value they place on each attribute level.

This DCE was designed according to health-based principles, ranging from technicalities, such as design efficiency, to participant-centered considerations, such as checking if experimental tasks were as clear as possible to participants. In our survey, individuals made 8 choices, and for each choice they needed to choose a preferred influenza vaccination program between 2 alternative influenza vaccination programs. The influenza vaccination programs were described by attributes and levels representing different characteristics of vaccination programs.

Attributes and Levels

Five attributes described the characteristics of vaccination programs in the choice tasks, summarized in Table 1. We selected attributes and levels including: variable cost of vaccine (CNY ¥0; CNY ¥50 [approximately US $7]; or CNY ¥100 [approximately US $14]), variable vaccine effectiveness against infection (20%, 50%, or 80%), variable risk of mild adverse events such as redness, swelling, or pain at the injection site (1%, 3%, or 5%), different vaccination campaign strategies (individual appointment or vaccination in a workplace setting), and different workplace attitudes (no notice or encouragement of vaccination).

Table . Attributes and levels of discrete choice experiment.

Attribute	Levels
1. Cost of vaccine	• CNY ¥0 • CNY ¥50 (approximately $7 USD) • CNY ¥100 (approximately $15 USD)
2. Vaccine effectiveness against infection	• Prevent 20% infection • Prevent 50% infection • Prevent 80% infection
3. Risk of mild adverse events (such as redness, swelling, or pain at the injection site)	• 1% risk • 3% risk • 5% risk
4. Vaccination campaign strategies	• Individual appointment • Vaccination in a workplace setting
5. Workplace attitudes	• No notice • Encouragement of vaccination

We selected attributes and levels related to influenza vaccination based on several sources of evidence: a rapid review of existing research [18-21], one-on-one interviews with 4 TCM clinicians and 4 Western medicine clinicians, and a consultation with subject matter experts. An orthogonal experimental design was used to reduce these choice tasks down to 8 choice tasks with 16 hypothetical vaccination programs. Levels were randomly assigned with equal probabilities and repeatedly recombined, with all combinations being plausible and realistic. Priors were obtained from a pilot study of 30 clinicians. Each clinician answered 8 choice tasks, reporting no understanding problem and respondent fatigue. The full choice tasks, as presented to

XSL•FO
RenderX

respondents, are shown in Table S2 in Multimedia Appendix 1.

Statistical Analyses

The rule of thumb, as proposed by Johnson and Orme [22], suggests that the sample size required for the main effects of a DCE analysis depends on the number of choice tasks (*t*), the number of alternatives for each choice task (*a*), and the largest number of levels for any of the attributes (*c*), according to the following equation [23]:

$$N>1000c/(t\times a)$$

For our study, there were 8 choice tasks; each choice task had 2 alternatives, and the largest number of levels was 3 for any of the attributes. Our sample, which exceeded the minimum sample size calculated, of approximately at least 376 clinicians (or 188 of both TCM and Western medicine clinicians), was sufficient for the purposes of our study.

Sex, age groups, and hospital levels were identified as confounders in propensity score matching, and the propensity score of the Western medicine sample and TCM sample was calculated. We then used a nearest-neighbor matching algorithm to match 3 Western medicine clinicians with 1 TCM clinician based on the propensity score. Descriptive statistics were used to summarize characteristics of TCM and Western medicine clinicians. For categorical variables, frequencies were reported, and Pearson χ^2 tests were used to test for differences between the 2 groups. For continuous variables, mean and standard deviation were reported after Shapiro-Wilk tests indicated that the continuous variables were normally distributed. We used *t* tests to compare differences across the 2 groups.

To estimate the relative impact of influenza vaccine attributes in the DCE, we conducted a mixed logit regression model (MLM) to compute preference weight. An MLM is based on the assumption that random error has a normal distribution, taking heterogeneity as well as correlation between the choice task completed by each participant into account. We validated the linear continuous effects of chosen attributes, and the variables of cost, vaccine efficacy, and risk of mild adverse events were considered as continuous, while the vaccination campaign strategies and workplace attitudes were considered as categorized in the analysis. The MLM allowed for the calculation of compensatory effects across any 2 attributes. For example, a 5% decrease of risk of mild adverse events can compensate the negative impact of a 10% reduction of vaccine effectiveness. The willingness to pay (WTP) refers to the compensatory effect between cost and any other attribute. We calculated the expected vaccine coverage for the base case and the change of coverage when the level of one attribute was changed.

Subsequently, we conducted an LCA to classify individuals based on their preference characteristics; an individual was assigned to the class with the highest posterior probability. For example, the LCA presented that 31.1% (644/2072) of Western medicine clinicians preferred free vaccinations over any other attribute. Our choice in the number of subgroups was based on model fit and interpretability of results. We compared classes across demographic characteristics among the estimated classes using χ^2 tests. The preference subgroups were named based on the most preferred attribute levels in each class.

All analyses were based on 2-sided *P* values, with $P<.05$ indicating statistical significance. Stata (Version 16.0, Stata Corp LLC) was used for analysis.

Ethical Considerations

The Zhejiang Chinese Medical University Ethics Committee reviewed and approved this protocol (no. 20221021 - 1). Prior to participation, all study participants were required to sign an informed consent form, thereby confirming their voluntary engagement in the survey process. The study data were anonymized. All participants who completed the questionnaire and successfully submitted it received a reward of CNY ¥20 (US $2.7), distributed via WeChat.

Results

Demographics

A total of 3644 clinicians from 6 tertiary hospitals, 6 secondary hospitals, and 36 primary hospitals were invited to participate in this survey. Among them, 559 (15.3%) were ultimately excluded for failing the basic math tests (n=124, 3.4%) or the pros-and-cons test (n=341, 9.4%) or in the post-hoc during propensity score matching (n=94, 2.6%). Finally, 3085 subjects, consisting of 1013 (32.8%) TCM clinicians and 2072 (67.2%) Western medicine clinicians, were included in the analysis (Figure 1).

The sample matching adjustment achieved the expected distributions of gender, age groups, and hospital level (Figures S2-S4 in Multimedia Appendix 1). Educational attainment showcased a significant discrepancy, with a notable proportion of Western medicine clinicians holding a bachelor's degree (1106/2072, 53.4%) compared to TCM clinicians (409/1013, 40.4%). Conversely, a higher percentage of TCM clinicians had attained a master's degree (274/1013, 27%) or a doctorate (110/1013, 10.9%) compared to their Western medicine counterparts. In terms of annual personal income, a higher percentage of TCM clinicians reported incomes of CNY ¥100,000 - ¥200,000 (US$13,649.18-$27,298.35) (345/1013, 34.1%) compared to Western medicine clinicians (570/2072, 27.5%). Conversely, a higher proportion of Western medicine clinicians reported incomes above CNY ¥200,000 (US $27,298.35) (413/2072, 19.9%) compared to TCM clinicians (133/1013, 13.2%). In terms of professional title, 50.4% (511/1013) of TCM clinicians held the title of resident compared to Western medicine clinicians (916/2072, 44.2%). Conversely, a higher proportion of Western medicine clinicians held the title of fellow (827/2072, 39.9%) compared to TCM clinicians (346/1013, 34.2%). For the length of time practicing medicine, there was no significant difference between TCM and Western medicine clinicians ($P=.44$). (Table 2).

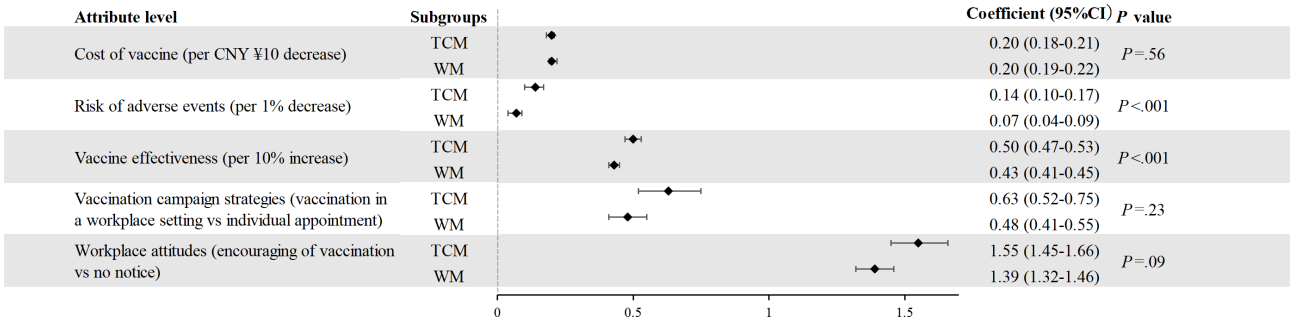
[a]CNY: Chinese yuan. CNY ¥1=US $0.14.

Preference Weight and Compensatory Effects (Including WTP)

All attributes and levels included were significantly associated with clinicians' preferences for influenza vaccination programs. Both TCM and Western medicine clinicians' preferences for influenza vaccination programs increased with higher vaccine effectiveness, with the vaccination campaign strategies changing from "individual appointment" to "vaccination in a workplace setting," or with the workplace attitude changing from "no notice" to "encouraging of vaccination." Nevertheless, the increase in the risk of mild adverse events and cost could undermine the utility of vaccination towards these 2 groups. The WTPs of TCM clinicians were calculated and showed that each 1% increase in risk of mild adverse events could be compensated by a CNY ¥6.97 (US $1.37) decrease of cost. Similarly, changing the mode of administration from "individual appointment" to "vaccination in a workplace setting" could compensate for the negative effect of a CNY ¥78.84 (US $15.44) increase of cost. Compensatory effects can be calculated between any attributes; for example, a hypothetical 5% increase in risk of mild adverse events could be compensated by a



XSL•FO
RenderX

simultaneous hypothetical 13.7% increase in vaccine effectiveness. WTP and the compensatory effect of Western medicine clinicians were calculated in the same way. The preference weights and WTP of attributes and levels of the 2 groups are shown in Table S3 in Multimedia Appendix 1.

Comparison of Preference Weights Among TCM and Western Medicine Clinicians

Significant differences were noted for the coefficients of the risk of mild adverse events and vaccine effectiveness between clinicians practicing TCM and Western medicine. TCM clinicians (odds ratio [OR] 0.14, 95% CI 0.10 - 0.17) expressed a stronger preference for an influenza vaccination program per 1% decrease of mild adverse events risk than Western medicine clinicians (OR 0.07, 95% CI 0.04 - 0.09; *P*<.001). Similarly, TCM clinicians (OR 0.50, 95% CI 0.47 - 0.53) expressed a stronger preference for an influenza vaccination program per 10% increase of vaccine effectiveness than Western medicine clinicians (OR 0.43, 95% CI 0.41 - 0.45; *P*<.001). Other attributes (cost, vaccination campaign strategies, and workplace attitudes) did not present significant differences between the 2 groups (Figure 2).

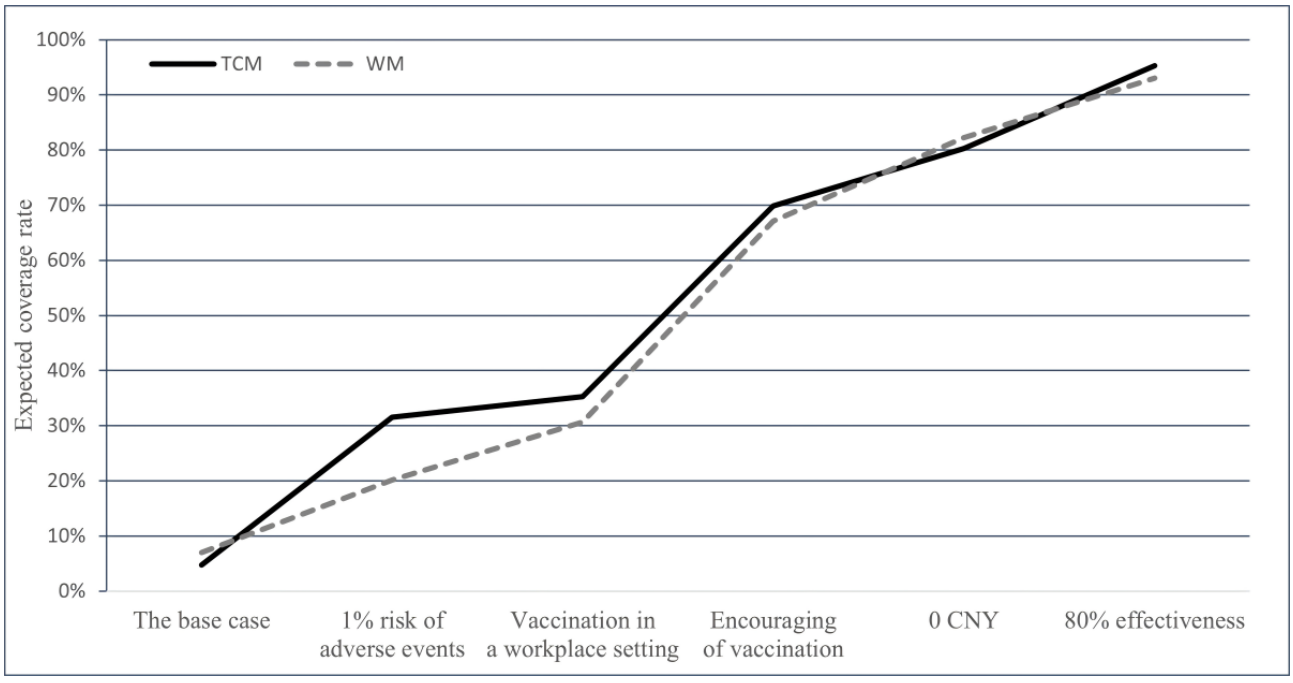


Figure 2. Comparison of preferences in clinicians practicing TCM and WM between January and May 2022 in China. TCM: traditional Chinese medicine; WM: Western medicine.

Expected Influenza Vaccine Coverage Under Various Influenza Vaccination Programs

We set the base case as having a cost of CNY ¥100 (US $13.64), 5% risk of mild adverse events, 20% effectiveness, vaccination by individual arrangement, and no notice from the workplace. The expected coverage of the base case to TCM clinicians was 4.75% and to Western medicine clinicians was 6.99%. Expected coverage increased by approximately 30% with a reduction in risk of mild adverse events from 5% to 1%; greater coverage increases could be achieved by either enhancing effectiveness from 20% to 80% or reducing costs from CNY ¥100 to CNY ¥0. An approximate hypothetical 60% increase could be obtained when the attitude of the workplace changed from “no notice” to “encouraging of vaccination,” and there was an approximate hypothetical 35% increase when vaccination campaign strategies changed from “individual appointment” to “vaccination in a workplace setting.” The changing of expected coverage due to improvements in the influenza vaccination program is depicted in Figure 3 (additional details available in Table S4 in Multimedia Appendix 1).

Figure 3. Changes in expected coverage rate, as attributes in influenza vaccination programs improve, between January and May 2022 in China. We set the base case as having a cost of CNY ¥100 (US $13.64), 5% risk of mild adverse events, 20% effectiveness, vaccination by individual arrangement, and no notice from the workplace. TCM: traditional Chinese medicine; WM: Western medicine; CNY: Chinese yuan.

Preference of Different Subgroups

Table 3 details the demographic composition variations across various subgroups, while the fitting and categorization process of these subgroups is recorded in Table S5 in Multimedia Appendix 1. In the entire sample, about 30% (946/3085) of clinicians preferred free vaccinations, while approximately 26% (819/3085) comprehensively considered all attributes except for vaccination campaign strategies. Notable trends were observed within 2 specific subgroups: clinicians preferring free vaccinations and those preferring vaccinations in a workplace setting. Among clinicians with different medical licenses, TCM practitioners exhibited a lower preference for free vaccinations (302/1013, 29.8%) compared to Western medicine clinicians (644/2072, 31.1%) and a higher preference for workplace vaccinations (186/1013, 18.4%) compared to Western medicine clinicians (351/2072, 17%) (P=.03). Differences were also noted across sex, with female clinicians indicating a lower preference for free vaccinations (533/1766, 30.2%) compared to male clinicians (414/1319, 31.3%) and a higher preference for workplace vaccinations (317/1766, 18%) compared to male clinicians (219/1319, 16.6%) (P=.04). Educational level revealed a U-shaped relationship, where the highest preference for free vaccinations was among those with junior college degrees or lower (270/804, 33.6%); however, this preference decreased significantly among those with postgraduate degrees (158/563, 28%; P<.001). Conversely, there was an inverted U-shaped relationship between educational level and preference for vaccinations in a workplace setting. A strong monotonic relationship was present between hospital level and clinicians' preference for free vaccinations, with 32.5% (303/932) of primary hospital workers preferring free vaccinations compared to 29.4% (416/1415) of those in tertiary hospitals (P<.001). On the other hand, clinicians in tertiary hospitals (262/1415, 18.5%) significantly preferred vaccinations in a workplace setting compared to those in primary (145/932, 15.6%) or secondary hospitals (131/738, 17.7%) (P<.001). No significant differences were found based on age group, annual personal income, length of time practicing medicine, or professional title.

Discussion

Principal Findings

We found that (1) TCM clinicians were more sensitive to changes to the risk of mild adverse events and vaccine effectiveness than Western medicine clinicians; (2) decreasing the price of influenza vaccinations, offering convenient vaccinations in workplace settings, and issuing notifications encouraging clinicians to get vaccinated could increase influenza vaccination coverage of both groups; and (3) compared to Western medicine clinicians, a larger proportion of TCM clinicians preferred vaccinations in workplace settings over any other attribute.

The findings indicate a higher probability of vaccines being received when paired with increased vaccine effectiveness and decreased likelihood of vaccine-related adverse events, which aligns with prior research conducted through questionnaire surveys [24]. In our survey, TCM clinicians placed significantly higher preference weights on the risk of mild adverse events and vaccine effectiveness, indicating that fluctuations in the safety and effectiveness of influenza vaccines could have a greater impact on them. A qualitative study shows that patients find vaccination information transmitted by complementary and alternative medicine providers to be more understandable, useful, and trustworthy [25]. A TCM clinician who receives and shares information regarding defective vaccine incidents could cause a chain reaction in the broad population. A systematic review indicated that the provision of free vaccinations, easy access to vaccinations, and modification through educational activities and reminders can effectively increase the influenza vaccine uptake [26]. In the simulation scenario, decreasing the price of the influenza vaccination from CNY ¥100 (US $13.64) to being free resulted in a significant increase in projected coverage. Offering free vaccinations to clinicians can provide additional benefits, such as mitigating absenteeism during the influenza season and preventing hospital-acquired influenza infections. We also found that other workplace-based interventions, such as providing vaccination opportunities at the workplace and promoting vaccination initiatives more broadly, demonstrated a favorable effect on the projected uptake of influenza vaccine. Given the feasibility and efficacy of these measures, we propose that health care facilities should (1) provide free annual influenza vaccinations, (2) furnish accessible vaccination services for employees, and (3) issue notifications encouraging clinicians to avail themselves of vaccination opportunities. In our LCA, the majority of clinicians prioritized free vaccinations, followed by a substantial group who took into account all attributes except vaccination campaign strategies when deciding whether to accept an influenza vaccination program. The results of our survey suggest that a higher proportion of TCM clinicians favored workplace-based vaccinations over any other attribute, whereas a greater number of Western medicine clinicians preferred free vaccinations over any other attribute. This finding can lend support to the creation of a vaccination policy that is more flexible and adaptable. Sex, educational level, and hospital level were all associated with latent classification. Among these considerations, the most significant distinction emerged between clinicians who preferred free vaccinations most and those who preferred vaccinations in a workplace setting most. This differentiation suggests that the other 3 categories (favoring workplace encouragement of vaccinations, prioritizing higher vaccine effectiveness, and considering attributes except vaccination campaign strategies) were evenly distributed across all demographics in our study. As a result, measures like releasing notices in health care workplaces to encourage clinicians to get vaccinated may achieve similar effects across all groups of Chinese clinicians. A previous study showed that women's perceptions of inflation (consumer prices increasing) were higher than men's, but fewer female clinicians preferred free vaccinations over vaccinations in a workplace setting, compared to male clinicians in our study [27]. A policy offering free vaccinations may hold greater appeal for clinicians with lower levels of education (bachelor's degree or below) or those employed in primary health care institutions. Conversely, providing vaccinations in a workplace setting was found to be more favorable among clinicians with higher levels of education (postgraduate degree or doctorate) or those working in tertiary hospitals. In China, clinicians employed in tertiary hospitals serve as the cornerstone of the nation's health care provision, handling extensive medical responsibilities that may make it challenging for them to get vaccinated during their

XSL•FO
RenderX

private leisure time. Consequently, providing convenient vaccination services for clinicians should be prioritized as a primary measure for these tertiary hospitals.

Limitations

Our study is subject to several limitations. First, our sample of clinicians did not perfectly mirror the sociodemographic characteristics of the entire nation. Additionally, there may be biases between individuals who completed the survey and those who did not. Second, as a cross-sectional study, potential recall bias is inevitable. Moreover, DCEs are susceptible to hypothetical bias, meaning that responses in surveys may not perfectly align with real-life behaviors [28]. This discrepancy could limit the accuracy of measured preferences. To mitigate this, we designed the experiment based on real-world influenza vaccination programs and ensured that the details and definitions of each attribute were comprehensible to participants.

Conclusions

In summary, while changes in mild adverse event rates and vaccine effectiveness had a greater impact on TCM clinicians, other attributes, such as workplace-provided free vaccinations, issuing notifications to encourage vaccinations, and providing accessible vaccination services, are practical methods to increase the uptake of influenza vaccination programs among both groups. Policymakers can utilize these insights to formulate flexible intervention measures that facilitate greater accessibility of influenza vaccination programs for clinicians, especially TCM clinicians, worldwide.

Abstract

Background: Prevalences of mental disorders are increasing worldwide. However, many people with mental health problems do not receive adequate treatment. An important factor preventing individuals from seeking professional help is negative attitudes toward psychotherapeutic treatment. Although a positive shift in attitudes has been observed in recent years, there is still substantial stigma surrounding psychotherapeutic treatment. First studies have linked higher health literacy with more positive attitudes toward psychotherapy, but more research is needed in this area.

Objective: This study aimed to examine how general and mental health literacy are associated with attitudes toward psychotherapeutic treatment in Germany. Additionally, associations between sociodemographic factors, experience with psychotherapy, and attitudes toward psychotherapy were explored.

Methods: A random sample was drawn from a panel representative of the German-speaking population with internet access in Germany and invited to participate in the study via email. Overall, 2000 individuals aged ≥16 years completed the web-based survey with standardized questionnaires in September and October 2022. Attitudes toward psychotherapy and both general and mental health literacy were assessed using the Questionnaire on Attitudes Towards Psychotherapeutic Treatment (QAPT) with 2 subscales ("positive attitudes" and "non-acceptance of society"), the European Health Literacy Survey instrument (HLS-EU-Q16) and the Mental Health Literacy Tool for the Workplace (MHL-W-G). Associations between the questionnaire scales were assessed with Pearson correlations. Additionally, basic sociodemographic information and information on personal and family experiences with psychotherapy were collected. Pearson correlations (age), ANOVAs (level of education and subjective social status), and *t* tests (experience with psychotherapy, gender, and migration background) were used to analyze how these relate to attitudes toward psychotherapy.

Results: More favorable attitudes toward psychotherapy and lower perceived societal nonacceptance were found in those with higher general (r=0.14, P<.001; r=−0.32, P<.001, respectively) and mental health literacy (r=0.18, P<.001; r=−0.23, P<.001, respectively). Participants with treatment experience for mental health problems ($t_{1260.12}$=−10.40, P<.001, Cohen d=−0.49; $t_{1050.95}$=3.06, P=.002, Cohen d=0.16) and who have relatives with treatment experience ($t_{1912.06}$=−5.66, P<.001, Cohen d=−0.26; t_{1926}=4.77, P<.001, Cohen d=0.22) reported more positive attitudes and higher perceived societal acceptance than those without treatment experience. In terms of sociodemographic differences, being a woman (t_{1992}=−3.60, P<.001, Cohen d=−0.16), younger age (r=−0.11, P<.001), higher subjective social status ($F_{2,1991}$=5.25, P=.005, η^2=.005), and higher levels of education ($F_{2,1983}$=22.27, P<.001, η^2=.021) were associated with more positive attitudes toward psychotherapeutic treatment. Being a man (t_{1994}=5.29, P<.001, Cohen d=0.24), younger age (r=−0.08, P<.001), and lower subjective social status ($F_{2,1993}$=7.71, P<.001, η^2=.008) were associated with higher perceived nonacceptance of psychotherapy.

Conclusions: Positive associations between attitudes toward psychotherapy and both general and mental health literacy were delineated. Future studies should investigate whether targeted health literacy interventions directed at individuals with lower

XSL•FO
RenderX

general and mental health literacy might also help to improve attitudes toward psychotherapeutic treatment and help-seeking behavior.

health literacy; mental health literacy; attitude to health; cross-sectional studies; Germany; adults; representative; psychotherapy

Introduction

In Germany, almost 30% of the population are estimated to have a mental disorder [1] but only about 10% have received treatment in the past year [2]. This means that about two-thirds of those with mental health problems do not receive adequate treatment. While the number of individuals not seeking help for mental disorders has decreased in recent years, the majority of individuals with mental disorders still do not seek treatment [3]. With a global rise in the prevalence of mental disorders [4], it becomes even more important to understand the factors that influence whether an individual seeks help or not.

Psychotherapy is considered effective for treating many mental disorders [5]. However, there are several reasons that prevent individuals from seeking psychotherapy. These encompass structural challenges such as long waiting periods and underprovision, especially in rural areas [2,6,7], as well as individual reasons often related to stigma against mental disorders and psychotherapy [8,9]. Specifically, in self-reports, about one-third of respondents report negative attitudes and stigma toward psychotherapy, with more negative attitudes in male individuals and in individuals with lower education [10]. Similarly, almost a third of the respondents believed that professional care was worse than or equal to no help when faced with serious emotional problems in a large European study [8]. In recent years, attitudes toward professional help, particularly toward psychotherapeutic and psychiatric treatment, have improved both on a global level and in Germany [11,12]. In addition, perceived public stigma toward people with mental disorders has substantially decreased in the past 30 years [13]. At the same time, the individual wish for social distance toward people with depression slightly decreased but increased toward people with schizophrenia [11,14]. Furthermore, in many non-Western countries, there are still substantial negative attitudes toward individuals with mental illnesses [15,16]. Critically, it has been shown that negative attitudes toward help seeking and stigmatizing attitudes toward people with mental illness predict help-seeking behavior [7,17-20]. In summary, this means that although some progress has been made in recent years, there is still considerable stigma associated with both mental illness and its treatment, which needs to be addressed to increase the number of individuals who receive treatment in addition to reducing structural barriers.

Health literacy refers to “people’s knowledge, motivation and competencies to access, understand, appraise, and apply health information in order to make judgments and take decisions in everyday life concerning health care, disease prevention and health promotion to maintain or improve quality of life during the life course” [21]. Low health literacy has been associated with several negative health-related outcomes, including higher rates of hospitalization, lower medical treatment adherence, decreased quality of life, fewer health-promoting behaviors, and higher mortality [22-27]. Mental health literacy was developed from general health literacy and applies the concept to mental health. It is defined as “understanding how to obtain and maintain positive mental health; understanding mental disorders and their treatments; decreasing stigma related to mental disorders; and, enhancing help-seeking efficacy” [28]. High mental health literacy has a number of positive correlates such as mental well-being, physical activity, life satisfaction, healthy eating habits, and self-efficacy [29-31].

First studies have linked increased health literacy with lower stigma and more positive attitudes toward mental disorders and psychotherapy [12,19,30,32-34]. For example, Svensson and Hansson [32] have shown that a higher degree of mental health literacy is related to less stigma and a lower wish for social distance toward individuals with depression and to a lesser extent also toward individuals with schizophrenia. However, this pattern of results was not found in all studies. In a Swiss community sample of young adults, no direct association between mental health literacy and the wish for social distance was delineated. Instead, it was shown that increased mental health literacy may also lead to more stigma by enhancing stereotypes of individuals with mental disorders (eg, perceived dangerousness) due to higher endorsement of biogenetic causal explanation of mental disorders [35]. It has been demonstrated in diverse cultural contexts that specific interventions may enhance both general and mental health literacy [36-41]. Moreover, it has been shown in longitudinal studies that more positive treatment attitudes can predict more frequent mental health service use in the future [19,20]. Along with significantly reducing structural barriers, indirectly improving attitudes toward psychotherapeutic treatment via increased health literacy may therefore be an important starting point to ensure that more people with mental health problems receive professional help.

Although some studies have started to investigate the relationship between general and mental health literacy and attitudes toward psychotherapeutic treatments, there are still substantial gaps in the literature as well as some limitations of previous studies that need to be addressed in order to get a better understanding of how to increase the number of individuals seeking psychotherapeutic treatment. First, in past investigations, mental health literacy was often assessed via unlabeled vignettes [32,35] describing the symptoms of a specific disorder (eg, depression or schizophrenia), and high mental health literacy was assigned to those individuals who correctly identified these vignettes. While this covers a small aspect of the broad definition of mental health literacy, that is, the recognition of mental disorders, other important aspects, such as promoting positive mental health, are not included [28]. This limitation in

XSL•FO
RenderX

previous methodological approaches is why we decided to use an instrument with a broader scope to assess mental health literacy in the present investigation [42,43]. Second, the literature on general health literacy and how it relates to treatment attitudes is relatively sparse and there is a need to replicate and extend previous findings [34]. Third, there is some evidence to suggest that there are substantial interindividual differences in attitudes toward psychotherapy in the community [19,34]. However, the specific determinants of these differences need to be explored more in depth to identify potentially vulnerable segments of the population that could particularly benefit from interventions. For example, it has been shown that gender, age, level of education, and social status play an important role in accessing psychiatric and psychotherapeutic services and might therefore also be related to attitudes [2,10]. In addition, having a migration background or being part of an ethnic minority has been associated with access to mental health care [44-48]. Finally, negative attitudes might be improved by hearing about the positive experiences of others or making these experiences themselves [19,49-51], which is why we decided to include 2 questions on personal and family experience with psychotherapy.

To address these previous limitations and gaps in the literature, in this study, we aimed to explore the relationship between attitudes toward psychotherapy and both general and mental health literacy with comprehensive questionnaires and in a large sample. Furthermore, we aimed at exploring how additional factors including basic sociodemographic factors and experience with psychotherapy relate to attitudes toward psychotherapy in order to inform the future development of target group-specific interventions with the aim of reducing individual barriers to seeking professional help.

Methods

Ethical Considerations

The ethics committee of the Berlin Medical Association had no ethical or professional objections to the study protocol (reference Eth-39/22). Participants gave informed consent to take part in the study. They were not directly compensated for their participation by the independent nonprofit foundation Stiftung Gesundheitswissen. Data collection was conducted by the market research institute forsa (forsa Gesellschaft für Sozialforschung und statistische Analysen mBH), which was commissioned and financially compensated for this work by the nonprofit foundation Stiftung Gesundheitswissen. Importantly, Stiftung Gesundheitswissen did not have any influence on the data collected and the direction of the results. Forsa provided only anonymized data to the Stiftung Gesundheitswissen.

Data Acquisition

Data collection was conducted by forsa using the forsa.omninet panel. Forsa.omninet is a representative panel for the German-speaking population with internet access aged 14 years and older in Germany and currently has around 100,000 participants. Panelists are recruited exclusively offline, that is, by telephone within the framework of forsa.omniTel, a telephone omnibus survey of forsa, in which randomly selected individuals aged 14 years and older are interviewed daily. The composition of the panel is continuously monitored on the basis of key characteristics (eg, region, age, and gender) and recruitment is adjusted accordingly. In addition, approximately 1000 new individuals are recruited monthly. There is no possibility to apply for participation in the panel so the selection of the participants is solely controlled by a random sampling procedure. Inclusion criteria for this investigation were the age of 16 years or older; sufficient German knowledge; and being able to use a computer, laptop, or mobile device for the survey. The only exclusion criterion was not fulfilling the inclusion criteria. With the aim of collecting data from at least 2000 individuals, 3927 panelists aged 16 years and older were randomly drawn from the panel and invited to take part in the survey by email. Exactly 2000 participants completed the study, equaling a response rate of 50.9% (2000/3927). The invitation email contained brief information on the overall topic of the survey as well as the incentive. If necessary, the selected panelists were reminded about their participation in 2 further emails. Recruitment and data collection took place in September and October 2022 with a standardized questionnaire presented in the form of computer-assisted web interviews. The total questionnaire consisted of 155 items, of which not all are relevant to this investigation. For economic reasons, data collection for different research objectives was combined. Results are published in separate and independent publications [31,52].

To minimize the effects of nonresponse and potential bias due to systematically missing data from certain population segments, survey weights were calculated by forsa using an iterative proportional fitting approach with the following weight variables and combinations: (1) gender × age (16-29 years, 30-45 years, 46-64 years, or ≥65 years) × region (West Germany and Berlin, or East Germany) and (2) federal state. This procedure resulted in a single weighting factor for each individual applied before further statistical analyses. The weighting was informed by the population update of the German Federal Statistical Office (as of December 31, 2020).

Measures

Attitudes Toward Psychotherapy

Attitudes toward psychotherapy were assessed with the German version of the Questionnaire on Attitudes Towards Psychotherapeutic Treatment (QAPT) in its revised 2-factorial form [44,53,54]. The questionnaire consists of 11 items answered on a 4-point Likert scale ranging from “do not agree” to “agree.” The items address how the respondents perceive psychotherapeutic treatments. The 2 subscales are “positive attitudes” (6 items) and “non-acceptance of society” (5 items). The positive attitude scale reflects the individuals’ beliefs about the positive effects of psychotherapeutic treatment and the competence of psychotherapists, whereas the nonacceptance scale reflects the fear of stigma and social isolation from others. The second scale is originally labeled “acceptance of society” (“Akzeptanz der Gesellschaft” in German [54]). However, as the items of this scale are negatively coded, that is, higher values indicate lower acceptance, we decided to label the scale “nonacceptance of society” for easier interpretability. For each

XSL•FO
RenderX

scale, a mean value is calculated across all items. The mean value reaches from 1 to 4 with higher values indicating more positive attitudes and higher nonacceptance (eg, lower acceptance), respectively.

Health Literacy

General health literacy was assessed with the German translation of the short version of the European Health Literacy Survey instrument (HLS-EU-Q16 [55-57]). This 16-item questionnaire addresses the subjective difficulty in accessing, understanding, appraising, and applying information in the fields of health care, disease prevention, and health promotion. Respondents are asked to answer each item on a 4-point Likert scale with the options “very easy,” “fairly easy,” “fairly difficult,” and “very difficult.” An overall sum score is calculated for the dichotomized items (eg, 1=“fairly easy” and “very easy,” 0=“fairly difficult” and “very difficult”). The sum score ranges from 0 to 16, with higher values indicating higher health literacy. Groups of individuals with varying degrees of health literacy were determined using this sum score: inadequate health literacy (scores 0-8), problematic health literacy (scores 9-12), and adequate health literacy (scores 13-16).

Mental Health Literacy

Mental health literacy was assessed with the German version of the Mental Health Literacy Tool for the Workplace (MHL-W-G [42,43]). Instructions were slightly adapted so that they also apply to people who are not currently working. Specifically, participants were instructed to imagine they worked if this was not the case. The instrument presents 4 case vignettes, in each of which current symptoms and the circumstances of one individual are described. The vignettes differ in the nature of the mental health issue, its impact on workplace performance, and the gender of the individual. Importantly, the nature of the mental health issue is not explicitly labeled. For each vignette, the same 4 questions are answered covering important aspects of mental health literacy, namely the ability to recognize specific mental disorders, knowledge and beliefs about risk factors and prevention, knowledge and attitudes to facilitate help seeking, and knowledge and beliefs about mental health interventions. After reading each of the vignettes, participants are asked to rate their knowledge about what might be happening, how they could prevent the situation from worsening, what to say or do in the situation, and which resources and services might be helpful. Answers are given on a 5-point Likert scale ranging from “very low” to “very high”. A sum score is calculated by adding up the ratings of each of the 4 questions in each of the 4 vignettes (ranging from a minimum of 16 to a maximum of 80 points), with higher scores reflecting higher levels of self-reported mental health literacy. So far, no generally accepted cut-off scores have been developed to compare groups of individuals with varying levels of mental health literacy using this questionnaire, which is why we do not present stratified data here.

Experience with Psychotherapy

In addition, the participants were presented with 2 simple yes-or-no-questions to assess whether they have ever received any treatments for mental disorders themselves and whether any of their close family members have ever received treatment for mental disorders.

Sociodemographic Information

Participants provided basic sociodemographic information including gender (men, women) and age.

In addition, participants were asked to provide their highest level of formal education. Participants were then categorized into 3 groups: low, middle, and high level of education. The low level of education is equivalent to no formal education or basic secondary school (ohne Haupt-/Volksschulabschluss, Haupt-/Volksschulabschluss); the middle level of education is equivalent to intermediate secondary school (Mittlere Reife, Realschulabschluss, Fachschulreife, Abschluss der Polytechnischen Oberschule, Fachhochschulreife, Abschluss einer Fachoberschule); and the high level of education is equivalent to most advanced secondary school, for example, grammar schools to obtain a general or specialized university entrance qualification or a university degree (Abitur, allgemeine oder fachgebundene Hochschulreife, Fach-/Hochschulstudium).

Subjective social status was assessed with the German version of the MacArthur scale [58,59], in which the participants rank themselves relative to other members of society. They are presented with a metaphor, in which a ladder represents the social structure of society with the highest ladder rung representing the individuals in society with the highest status and the bottom rung presenting the individuals in society with the lowest status. The respondents are asked to identify the rung on which they place themselves. Three categories of subjective social status were determined according to the respondents’ answers, that is, low subjective social status (scores 1-4), middle subjective social status (scores 5-7), and high subjective social status (scores 8-10).

Migration status was assessed with a simple yes-or-no-question. The participants were asked to indicate if they have a migration background. They were instructed to answer with yes if they or one of their parents were not born in Germany.

Statistical Analysis

Statistical analyses were performed with the software SPSS (version 29.0.2.0; IBM). All analyses reported in the main manuscript were conducted with the weighted dataset (details on weighting can be found in the “data acquisition” paragraph). Results for the unweighted dataset can be found in the Multimedia Appendix 1. Cronbach α was calculated to determine the internal consistency of the attitudes and nonacceptance subscales of the QAPT as well as the HLS-EU-Q16 and MHL-W-G total scores. The resulting reliability coefficients were interpreted using the following rule of thumb: >.90 excellent, >.80 good, >.70 acceptable, >.60 questionable, >.50 poor, and <.50 unacceptable [60]. For all inferential analyses, a threshold of α=.05 was used as the significance level and 2-sided *P* values are reported. Associations between the 2 attitudes toward psychotherapy scales and both mental and general health literacy were assessed with Pearson correlations, including 95% CI. Likewise, for the associations between the 2 attitudes toward psychotherapy scales and the metric sociodemographic measure of age, Pearson

XSL•FO
RenderX

correlations were calculated. For each of the dichotomous sociodemographic measures and the 2 experiences with treatment for mental disorder questions (ie, gender, migration status, personal experience, and the experience of a close family member) separate 2-tailed *t* tests were performed for the 2 attitudes toward psychotherapy scales. Effect sizes for the *t* tests are reported as Cohen *d*, with the values of Cohen *d*=0.20, Cohen *d*=0.50, and Cohen *d* = 0.80 corresponding to small, medium, and large effects, respectively [61]. If the Levene test for equality of variances indicated that variances were not homogeneous, degrees of freedom were adjusted accordingly. For each categorial sociodemographic measure with more than 2-factor levels (ie, level of education and subjective social status), separate one-way ANOVAs were conducted. These included the sociodemographic measures as predictors and the attitudes toward psychotherapy scales as the dependent variables. Effect sizes for the ANOVAs are reported as η^2, with the values η^2=.01, η^2=.06, and η^2=.14 corresponding to small, medium, and large effects, respectively [62]. Significant main effects in the ANOVAs were followed up with Bonferroni-corrected pairwise *t* tests. Uncorrected *P* values and corrected α-thresholds are reported for these post hoc *t* tests. Participants could opt out of any question, resulting in a missing value for that item. Individuals with missing data for one item were excluded from all analyses including this item, for example, a scale or mean sum score was not calculated for an individual if a specific item relevant to that scale or mean sum score was missing, but it was calculated for other scales of the same questionnaire that do not contain that item if all other items were complete.

Results

Sample Characteristics and Descriptive Statistics

A sample of 2000 individuals was recruited. The sample characteristics can be found in Table 1 (cumulative percentages may not add up to precisely 100% and sample sizes may vary due to weighting and rounding). Descriptive statistics for the QAPT, HLS-EU-Q16, and MHL-W-G questionnaires across the entire sample are in Table 2. Detailed descriptive statistics for the QAPT attitudes and nonacceptance subscales are in Tables 3 and 4, respectively, and detailed descriptive statistics for each QAPT item can be found in Multimedia Appendix 1.

[a]QAPT: Questionnaire on Attitudes Towards Psychotherapeutic Treatment.

Reliability Analyses

The reliability analyses revealed an internal consistency of α=.83 (good) for the attitudes subscale and α=.74 (acceptable) for the nonacceptance subscale of the QAPT. The internal consistency was α=.80 (good) for the HLS-EU-Q16 and α=.92 (excellent) for the MHL-W-G.

Attitudes Toward Psychotherapy and General and Mental Health Literacy

The attitudes subscale of the QAPT correlated negatively with the nonacceptance subscale questionnaire (r=−0.17, 95% CI −0.21 to −0.13; P<.001). General health literacy correlated positively with the attitudes subscale (r=0.14, 95% CI 0.10-0.18; P<.001) and negatively with the nonacceptance subscale (r=−0.32, 95% CI −0.36 to −0.28; P<.001). Mental health literacy correlated positively with the attitudes subscale (r=0.18, 95% CI 0.13-0.22; P<.001) and negatively with the nonacceptance subscale (r=−0.23, 95% CI −0.27 to −0.19; P<.001).

Attitudes Toward Psychotherapy and Experience with Psychotherapy

Participants who have received treatment for a mental disorder reported significantly more positive attitudes toward psychotherapy than participants without treatment experience ($t_{1260.12}$=−10.40, P<.001, Cohen d=−0.49). Likewise, participants who have received treatment for a mental disorder reported significantly less nonacceptance regarding psychotherapy than participants without treatment experience ($t_{1050.95}$=3.06, P=.002, Cohen d=0.16).

Similarly, participants who have a close family member who received treatment for a mental disorder reported significantly more positive attitudes toward psychotherapy than participants without family treatment experience ($t_{1912.06}$=−5.66, P<.001, Cohen d=−0.26). Likewise, participants who have a close family member who received treatment for a mental disorder reported significantly less nonacceptance regarding psychotherapy than participants without family treatment experience (t_{1926}=4.77, P<.001, Cohen d=0.22).

Attitudes Toward Psychotherapy and Sociodemographic Measures

Age correlated negatively with the attitudes subscale (r=−0.11, 95% CI −0.16 to −0.07, P<.001) and negatively with the nonacceptance subscale (r=−0.08, 95% CI −0.12 to −0.03, P<.001).

There were significant gender differences for both subscales. Women reported higher positive attitudes toward psychotherapy than men (t_{1992}=−3.60, P<.001, Cohen d=−0.16). Women also reported lower nonacceptance than men (t_{1994}=5.29, P<.001, Cohen d=0.24).

XSL•FO
RenderX

Subjective social status had a significant effect on both the attitude subscale ($F_{2,1991}$=5.25, P=.005, η^2=.005) and the nonacceptance subscale ($F_{2,1993}$=7.71, P<.001, η^2=.008). Post hoc Bonferroni-corrected t tests for the attitudes subscale (Bonferroni-corrected α=.017) revealed significant differences between the low and high subjective social status groups (t_{607}=−3.08, P=.002, Cohen d=−0.25). Differences between the middle and high (t_{1678}=−2.34, P=.02, Cohen d=−0.15) and the low and middle subjective social status groups (t_{1698}=−1.82, P=.07, Cohen d=−0.11) were not significant after Bonferroni correction. Descriptively, positive attitudes were lowest in individuals with low subjective social status, followed by middle and high subjective social status. Post hoc Bonferroni-corrected t tests for the nonacceptance subscale (Bonferroni-corrected α=.017) revealed significant differences between the low and middle (t_{1699}=2.72, P=.007, Cohen d=0.17) and low and high subjective social status groups (t_{608}=3.88, P<.001, Cohen d=0.32). The difference between the middle and high subjective social status groups was not significant after Bonferroni correction (t_{1679}=2.32, P=.02, Cohen d=0.15). Descriptively, nonacceptance was highest in individuals with low subjective social status, followed by middle and high subjective social status.

Level of education had a significant effect on the attitudes subscale ($F_{2,1983}$=22.27, P<.001, η^2=.021). Post hoc Bonferroni-corrected t tests for the attitudes subscale (Bonferroni-corrected α=.017) revealed significant differences between the low and high educational levels (t_{1126}=−5.52, P<.001, Cohen d=−0.36) and the middle and high educational levels ($t_{1635.23}$=−5.82, P<.001, Cohen d=−0.29), but not between the low and middle educational levels (t_{1204}=−1.01, P=.32, Cohen d=−0.06). Descriptively, positive attitudes were highest in individuals with high educational levels, followed by middle and low educational levels.

There was no significant effect of level of education on the nonacceptance subscale ($F_{2,1984}$=0.02, P=.99, η^2<.001). Descriptively, participants with low, middle, and high levels of education reached similar scores.

There were no significant differences for the attitude subscale between individuals with and without a migration background (t_{1992}=0.73, P=.46, Cohen d=0.07). Likewise, there were no significant differences for the nonacceptance subscale between individuals with and without a migration background (t_{1994}=−0.29, P=.77, Cohen d=−0.03).

Results of the inferential analyses for the unweighted dataset can be found in the Multimedia Appendix 1. Importantly, weighting had no effect on the inferential conclusions except for one analysis. The post hoc t test for the difference between the low and high subjective social status groups did not reach significance in the unweighted dataset after the Bonferroni correction.

Discussion

Overview

This study investigated the associations between attitudes toward psychotherapeutic treatment and both general and mental health literacy in a large and representative sample of the general population in Germany. In addition, attitudes toward psychotherapeutic treatment were analyzed concerning interindividual differences in terms of experience with mental health treatment and sociodemographic factors.

Principal Findings

Overall, participants expressed largely positive attitudes toward psychotherapeutic treatment and reported relatively low perceived nonacceptance. However, significant interindividual differences were observed and are discussed below.

Importantly, while our results demonstrate several statistically significant results, the practical significance of these findings has to be considered before interpretation. All effect sizes (Cohen d and η^2) reported here fall into the small to medium range [61,62]. In addition, some of the CI of the means overlap. This means that the practical impact of our findings in real-world settings may be limited. Nonetheless, these findings point to potentially vulnerable sociodemographic groups in need of specific interventions to promote positive attitudes toward psychotherapy. The small effect sizes observed here suggest that while tailored interventions for specific groups may be more effective due to a better fit between the specific needs of a sociodemographic group and the intervention, there is also a potential overall benefit of broader general-population interventions [63,64].

The questionnaire scales used in this study reached acceptable to excellent internal consistency coefficients speaking for a high degree of interrelatedness of the scale items and their overall reliability which is an important prerequisite for the validity of the results [60]. Furthermore, weighting did not have a marked effect on the conclusions drawn from the statistical findings which highlights the generalizability of the findings.

General and Mental Health Literacy

Both higher general and higher mental health literacy were associated with more positive attitudes and lower nonacceptance of psychotherapeutic treatment. For mental health literacy, this finding aligns well with previous research [12,32,33,35]. Of note, these previous studies mostly used the simple identification of vignettes as a measure of mental health literacy. Here, we used a much broader instrument for mental health literacy more closely mirroring the definition of mental health literacy by also covering aspects of support, prevention, and use of resources [28,53]. For the first time, we show here that by including these broader aspects of mental health literacy positive associations with positive attitudes and negative associations with nonacceptance can be obtained, significantly extending previous observations in studies using vignette identification as a proxy for mental health literacy. Another novel contribution of our investigation is that we replicated initial findings of the associations between the QAPT and MHL-W-G scales

XSL•FO
RenderX

previously observed only in a small sample of working individuals in a substantially larger general population sample with similar effect sizes [43]. Notably, here, we also add to the literature by showing a positive association between general health literacy and the attitudes measure, which to our knowledge was previously only reported in one study [34]. Here, we replicate these initial findings in a larger sample and generalize them to another measure of general health literacy, namely the widely used HLS-EU-Q16. This suggests that individuals with higher levels of both general and mental health literacy are more likely to exhibit positive attitudes toward psychotherapy and perceive societal acceptance to be higher. Consequently, they might also be more likely to seek treatment when faced with mental problems [19]. Crucially, however, it has to be noted that our cross-sectional study design does not allow to infer causal associations between the investigated constructs (also refer to limitations below; [65]). Therefore, we cannot unequivocally conclude whether inadequate or problematic health literacy is indeed the antecedent and origin of less positive attitudes toward psychotherapy. We recommend future studies with appropriate study designs to test for causal effects, for example, randomized controlled trials. In addition, other potentially confounding variables should be carefully assessed and controlled for.

The present findings should also be interpreted in the context of mental health stigma in general. Although some progress in reducing stigma has been made in the past years substantial stigma against people with mental health problems remains [13,14]. Crucially, individuals with more stigmatizing attitudes show less active help-seeking behavior [17]. The promotion of health literacy with targeted interventions along with far-reaching antistigma campaigns could therefore also lead to higher rates of individuals seeking treatment [66]. Importantly, antistigma interventions may be more effective when focusing on psychosocial instead of biogenetic causes for mental disorders [35]. In addition to these interventions focusing on individual barriers, structural barriers to psychotherapeutic treatment (although not the focus of the present research) should not be disregarded and must be addressed as well. For example, waiting periods should be significantly reduced and provision should be increased, especially in rural areas [2,6,7].

Experience with Psychotherapy

Attitudes were more positive, and nonacceptance was lower in participants who have received treatment for mental disorders in the past or those who have a close relative with treatment experience. This is consistent with previous research [8,35]. It is noteworthy, that the treatment experience of a close family member may already improve the treatment attitudes of their relatives although with lower effect sizes than personal experience. Speaking openly about mental health treatment experiences and thus providing information about treatments might therefore be a valuable path to lowering psychotherapy stigma [49]. However, as no causal conclusions can be drawn from our study design, it is possible that positive treatment attitudes are not the result of personal or family treatment experience but that those with a priori more positive treatment attitudes are more likely to seek treatment.

Sociodemographic Factors

Women exhibited significantly more positive attitudes and reported lower perceived societal nonacceptance (ie, higher acceptance) of psychotherapeutic treatment compared to men. This finding aligns with previous research [10,67] and may be attributed to masculinity ideals and self-stigma, preventing men from seeking help for mental health problems [68,69].

Regarding age, more positive attitudes toward psychotherapeutic treatment were found in younger individuals, consistent with some [8] but not all previous investigations [10,70]. However, surprisingly, younger individuals also displayed higher levels of nonacceptance compared to older individuals, suggesting a discrepancy between perceived societal acceptance and individual attitudes. This pattern of results might be interpreted as higher awareness of the persisting mental health stigma in the community in younger individuals, although a generational shift toward less stigma is slowly taking place [14]. Notably, in our data, correlations with age were relatively small for both subscales. Integrating our results with previous literature, an overall heterogeneous picture emerges [8,10,70]: age seems to have no or a very small effect on attitudes toward psychotherapy and how it is perceived to be accepted by society. Future interventions to improve help-seeking for mental problems should therefore address all age groups.

Attitudes toward psychotherapy were also related to the subjective social status of the participants. Specifically, positive attitudes increased, and nonacceptance decreased with higher subjective social status, although the post hoc test between the high and low social status groups for the attitudes subscale narrowly missed significance in the unweighted dataset (refer to Multimedia Appendix 1). Social status has been identified as a major determinant of help-seeking behavior in the past [71,72]. However, more research is needed to determine the role of social status in attitudes toward psychotherapy. Critically, social status also plays a role in access to psychotherapy. Individuals with lower social status are less likely to be offered treatment than individuals with higher social status suggesting that structural barriers are also higher for these individuals than those with higher social status [73]. Potential financial barriers to access to psychotherapeutic treatment should also be considered but do not apply to the majority of our participants as the German public health insurance that insures about 90% of the population covers psychotherapeutic treatment for many diagnoses [74-76]. Treatment attitudes and treatment seeking should be carefully addressed in help-seeking interventions for individuals with lower social status and treatment should be provided equally to individuals of all social status groups. As general and mental health literacy were found to be low in individuals with lower subjective social status, these groups might particularly benefit from interventions [31,77]. There is first evidence to suggest that individuals with low social status might particularly benefit from culturally appropriate and tailored interventions that are based on scientific theories and incorporate different modalities, for example, using print materials and offering direct contact with the interventionists [63,64,78].

XSL•FO
RenderX

Higher educational levels were associated with more positive attitudes toward psychotherapy. However, there was no association between education and perceived acceptance of psychotherapy. In the literature, there is heterogeneous evidence concerning the role of education in attitudes toward mental health help-seeking [8,10,53]. Therefore, more research in this area is recommended to determine the role of education in help-seeking attitudes. Our results carefully suggest that programs directed at individuals with lower levels of education could be particularly beneficial.

Migration background was not related to neither positive attitudes nor perceived nonacceptance in our sample. This result is surprising given previous evidence of more negative attitudes toward psychotherapeutic treatment, and simultaneous higher endorsement of pharmacotherapy, in people with a migration background [44-46]. However, as we only included individuals with sufficient knowledge of the German language, it cannot be ruled out that our sample of individuals with a migration background was not representative of all individuals with a migration background in Germany (refer to *Limitations* section). Future studies could try to overcome this problem by providing translated questionnaires to reach a broader segment of the population with a migration background. In addition, substantial cultural differences have been delineated in the past, which is why we recommend investigating more thoroughly how the cultural backgrounds of the individuals with migration backgrounds are associated with their endorsement of psychotherapeutic treatment [44,79,80], but our data does not allow more fine-grained analyses. Notably, however, interventions to increase the use of mental health care may be more effective when tailored to the specific needs of minority groups and different cultures [47,63,64,78].

Overall, the findings presented here imply that more interventions to improve attitudes toward psychotherapy might be necessary and might be achieved by explicitly targeting both general and health literacy in vulnerable segments of the community. Our findings suggest that male individuals, those with higher age, lower social status, and lower levels of education might particularly benefit from interventions to promote positive attitudes toward psychotherapy. Of note, while a large number of interventions have already been developed and evaluated in the past, systematic reviews of the literature show substantial heterogeneity in the efficacy of these interventions and call for more high-quality evaluations [36-39]. In particular, more effort needs to be put into interventions in different cultures and across ethnic minority groups [40,41,80]. Notably, there are first promising results, for example concerning digital mental health interventions that are both cost-effective and easy to implement [39]. Web-based interventions appear to be generally efficacious when they include certain active components such as interactivity, target-group specificity, evidence-based content, and a sequential modular concept [81], for example as part of an e-learning platform [82,83]. While potential improvements in health literacy may not directly translate to increased help-seeking behavior, further research is needed to explore this connection [81].

Limitations

The findings presented here have to be interpreted in the light of some limitations. First, both attitudes and health literacy were assessed via self-reports. Future studies could focus on more applied measures rather than self-reports for a broader scope and higher ecological validity. Second, 6.2% of the participants in the weighted sample reported having a migration background. This is substantially lower than recent census data from Germany [84], suggesting that our sample may not be representative in terms of the proportion of individuals with a migration background. Third, giving our participants the option to opt-out from specific items might have resulted in systematically missing data which could have affected the generalizability of the results. However, the number of individuals using that option was relatively low, with the highest number (3.4%) for the item asking about family experience with psychotherapy which we speculate might have been the result of lack of knowledge. Importantly, the proportions of missing values were smaller for the main questionnaires used here (eg, 0.3% and 0.2% for the QAPT scales, refer to Table 2). As these proportions are substantially lower than the recommended threshold of 5%, no imputation analyses for missing values were conducted and all analyses were conducted with all available data [85]. Fourth, we relied on data collected on the web which might have resulted in lower data quality [86,87]. However, with this interview mode, a substantially larger sample size could be achieved, simultaneously reducing error variance. In addition, by working with the forsa.omninet panel a few issues common to web-based surveys could be mitigated. For example, participants were randomly selected and could not apply to take part in the study, people who rarely use the internet were also represented due to the panel recruitment via telephone, and multiple registrations of the same individuals were prevented. However, the sample is only representative of the population with internet access as data collection took place exclusively on the internet, which is why results may not be generalizable to individuals without internet access. Finally, as noted above, the present investigation used a cross-sectional study design. Consequently, the results cannot be interpreted in terms of causal relationships [65], which is why further research is needed with more sophisticated study designs including longitudinal and experimental studies that control for potentially confounding factors.

Summary and Conclusion

In this study, positive attitudes toward psychotherapy and perceived societal acceptance of psychotherapeutic treatment were investigated in a large general population sample in Germany. Our results highlight a positive association between these factors and both general and mental health literacy. Individuals who have been treated for mental problems or who have relatives with treatment experience reported more favorable attitudes and higher perceived acceptance of society than those without treatment experience. In terms of sociodemographic differences, it was shown that being a woman, younger age, higher social status, and higher levels of education were associated with more positive attitudes toward psychotherapeutic treatment. Being a woman, older age, and higher subjective social status were associated with higher perceived societal

XSL•FO
RenderX

acceptance of psychotherapy. Since previous studies suggest that target group-specific interventions have the potential to improve health literacy, future studies should focus on establishing whether tailored interventions designed to increase general or mental health literacy and aimed at individuals with deficits in this area may improve attitudes toward seeking help for mental problems.

Abstract

Background: Although understanding long-term trends in adolescent screen time and the influence of family structure is essential, there is a lack of research addressing these issues comprehensively.

Objective: This study aimed to conduct comprehensive investigations into adolescent screen time before and during the COVID-19 pandemic, with a particular focus on family structures.

Methods: This study used nationwide, large-scale data from the Korea Youth Risk Behavior Web-Based Survey from South Korea. We aimed to indicate the changes in adolescent screen time over 15 years from 2008 to 2022. Weighted linear regression was used to analyze annual trends in screen time before and during the pandemic, and stratified analyses were conducted to examine associated risk factors across different family structures.

XSL•FO
RenderX

Results: This study used data from a total of 836,972 individuals (n=403,456, 48.2% women), with an age range of 12-18 years. The analysis revealed an overall increase in screen time prepandemic (β=8.06, 95% CI 7.74-8.39), with a notable increase observed at the onset of the pandemic (β=162.06, 95% CI 159.49-164.64). Among diverse family structures, the orphanage group showed the most substantial increase in screen time during the pandemic (β_{diff}=221.90, 95% CI 159.62-284.17). Risk factors associated with screen time during the pandemic varied by family structure. Notably, the nuclear family group presented distinct screen time–related risk factors, including grade, region of residence, physical activity frequency, sadness and despair, and the highest education level of parents.

Conclusions: There has been a notable increase in average screen time among adolescents since the onset of the pandemic, with the orphanage group exhibiting a pronounced trend. The risk factors associated with screen time during the pandemic varied for each family structure. Findings from this study suggest that the implementation of individualized measures tailored to each family structure should be adopted to effectively address the increased issue of adolescent screen time since the pandemic.

Introduction

There was a declaration of COVID-19 as a global pandemic by the World Health Organization in March 2020 [1]. With the proclamation, countries worldwide have advocated for indoor living, remote work, and web-based learning to prevent the spread of COVID-19. For example, the National Health Service in England advised individuals to remain at home and participate in remote work unless necessary, while the Chinese government implemented restrictions on public transport and postponed the reopening of schools following the vacation period [2]. Globally, universities and educational institutions were closed, prompting a rapid digital transition in the education system [3,4]. The increase in indoor time since the pandemic has likely induced a concurrent increase in screen time [5,6]. Throughout the pandemic, social distancing and economic hardships restricted daily activities and social interactions, negatively impacting individuals' mental health worldwide [7,8]. Among preschool children, psychological resilience has been identified as a factor that amplifies the positive outcomes associated with the use of digital technologies [9]. The need for discussing how the utilization of digital technologies evolves in response to mental health changes brought about by the pandemic is increasingly evident. In such circumstances, specific focus is placed on the increased screen time of adolescents, due to the association with adolescent depression and mental health [10,11]. Global guidelines, such as Canada's 24-Hour Movement Guidelines for Children and Youth, recommend limiting recreational screen time to 2 hours or less per day, highlighting the potential risks of excessive screen use [12]. With the onset of the COVID-19 pandemic, there is growing global attention to screen time among adolescents.

In South Korea, concerns about excessive screen time among adolescents predate the pandemic. The "Shutdown Law," implemented in 2011, restricted web-based gaming for those younger than 16 years old during late-night hours to prevent gaming addiction but was abolished in 2021 [13]. A recent study highlighted a significant increase in screen time among Korean adolescents, with teenagers spending an average of 303.66 minutes daily during the pandemic, a substantial rise from 133.24 minutes in the prepandemic period [14]. The screen time of adolescents appears to be influenced by their family structure, likely due to variations in parental monitoring, restrictions on screen use, and the promotion of outdoor activities [15]. However, studies on this topic are limited by small sample sizes, a narrow focus on specific family structures, and a lack of consideration for the significant changes brought about by the COVID-19 pandemic [15,16]. This underscores the need for a comprehensive analysis of long-term trends in adolescent screen time, particularly about diverse family structures, both before and during the pandemic.

Therefore, this study investigated the 15-year trends in adolescent screen time and potential risk factors based on family structures, using a nationwide dataset of Korean adolescents surveyed between 2008 and 2022. The primary aim of this study was to assess the changes in adolescent screen time trends and associated risk factors in each family structure since the onset of the pandemic.

Methods

Study Design and Population

This study used the Korea Youth Risk Behavior Web-Based Survey (KYRBS). KYRBS is a large-scale, nationwide survey covering health-related behaviors of Korean adolescents [17]. The KYRBS is designed to collect data from middle and high school students (grades 7 to 12) aged 12 to 18 years enrolled in public and private schools throughout South Korea. To achieve national representativeness, the survey uses a stratified, multistage cluster sampling approach [18]. Schools are chosen as the primary sampling units based on regional and school-type stratifications, followed by a random selection of classes within these schools [18]. This methodology ensures a balanced representation of students from both urban and rural areas. Administered annually by the Korea Disease Control and Prevention Agency, the survey has consistently maintained an average response rate of 95.7% over the past 15 years. Students voluntarily completed a web-based anonymous questionnaire following a standardized protocol in a computer lab in each school [19].

To ensure the data's representativeness, sampling weights were determined and applied. The weighting process considers the

XSL•FO
RenderX

probability of selection at each stage of sampling (schools and classes), adjusts for nonresponse, and incorporates poststratification adjustments to align with the overall student population distributions by grade, sex, and school type for each survey year. To avoid overrepresentation, extreme weights were capped using interquartile range techniques. These adjustments ensure that the results reliably represent the health behaviors of the adolescent population across South Korea. In this study, an initial cohort of 992,702 respondents completed the questionnaires from 2008 to 2022. Following the exclusion of participants with missing data, the final dataset comprised 836,972 samples (84.3% of the initial raw data). The exclusion of missing data was conducted systematically to maintain dataset robustness and minimize bias.

Ethical Considerations

The study protocol was approved by the Institutional Review Board of the Korea Disease Control and Prevention Agency (2014-06EXP-02-P-A), and all participants provided written informed consent. Additionally, the study complied with the Population Health Promotion Act 19 (117058) as mandated by the Korean government. This study was conducted following the principles of the Declaration of Helsinki.

Endpoints

We aimed to investigate trends in screen time and explore associated risk factors, with a focus on the diverse family structures of adolescents. The COVID-19 pandemic period was defined as 2020-2022, starting with the first observed COVID-19 case in South Korea on January 20, 2020, and aligning with widespread public health measures [20,21]. The prepandemic years were grouped into 6-year intervals, each spanning two consecutive years, as follows: 2008-2009, 2010-2011, 2012-2013, 2014-2015, 2016-2017, and 2018-2019. This classification allows for a clear comparison of trends before and during the pandemic.

Screen time was defined as the average daily time spent on the internet or using smartphones for noneducational purposes. Participants were asked: “What was your average daily internet or smartphone use on weekdays in the past 30 days?” and “What was your average daily internet or smartphone use on weekends in the past 30 days?” The overall average screen time was calculated by combining weekday and weekend use, weighted to reflect their relative proportions within a week [19].

Family structures were categorized into 4 groups: nuclear family, living with relatives, living alone, and orphanage. A nuclear family was defined as adolescents living with one or both parents, regardless of biological relationships. The “living with relatives” category included adolescents residing with extended family members, such as grandparents or uncles or aunts, excluding parents. “Living alone” referred to those managing households independently without the presence of any family members. The “orphanage” category encompassed adolescents living in child welfare facilities. These classifications are based on established definitions in prior studies on family dynamics and adolescent health [22].

Covariate Definitions

A total of 11 covariates were included in the analytical models: sex, BMI group (underweight, normal, overweight, and obese), grade (7th to 9th [middle-school] and 10th to 12th [high-school]), region of residence (urban and rural) [23,24], smoking status, alcoholic consumption, school performance (low, middle-low, middle, middle-high, and high), sexual experience, physical activity frequency (lower activity, moderate activity, and higher activity), sadness and despair, and highest education level of parents (high school or lower and college or higher). BMI was calculated using self-reported height and weight data. Conforming to the 2017 Korean National Growth Charts, BMI was categorized into the following four groups: underweight (<5%), normal (5% to 84 %), overweight (85% to 94%), and obese (≥95%) [19]. School performance was categorized into the following five groups according to the self-reports of students: low (<20%), middle-low (20% to 39%), middle (40% to 59%), middle-high (60% to 79%), and high (≥80%). Physical activity frequency was classified into the following three groups based on the engagement in vigorous aerobic and resistance training more than three days per week: lower activity (neither activity is done for more than three days per week), moderate activity (either one activity), and higher activity (both activities). The definitions of variables were extracted from peer-reviewed literature [19].

Statistical Analysis

We used a weighted linear regression model to compute β coefficient and β difference (β_{diff}) along with a 95% CI [25]. This strategy was selected for trend analysis and associated factor analysis. In the analysis of screen time trends, the β coefficient expressed the annual trend of screen time among adolescents in prepandemic or pandemic. β_{diff} was used to indicate the trend difference between the divided year groups based on the onset of the pandemic. In the analysis of screen time-associated factors, the β coefficient represents the correlation between screen time and each biological, social, and familial factor. β_{diff} was also used to reveal the difference in correlation between the year groups divided by the onset of the pandemic. In addition, the associations between screen time and each variable were recalculated after adjusting for potential influencing factors, including age, sex, BMI group, grade, region of residence, smoking status, alcoholic consumption, school performance, sexual experience, physical activity frequency, sadness and despair, and highest education level of parents. Statistical significance, as applied in all the above analyses, was determined by a 2-sided *P* value less than .05. Statistical analysis in this study was conducted using SAS software (version 9.4; SAS Institute Inc).

Results

This study was conducted using KYRBS spanning from 2008 to 2022. A total of 836,972 individuals (n=403,456, 48.20% women) with an average age of 15.01 (SD 1.75) years were finally selected for the analysis following the missing data handling. Baseline characteristics of the raw data are indicated in Table 1.

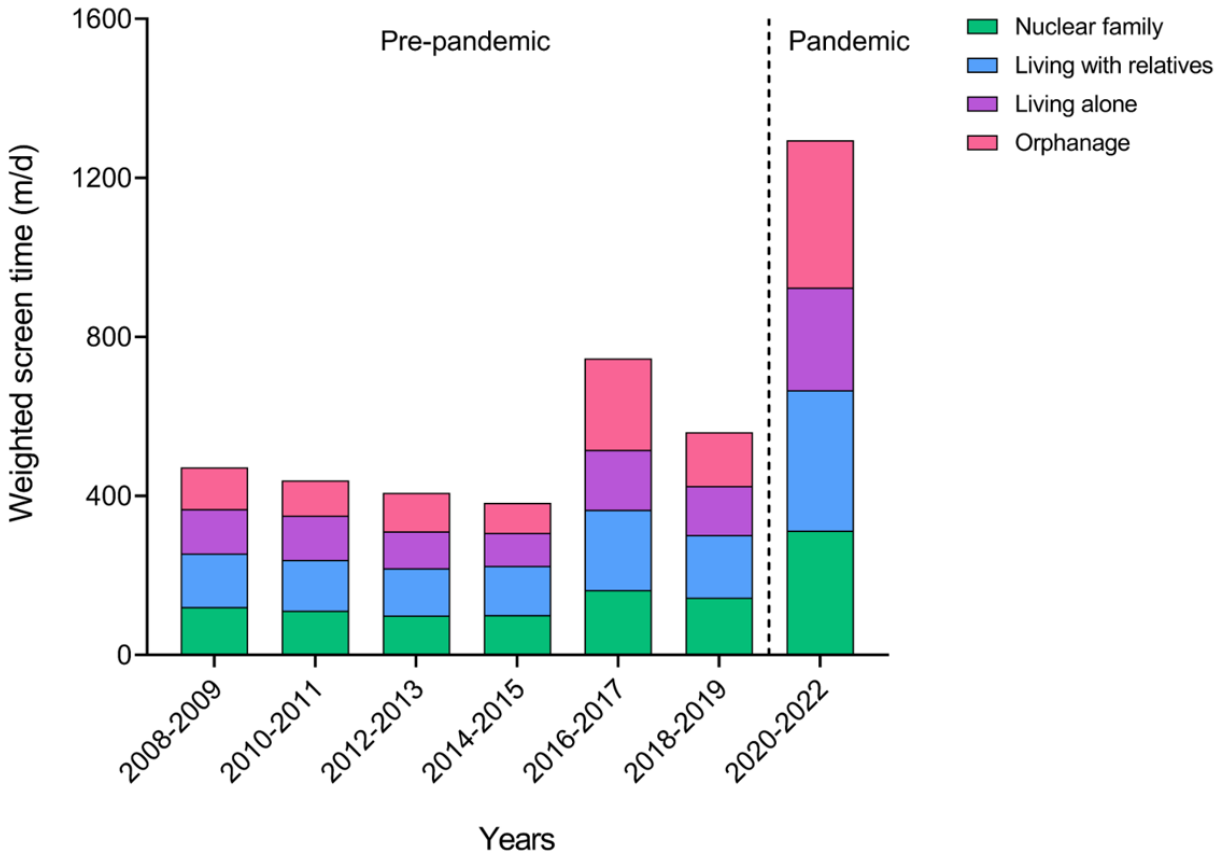
[a]KYRBS: Korea Youth Risk Behavior Web-Based Survey.

[b]BMI was divided into four groups according to the 2017 Korean National Growth Charts: underweight (<5%), normal (5% to 84%), overweight (85% to 94%), and obese (≥95%).



[c]School performance was divided into five groups: low (<20%), middle-low (20% to 39%), middle (40% to 59%), middle-high (60% to 79%), and high (≥80%).

[d]Physical activity frequency was divided into three groups based on the engagement in vigorous aerobic and resistance training more than three days per week: lower activity (neither activity is done for more than three days per week), moderate activity (either one activity), and higher activity (both activities).

The average weekly screen time and the trend change before and during the pandemic for each demographic over 15 years are exhibited in Multimedia Appendix 1 and Tables S1-S4 in Multimedia Appendix 2. Particularly, the trend in average screen time for each family structure is illustrated in Figure 1. Screen time showed a consistent increase from 2008 to 2022. Starting at 119.80 minutes per day (m/d; 95% CI 118.63-120.98) in 2008-2009, it temporarily decreased to 99.64 m/d (95% CI 98.45-100.83) in 2012-2013, then increased to 165.68 m/d (95% CI 163.27-168.08) in 2016-2017, and finally reached 306.80 m/d (95% CI 304.30-309.30) in 2020-2022, reflecting a sharp increase during the pandemic.

XSL•FO
RenderX

Figure 1. Trends in weighted screen time among adolescents in South Korea by family type, 2008-2022.

The pandemic had a significant impact on screen time, as detailed in Tables S1-S4 in Multimedia Appendix 2. The analysis showed a modest increase in screen time during the prepandemic period (β=8.06, 95% CI 7.74-8.39) and a substantial rise during the pandemic (β=162.06, 95% CI 159.49-164.64), with a significant difference in growth rate (β_{diff}=149.43, 95% CI 132.79-166.07). Among family structures, students in orphanages exhibited the largest increase (β_{diff}=221.90, 95% CI 159.62-284.17).

Table 2 highlights associations between screen time and biological, social, and familial factors. Women (β_{diff}=74.91, 95% CI 71.52-78.30) and higher BMI (β_{diff}=2.11, 95% CI 0.80-3.42) were identified as significant biological vulnerabilities. Among social factors, smoking (β_{diff}=79.09, 95% CI 63.13-95.06), alcohol consumption (β_{diff}=54.37, 95% CI 50.40-58.35), and sexual experience (β_{diff}=46.73, 95% CI 40.78-52.68) had the strongest associations with increased screen time. Academic achievement (β_{diff}=28.05, 95% CI 27.04-29.06]), rural residence (β_{diff}=–11.61, 95% CI –15.49 to –7.73), sadness and despair (β_{diff} 10.71, 95% CI 8.34-13.07), higher physical activity (β_{diff}=5.35, 95% CI 3.95-6.75), and higher grade (β_{diff}=3.99, 95% CI 1.52-6.46) showed varying impacts (Figures 2 and 3).

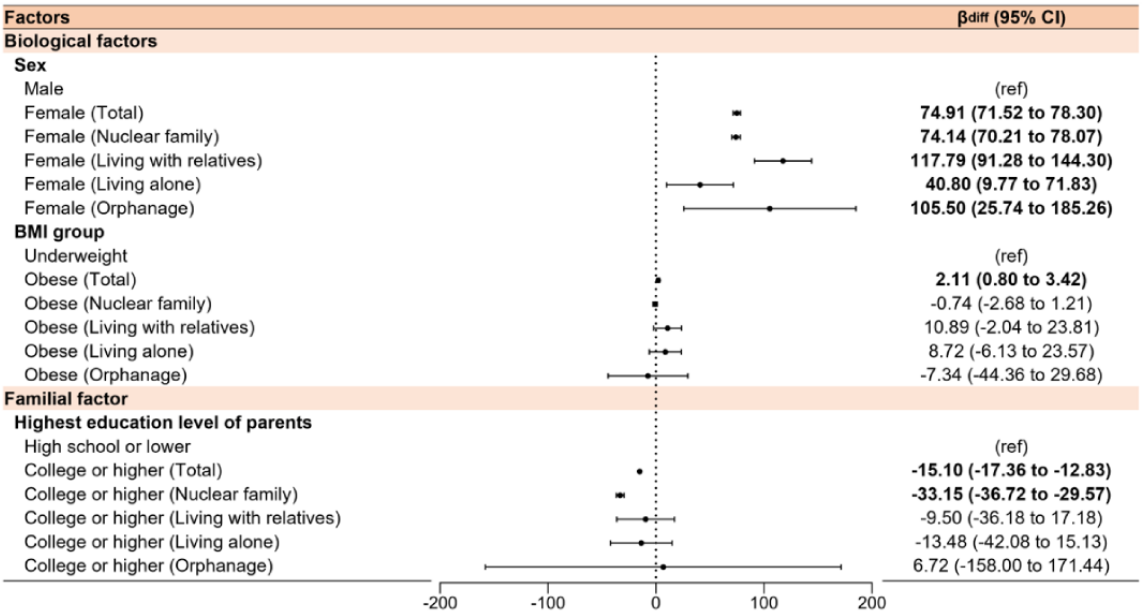
[a]KYRBS: Korea Youth Risk Behavior Web-Based Survey.

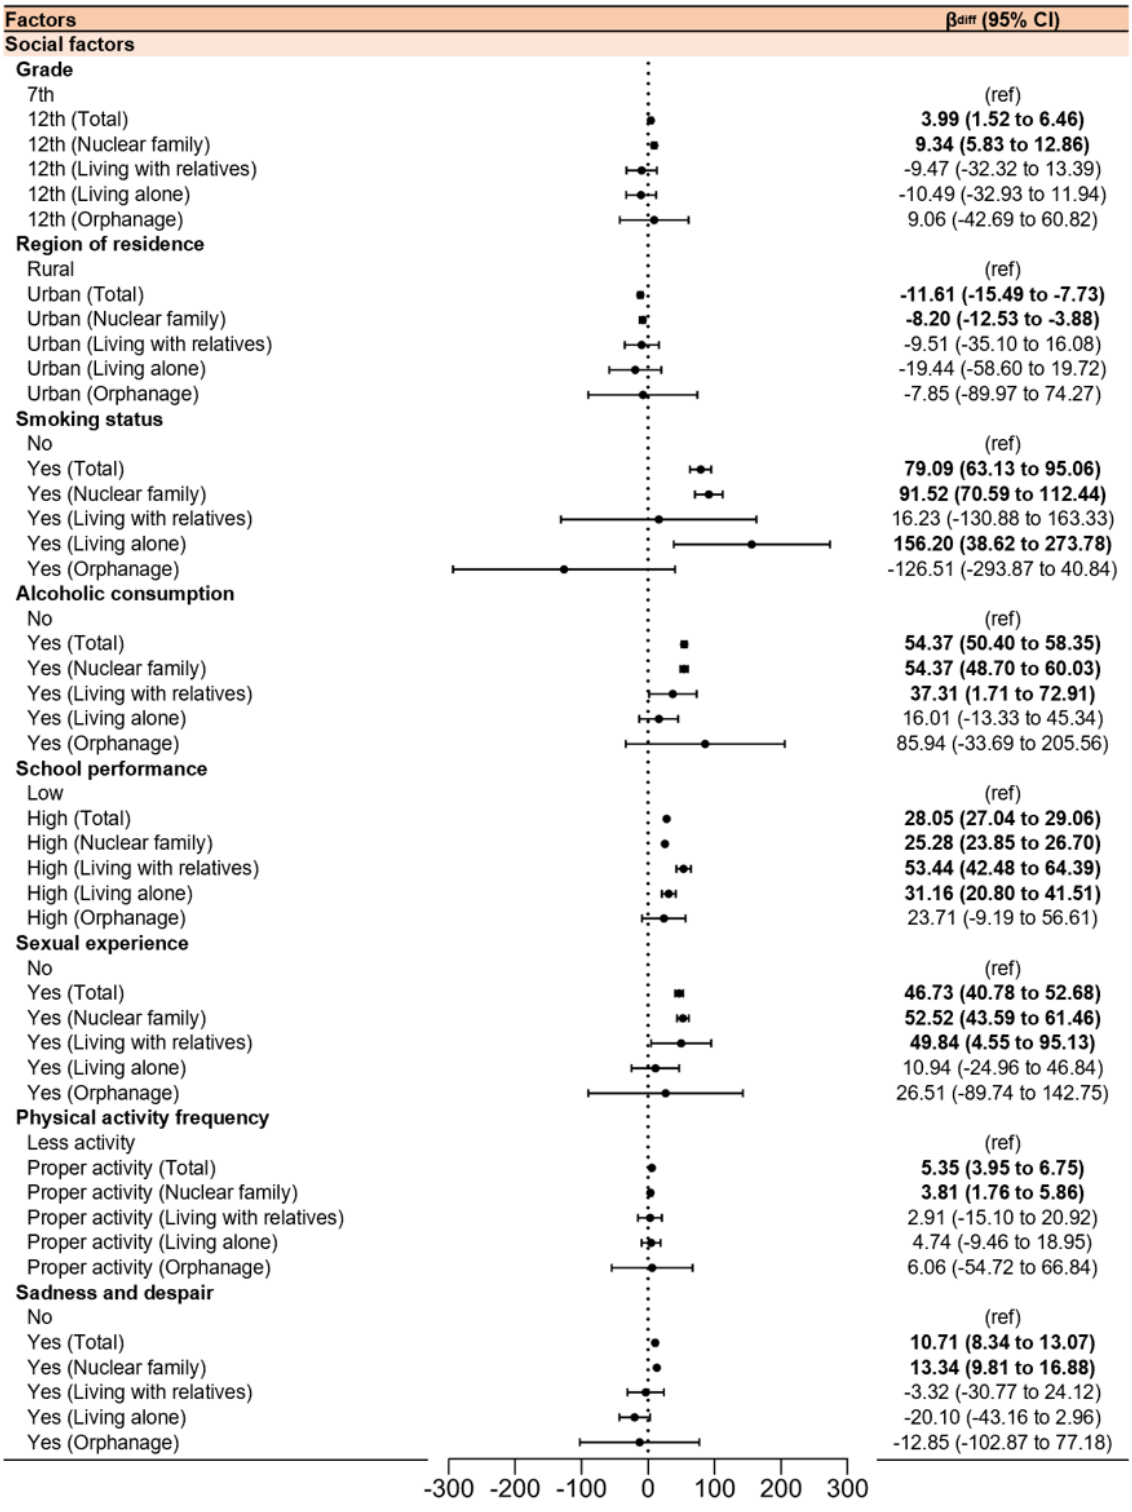
[b]Adjustment for age, sex, BMI group, grade, region of residence, smoking status, alcoholic consumption, school performance, sexual experience, physical activity frequency, sadness and despair, and highest education level of parents.



[c]Indicate a significant difference (P<.05).

[d]BMI was divided into four groups according to the 2017 Korean National Growth Charts: underweight (<5%), normal (5% to 84%), overweight (85% to 94%), and obese (≥95%). BMI was calculated as weight in kilograms divided by height in meters squared.

[e]School performance was divided into five groups: low (<20%), middle-low (20% to 39%), middle (40% to 59%), middle-high (60% to 79%), and high (≥80%).



[f]Physical activity frequency was divided into three groups based on the engagement in vigorous aerobic and resistance training more than three days per week: lower activity (neither activity is done for more than three days per week), moderate activity (either one activity), and higher activity (both activities).

Figure 2. β differences of biological and familial factors in weighted average screen time among adolescents before and during the COVID-19 pandemic in KYRBS. KYRBS: Korea Youth Risk Behavior Web-Based Survey.

Figure 3. β differences of social factors in weighted average screen time among adolescents before and during the COVID-19 pandemic in KYRBS. KYRBS: Korea Youth Risk Behavior Web-Based Survey.

Adjusted models presented in Tables S5-S8 in Multimedia Appendix 2 explored associations across family structures. Before the pandemic, men in nuclear families (β=–10.50, 95% CI –11.92 to –9.08) and those living with relatives (β=–15.14, 95% CI –21.58 to –8.71) had lower screen time. In contrast, women living alone (β=14.80, 95% CI 3.57-26.03) showed higher screen time. During the pandemic, screen time significantly increased for women across all family structures: nuclear families (β_{diff}=74.14, 95% CI 70.21-78.07), living with relatives (β_{diff} 117.79, 95% CI 91.28-144.30), living alone (β_{diff} 40.80, 95% CI 9.77-71.83), and in orphanages (β_{diff} 105.50, 95% CI 25.74-185.26; Figure 3).

Discussion

Key Findings

This study stands out as the initial comprehensive long-term trend analysis of adolescent screen time and associated factors across various family structures, encompassing the COVID-19 era (Figure 4). There was an overall increase in screen time from 2008 to 2022. Specifically, throughout the pandemic spanning from 2020 to 2022, there was a substantial increase in adolescent screen time compared to the prepandemic. Among various family structures, students within the orphanage group exhibited the most significant increase in screen time since the pandemic onset. All examined factors exhibited statistically significant alterations in their association with adolescent screen time during the pandemic. Particularly, stratified by family structure, it was consistently observed that women had more vulnerability to increased screen time during the pandemic regardless of family structure. Meanwhile, the nuclear family group showed distinctive screen time-associated factors, including grade, region of residence, physical activity frequency, sadness and despair, and highest education level of parents, which were not present in the other family groups.

Figure 4. Graphical conclusion.

Comparison With Previous Studies

Earlier investigations have predominantly focused on the changes in adolescent screen time trends during the COVID-19 pandemic. Studies conducted in countries such as Canada (n=29,027), Germany (n=1711), the United States (n=5412), China (n=1680), and South Korea (n=913,191) consistently reported significant increases in screen time following the onset of the pandemic [14,26-28]. Many of these studies also examined factors influencing screen time, including depression and mental health [10,11]. However, most were limited by relatively small sample sizes, restricted age ranges of participants, or insufficient analysis of trends across specific demographic subgroups, such as those defined by family structure [26-29].

Additionally, while existing studies from Norway (n=4509) and France (n=3720) have explored the association between adolescent screen time and family structure, they often lack diversity in the types of family structures considered and fail to account for the profound shifts introduced by the pandemic [15,16]. These limitations highlight the importance of considering a wider range of family structures and the influence of contextual factors like the pandemic when analyzing screen time trends [27,28].

In contrast, this study addresses these gaps by analyzing a significantly larger sample size (n=836,972) collected over 15 years, allowing for a more robust examination of long-term trends. Furthermore, the stratification of adolescents by diverse family structures—nuclear families, living with relatives, living alone, and orphanages—enables a unique comparative analysis of disparities in screen time trends across these groups. This approach not only provides a more comprehensive understanding of the changes in adolescent screen time but also sheds light on the distinct risk factors associated with different family structures during the pandemic.

Plausible Mechanism

The overall elevation in average screen time of adolescents spanning from 2008 to 2022 could be elucidated by the rise in smartphone penetration among adolescents. The prevalence of smartphones among adolescents in South Korea increased by 15.3%, rising from 79.3% in 2015 to 94.6% in 2022 [30]. This upward trend would have played a role in the elevation of screen time among Korean adolescents over the 15 years. Particularly, a substantial increase in screen time with the onset of the pandemic is likely due to the increased duration of indoor activities. During the pandemic, there was an increase in time spent indoors at home and a decrease in outdoor activities,

XSL•FO
RenderX

including walking, cycling, and commuting [31]. Students were restricted from the absence of the school community covering a range of cultural, sports, social, and emotional experiences. Instead, there was an increase in internet use time for video watching and gaming with the onset of the pandemic, suggesting an influence on the rapid rise in screen time [32]. Fundamentally, the rise in screen time could be attributed to the shift in the pandemic lifestyles of students: decreased outdoor activities and various web-based engagements.

Across all family structures, a marked increase in screen time was evident following the pandemic. However, there was a specific increase in screen time among students belonging to the orphanage group. This suggests a potential influence of the presence of parents or relatives on screen time during the pandemic. The Royal College of Paediatrics and Child Health emphasized the significance of the roles of guardians in managing adolescent screen time. They recommended careful parental consideration when introducing technology to adolescents and setting individualized regulations for their screen time [16]. This detailed assistance, initially inadequate for the orphanage group, became further deficient during the pandemic due to the obstruction of support from teachers in schools. It is likely to have contributed to the substantial screen time adjustment failure observed in the orphanage group.

We analyzed the association between various biological, social, and familial factors and screen time according to the family structure. Among the diverse family structures, the nuclear family group exhibited several unique screen time-associated factors from the onset of the pandemic that were not observed in other family structures. In particular, the region of residence indicated that students residing in urban regions were less susceptible to increased screen time during the pandemic compared to their counterparts in rural regions. This finding is likely linked to parental abilities associated with the region of residence. Parents have been identified as having heightened concerns related to screen-related risks, such as cyberbullying and exposure to inappropriate or harmful content [33]. The perceived difference in screen time between regions is likely because parents residing in urban regions exhibited higher levels of parenting compared to those living in rural regions [34]. Particularly, the increase in indoor time during the pandemic induced an increase in the time spent with parents, indicating an intensified influence of parenting on adolescents. Therefore, it may be that students residing in urban regions were less vulnerable to increased screen time during the pandemic than students residing in rural regions.

Clinical and Policy Implications

This study offers a reminder of the recent rapid increase in screen time among adolescents. Considering the rise in screen time since the pandemic, it is imperative for clinical professionals and policymakers to promptly propose relevant regulation solutions. As a noticeable increase in screen time has been observed among adolescents belonging to the orphanage group following the pandemic, officials should implement more intensive management strategies for this particular group. Heightened management is also required for women adolescents, who exhibited vulnerability to increased screen time across all family structures during the pandemic. We additionally suggest the development of a customized screen time management strategy tailored to the specific family structures of each adolescent. Providing individualized solutions targeting the risk factors associated with each family structure can contribute to a more effective reduction in screen time. Specifically, focusing on the distinct risk factors (grade, region of residence, physical activity frequency, sadness and despair, and highest education level of parents) within the nuclear family group could prompt targeted management strategies for this particular cohort. Given the physical and mental health and socioemotional well-being concerns associated with excessive screen time [10,35,36], appropriate efforts from clinical, social, and political professionals are needed to normalize the rapidly increased screen time among adolescents since the pandemic. To address this, it is essential to expand international health expenditure for pandemic response and preparedness [37]. Thus, securing long-term and sustainable funding is crucial to address the rise in adolescents' digital device use and the associated mental health challenges [38].

In particular, investments in digital education programs, enhanced mental health services, and community support networks are vital to mitigate the physical and mental health impacts of increased screen time among adolescents during the pandemic. Additionally, policy and educational initiatives should focus on leveraging the already identified positive aspects of increased screen time during restricted social interactions, such as its potential for information exchange, education, and communication [39]. Pandemic response funds should be prioritized to address these issues and support adolescents in growing up in a healthy digital environment. Appropriate allocation of funds and policy support will play a critical role in addressing the challenges of increased adolescent screen time and alleviating health disparities exacerbated by the pandemic.

Limitations

This study has several limitations. First, variations in survey questions from 2008 to 2022 affected data comparability. Specifically, while smartphone use time was the focus in 2017 and from 2020 to 2022, other years emphasized internet use time, excluding total screen time such as television viewing. Nevertheless, to the best of our knowledge, this is the first study to analyze long-term data spanning 15 years, providing comprehensive insights into prepandemic and pandemic-era trends in adolescent screen time. Second, the self-response methodology in KYRBS may not fully reflect the characteristics of the actual population. However, KYRBS has been historically acknowledged as a credible dataset [40,41], and the weight-based analysis conducted with over 800,000 survey respondents further enhances the representativeness and validity of the screen time trends observed in this study. Third, this study is limited to Korean adolescents, restricting its representation of global trends. Despite this, the focus on a specific demographic allowed us to examine the nuanced relationships between screen time and family structures in the Korean context, providing insights relevant to similar societies. Finally, the cross-sectional design prevents establishing causal relationships between screen time and associated factors, highlighting the need for longitudinal and comprehensive studies. However, the

XSL•FO
RenderX

study emphasizes the need for longitudinal research and offers a foundational understanding of screen time trends and influencing factors across diverse family structures.

Conclusions

This study examined adolescent screen time trends from 2008 to 2022 across various family structures, revealing a consistent increase over time, with the steepest rise observed during the COVID-19 pandemic. Screen time patterns varied significantly by family structure, with orphaned adolescents experiencing the most pronounced increase, while other groups, such as those in nuclear families, also showed distinct trends influenced by factors like parental education and region of residence. These findings underscore the importance of tailored interventions, including family-type–specific workshops, institutional programs, and digital literacy resources, to address the diverse needs of adolescents. Reducing regional disparities and promoting alternative activities are also critical for mitigating the negative impacts of excessive screen time. Future research on broader structural and cultural influences on digital engagement is necessary to develop comprehensive and sustainable strategies for managing adolescent screen time.

Abstract

Background: Exposure to information about mpox may shape distinct perceptual processes that influence vaccination intent. Understanding how such information impacts perceived risk and vaccination intention is crucial for designing effective risk communication and public health messaging, particularly among populations at high risk such as gay, bisexual, and other men who have sex with men (GBMSM).

Objective: This study examined the specific pathways through which mpox information exposure and associated perceptual processes influence vaccination intent. Differences between GBMSM in Beijing and Hong Kong were also examined to explore potential contextual influences.

Methods: We conducted a cross-sectional survey of mpox-unvaccinated GBMSM in Hong Kong (n=470) and Beijing (n=519) between November 2023 and March 2024. Structural equation modeling was conducted to estimate the direct and indirect effects of information exposure, perceptual processes (eg, perceived control and threat perceptions), and perceived risk on vaccination intent. Multigroup structural equation modeling was used to estimate the effect measure modification by city.

Results: Exposure to positive mpox information significantly enhanced perceived control (β=0.33; *P*=.001) and increased vaccination intention through heightened perceived risk of contracting mpox (β=0.27; *P*<.001) in the following 6 months. The indirect effect of positive information exposure on vaccination intent via perceived control and risk was significant in Hong Kong (*B*=0.01; Wald test: *Z*=3.05 and *P*=.002) but not in Beijing (*B*=−0.01; *P*=.25). Conversely, negative information exposure primarily increased threat perceptions (Hong Kong: *B*=0.33 and *P*=.001; Beijing: *B*=0.93 and *P*<.001) but did not consistently translate to increased perceived risk of contracting mpox (Hong Kong: *B*=−0.10 and *P*=.31; Beijing: *B*=0.20 and *P*=.11). Notable contextual differences emerged between Beijing and Hong Kong—participants in Beijing reported higher levels of information exposure (eg, international mpox statistics; mean score 2.17, SD 0.97 vs 1.79, SD 0.89; *P*<.001) and more nonregular sex partners (mean 2.20, SD 6.73 vs 1.65, SD 3.37; *P*=.02), but the associations among information exposure, perceived risk, and vaccination intent were weaker than in Hong Kong participants.

XSL•FO
RenderX

Conclusions: Positive mpox-related information strongly promotes vaccination intent by enhancing perceived control and amplifying perceived risk, particularly in settings with accessible vaccination programs such as Hong Kong. Conversely, negative information appears less effective in driving vaccination intention. Tailored, stigma-free communication is crucial for improving vaccination uptake, especially in mainland China, where subsidized vaccines are scarce and perceptual pathways linking information exposure to vaccination intent are relatively weak. Enhancing access to vaccines and addressing contextual barriers can further optimize the impact of such interventions.

Introduction

Background

The 2022 multicountry mpox outbreak spread rapidly via air travel and undetected local transmissions among gay, bisexual, and other men who have sex with men (GBMSM) driven by social stigma, marginalization, and discrimination [1-5]. These factors often compel GBMSM to seek anonymous and multiple same-sex connections in high-risk environments, facilitating "superspreader" events and exacerbating both local and global mpox transmission [2,5-8]. The mpox outbreak exemplifies the critical importance of a One Health approach by revealing the fundamental interconnectedness or existential disconnectedness among human, animal, and environmental health. Of concern, originally a zoonotic disease with animal-human transmission in parts of Africa, mpox has adapted to "human-to-human" transmission networks worldwide, particularly in urban environments and initially mostly affecting GBMSM. This evolution demonstrates how ecological shifts, human mobility, and social determinants—including stigma and health care inequities—collectively shape infectious disease dynamics [2]. In 2023, Asia experienced sustained imported mpox cases, with mainland China documenting 501 cases in August alone [9-11]. The region faces unique challenges due to persistent stigmatization of same-sex behaviors, limited mpox vaccination programs, and the easing of COVID-19 travel restrictions [12,13], raising concerns about a resurgence if vaccine uptake among GBMSM remains low [4,6,14].

While Western countries effectively curtailed the outbreak through culturally sensitive campaigns—such as leveraging gay-identifying physicians and influencers to boost vaccine acceptance [15,16]—Asian contexts have struggled [17]. Despite the US Centers for Disease Control and Prevention recommending the 2-dose JYNNEOS vaccine for high-risk GBMSM [18], costs and access remain significant barriers. For example, JYNNEOS costs up to US $300 per dose in higher-income settings, whereas Hong Kong has offered fully subsidized vaccination since October 2022. However, this program is largely inaccessible to mainland Chinese GBMSM, and mpox-specific vaccines are still under development [19-21]. Even in places with subsidized programs such as Hong Kong and Taiwan, vaccine uptake remains suboptimal (21.7% in Hong Kong [22] and 59.9% in Taiwan [23], much lower than in Western cities such as Paris at 78% [24]) and below the modeled 80% threshold needed to prevent further outbreaks [25].

A growing body of research has examined risk perception and media exposure among GBMSM [22,26-28], but few studies have explored how varying types and sources of mpox-related information shape illness perceptions and vaccination intentions—especially in Chinese contexts. Most notably, the psychological mechanisms connecting information exposure with preventive intentions and actions remain poorly understood in Asia, where negative media portrayals and lesbian, gay, bisexual, transgender, and queer (LGBTQ+) stigma are widespread [29-31]. This constitutes a critical research gap as understanding these mechanisms is essential for designing effective, culturally sensitive risk communication strategies.

The common sense model of illness self-regulation (CSM) provides a valuable framework for examining how different types of mpox-related information influence GBMSM's preventive intentions and behaviors. The extended CSM framework proposes that emotional states such as concerns, depression, and distress are more strongly correlated with threat-related illness perceptions, including the identification of symptom severity, duration, and their impacts on individuals [32]. For example, exposure to stigmatizing news about deaths due to mpox and HIV or AIDS coinfection may evoke negative emotions and elevate GBMSM's perceptions of mpox severity and impact, leading to maladaptive coping responses such as denial, avoidance, or delayed treatment seeking [32,33]. Conversely, accurate and timely information about mpox transmission, symptoms, and prevention methods may contribute to adaptive illness representations, such as illness coherence and controllability, which predict positive coping behaviors such as adherence to preventive measures and timely health care seeking [34,35]. Applying the extended CSM to mpox-related information exposure among GBMSM can provide insights into the psychological mechanisms driving preventive intentions and behaviors. This understanding can inform the development of targeted risk communication strategies that promote adaptive coping and vaccination. These relationships remain unexplored in the context of culturally sensitive mpox risk communication and vaccination campaigns for GBMSM in the Asia-Pacific region.

Behavioral intentions have been theorized (eg, theory of planned behavior) and shown to predict actual health-seeking behaviors [36], such as COVID-19 vaccination among UK adults aged 50 to 64 years [37], human papillomavirus vaccination among Dutch girls [38], and influenza vaccination for patients with diabetes in China [39]. However, Jongen et al [40] found that an increased level of perceived risk for mpox more consistently

XSL•FO
RenderX

predicted and explained the difference between high intention for mpox vaccination and actual vaccination uptake among Dutch GBMSM attending sexual health services in a later survey wave. Similarly, in a cross-sectional survey of Canadian GBMSM, those with a lower perceived susceptibility to mpox were more likely to remain unvaccinated despite being offered vaccination after attending a sexually transmitted infection (STI) clinic [41]. Therefore, mpox illness perceptions may play a stronger role in the relationship between behavioral intent and subsequent uptake for GBMSM if it increases the perceived risk of contracting mpox—this hypothesized relationship is yet to be explored [42].

Mainland China and Hong Kong play pivotal roles in the global resurgence of mpox, largely due to their extensive interconnectivity and prominence as international air travel hubs. These 2 regions present distinct policy and social environments—Beijing, as the capital of mainland China, has limited vaccine availability and a higher level of societal stigma [43], whereas Hong Kong has implemented a fully subsidized vaccine program and has generally more open societal attitudes toward sexual minority groups [44]. Both cities experience significant cross-border interaction and are major population centers yet differ markedly in their public health policies, media environments, and levels of LGBTQ+ acceptance [44]. This contrast allows for a nuanced comparison of how structural factors—such as vaccine access, stigma, and risk communication—interact to shape health behaviors among GBMSM.

Objectives

In 2023, China reported 1712 confirmed mpox cases, with the Beijing municipality (258 cases) and Guangdong province (342 cases) accounting for more than one-third of the country's total cases [9]. Hong Kong, despite having only 68 confirmed cases, is surrounded by the Guangdong province with millions of daily cross-border travelers and observed steady local confirmed cases from January 2024 to August 2024 [45]. Using the extended CSM framework applied through multigroup structural equation modeling (SEM), this study aimed to examine how differential exposure to mpox information and perceptual processes may influence perceived susceptibility and vaccination intentions among GBMSM in these 2 highly interconnected municipal areas.

Given the multidimensional nature of information exposure, illness perceptions, and behavioral intent, this study used SEM because it enables the simultaneous estimation of complex, interrelated pathways and mediating effects, which are essential for understanding how latent constructs—such as threat perception and personal control—link information exposure to risk perception and vaccination intent. Unlike standard regression, SEM allows for the modeling of latent variables using multiple observed indicators, providing a more accurate representation of psychosocial processes. In addition, we used multigroup SEM to directly compare these pathways between GBMSM in Hong Kong and Beijing, allowing us to test for contextual differences in the relationships among key variables.

We hypothesized that regional differences in case numbers, risk communication, vaccine program availability, and cultural values lead to different levels of mpox information exposure, illness perceptions, and subsequent perceived risk and vaccination intentions. Specifically, we propose that the content of mpox information—factual, positive, or negative—may affect vaccination intentions through distinct perceptual processes by shaping threat or control perceptions. We further anticipate that these information attributes will differentially impact perceived risk and vaccination intent and that geographical and social differences between Hong Kong and Beijing may moderate these effects based on local case burdens, information exposure, perceived susceptibility, and vaccine access.

Methods

Study Design and Sample

A cross-sectional survey was conducted with GBMSM in Beijing and Hong Kong from November 2023 to March 2024. Participants had to meet the following inclusion criteria: (1) being Chinese male individuals aged ≥18 years and (2) having engaged in anal intercourse with at least one man in the previous 6 months (geographic information and location of the study sites are presented in Figure 1). Recruitment and data collection methods were similar between Beijing and Hong Kong. In both cities, upon approval of the owners, trained and experienced field-workers approached potential participants in gay bars at different time slots on weekdays and weekends. On sites, the field-workers briefed potential participants about the study and gave them an information sheet. Online recruitment was also conducted in both cities by posting study advertisements on popular gay websites (in Hong Kong only), social media platforms such as Facebook (in Hong Kong only) or Weibo and WeChat (in Beijing only), and partner-seeking mobile apps frequently used by local GBMSM (Blued in Beijing and Grindr in Hong Kong). In Hong Kong, Facebook is the most popular social media platform, and Grindr is the most widely used gay dating app. However, these 2 online platforms are not available in mainland China. Weibo and WeChat are the 2 most commonly used social media platforms in mainland China, with functions very similar to those of Facebook. Blued is the most widely used gay dating app in mainland China, with features and functions similar to those of Grindr. Therefore, Weibo, WeChat, and Blued were chosen to facilitate online recruitment in Beijing. Potential participants who were interested in the study could contact the research team via private messaging, telephone, WhatsApp or WeChat, or email. Recruitment was supplemented through referrals made by peers and community-based organizations. Participants were screened for study eligibility. Participant anonymity was strictly maintained, and verbal informed consent was obtained. Various contact methods were used to arrange telephone interviews, which were conducted in Mandarin in Beijing and in Cantonese in Hong Kong.

XSL•FO
RenderX

Figure 1. Geographical mapping of Beijing and Hong Kong with respect to gay, bisexual, and other men who have sex with men participants recruited from these municipal areas.

Ethical Considerations

This study was reviewed and approved by the Survey and Behavioural Research Ethics Committee of the Chinese University of Hong Kong (reference SBRE-22-0488). The research adhered to established ethical guidelines for human participant research. Verbal informed consent was obtained from all participants before taking part in the study. Participants were provided with a detailed information sheet outlining the purpose of the study, procedures, risks, and benefits before consenting. Consent was specifically obtained for the primary data collection, and no additional consent was required for the analysis as all data were anonymized.

Participant anonymity was strictly maintained throughout the study. Data collected during the phone interviews were deidentified at the point of collection, ensuring that no personally identifiable information was stored or linked to the responses. All data were securely stored in encrypted files accessible only to authorized researchers. Participants were compensated for their time upon completing the 30-minute phone interviews. In Hong Kong, participants received an HK $50 (US $6.40) supermarket coupon, and in Beijing, they were provided with a ¥20 (US $3) e-coupon. No identifiable images or personal data of individual participants were included in the manuscript or supplementary materials. As such, there is no risk of participant identification.

Participants and Data Collection

Recruitment and data collection procedures were standardized for both Beijing and Hong Kong. Trained field-workers, with permission from venue owners, approached potential participants at various times during the week and on weekends in gay bars. The participants were given a brief description of the study and an information sheet. Online recruitment included posting advertisements on popular gay websites (in Hong Kong), social media platforms (Facebook in Hong Kong and Weibo and WeChat in Beijing), and partner-seeking apps (Blued in Beijing and Grindr in Hong Kong). Interested individuals could contact the research team via private messages, phone, WhatsApp or WeChat, or email. Peer referrals and community-based organizations also supported recruitment efforts. Participant anonymity was strictly maintained, and verbal informed consent was obtained. Various contact methods were used to arrange telephone interviews, which were conducted in Mandarin in Beijing and in Cantonese in Hong Kong. To ensure content consistency, the study questionnaire was available in simplified Chinese for Beijing and traditional Chinese for Hong Kong.

Questionnaire Design

The questionnaire was developed by a team of public health researchers, epidemiologists, health psychologists, physicians, and representatives of nongovernmental organizations. It was then pilot-tested with 5 GBMSM, and their feedback was used to refine the final version.

Measures

Background Characteristics

Participants provided information on their sociodemographic characteristics (such as age, educational level, relationship

XSL•FO
RenderX

status, income, and employment status); sexual orientation; and their experiences with HIV and STI testing, HIV pre-exposure prophylaxis (PrEP), and other HIV prevention services used in the previous 12 months. They also reported HIV-related risk behaviors over the previous 6 months, including engaging in condomless anal intercourse with different types of male partners, the number of sexual partners, psychoactive substance use, and the use of drugs during sexual activity. Sexualized drug use was defined as the consumption of substances such as ketamine, methamphetamine, cocaine, cannabis, ecstasy, nonprescription hypnotics, heroin, cough suppressants, amyl nitrite (poppers), γ-hydroxybutyric acid or γ-butyrolactone, foxy, and mephedrone before or during sex.

Mpox-Specific Information Content Exposure

Participants were asked to rate how often they encountered information on 7 common mpox-related topics using a scale from 1 (almost never) to 4 (often). The topics were (1) mpox statistics from other countries (eg, case numbers and mortality rates); (2) mpox statistics specific to Hong Kong (eg, case numbers and mortality rates); (3) the Hong Kong government's response to the mpox outbreak; (4) information on mpox discrimination and stigma toward LGBTQ+ individuals; (5) negative information about patients with mpox, such as severe symptoms and fatalities; (6) positive information about patients with mpox, such as recovery stories; and (7) information regarding mpox prevention and treatment. Details on the aforementioned items have been published elsewhere [22].

Perceived Risk of Contracting Mpox

Participants were asked the following: "Based on your current health and sexual behaviors, how do you rate your risk of contracting mpox within the following year?" (1=none; 5=very high).

Mpox Illness Representations

Mpox illness representations were assessed using the Brief Illness Perception Questionnaire [46], modified by asking participants to imagine a hypothetical scenario of contracting mpox and replacing "illness" with "mpox" in the original format [46]. This approach has been used in previous studies to assess illness representations of those at risk of a disease but who do not have the disease [47,48]. Participants were asked to rank each item on a Likert scale ranging from 0 to 10. These items included consequences ("If you contracted mpox, how much does your illness affect your life?"), timeline ("If you contracted mpox, how long do you think your illness will continue?"), personal control ("If you contracted mpox, how much control do you feel you have over your illness?"), treatment control ("If you contracted mpox, how much do you think existing treatment can help your illness?"), identity ("If you contracted mpox, how much do you experience symptoms from the illness?") and concern ("If you contracted mpox, how concerned are you about your illness?"), coherence ("If you contracted mpox, how well do you feel you understand mpox?"), and emotions ("If you contacted mpox, how much does your illness affect you emotionally?").

Mpox Vaccination Intent and Uptake Behaviors

Participants were asked whether they had received the mpox vaccine (yes or no) and, if not, how likely they were to receive it in the following 6 months (1=very low; 5=very high).

Analysis

Sample characteristics were described using total row proportions, means, and SDs and by location (Beijing and Hong Kong), with differences between locations evaluated using the Pearson chi-square test or Wilcoxon rank sum test (analytic sample size: N=989; Hong Kong: n=470; Beijing: n=519) [49]. Zero-order (Pearson) correlations were computed to evaluate correlations between key variables in this study. Missing data were imputed using the nonparametric random forest algorithm [50]. Linear regression was conducted to examine the bivariate relationship between background variables and mpox vaccination intention in the following 6 months. All significant background variables in univariate regression were adjusted for in the following analyses aided by directed acyclic graphs to avoid omitted confounding effects and conditioning on a collider [49,51].

SEM was conducted to examine the hypothesized model using a 2-step approach. First, a confirmatory factor analysis was conducted to assess the goodness of fit of the measurement model. The construct reliability of the latent variables was evaluated using both the Cronbach α and McDonald ω [52]. SEM was used to test the proposed structural model. The mean and variance–adjusted weighted least squares estimator was used to estimate modeled parameters accounting for ordinally distributed endogenous outcomes [49,53]. Indirect effects were estimated using Bollen-Stine bootstrapping with 5000 repetitions, which is robust against deviation from multivariate normality corresponding to mean and variance–adjusted weighted least squares estimator and ordinal endogenous outcomes [54]. Overall model fit was determined using (1) the scaled chi-square badness-of-fit index (P>.05), (2) a scaled root mean square error of approximation (S-RMSEA) of <0.06, (3) the scaled comparative fit index (S-CFI), and (4) a scaled Tucker-Lewis index (S-TLI) of >0.95 [51,55,56].

Multigroup SEM was further used to examine potential differences in mpox information exposure and their associations with mpox perceptions across cities (moderation by city). We tested for partial scalar invariance in the measurement model and partial path coefficient invariance in the structural model. Invariance was determined by a difference in the S-CFI of <0.01 and a significant log-likelihood ratio test (P<.05) between the baseline models (ie, configural fits) and models with equality constraints on each of the latent factor loadings (weak or metric invariance) and thresholds or intercepts (strong or scalar invariance) [57,58]. The moderation of parameter estimates from the final multigroup structural equation model was examined using a 2-sided Wald test for heterogeneity using the appropriate unstandardized coefficients (B) and variance parameters [59], with P<.05 indicating a significant difference. We conducted sensitivity analyses of the direct and indirect effects of multigroup SEM by replicating the same model restricted to participants from Hong Kong and Beijing separately (Multimedia Appendix 1). Psychometric analyses were

XSL•FO
RenderX

conducted using the *psych* and *lavaan* packages in R (R Foundation for Statistical Computing) [60,61].

Results

Sample Description

Of the eligible participants approached through outreach in gay venues, online recruitment, and peer referral (n=713 from Hong Kong and n=602 from Beijing), 86% (613/713) from Hong Kong and 87% (524/602) from Beijing provided verbal consent and completed telephone interviews. Of the original total sample (N=1137), 0.44% (5/1137) of participants from Beijing and 12.58% (143/1137) of participants from Hong Kong were vaccinated against mpox and were removed from the analytic sample. Table 1 presents the unvaccinated participant characteristics by total sample (N=989) and group (Beijing: 519/989, 52.5%; Hong Kong: 470/989, 47.5%). Among the participants from both groups, most were aged ≥25 years (859/989, 86.9%), tertiary educated (836/989, 84.5%), single (752/989, 76%), and employed full time (774/989, 78.3%); identified as homosexual (823/989, 83.2%); and earned above the median city income (612/989, 61.9%). Mpox vaccination rates were significantly higher in Hong Kong than in Beijing (116/519, 22.4% vs 4/470, 0.9%; *P*<.001); however, the average levels of vaccination intention (mean score 2.31, SD 1.24 in Beijing vs mean score 2.32, SD 1.22 in Hong Kong; *P*=.60) and perceived risk of contracting mpox (mean score 1.84, SD 0.88 in Beijing vs mean score 1.86, SD 0.82 in Hong Kong; *P*=.90) among those who were unvaccinated were not significantly different between Beijing and Hong Kong. GBMSM in Hong Kong were less likely to be married, cohabit with a woman, or identify as bisexual or other. Participants in Beijing reported a higher uptake of sexual health services, including HIV testing (440/517, 85.1% vs 185/470, 39.4%; *P*<.001) and PrEP use (100/517, 19.3% vs 39/470, 8.3%; *P*=.03), in the previous 6 months.

Distribution, Construct Reliability, and Validity Among Latent Variables

Table 2 shows the means and SDs of the observed items of the latent factors from the measurement model. The average self-rating of most observed items of the latent factors was higher among participants in Beijing than among those in Hong Kong except for some mpox illness perceptions (Brief Illness Perception Questionnaire) measures. Reliability coefficients indicated adequate internal consistency for most latent factors except for the control perception domain of mpox illness perception. Thus, only 1 personal control item from mpox illness perceptions was used in subsequent structural equation models. Zero-order correlations showed high correlations among factual, positive, and negative mpox information content (Table 3). The threat and personal control perception domains of mpox illness perceptions had low to moderate correlations with other latent variables, indicating discriminant validity that was consistent across the Beijing and Hong Kong subsamples.

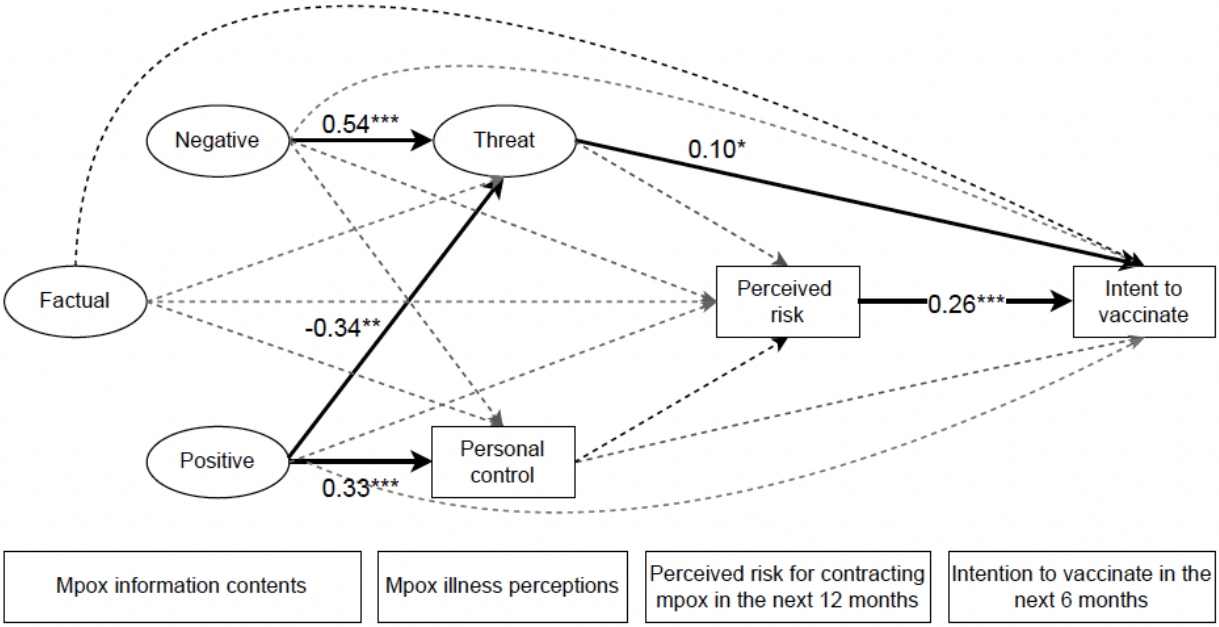
SEM Results



Model Fit Statistics

The measurement model yielded a good fit to the data (χ^2_{124}=161.0; S-CFI=0.989; S-TLI=0.986; S-RMSEA=0.049, 90% CI 0.041-0.057; standardized root mean square residual=0.030; weighted root mean square residual=0.920). Its standardized factor loading ranged from 0.72 to 0.89 (*P*<.001 in all cases). The structural model also yielded a good fit to the data (χ^2_{356}=323.0; S-CFI=0.986; S-TLI=0.992; S-RMSEA=0.030, 90% CI 0.025-0.035; standardized root mean square residual=0.019; weighted root mean square residual=1.083).

Path Coefficient (Direct Effects)

Figure 2 shows the statistically significant path coefficients of the structural equation model combining Hong Kong and Beijing participants. Positive mpox information content (standardized path coefficient β=−0.34; *P*=.001) was negatively associated with threat perceptions, whereas negative mpox information content (β=0.54; *P*<.001) was positively associated with threat perceptions of mpox. Only positive mpox information content (β=0.33; *P*=.001) was positively associated with personal control perceptions of mpox; factual mpox information content (β=0.17; *P*<.001) was marginally associated with personal control perceptions. Neither threat perceptions nor personal control perceptions were associated with perceived risk of contracting mpox. Perceived risk of contracting mpox (β=0.27; *P*<.001) and threat perceptions (β=0.10; *P*=.01) were both positively associated with intention to receive the mpox vaccine in the following 6 months.

Figure 2. Path diagram of structural equation model with statistically significant standardized coefficients for the total mpox-unvaccinated gay, bisexual, and other men who have sex with men participants (N=989). The model was adjusted for educational level, age, HIV testing, and pre-exposure prophylaxis use; number of nonregular partners; and number of regular partners in the previous 6 months. **P*<.05; ***P*<.01; ****P*<.001.

Mediated Pathways (Indirect Effects)

Threat perceptions of mpox negatively mediated (unstandardized path coefficient [B]=−0.043, 95% CI −0.82 to −0.004) the association between positive mpox information content and the intention to receive the mpox vaccine. Threat perceptions of mpox positively mediated (B=0.07, 95% CI 0.012-0.128) the association between negative mpox information content and vaccination intention.

Multigroup Analysis and Invariance Testing

Overview

As indicated in Table 4, the results of the multigroup analysis of the measurement model showed that the configural model (baseline) had an acceptable fit (comparative fit index [CFI]=0.991; root mean square error of approximation [RMSEA]=0.050). The metric invariance model, with all factor loadings constrained to be equal across groups, showed a statistically meaningful decrease in model fit compared to the configural model (ΔCFI=−0.006; ΔRMSEA=0.011). However, partial scalar invariance was achieved by freeing the intercepts of the 2 indicators (ΔCFI=0.000; ΔRMSEA=−0.003). As in the SEM literature, multigroup analyses can be conducted if partial scalar invariance is supported [64-66].

Figure 3 shows the standardized regression path coefficients of the multigroup structural equation model. To determine whether the city moderated the paths, nested models were formed by comparing equality-constrained parameter models with the unconstrained free parameter model by city using the likelihood ratio test (chi-square≥3.8 per df as the critical value). Bolded paths indicate significant coefficients for either the Hong Kong or Beijing subsample. Estimates in parentheses indicate coefficients estimated with equality-constrained parameters and vice versa.

Figure 3. Path diagram of multigroup structural equation model with statistically significant standardized coefficients for gay, bisexual, and other men who have sex with men participants in Hong Kong (HK; n=470) and Beijing (BJ; n=519). The model was adjusted for education, age, HIV testing, and pre-exposure prophylaxis use; number of nonregular partners; and number of regular partners in the previous 6 months. Path coefficients in parentheses indicate that the coefficient parameters were estimated with equality constraints. **P*<.05; ***P*<.01; ****P*<.001.

Relationships Among Attributes of Mpox Information Exposure, Threat Perceptions, Perceived Risk, and Vaccination Intent

Table 5 shows unstandardized direct and indirect effect coefficients of the relationships among attributes of mpox information exposure, threat perception, perceived risk, and vaccination intent. Exposure to positive mpox information was negatively associated with threat perceptions in Hong Kong (*B*=−0.22, 95% CI –0.38 to –0.06) and Beijing (*B*=−0.65, 95% CI –1.00 to –0.30), with a stronger association in Beijing (Wald test: *Z*=2.34 and *P*=.02). Exposure to negative information was positively associated with threat perceptions in Hong Kong (*B*=0.33, 95% CI 0.15-0.51) and Beijing (*B*=0.93, 95% CI 0.52-1.34), with a stronger association in Beijing (Wald test: *Z*=−3.40 and *P*=.002). Threat perception was positively associated with vaccination intent in Hong Kong (*B*=0.39, 95% CI 0.15-0.63) and Beijing (*B*=0.12, 95% CI 0.01-0.23), with a stronger association in Hong Kong (Wald test: *Z*=2.14 and *P*=.03). Negative information exposure had an insignificant negative association with perceived risk in Hong Kong (*B*=−0.10, 95% CI –0.30 to 0.10) and an insignificant positive association with perceived risk in Beijing (*B*=0.20, 95% CI –0.05 to 0.46), but the difference between cities was significant (Wald test: *Z*=−2.06 and *P*=.04).

Relationships Among Personal Control Perceptions, Perceived Risk of Contracting Mpox, and Vaccination Intent

Personal control perception was positively associated with perceived mpox risk in Hong Kong (*B*=0.05, 95% CI 0.01-0.09) and insignificantly negatively associated with perceived mpox risk in Beijing (*B*=−0.02, 95% CI –0.04 to 0.01), with a significant city difference (Wald test: *Z*=3.05 and *P*=.002). It was also positively associated with vaccination intent in Hong Kong (*B*=0.06, 95% CI 0.001-0.12) but not in Beijing (*B*=−0.02, 95% CI –0.05 to 0.02), with a significant city difference (Wald test: *Z*=2.53 and *P*=.01).

Indirect Effects

The indirect effect of positive mpox information exposure on vaccination intent through personal control and mpox risk was significant and positive in Hong Kong (*B*=0.01, 95% CI 0.002-0.03) but not in Beijing (*B*=−0.01, 95% CI –0.01 to 0.003), with a significant difference between cities (Wald test: *Z*=2.52 and *P*=.01). The indirect effect through personal control was significant and positive in Hong Kong (*B*=0.05, 95% CI –0.002 to 0.01) but not in Beijing (*B*=−0.01, 95% CI –0.007 to 0.01), with a significant difference between cities (Wald test: *Z*=2.17 and *P*=.03).

Discussion

Principal Findings

Since the 2022 multicountry mpox outbreak, mpox has continued to spread in places with little access to vaccines, whereas its resurgence across countries is imminent [67]. China is home to >12 million GBMSM and has the highest mpox case burden in the Western Pacific region [4,68]. However, only 1% (5/524) of participants from China's mpox epicenter, Beijing, had been vaccinated against mpox. To anticipate the regulatory approval of mpox vaccines in mainland China, this study examined the novel pathways through which exposure to different attributes of mpox information and perceptual processes could influence GBMSM's vaccination decisions, specifically by raising GBMSM's level of perceived risk of contracting mpox. Our findings provide timely implications for GBMSM-tailored risk communication and community partnerships to raise awareness of mpox among GBMSM across borders.

Our study highlights the critical roles of mpox-related information content and disease-related perceptions in shaping perceived risk and subsequent vaccine-related decision-making among GBMSM, extending the findings of Jongen et al [40]. In Hong Kong, increased exposure to positive mpox information was associated with higher personal control and vaccination intent, mediated by increased perceived risk. However, this relationship was not observed in Beijing. Factual mpox information was associated with increased vaccination intent in both cities, as demonstrated by the multigroup structural equation model. Correlation analyses also revealed that perceived risk was positively correlated with personal control perceptions in Hong Kong but not in Beijing. Vaccination intent had a stronger positive correlation with personal control in Hong Kong than in Beijing. These results suggest that, in places where fully government-sponsored mpox vaccines are in place, promoting factual and positive mpox information (eg, positive portrayal of patients with mpox, recovery stories, and health advice) could potentially increase vaccination intent by raising the awareness of their level of perceived risk of contracting mpox, which may also promote GBMSM's personal control of mpox, which may include having accessible vaccination programs in place at GBMSM's disposal and their related promotional campaigns enacting effective coping strategies. This finding is consistent with behavior change theories, including the extended CSM framework underlying the role of control perceptions in motivating vaccine uptake behaviors [32].

Our study shows that exposure to negative mpox information could raise GBMSM's threat perceptions of mpox without necessarily increasing their perceived risk of contracting mpox and subsequent vaccination intent but that it is associated with increased behavioral intention for mpox vaccination. These results suggest that the association between negative mpox information and behavioral intention for mpox vaccinations through threat perceptions may be less predictive of actual vaccination behaviors as compared to positive content through personal control, which in turn increases both risk perceptions and behavioral intention to receive the mpox vaccine. Highly threatening or stigmatizing content may trigger maladaptive coping behaviors such as denial, avoidance, or disengagement [33]. Rather than motivating action, overwhelming threat can result in fatalism or psychological withdrawal, especially in communities with limited resources or structural barriers to prevention (eg, lack of vaccine access in mainland China). This finding may correspond to the high prevalence of sensationalized headlines and exaggerated reporting of severe mpox cases, mortality, and HIV or AIDS coinfection across regions [69]. This negatively charged media coverage that appeals to the public's consumption of polarizing views and affective processes without providing risk information relevant to GBMSM, including unmoderated homophobic user comments on media outlets (homophobic slurs remain unmoderated in one of Hong Kong's online news outlets [70]), could counter mpox control efforts [4]. Among Chinese adults exposed to disgusting graphic mpox information, those with higher disgust endorsed more avoidant preventive measures and perceived higher mpox severity but not susceptibility or perceived risk of contracting mpox [71]. In addition, higher levels of mpox-related stigma attenuate the association between perceived severity and preventive intent [71]. Emotionally provoked viewers, including GBMSM, may dissociate from their own mpox risk and view those at risk as "distant others" (eg, people living with HIV) who should be receiving the vaccine rather than themselves [72]. In addition, exposure to stigmatizing mpox information could galvanize GBMSM's self-stigma and identity concealment, which negatively predicted mpox vaccination intent and uptake among Canadian GBMSM in the study by Le Forestier et al [8].

Despite higher levels of mpox information exposure and illness perceptions, GBMSM from Beijing were different from those from Hong Kong. This suggests that GBMSM from Beijing may not be able to identify relevant mpox risk information even

XSL•FO
RenderX

with more exposure to local cases and case information. In Hong Kong, health authorities collaborate with community partners and media channels to disseminate tailored mpox risk communication and vaccination promotion for GBMSM and remove hate speech toward LGBTQ+ individuals in online news outlets [73,74]. Moreover, our finding that personal control perception more strongly predicted vaccination intention among GBMSM in Hong Kong than in Beijing may be explained by several contextual and theoretical factors. First, Hong Kong's public health infrastructure and government-sponsored vaccination programs are widely regarded as transparent and accessible, which can enhance individuals' trust in health authorities and the perceived efficacy of their own preventive actions. This aligns with the CSM, which posits that, when individuals believe that their actions (such as seeking vaccination) will be supported and effective within their health care environment, perceptions of personal control are more likely to translate to concrete health behaviors [32,33]. In contrast, in Beijing and mainland China, limited access to mpox vaccines, lower visibility of LGBTQ+-inclusive health campaigns, and persistent stigma may undermine individuals' confidence that their actions will be effective or socially supported. In addition, Hong Kong's relatively open media environment and consistent dissemination of affirmative health messages may reinforce the notion that vaccination is both accessible and beneficial, thus strengthening the link between personal control and intent. Conversely, in Beijing, mixed or negative messaging, combined with structural and social barriers, may weaken this relationship [75,76]. Thus, the interplay among health care system trust, policy transparency, and supportive media narratives likely explains why personal control perceptions are more predictive of vaccination intention in Hong Kong.

Conversely, GBMSM from mainland China may lack adequate exposure to relevant environmental risk communication. Leiwen et al [77] found that only one-fourth of mainland Chinese GBMSM correctly identified GBMSM as being at risk of contracting mpox, whereas half believed that only people living with HIV are at risk. Similarly, Zheng et al [78] found that more than half of GBMSM incorrectly identified that there were effective medications for mpox and less than half could identify >3 ways to prevent mpox infections. These findings suggest that tailored and comprehensive risk communication for GBMSM in mainland China could improve their mpox risk self-assessment and promote preventive measures even when vaccines are not within the range of options, for example, reducing the number of sexual partners and using condoms to reduce the risk of mpox transmission through direct genital contact [79]. Such communication could be synergized with positive portrayals of stories of patients with mpox, such as gay-identifying physicians and social media influencers with mpox [15,16], in raising GBMSM's cognitive perceptions of mpox and reducing their emotional distance on perceived susceptibility while empowering them to enact preventive behaviors.

Limitations

The results of this study should be interpreted within their limitations. First, the cross-sectional design cannot ascertain causality, specifically the temporal direction of how previous information affects subsequent intent. It is causally plausible that behavioral intent assessed at 1 point in time is a function of previous information and psychological processes. Longitudinal studies are preferred to clarify causality and the potential for reverse or bidirectional effects. Second, our recruitment strategy—using social media, gay bars, and peer referrals—may have introduced selection bias. This approach likely overrepresented younger, more digitally connected, and socially active GBMSM who are comfortable accessing online platforms or community venues while potentially underrepresenting older, less connected, or more marginalized individuals who may not participate in such spaces. As a result, the findings may not fully reflect the experiences or perspectives of the entire GBMSM population in Beijing and Hong Kong, particularly those less engaged with the LGBTQ+ community or less reachable through digital or venue-based outreach. Third, there is a possibility that unmeasured confounders influenced our study results. Factors such as previous vaccination hesitancy, underlying attitudes toward vaccination, previous experiences with health care systems, or structural barriers to health care access were not directly measured but could have independently affected both information exposure and vaccination intentions. Fourth, although our study included participants from 2 major urban centers—Beijing and Hong Kong—the generalizability of our findings to GBMSM living in smaller cities, rural areas, or other regions of China may be limited. GBMSM in less urbanized areas may have different patterns of information exposure, levels of stigma, health care access, or vaccine availability, which could influence both risk perceptions and preventive behaviors. Finally, our sample of participants from Beijing had a higher level of education, included less individuals who identified as bisexual, and had been more recently HIV tested than participants in another respondent-driven sample of GBMSM from Beijing [80]. This indicates that we were more likely to have overestimated the prevalence of behavioral intent for mpox vaccination. However, our population parameter estimate is still more conservative than those in other studies (>80%) with larger sample sizes [78,81]. On the other hand, participants from Hong Kong had similar characteristics to those of a larger, more representative sample [82]. All data were self-reported and, therefore, were subject to recall and social desirability biases. The use of trained interviewers with structured questionnaires and interview designs in this study may have reduced some reporting bias. However, questions related to sexual behavior could be stigmatized when asked by interviewers, which could have been underreported.

Conclusions

This study highlights the critical role of mpox-related information exposure in influencing behavioral intentions toward vaccination among GBMSM in Beijing and Hong Kong. Positive information exposure, particularly regarding recovery stories and prevention, significantly increased vaccination intent by enhancing personal control perceptions and perceived risk of contracting mpox among GBMSM in Hong Kong, where a fully government-subsidized mpox vaccination program is in place. Conversely, while negative information related to mpox increased threat perceptions and vaccination intentions, it did

XSL•FO
RenderX

not reliably translate to a higher perceived risk, especially in Beijing. These findings suggest several practical implications for public health messaging aimed at increasing mpox vaccine uptake among GBMSM in China. Health agencies should prioritize accurate, positively framed, and stigma-free information—such as recovery stories and practical prevention advice—delivered through channels or key opinion leaders trusted by the target community. Proactive efforts are needed to counter misinformation and stigma, for example, through myth-busting campaigns and the promotion of supportive narratives on both social and traditional media platforms. In addition to the careful moderation of stigmatizing messaging, news media channels should implement stricter standards when framing their reporting on mpox and moderate user comments on their platforms to prevent the spread of misinformation that could harm public health. Partnerships with LGBTQ+ organizations and community leaders can enhance the credibility and reach of messaging, whereas targeted outreach via social media and mobile apps can ensure that information is accessible to those most at risk. Finally, communications should provide clear guidance on accessing vaccination and related services and be culturally sensitive and inclusive to empower GBMSM to assess their risk realistically and take preventive action.

Acknowledgments

The authors would like to thank all participants of this study. The authors did not use generative artificial intelligence in any portion of the manuscript. This study was supported by the AIDS Trust Fund (reference MSS376R) and the 2021 Beijing Key Specialty Program for Major Epidemic Prevention and Control. The content of this paper represents the opinions of the authors' organizations. It does not represent the position of the AIDS Trust Fund. The AIDS Trust Fund is not responsible for any claims, demands, or liabilities whatsoever from or in connection with the use of any information contained in this paper or the participation in the sponsored project. Patients or the public were not involved in the design, conduct, reporting, or dissemination plans of this research.

Data Availability

The datasets generated or analyzed during this study are not publicly available because they contain sensitive personal behaviors but are available from the corresponding author on reasonable request.

Authors' Contributions

DC, LX, LW, SC, FS, PM, YL, and ZW conceived and designed the study. DC, LX, LW, SC, and ZW developed the methodology. LW, SC, LX, ZZ, SG, XC, FY, YF, ZC, and ZL handled data curation. DC, LX, and ZW conducted formal analyses. LW, SC, LX, ZZ, SG, XC, FY, YF, ZC, ZL, FS, PM, YJ, and ZW were responsible for project administration. DC, LX, and ZW drafted the manuscript. LW, SC, XL, ZZ, SG, XC, YF, ZC, ZL, FS, PM, and YL reviewed and edited the first draft of the manuscript. All authors have read and agreed to the published version of the manuscript.

Abstract

Background: Adolescents in child welfare institutions often face inadequate facility resources, limited caregiver support, and restricted access to health care services. These obstacles impede their physical, mental, and social development during adolescence, resulting in significant health vulnerabilities. Engaging in health-promoting behaviors (HPBs) can enhance their overall health and quality of life, potentially contributing to improved long-term well-being.

Objective: This study aimed to identify the HPBs of adolescents in child welfare institutions in Indonesia and explore the determinants influencing these behaviors using the health promotion model.

Methods: This study used a cross-sectional survey design. Adolescents living in welfare institutions were recruited from January 14, 2024, to February 3, 2024. After obtaining institutional review board approval, 6 research assistants visited 17 institutions in Malang and collected data from participants who provided their consent using tablet PCs that linked to the questionnaire. The variables studied included HPBs, health literacy, self-esteem, perceived barriers to action, perceived self-efficacy, and social support. Multivariate structural analysis was conducted using SPSS Statistics (version 26.0; IBM Corp) and SPSS Amos (version 26.0; IBM Corp).

Results: A total of 276 adolescents participated in this study. Adolescents' HPBs differed significantly based on age group (P=.03), educational level (P=.04), duration of stay in child welfare institutions (P=.03), and the institutions' accreditation level (P=.02). In the final model, perceived self-efficacy (β=0.538; P<.001) and social support (β=0.256; P<.001) together accounted for 47.9% of the variance in HPBs. Self-esteem was positively correlated with perceived self-efficacy (β=0.184; P<.001) and social support (β=0.303; P<.001) but negatively correlated with perceived barriers to action (β=−0.194; P<.01). Health literacy was also negatively correlated with perceived barriers to action (β=−0.234; P<.001). Self-esteem indirectly affected HPBs through perceived self-efficacy (β=0.099; P<.01) and social support (β=0.078; P<.001).

Conclusions: To improve the HPBs of adolescents living in child welfare institutions, their self-esteem needs to be increased to further enhance their self-efficacy and social support. Careful attention and monitoring of HPBs among these adolescents may lead to better health outcomes and support their transition from child welfare institutions to the broader community.

KEYWORDS

adolescents; health-promoting behaviors; child welfare institutions; Indonesia; health promotion model; structural equation model

Introduction

Background

Adolescents living in child welfare institutions—commonly referred to as orphanages or childcare institutions—face unique challenges that may adversely affect their overall health and well-being. These adolescents are more prone to experiencing physical, mental, and social difficulties than their peers living in family environments [1]. Furthermore, these challenges can lead to hopelessness and hinder their ability to thrive [2].

Health-promoting behaviors (HPBs) refer to individuals' actions and choices to improve their health and prevent the occurrence of diseases [3]. The World Health Organization emphasizes HPBs as a key strategy for improving health outcomes and enhancing quality of life [4]. During adolescence, engagement in HPBs is linked to improved academic performance, stronger interpersonal relationships, and a lower risk of future chronic diseases [5]. Thus, adopting HPBs during adolescence not only is beneficial for the present but also serves as a crucial investment in their future health and well-being.

Although HPBs have many advantages, barriers to their adoption exist for adolescents in child welfare institutions. Limited facility resources and a lack of caregiver support to fulfill adolescents' physical and psychological needs can lead to low self-esteem and poor decision-making skills [6]. In addition, poor national health insurance coverage and inadequate government registration may lead to low awareness and limited access to health care services, further restricting HPBs [7].

This is especially true in the Indonesian context, which faces its own unique challenges. Because of family economic hardships, adolescents are placed in child welfare institutions with the expectation that they will receive better care and education than they did with their families [8]. However, the vast majority of institutions in Indonesia are private and lack adequate government oversight and support, meaning that they do not always comply with national care standards [9]. Consequently, adolescents living in such conditions become more susceptible to unhealthy behaviors, including smoking, poor sleep, low physical activity, and challenges in maintaining overall well-being [10]. Despite the recognized importance of HPBs during adolescence, research on the factors influencing HPBs among adolescents living in child welfare institutions in Indonesia remains limited.

The health promotion model (HPM) developed by Pender and Murdaugh [3] has frequently been used to examine the relationship between relevant factors and HPBs in the adolescent population. The HPM encompasses 3 interconnected domains: individual characteristics and experiences, behavior-specific cognitions and affect, and behavioral outcomes and HPBs. These serve as the end point, with the aim to achieve positive health outcomes. Individual characteristics such as previous behavior, health literacy, self-esteem, and sociodemographic factors significantly shape subsequent actions, with their impact varying depending on the specific behavior being considered. Behavior-specific cognitions and affect—including perceived benefits and barriers to action, perceived self-efficacy, activity-related affect, and interpersonal and situational influences—are highly motivational. These factors can be modified through targeted interventions, making their measurement essential for evaluating intervention effectiveness.

Previous studies have established an explicit connection between various factors that are considered determinants of HPBs among adolescents [11-14]. Perceived barriers to action were the strongest and most important predictor of HPBs, exhibiting a negative relationship—the lower the perceived barriers to action, the higher the HPBs among adolescents and young adults [11,12]. Perceived self-efficacy also plays a crucial role in determining HPBs, with higher perceived self-efficacy correlating with increased HPBs [13]. Higher perceived self-efficacy is also correlated with lower perceived barriers to action [14].

Social support also contributes to HPBs, with greater social support associated with higher levels of HPBs [15,16]. Moreover, social support can enhance a sense of belonging, which, in turn, increases perceived self-efficacy and further promotes HPBs among adolescents. This is especially critical during adolescence, when individuals begin to understand health-related information and make independent health decisions [17]. Health literacy not only reduces perceived barriers to action but also improves perceived self-efficacy [18,19]. Furthermore, individuals with higher health literacy are more likely to seek and receive greater social support from their networks [20].

Self-esteem as a key individual characteristic is a significant factor. Higher self-esteem reduces perceived barriers to action while simultaneously promoting greater perceived self-efficacy and social support [21-23].

Objectives

This study aimed to identify the HPBs of adolescents in child welfare institutions in Indonesia and explore the determinants influencing these behaviors using the HPM. Given the relationships between the variables reviewed, this study examined health literacy and self-esteem as components of the individual characteristic domain and perceived barriers to action, perceived self-efficacy, and social support as elements of the behavior-specific cognitions domain. The HPBs examined as behavioral outcomes in this study were health responsibility, physical activity, nutrition, positive life perspective, interpersonal relationships, stress management, and spiritual health [24]. We specifically hypothesized that perceived barriers to action would be negatively correlated with HPBs, whereas perceived self-efficacy and social support would be positively correlated with HPBs. The findings of this study will provide insights into the challenges and opportunities for promoting HPBs in this population by identifying their determinants using structural equation modeling (SEM).

Methods

Study Design and Setting

This study used a cross-sectional design. Conducted in January 2024 and February 2024, this study took place in Malang, Indonesia. First, convenience sampling was used to select the child welfare institutions in Malang. A total of 17 child welfare institutions agreed to participate in this study. Inclusion criteria for this study were adolescents aged 13 to 18 years who had been living in child welfare institutions for at least 6 months and were willing to participate. Adolescents with developed mental or physical disabilities were excluded.

The sample size estimation for SEM is flexible. Several rules of thumb are commonly used, such as 10 cases per variable, 5 or 10 observations per estimated parameter, and a minimum sample size of 100 to 200 [25]. A sample size of 200 is often considered the gold standard in SEM and is widely used in studies [26,27]. Thus, this recommendation was applied while accounting for a 20% dropout rate, as reported in previous studies [28,29]. The required sample size for this study was calculated to be a minimum of 240.

Six research assistants collected data from participants. These assistants were third- and fifth-semester undergraduate nursing students who had completed the pediatric nursing theory and clinical practicum courses. The principal investigator provided instructions on the study's purpose and managed the link to the questionnaire and other relevant procedures. During data collection, research assistants visited the institutions and presented the questionnaire to participants using tablets or notebooks, allowing them to complete the survey via the KoboToolbox platform. In addition, when participants needed help understanding any question, research assistants provided individualized explanations. Participants were given sufficient time to provide their answers, and completing the questionnaires took approximately 45 minutes.

Before the answers were submitted online, the research assistants verified that no responses were missing. Of the 280 adolescents who participated, 4 (1.4%) were excluded because they selected identical responses to every question. The final analysis included 276 participants.

Ethical Considerations

The institutional review board of the Institute of Technology, Science, and Health RS Dr Soepraoen in Malang, Indonesia, approved this study (approval KEPK-EC-10/XII/2023). As adolescents are a vulnerable group requiring guardian consent for participation, the heads of the child welfare institutions provided written consent for the study, and all participants were asked to provide assent before data collection. The researchers ensured the privacy and confidentiality of participant data by not recording personal identifiers and by storing data in password-protected web-based storage accessible only to the research team. Participants who completed the questionnaire received a souvenir and a lunch box with an equivalent value of approximately US $1.50.

General Participant Demographics

Demographic information about the participants included age (in years), sex (male or female), educational level (primary school, junior high school, senior high school, or undergraduate), orphan status (maternal orphan, paternal orphan, double orphan, or not orphan), and duration of residence in child welfare institutions (in years). In addition, the accreditation level of the child welfare institutions was recorded. Indonesian child welfare institutions receive accreditation ratings of A (excellent), B (good), or C (satisfactory) or are unaccredited, reflecting varying levels of compliance with national standards for child welfare services. Higher ratings indicate a greater capacity to provide quality care within an institution.

HPB Measurement

In this study, HPBs refer to actions taken by adolescents to maintain and improve their health within the environment of a child welfare institution. The Adolescent Lifestyle Profile–Revised 2 [30] was used to measure HPBs. This instrument consists of 44 items across 7 domains: health responsibility, physical activity, nutrition, positive life perspective, interpersonal relationships, stress management, and spiritual health. The items were rated using a 4-point Likert scale (1=*never*, 2=*sometimes*, 3=*often*, and 4=*always*), with total possible scores ranging from 44 to 176. Higher scores indicate better HPBs among adolescents. The overall Cronbach α was 0.86 in this study.

Health Literacy Measurement

Health literacy refers to adolescents' ability to seek, understand, evaluate, and use health information to make informed decisions about their health. The Health Literacy Assessment Scale for Adolescents [31], consisting of 15 items, was used to measure health literacy. The instrument includes 3 subscales: communication, confusion, and functional health literacy. Items were rated on a 5-point Likert scale (1=*always*; 5=*never*), with total possible scores ranging from 15 to 75. Higher scores indicate greater health literacy. The Cronbach α for the scale was 0.70 in this study.

Self-Esteem Measurement

Self-esteem refers to adolescents' self-perception and evaluation of their own personal worth and abilities. The Rosenberg Self-Esteem Scale [32] adapted for the Indonesian context [33] was used to measure adolescents' self-esteem. This instrument consists of 8 items rated on a 4-point Likert scale (1=*strongly disagree*, 2=*disagree*, 3=*agree*, and 4=*strongly agree*) for items 1, 2, 3, 6, and 8, with reverse scoring applied to items 4, 5, and 7. The scores range from 8 to 32, with higher scores indicating higher self-esteem. In this study, the Cronbach α was 0.68.

Perceived Barrier to Action Measurement

Perceived barriers to action refer to adolescents' perceptions of the barriers or obstacles that prevent them from engaging in HPBs. The Barriers to Health-Promoting Activities Scale [34], consisting of 18 items, was used to measure this perception. Items were rated on a 4-point Likert scale (1=*never*; 4=*routinely*), with total possible scores ranging from 18 to 72.

XSL•FO
RenderX

Higher scores indicate greater perceived barriers to HPBs. In this study, the Cronbach α of the scale was 0.85.

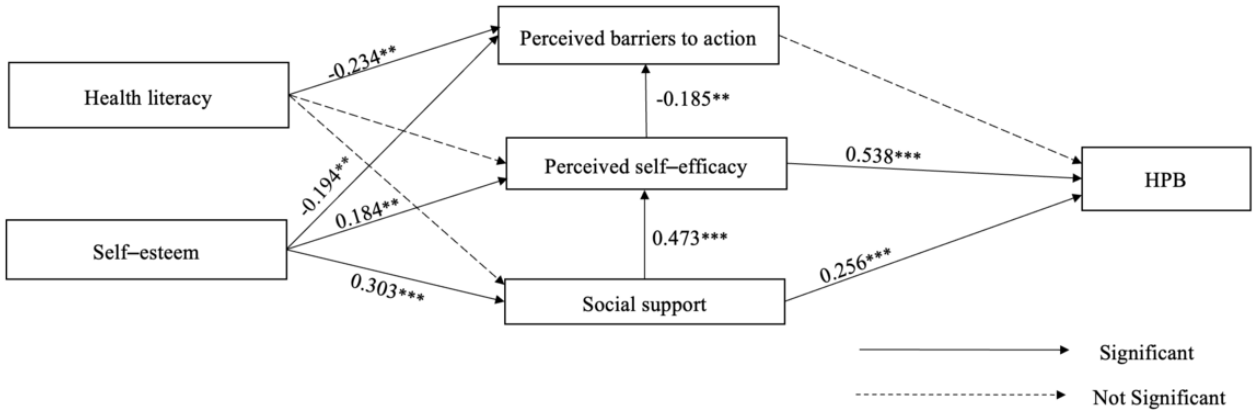
Perceived Self-Efficacy Measurement

Perceived self-efficacy refers to adolescents' belief in their ability to perform and maintain HPBs. The Self-Rated Abilities for Health and Practices Scale–Adolescent Version [35] was used. This instrument includes 28 items across 4 subscales: nutrition, psychological well-being, exercise, and responsible health practices. This instrument was rated on a 5-point Likert scale (1=*cannot do at all*, 2=*a little*, 3=*somewhat*, 4=*mostly*, and 5=*certainly can do*), with total possible scores ranging from 28 to 140. Higher scores indicate greater perceived self-efficacy among adolescents. In this study, the Cronbach α was 0.92.

Social Support Measurement

Social support refers to the emotional, instrumental, appraisal, and informational support that adolescents receive from caregivers, peers, and friends to help them engage in HPBs. The original Child and Adolescent Social Support Scale for Healthy Behaviors [36] is used to assess social support for healthy behaviors in children and adolescents from parents, teachers, classmates, close friends, and people in the school environment. For this study, this instrument was adapted to focus on 3 sources of support: caregivers, peers, and friends residing in child welfare institutions. This instrument consists of 36 items and 2 subscales: frequency and importance of social support. Frequency responses were rated on a 6-point Likert scale (1=*never*; 6=*always*), and importance responses were rated on a 3-point Likert scale (1=*not important*; 3=*very important*), with total possible scores ranging from 72 to 324. Higher scores indicate greater social support. The Cronbach α of the scale was 0.96 in this study.

Translation Process



Among the instruments, the following 5 questionnaires—the Adolescent Lifestyle Profile–Revised 2, Health Literacy Assessment Scale for Adolescents, Barriers to Health-Promoting Activities Scale, Self-Rated Abilities for Health and Practices Scale–Adolescent Version, and Child and Adolescent Social Support Scale for Healthy Behaviors—were translated into Indonesian using forward and backward translation techniques before use [37]. To ensure the validity of the translated scales, a translation process was followed step by step. Two faculty members from the pediatric nursing department and one with a background in English literature who had worked in the health field for >5 years took part in the following translation process: (1) 2 translators independently translated the original instrument from English into Indonesian (version A); (2) a third translator, who was unfamiliar with the original instruments, translated version A back into English (version B); (3) all translators reviewed and compared version B with the original version to identify conceptual discrepancies, adapt culturally relevant terms, and develop a refined forward translation (version C); (4) for cognitive debriefing, 5 adolescents were interviewed to assess whether the translated items were easily understood and accurately conveyed the intended meaning of the original questionnaire (version D); and (5) the translators reconvened to review version D for conceptual equivalence and make final proofreading adjustments, resulting in the finalized version used in this study (version E).

Statistical Analysis

SPSS Statistics (version 26.0; IBM Corp) was used to conduct descriptive analyses of variables, internal consistency tests, independent 2-tailed *t* tests, 1-way ANOVAs, Pearson correlations, and post hoc analyses. The SPSS Amos software (version 26.0; IBM Corp) was used to conduct path analyses examining the regression coefficients and the effects (direct, indirect, and total) among variables, as well as evaluating the fit of the structural model.

The determinants of HPBs among adolescents living in child welfare institutions were identified using SEM. In this study, 6 variables included in the model were observed variables with a single indicator. The 2 exogenous variables—health literacy and self-esteem—served as independent variables (predictors) of the other observed variables in the model. The 4 endogenous variables included perceived barriers to action, perceived self-efficacy, social support, and HPBs. HPBs were identified as the outcome of the model, whereas perceived barriers to action, perceived self-efficacy, and social support were identified as mediators between the exogenous variables and HPBs. Figure 1 shows the hypothesized model for this study.

Figure 1. Path coefficient diagram of the final model of health-promoting behaviors (HPBs) among Indonesian adolescents living in child welfare institutions. *P<.05; **P<.01; ***P<.001.

XSL•FO
RenderX

A structural equation model was also used to test the hypotheses. First, the model was identified, followed by an evaluation of its overall fit. The number of distinct sample moments in this model was 21, and the number of distinct parameters to be estimated was 18. Therefore, the *df* were calculated as 21−18=3. As the *df* were positive, a minimum was achieved, allowing for further testing [27]. Four tests were used to assess the goodness of fit: the Tucker-Lewis index (>0.90), comparative fit index (>0.90), standardized root mean square residual (<0.08), and root mean square error of approximation (<0.08) [38]. Bootstrapping analysis with 5000 samples and 95% bias-corrected CIs determined the significance of both indirect and direct effects.

Results

Participant Demographic and HPB Analysis

Of the 276 participants, 149 (54%) were female. Most (155/276, 56.2%) were aged 13 to 15 years, with a mean age of 15.3 (SD 1.7) years. In addition, 43.1% (119/276) were in senior high school, whereas 42.8% (118/276) were in junior high school. Approximately half (141/276, 51.1%) of the participants were not orphans, and 60.9% (168/276) had been living in child welfare institutions for 1 to 3 years, with a mean duration of 3.4 (SD 2.5) years. Table 1 presents participants characteristics and comparison of HPBs.

Table 1. Participant characteristics and comparison of health-promoting behaviors (HPBs) between groups (N=276).

Variable and category	Participants, n (%)	Variable mean (SD)	HPBs—ALP-R2[a] (score range 44-176), mean (SD)	*P* value
Age (y)		15.3 (1.7)		.03

[a]ALP-R2: Adolescent Lifestyle Profile–Revised 2.

[b]Not applicable.

HPB scores were significantly different by age group (*P*=.03), educational level (*P*=.04), duration of residence in child welfare institutions (*P*=.03), and accreditation level of institutions (*P*=.02). On the basis of the post hoc analysis, adolescents aged 13 to 15 years had lower HPB scores than adolescents aged 16 to 18 years (*P*=.03). Primary school students had lower HPB scores than college students (*P*=.03). HPB scores were higher among those living in child welfare institutions for 1 to 3 years and 4 to 5 years than among those living in them for >5 years (*P*<.05). Adolescents in level B institutions had higher HPB

XSL•FO
RenderX

scores than those in level C institutions (*P*=.02), and adolescents living in unaccredited institutions had higher HPB scores than those living in level C institutions (*P*=.03).

Correlation Between Major Variables

The correlation analysis showed that HPBs had a significant positive correlation with perceived self-efficacy (*r*=0.66; *P*<.001), social support (*r*=0.53; *P*<.001), health literacy (*r*=0.13; *P*=.03), and self-esteem (*r*=0.31; *P*<.001). Conversely, HPBs had a significant negative correlation with perceived barriers to action (*r*=−0.15; *P*=.01). Table 2 presents the results of the correlation analysis between variables.

Table 2. Correlation analysis between variables.

[b]HPB: health-promoting behavior.

HPBs and Significant Determinants

The model in this study indicated a good fit (Tucker-Lewis index=0.947; comparative fit index=0.989; standardized root mean square residual=0.000; root mean square error of approximation=0.070). The results of the SEM analysis are presented in Table 3. In the HPB pathway, only perceived self-efficacy (β=0.538; *P*<.001) and social support (β=0.256; *P*<.001) had significant positive correlations with HPBs. These 2 variables explained 47.9% of the variance in HPBs. In the perceived barriers to action pathway, perceived self-efficacy (β=−0.185; *P*<.01), health literacy (β=−0.234; *P*<.001), and self-esteem (β=−0.194; *P*<.01) showed significant negative correlations with perceived barriers to action, collectively explaining 18.8% of its variance. In the perceived self-efficacy pathway, only self-esteem (β=0.184; *P*<.001) and social support (β=0.473; *P*<.001) had significant positive correlations, explaining 32.8% of its variance. In the social support pathway, only self-esteem (β=0.303; *P*<.001) had a significant positive correlation with social support, explaining 8.6% of its variance.

[c]*P*<.001.

[d]*P*<.01.

In addition, there was a significant indirect effect of self-esteem on HPBs through perceived self-efficacy (β=0.099; *P*<.001), social support (β=0.078; *P*<.001), and the combination of social support and perceived self-efficacy (β=0.077; *P*<.001). The final model of HPBs among adolescents living in child welfare institutions is shown in Figure 1.

Discussion

Principal Findings

This study explored the determinants of HPBs among adolescents living in Indonesian child welfare institutions. It primarily found significant differences in adolescents' HPBs based on age group, educational level, duration of stay in child welfare institutions, and the accreditation level of the institutions. Older adolescents and those with higher educational levels demonstrated better HPBs, which may be attributed to greater responsibility and autonomy [39]. Interestingly, adolescents who had lived in child welfare institutions for >5 years had significantly lower HPBs than those who had lived there for shorter periods, such as 1 to 3 years and 4 to 5 years. This may be due to adaptation to regular daily schedules, although prolonged stays without proper knowledge might lead to the normalization of poor HPBs. In addition, adolescents who have just entered these institutions might receive more attention and support from caregivers and peers than long-term residents. These findings provide valuable insights into the necessity and timing of delivering internal education to promote healthy behaviors. In terms of accreditation levels, adolescents living in level B institutions showed significantly higher HPBs than those in level C institutions. However, adolescents living in level A institutions did not demonstrate better HPBs than those living in level B or C institutions. Higher-level institutions are assumed to have better access to services and more structured systems than lower-level ones, potentially offering adolescents more resources to engage in good HPBs. These unexpected findings might be due to the small sample size of level A institutions and the fact that the accreditation process primarily focuses on environmental and human support factors rather than the promotion of health behaviors among the residents. This aspect is suggested as a criterion in the future accreditation process for Indonesian child welfare institutions.

Through the SEM analysis, this study found that perceived self-efficacy and social support together accounted for 47.9% of adolescents' HPBs. HPBs are key to happiness and a good quality of life, and self-efficacy increases HPBs at every stage of life [40]. When individuals have confidence in their ability to perform HPBs, they are more likely to engage in these behaviors [4]. Among adolescents in child welfare institutions, social support appears to play a crucial role in the development of good HPBs, helping bring more structure to their daily activities.

XSL•FO
RenderX

This study challenges existing frameworks by highlighting that perceived barriers to action were not significant to HPBs in this context, providing insights into the unique needs of these adolescents. This finding aligns with findings from Thailand [41]. This could be attributed to the unique environment of child welfare institutions, where structured activities and support systems mitigate the barriers typically faced by adolescents living with their families. The organized nature of these institutions—with regulated schedules and caregiver supervision—can encourage adolescents to engage in HPBs, often leaving health decision-making to caregivers and the institution. This is supported by the fact that most participants in this study (196/276, 71%) lived in accredited child welfare institutions (level A, B, or C), which have already met the minimum national care standards for children.

Interestingly, health literacy did not correlate with perceived self-efficacy in this study. This finding differs from those of studies conducted in Australia, China, Turkey, and Germany, which found a positive correlation between health literacy and adolescent self-efficacy [18]. This discrepancy may be due to adolescents in child welfare institutions having moderate health literacy but lacking confidence in performing HPBs. In general, adolescents are not fully independent at this stage and often lack autonomy in their activities, as well as practical experience in carrying them out [42].

In addition, this study identified the link between self-esteem, social support, and perceived self-efficacy and HPBs, a connection that has emerged in recent literature on this unique population. It may provide a foundation for health professionals to develop interventions that address HPBs by improving self-esteem and enhancing social support for targeted adolescents such as those in this study.

Comparison With Prior Work

No previous studies—to our knowledge—have examined HPBs among adolescents living in child welfare institutions. Much of the existing research has focused on healthy adolescent populations, with studies conducted in Turkey [43], Portugal [44], Iran [45], and India [46]. However, this study explored HPBs among a specific group of adolescents—those living in child welfare institutions—which has been understudied in Indonesia and other countries. This study also highlights several factors under the HPM that influence HPBs, providing a comprehensive understanding of the determinants of these behaviors.

This study found that self-esteem had a significant indirect effect on HPBs through perceived self-efficacy and social support. This supports previous studies indicating that higher self-esteem improves perceived self-efficacy, which is crucial for problem-solving and adopting HPBs [47,48]. Individuals with high self-esteem tend to have greater perceived self-efficacy in problem-solving [49,50].

This study also found that only self-esteem showed a significant positive correlation with social support and self-efficacy and indirectly affected HPBs. Higher self-esteem leads to more active social engagement, thereby increasing perceived social support [51]. Interestingly, self-esteem explained only 8.6% of the variance in social support. Social support is a complex and multidimensional construct [52], and we assessed it only from caregivers, peers, and friends living in child welfare institutions. In addition, only 8.7% (24/276) of the participants were double orphans, indicating that most participants still had family members with whom they maintained contact, which may also influence their social support. The limitation of the social support measurement may have affected the strength of the observed relationship, and future studies should investigate the role of family support among adolescents living in child welfare institutions who are not double orphans.

Furthermore, self-esteem was found to be moderate in this study, which is consistent with previous research indicating that adolescents living in child welfare institutions generally exhibit low to moderate levels of self-esteem [53]. Hence, interventions to improve self-esteem could enhance social support and, consequently, HPBs. In child welfare institutions, fostering a nurturing environment that enhances self-esteem and interpersonal relationships can be used to boost adolescents' perceived self-efficacy, thereby promoting positive HPBs.

This study also confirmed that social support is positively correlated with perceived self-efficacy, which helps reduce perceived barriers to action. These findings align with those of a study from the United States that showed that higher perceived self-efficacy reduces perceived barriers to physical activity—a component of HPBs [54]. Greater social support leads to higher perceived self-efficacy and fewer perceived barriers. Given the limited studies on this topic—especially among adolescents—this study provides valuable insights into the relationships among self-esteem, social support, perceived self-efficacy, and perceived barriers to action.

The key finding of this study was the nuanced relationship between health literacy and HPBs among adolescents in child welfare institutions. Surprisingly, health literacy did not significantly influence perceived self-efficacy or social support, suggesting that the structured environment of these institutions provided consistent information and support, reducing reliance on individual health literacy. In addition, adolescents are still in the process of developing their health-related knowledge, and the lack of health education interventions within child welfare institutions may limit the impact of health literacy on their ability to benefit from social support. However, lower health literacy significantly increased perceived barriers to action, indicating that, even within a supportive environment, understanding health information is crucial for overcoming challenges. The structured environment of the institutions mitigated the negative impact of these perceived barriers to HPBs, suggesting that consistent support and resources can buffer the effects of perceived obstacles. These findings underscore the need for interventions that enhance health literacy, empowering adolescents to overcome barriers while leveraging the supportive nature of structured environments in child welfare institutions to promote healthier behaviors and improve adolescents' overall well-being.

Clinical and Policy Implications

The findings of this study highlight the need for policies specific to the improvement of HPBs in adolescents living in child

XSL•FO
RenderX

welfare institutions in Indonesia. The large number of unrecorded child welfare institutions hinders the provision of nursing interventions to these children and adolescents. Coordination between the Ministry of Social Affairs and Ministry of Health is essential, starting with data collection from child welfare institutions and regular monitoring of the health and welfare of children in these institutions. This will enable health professionals to provide optimal health services and interventions for these adolescents.

While school-based interventions are often considered effective, a review found that these interventions were insufficient for improving HPBs [55]. This is consistent with conditions in Indonesia, where the concept of school nurses or other health professionals at school is not widespread. Only a few private schools have health care professionals who work full time or part time. This may lead to inadequate health interventions in schools. Public health centers are the closest access points for adolescents. Public health centers conduct annual health screenings for students and have a youth health care program that usually provides health services and education for schools at least twice a year. Within these programs, health professionals can also administer HPB assessments and provide education for adolescents in schools.

It has also been suggested to extend interventions beyond the school setting into the home [55]. This is feasible in Indonesia. This study found that social support from caregivers and friends in child welfare institutions was more significant than that from peers. Unfortunately, public health centers do not have specific programs for child welfare institutions. However, they have an Islamic boarding school health care center (*poskestren*) program, which focuses on health services to Islamic boarding schools. Public health centers can include child welfare institutions in this program, conducting health interventions for adolescents, caregivers, and other children in these institutions, thus improving HPBs among adolescents in Indonesia.

Study Limitations

Despite our best efforts, a few limitations exist in this study. First, convenience sampling methods were used in a single city, so generalizing the findings should be done with caution. Second, this study had a cross-sectional design, which requires careful interpretation of causality as bidirectional relationships between variables may exist. Therefore, we encourage future studies to use a longitudinal design to gain a deeper understanding of HPBs among adolescents living in child welfare institutions over time. Third, because half of the participants had at least one parent, social support from parents—which was not assessed—may have influenced the level of social support they received. Therefore, we suggest that future studies assess social support from parents and its potential impact on HPBs. Fourth, exploratory factor analysis was conducted; however, no confirmatory factor analyses were conducted on the translated instruments, which may have impacted the validity of the measures. Finally, although the research assistants were trained to ensure consistent interpretation of the instruments, periodic meetings were not held to calibrate interpretations or address issues that arose during data collection. This may have affected the reliability and accuracy of the data collection process.

Conclusions

On the basis of the HPM and testing using SEM analysis, both perceived self-efficacy and social support directly affected HPBs, whereas self-esteem indirectly affected HPBs among adolescents in child welfare institutions in Indonesia. In addition, health literacy only influenced perceived barriers to action, but these perceived barriers to action did not contribute to HPBs. The key findings of our study contribute to the development of health interventions aimed at improving self-efficacy and social support by enhancing self-esteem, ultimately leading to increased HPBs among adolescents living in child welfare institutions in Indonesia. We hope that these interventions will lead to improved health outcomes and quality of life for these individuals as they transition into adulthood and move from child welfare institutions to the broader community.

Acknowledgments

This study was supported by the Yonsei University College of Nursing and the Lee (SK) Mija Global Leadership Research Scholarship. The authors would also like to thank all the heads and caregivers of the 17 child welfare institutions for granting them access to participants. They also extend their gratitude to the 6 nursing students who assisted with data collection. The authors declare that no generative artificial intelligence was used while writing the manuscript. The funder had no involvement in the study design; data collection, analysis, or interpretation; or writing of the manuscript.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

AI and HL developed the study concept. SK, HL, and AL contributed to the study design, and CP provided statistical expertise for the analysis. All authors contributed to writing the manuscript and approved the final version.

Conflicts of Interest

None declared.

Abstract

Background: Ultraprocessed food (UPF) consumption is very common among adolescents. Previous studies have suggested an association between UPF consumption and adolescent mental health problems, but studies on multiethnic adolescents in China are rare.

Objective: This study investigated the association between UPF consumption and depressive symptoms in multiethnic adolescents in Yunnan Province, China.

Methods: A cluster sampling of 8500 middle school students from 11 counties in Yunnan Province was conducted. The Chinese version of the Depression Anxiety Stress Scale-21 was administered to assess depressive symptoms, and a food frequency questionnaire was used to collect UPF consumption data. A generalized linear model was used to analyze the association between UPF consumption and depressive symptoms, and a restricted cubic spline was used to fit the correlation plot. The association analysis was performed after adjusting for demographic and confounding variables that might have influenced depressive symptoms.

Results: The detection rates of depressive symptoms in adolescents were 28.3% (2402/8500) for the sample, 25.5% (1069/4184) for males, and 30.9% (1333/4316) for females. After adjusting for confounding variables, instant food (all participants: β=.22, 95% CI 0.13-0.32; *P*<.001; males: β=.15, 95% CI 0.03-0.27; *P*=.01; females: β=.29, 95% CI 0.15-0.43; *P*<.001), carbonated beverage (β=.20, 95% CI 0.12-0.29; *P*<.001; β=.15, 95% CI 0.04-0.26; *P*=.006; β=.29, 95% CI 0.16-0.43; *P*<.001;), energy beverage (β=.21, 95% CI 0.10-0.32; *P*<.001; β=.22, 95% CI 0.08-0.36; *P*=.002; β=.22, 95% CI 0.04-0.40; *P*=.01), and other beverage (β=.24, 95% CI 0.14-0.34; *P*<.001; β=.21, 95% CI 0.08-0.35; *P*=.002; β=.25, 95% CI 0.10-0.41; *P*=.001) consumption were associated with depressive symptoms for all participants, males, and females, respectively. Females were more sensitive to the association between UPF consumption and depressive symptoms. Moreover, female interaction with instant foods (β=.31, 95% CI 0.18-0.44; *P*<.001), carbonated beverages (β=.27, 95% CI 0.15-0.39; *P*<.001), energy beverages (β=.18, 95% CI 0.01-0.35; *P*=.04), and other sugar-sweetened beverages (β=.17, 95% CI 0.02-0.32; *P*=.03) was associated with depressive symptoms, respectively.

Conclusions: These results indicated that UPF consumption was related to depressive symptoms in Yunnan multiethnic adolescents. Health education and behavioral interventions that reduce UPF consumption could protect adolescents from depressive symptoms.

Introduction

Depression is one of the most common mental illnesses in the world. In 2008, the World Health Organization ranked major depression as the third leading cause of disease burden worldwide and projected that the disease would rank first by 2030 [1]. The Global Burden of Disease Study from 1990 to 2019 shows that depression rates are on the rise [2]. Recently, mental health problems among adolescents have become a widespread concern [3] and are a main disease burden for adolescents [4]. Adolescence is a peak period for mental health problems [5]. Depression is the primary cause of disability in adolescents [6]. Depressive symptoms are the most common psychopathological symptoms in adolescents and significantly increase self-injury risk (odds ratio [OR] 2.19, 95% 2.03-2.36) and death by suicide (OR 2.67, 95% CI 1.72-4.14) [3]. A systematic review and meta-analysis demonstrated that the point prevalence of elevated depressive symptoms among adolescents increased from 24% (95% CI 19%-28%) between 2001 and 2010 to 37% (95% CI 32%-42%) between 2011 and 2020 [7]. A German study reported that the prevalence of depressive symptoms in adolescents aged 12-17 years was 8.2% (95% CI 6.5%-9.9%) [8]. In a UK school-based survey, the prevalence of depressive symptoms among 11- to 16-year-olds ranged from 24% to 32% [9]. The prevalence rates of depressive symptoms among adolescents may be higher in developing countries than in developed countries; the rates were 52.3% in India [10] and 26.2% among Malaysian secondary school students [11]. A meta-analysis of Chinese children and adolescents showed a total prevalence of depressive symptoms of 19.85% (95% CI 14.75%-24.96%), and the prevalence rates in the eastern, central, western, and northeastern regions were 17.8%, 23.7%, 22.7%, and 14.5%, respectively [12]. Our previous sample survey of 10- to 20-year-olds from 4 cities in China determined a 27.3% detection rate for depressive symptoms [13]. Current studies claim depressive symptoms are affected by various factors such as academic pressure, growth and development, eating behavior, physical activity, and social media use [3,14,15].

The global consumption of ultraprocessed foods (UPF) has rapidly increased. In 2010, the NOVA food classification system was proposed [16]. After undergoing physical, biological, and chemical processes and containing multiple ingredients and additives, UPF is separated from nature before consumption or preparation as dishes [16]. UPF has the advantages of attractive packaging, ease of consumption, attractive taste, and high palatability, and has gained popularity, especially among adolescents [17]. UPF consumption by adolescents in developed countries is higher; the proportion of energy intake from UPF in American adolescents is higher than that in adults [18]. The UPF energy intake in British middle school students accounts for 77.8% of their total lunch energy intake [19]. UPF consumption among adolescents in developing countries has also attracted widespread attention. According to a Romanian survey, 18- to 23-year-olds generally consume pastries (41.4%), while sweets (12.4%), pastries (11.1%), and sugar-sweetened beverages (SSB; 11.2%) are highly addictive, and males consume more than females [20]. Data from the Global School Health Survey of 9 Southeast Asian countries suggest that 40% of 12- to 15-year-olds consume carbonated beverages [21]. Adolescents aged 14-17 years in Spain consume 7.72 UPF servings per day; the reported consumption rates for processed meats, chocolate products, snacks, chocolate drinks, and soft drinks were 52.14%, 49.29%, 48.21%, 46.07%, and 33.57%, respectively [22]. UPF consumption by adolescents is associated with social isolation, diet globalization, and parental rearing style [23].

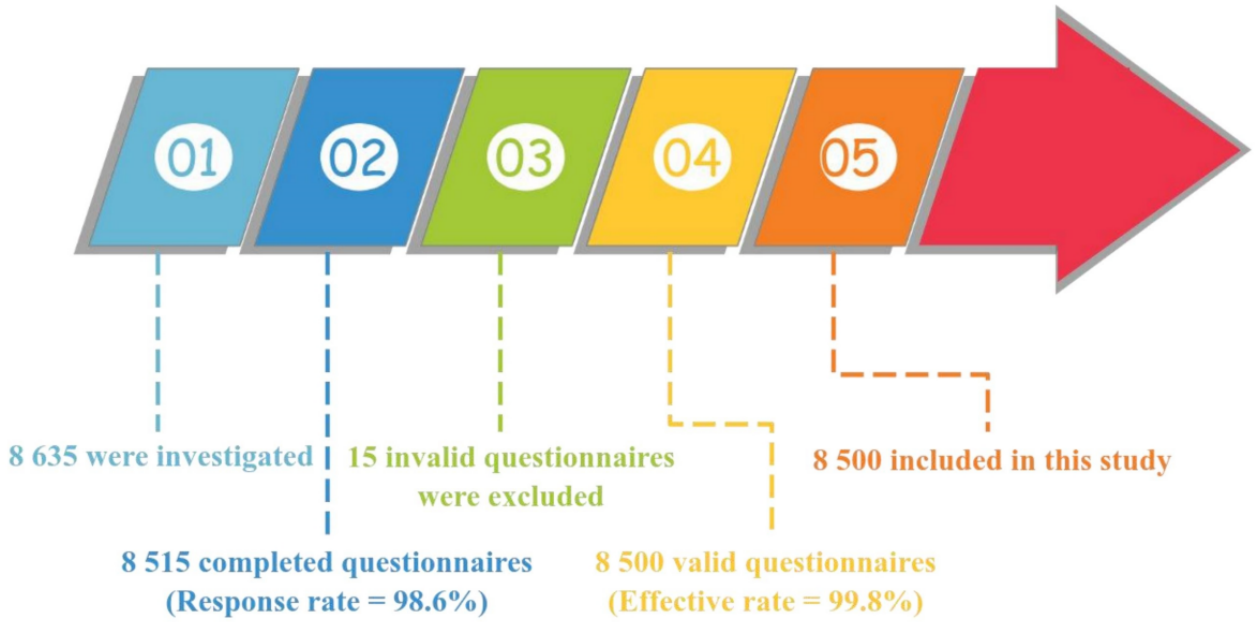
Existing research demonstrates that unhealthy eating behaviors and eating patterns of adolescents are potentially associated with mental health issues [24]. UPF consumption is associated with depressive symptoms (OR 1.44, 95% CI 1.14-1.82) [25] and significantly associated with an increased risk of depression (relative risk 1.31, 95% CI 1.21-1.41) [26]. Western dietary patterns (sweetened beverages, processed or junk foods, and foods rich in saturated fatty acids) have been linked to an increased risk of depression among adolescents [27]. SSB, fried foods, processed meats, and baked products are associated with an increased risk of depression. SSB, sweets, and snack consumption are associated with depressive symptoms in adolescents (OR 1.62, 95% CI 1.35-1.95) [28]. Studies in China, the United Kingdom, Brazil, and other countries have found that the consumption of sweets, biscuits, snacks, and fast foods and depressive symptoms in adolescents are significantly positively correlated [29-32]. For instance, in the Brazilian National School Health Survey, boys and girls who consumed ≥6 UPF reported more depressive symptoms and other psychopathologies than those who consumed ≤3 UPF 24 hours before the survey (boys: β=.27, girls: β=.31) [33].

Although several studies have explored the association between UPF consumption and depressive symptoms in adolescents, their findings have been inconsistent. Studies have shown that the consumption of soft drinks and processed meat products is not associated with depressive symptoms in adolescents [30]. There are limited studies on the association between UPF consumption and depressive symptoms of adolescents in China, and no studies on multiethnic adolescents in China have been conducted. Chinese multiethnic adolescents mainly live in the border areas of China and are influenced by the dietary culture of neighboring countries and multiethnic groups; thus, their UPF consumption may be higher. Therefore, this study investigated the association between UPF consumption and depressive symptoms in Chinese multiethnic adolescents.

Methods

Study Design

This is a cross-sectional study. This study is part of a behavior and subhealth study of Yunnan adolescents that aims to explore the association between lifestyle factors and physical and mental subhealth among adolescents in Yunnan, China, through a series of cohort studies [34].



Study Setting and Sample

From October to December 2022, a sample questionnaire survey was conducted with first-year (grade 7) middle school students from 11 counties in Yunnan Province, China. Yunnan Province lies along China's southwestern border with Myanmar, Laos,

XSL•FO
RenderX

and Vietnam. Yunnan has 26 ethnic groups and 25 ethnic minority groups. A total of 8635 multiethnic adolescents were surveyed, and 8515 questionnaires were completed, for a 98.6% response rate. There were 8500 valid questionnaires; the effective response rate was 99.8%. The average age of participants was 12.64 (SD 0.63; range 12-15) years; 4184 (49.2%) were males and 4136 (48.8%) were females; and 6358 (74.8%) were from rural areas and 2142 (25.2%) were from urban areas. There were 3856 (45.3%) Han and 4659 (54.7%) ethnic minority participants. Figure 1 presents the flowchart of participants. Tables 1 and 2 present the distributions of the demographic variables.

Cluster random sampling was used to conduct a questionnaire survey among adolescents in 11 counties of Yunnan Province, and 1-2 middle schools were selected from each county. SPSS software (version 23.0; IBM Corp) was used for random sampling. All students in grade 7 from the sampled middle schools were included in the survey.

The survey included demographic variables, eating behaviors, anxiety symptoms, and confounding factors that may influence depressive symptoms in adolescents, such as family changes, hospital experiences, screen time, smoking, drinking behavior, physical activity, family history of depression, learning stress, and the impact of COVID-19. The selection of these confounding factors was based on references and previous research findings of the research group.

A pilot test was conducted on 131 middle school students before the field survey to assess participant understanding of the questionnaire. The pilot test results showed that middle school students were able to fully understand the content of the questionnaire, and the average time taken to complete the questionnaire was 16 minutes. The adolescents gathered in a classroom to complete the survey. Trained investigators were on-site to answer questions from adolescents face-to-face. Adolescents completed the paper version of the questionnaire independently, which takes approximately 15-20 minutes.

Measures

Covariates

The demographic variables included sex, age, ethnicity, only child status, family residence, self-rated family economic status, family type, number of close friends, parental education, and parental occupation.

Depressive Symptom Assessment

The Children's Depression Inventory (CDI) was used to assess depressive symptoms in adolescents [35]. The CDI is applicable for the self-assessment of depressive symptoms in children and adolescents between the ages of 7 and 17 years; it is based on self-perception within the past 2 weeks. The CDI consists of 27 items, each of which is scored on a 3-point scale of "occasionally," "often," and "always" (0-2 points), respectively. The total CDI score ranges from 0 to 54; higher scores indicate more severe depressive symptoms. In this study, a total score of ≥19 was considered positive for depressive symptoms, and a score <19 was considered negative for depressive symptoms [35]. Research on Chinese children and adolescents aged 7-17 years shows that the CDI has good reliability and validity with a Cronbach α of 0.84 [36]. In this study, Cronbach α for the CDI was 0.853.

UPF Consumption Assessment

The eating frequency questionnaire prepared by our research group, which has good reliability and validity, was used to evaluate the eating behavior of adolescents [37]. According to the NOVA food classification system proposed by Monteiro [16], UPF refers to food that is separated from nature before being consumed or prepared as dishes, undergoes physical, biological, or chemical processes, and contains multiple ingredients and additives, for example, soft drinks, ice cream, packaged sweets, salty snacks, processed meat, and prepared frozen foods. This survey focused on the average weekly UPF consumption of adolescents in the previous month, including staple processed food (eg, fried bread stick, fried dough cake, 200 g per serving), processed meat (eg, ham, sausage, ham sausage, Chinese bacon, canned meat, beef jerky, chicken steak, 100 g per serving), processed eggs (eg, salted duck egg, spiced corned egg, 60 g per serving), preserved fruits (eg, preserved apple, 100 g per serving), instant foods (eg, instant noodles, 100 g per serving), salted snacks (refers to industrial production, packaging, and sales, as well as long-term preserved salty food; eg, spicy strip, salty crackers, 100 g per serving), sweet snacks (refers to industrial production, packaging, and sales, as well as long-term preserved sweet food; eg, chocolate, candy, 50 g per serving), SSB (eg, carbonated beverages, juice beverages, energy beverages, milk beverages [refers to a category of SSB made by blending milk with various additives, such as sugar, sweeteners, and acidifiers, eg, wang zai milk], 500 mL per bottle), other SSB (refers to SSB other than the sweet snacks, carbonated beverages, juice beverages, energy beverages, and milk beverages; eg, vitamin beverages, sports beverages, 500 mL per bottle). We used concise questions to assess UPF consumption frequency. For instance, how many bottles of Coca-Cola (500 mL per serving) did you drink per week in the last 1 month? There were 10 options: 0, 1, 2, 3, 4, 5, 6, 7, 8, and ≥9 times. Adolescents choose their consumption patterns based on their actual situations. The Cronbach α of the dietary frequency questionnaire in this study was 0.935.

Data Analysis

We used EpiData (version 3.0; EpiData Association) to build the database, and SPSS software (version 23.0; IBM Inc) and

XSL•FO
RenderX

R software (version 4.3.1; R Foundation for Statistical Computing) were used for statistical analysis. In the SPSS software, descriptive statistics, a chi-square test, and a generalized linear model (GLM) analysis were performed. Restricted cubic spline (RCS) analysis was performed using R software. A chi-square test was used to compare the difference in depressive symptoms detection rate among middle school students with different demographic characteristics. A GLM and RCS were used to analyze the association between UPF consumption and depressive symptoms. In the model, the UPF consumption frequency (independent variable) and depressive symptom score (dependent variable) were continuous variables. An association analysis was performed after adjusting for demographic and confounding variables that might have influenced depressive symptoms. The association between UPF consumption and depressive symptoms was analyzed using the RCS, and an RCS correlation plot was fitted. A GLM was used to analyze the association between the interaction term of sex, UPF consumption, and depressive symptoms. The test standard was α=.05.

Ethical Considerations

This study was approved by the Ethics Committee of the School of Medicine, Kunming University (approval 20210222), and was carried out in accordance with the Declaration of Helsinki. Ethical guidelines were followed during all the stages of this study. The survey was conducted anonymously with informed consent from the schools, guardians, and students. All participants joined the study voluntarily, and no compensation was provided to them. All data were kept confidential, deidentified, and anonymous.

Results

Distribution of Depressive Symptoms in Adolescents With Different Demographic Variables

The total detection rate of depressive symptoms was 28.3% (2402/8500) among middle school students, 25.5% (1069/4184) among males, and 30.9% (1333/4316) among females; the difference was statistically significant (χ^2_1=29.83; *P*<.001). The detection rate of depressive symptoms in 12-year-olds was 26.7% (987/3698), and that in 13- to 15-year-olds was 29.5% (1415/4802); the difference was statistically significant (χ^2_1=7.95; *P*=.005). The stratified analysis by age (12 years and 13-15 years) showed statistically significant differences in the detection rate of depressive symptoms among 12-year-olds for all demographic variables except parental education level and maternal occupation. Among adolescents aged 13-15 years, there were statistically significant differences in the detection rates of depressive symptoms for other demographic variables except for only child, residence, and parental occupation (*P*<.05).

Association of UPF Consumption With Depressive Symptoms in Adolescents

The consumption rates (frequency ≥1) of staple processed food, processed meat, processed eggs, preserved fruits, instant foods, salted snacks, sweet snacks, carbonated beverages, juice beverages, energy beverages, milk beverages and other SSB for adolescents are presented in Table 3.

Table 3. Consumption of ultraprocessed foods among adolescents.

Variable	Adolescents (N=8500), n (%)	Males (n=4184), n (%)	Females (n=4316), n (%)
Staple processed food	4712 (55.4)	2274 (54.3)	2438 (56.5)
Processed meat	5761 (67.8)	2870 (68.6)	2891 (67.0)
Processed eggs	3878 (45.6)	1943 (46.4)	1935 (44.8)
Preserved fruits	4387 (51.6)	2037 (48.7)	2350 (54.4)
Instant foods	5234 (61.6)	2648 (63.3)	2586 (59.9)
Salted snacks	5702 (67.1)	2759 (65.9)	2943 (68.2)
Sweet snacks	5271 (62.0)	2490 (59.5)	2781 (64.4)

Table 4 presents the results of the GLM analysis of the association between UPF consumption and depressive symptoms in adolescents after adjusting for variables (Model 2). Table S1 in Multimedia Appendix 1 shows the analysis results without adjusting for variables (Model 1). After adjusting for confounding variables, instant food (β=.22, 95% CI 0.13-0.32; *P*<.001), carbonated beverage (β=.20, 95% CI 0.12-0.29; *P*<.001), energy beverage (β=.21, 95% CI 0.10-0.32; *P*<.001), and other SSB (β=.24, 95% CI 0.14-0.34; *P*<.001) consumption were associated with depressive symptoms for all participants. The sex-stratified analysis showed that instant food (β=.15, 95% CI 0.03-0.27; *P*=.01), carbonated beverage (β=.15, 95% CI 0.04-0.26; *P*=.006), energy beverage (β=.22, 95% CI 0.08-0.36; *P*=.002), milk beverage (β=–0.14, 95% CI –0.26 to

XSL•FO
RenderX

–0.02; *P*=.03), and other SSB (β=.21, 95% CI 0.08-0.35; *P*=.002) consumption was associated with depressive symptoms in males. In addition, instant food (β=.29, 95% CI 0.15-0.43; *P*<.001), carbonated beverage (β=.29, 95% CI 0.16-0.43; *P*<.001), energy beverage (β=.22, 95% CI 0.04-0.40; *P*=.01), and other SSB (β=.25, 95% CI 0.10-0.41; *P*=.001) consumption were associated with depressive symptoms in females.

Tables 5 and 6 present the association between the interaction of sex, UPF consumption, and depressive symptoms in adolescents. The results showed that female×instant foods (β=.31, 95% CI 0.18-0.44; *P*<.001), female×carbonated beverages (β=.27, 95% CI 0.15-0.39; *P*<.001), female×energy beverages (β=.18, 95% CI 0.01-0.35; *P*=.04), and female×other SSB (β=.17, 95% CI 0.02-0.32; *P*=.03) were associated with depressive symptoms, respectively. However, no association was observed between the interaction of these UPFs and male and depressive symptoms.

Table 5. Association between interaction of sex, ultraprocessed food consumption, and depressive symptoms in adolescents (Model 1: unadjusted for variables).

Discussion

Principal Findings

In this study, the detection rate for depressive symptoms among adolescents of multiple ethnic groups in Yunnan was higher (2402/8500, 28.3%), which is consistent with the results of our previous study on adolescents in 4 cities in China (27.3%) [13]. This detection rate was higher than that in a meta-analysis of middle school students in mainland China (24.3%) and that of middle school students in eastern China (23.3%) [38,39]; however, it was lower than that for Bangladeshi adolescents (36.6%) [40] and Indian adolescents (52.3%) [10]. Our data showed the detection rate of depressive symptoms for adolescents aged 13-15 years (1415/4802, 29.5%) was higher than that for adolescents aged 12 years (987/3698, 26.7%). A school-based survey in the United Kingdom determined that the detection rate of depressive symptoms among 15- to

XSL•FO
RenderX

16-year-olds (32%) was higher than that among 11- to 12-year-olds (24%) [9]. In addition, we found the detection rate of depressive symptoms in females (1333/4316, 30.9%) was significantly higher than that for males (1069/4184, 25.5%), which is consistent with the conclusions of other studies [40]. For example, a Bangladeshi study reported a significantly higher prevalence of depressive symptoms among female adolescents than male adolescents (32.5% vs 25.3%) [40]. The higher prevalence of depressive symptoms among female adolescents is consistent worldwide. Numerous studies have suggested that depressive symptoms increase during adolescence, adolescent females are more susceptible to depressive symptoms, and sex differences appear only during adolescence [41]. A meta-analysis found that sex differences peaked in adolescence (OR 3.02, 95% CI 2.76-3.30 for ages 13-15 years), then declined and remained stable in adulthood [42]. Moreover, the longitudinal study of Australian children also found that between the ages of 4 and 14 years, females were more likely than males to be on a trajectory for increased depressive symptoms [43]. Therefore, schools and families need to pay more attention to depressive symptoms in adolescents, especially female adolescents.

Our study suggests that fast foods, carbonated beverages, energy beverages, and other SSB (except those listed in this study) were positively associated with depressive symptoms in both males and females. Other studies have also determined that UPF consumption is associated with depressive symptoms [25,29,31]. Our survey of Chinese college freshmen demonstrated that carbonated beverage and milk tea consumption were associated with depressive symptoms in males, whereas carbonated beverages, tea beverages, and milk tea consumption were associated with depressive symptoms in females [44]. Higher UPF consumption in Spanish adolescents aged 14-17 years was associated with a higher detection rate of depressive symptoms, and the higher the intake, the more pronounced the depressive symptoms [22]. The consumption of sweets, biscuits, snacks, and fast food among adolescents in England, Wales, and Northern Ireland was significantly positively associated with depressive symptoms [30]. Instant noodles, instant rice, and other instant foods are very popular among Chinese adolescents because they are easy to carry and eat. Our survey indicated that the consumption rate of instant foods such as instant noodles was as high as 61.6% (5234/8500), which has not been previously reported in China. Our previous research found an association between carbonated beverage and processed snack consumption and anxiety symptoms in Yunnan college students [45]. This was the first study to report a correlation between instant food consumption and depressive symptoms among Chinese multiethnic adolescents.

Furthermore, the data from this study showed that milk beverage consumption was negatively associated with depressive symptoms in males. The milk beverages in this study were also SSB; thus, we will further observe and evaluate these associations in a cohort study. The RCS analysis revealed that instant food, carbonated beverages, energy beverages, and other SSB were associated with depressive symptoms in males and females, and the association between UPF consumption and depressive symptoms in females was more sensitive. We further analyzed the interaction between sex and UPF and its association with depressive symptoms. The results indicated that females who interact with instant foods, carbonated beverages, energy beverages, and other SSBs were associated with depressive symptoms, respectively. However, no association was observed between the interaction of males and these 4 types of UPFs and depressive symptoms. The research data further support the view that females who consumed UPF were more likely to experience depressive symptoms. Therefore, when schools develop intervention measures to reduce depression symptoms among adolescents through dietary behavior intervention, they need to take into account sex-specific factors. For female adolescents, it is even more necessary to strengthen health education and behavioral intervention.

Several mechanisms by which UPF consumption is associated with depressive symptoms are possible. First, UPF consumption is associated with sleep dissatisfaction in adolescents [28]. The low sleep quality is a predictor of depressive symptoms in adolescents. Previous studies have suggested that the fourth quartile of UPF (44.3%-81.8% of total calories; prevalence ratio=1.14) was associated with a higher prevalence of poor sleep quality in adolescents [46]. A systematic review and meta-analysis showed that the higher the intake of UPF, the greater the risk of insomnia among adolescents (OR 5, 95% CI 1.21-1.99), and there is a clear dose-response relationship [47]. Second, UPF consumption may lead to disturbances in the intestinal flora and increase stress susceptibility of adolescents through the hypothalamic-pituitary-adrenal axis, which can lead to depressive symptoms occurring [5]. Experimental studies have shown that excessive intake of UPF leads to a reduced abundance of potentially beneficial butyrogenic microbes (*Roseburia*, *Faecalbacterium prausnitzii*, *Lactobacillus*, *Bifidobacterium*, and *Lachnospiraceae*), and the abundance of potentially pathogenic or opportunistic microorganisms (*Alistiopsis and Pasteurella*) increases [48]. Finally, the intake of UPF leads to an increase in chronic inflammatory levels, which causes the occurrence of depressive symptoms [49]. Adolescents with UPF energy consumption ≥30% (tertile 3 of UPF) had a 79% increase in interleukin-8 levels and had higher C-reactive protein levels when compared with adolescents in tertile 1 of UPF [50]. UPF intake may lead to a dysregulation of immune cell homeostasis and inflammation, including decreased levels of anti-inflammatory cytokines and increased levels of proinflammatory cytokines and chemokines [51].

Adolescents have great potential for physical, cognitive, and social development, and adolescence is regarded as the second critical window after infancy [52]. The mental health and growth of adolescents are related to the future of a country and require extensive attention. Adolescent depression is a global concern. Adolescence is a period of rapid emotional and cognitive development and critical life transitions. Notably, the treatment of depression is expensive. A Netherlands study of 11- to 18-year-olds with subclinical depressive symptoms showed that the social costs associated with depressive symptoms amounted to €54 million (US $57 million) per year [53]. Therefore, prevention and early intervention of adolescent depression is a top priority, using strategies that target predisposing factors, causes, and depression symptoms. Modifiable risk factors are

XSL•FO
RenderX

critical for reducing depression prevalence among adolescents. Eating behavior interventions have been recommended as an effective measure to prevent mental illness [31]. Therefore, it may be necessary to expand the monitoring of UPF consumption behaviors and depressive symptoms in adolescents, strengthen health education in schools and families, and promote healthy eating environments in schools to reduce UPF consumption and improve depressive symptoms in adolescents.

Strengths and Limitations

This study has several strengths. First, the sample comprised adolescents from 11 counties in Yunnan Province, China, with good representativeness and extrapolation of research results. Second, this study was the first to report the association between UPF consumption and depressive symptoms in Chinese multiethnic adolescents. Finally, we used a variety of models to analyze the association between UPF consumption and depressive symptoms and obtained stable results.

This study also has a few limitations. First, information bias was inevitable in the investigation, such as recall and social expectation biases. Second, the current assessment of UPF intake relies on frequency data without quantification in terms of grams or caloric contribution, which is limited for an accurate analysis of the association between the precise intake of UPF and depressive symptoms in adolescents. Finally, cross-sectional data cannot determine causal associations, and bidirectional associations may need to be clarified in further cohort studies.

Conclusion

This study found that the consumption of instant foods, carbonated beverages, and energy beverages was related to depressive symptoms among Chinese multiethnic adolescents. It is important to note that the observed association may have a reverse correlation, where depressive symptoms could lead to an increase in the intake of ultrapalmitic fatty acids among adolescents. This needs to be further confirmed in cohort studies. The results highlighted the importance of reducing UPF consumption among adolescents. These findings should be replicated in cohort studies to determine the causal relationship and the direction. The government, schools, and families should take effective measures to reduce UPF consumption among Chinese multiethnic adolescents to support mental health development in adolescence.

Acknowledgments

We thank the schools that took part in the survey and all the participants. This work was supported by the National Natural Science Foundation of China (82160622), the Young Talents Special Project of the “Xingdian Talent Support Plan” in Yunnan Province (XDYC-QNRC-2022-0289), the Yunnan Fundamental Research Projects (202501AT070481), the Scientific Research Foundation of Yunnan Provincial Department of Education (2025Y1087), and the Introduced Talents Scientific Research Project of Kunming University (YJL2103).

Abstract

Background: Men who have sex with men (MSM) face a disproportionately high risk of mpox infection, and China has recently experienced a rapid increase in the reported cases. This population also has a high prevalence of HIV, which has been identified as a critical factor in understanding the vulnerability to mpox. In addition, metabolic diseases frequently co-occur with HIV and share immunometabolic pathways, raising concerns that they may interact to confer additional risk of mpox infection.

Objective: This study examines the potential interaction between HIV and metabolic comorbidity in relation to self-reported mpox among MSM in China.

Methods: A cross-sectional study was conducted among MSM aged 18 to 76 years from October 2023 to March 2024 in 6 representative provincial regions of China. Participants completed an anonymous questionnaire on HIV infection, metabolic diseases (hypertension, diabetes mellitus, and hyperlipidemia), and mpox infection. Metabolic comorbidity was defined as the presence of more than one of these conditions. Logistic regression models were used to examine associations, and additive and multiplicative interactions between HIV and metabolic comorbidity were assessed.

Results: Of the 2403 MSM, 56 (2.33%) reported mpox, 199 (8.28%) reported HIV, and 325 (13.52%) reported at least one metabolic comorbidity (hypertension, diabetes, or hyperlipidemia). Both HIV (odds ratio [OR] 4.81, 95% CI 2.29-9.64) and metabolic comorbidity (OR 2.62, 95% CI 1.27-5.14) were associated with higher odds of mpox infection. A dose-response relationship was observed, with the odds of mpox increasing with the number of conditions (per-condition trend: OR 3.03, 95% CI 1.86-4.83). While multiplicative interaction was not statistically significant (interaction term=2.98, 95% CI 0.68-13.70; *P*=.15), additive interaction metrics suggested a possible excess association (relative excess risk due to interaction=10.80, 95% CI 1.21-37.52; attributable proportion due to interaction=0.74, 95% CI 0.07-0.87; synergy index=4.99, 95% CI 1.19-20.86). Compared to the participants without HIV or metabolic comorbidity, those with HIV and metabolic comorbidity had higher odds of mpox infection (OR 14.51, 95% CI 4.83-40.70).

Conclusions: This study suggests that HIV and metabolic comorbidity were each associated with higher odds of self-reported mpox, and exploratory analyses indicated a possible additive interaction. Given the reliance on self-reported diagnoses and the cross-sectional design, the findings should be interpreted with caution due to reporting bias and reverse causation. Further studies

XSL•FO
RenderX

are needed to confirm these associations and better understand the comprehensive health needs of MSM with co-occurring conditions.

Introduction

Human mpox is a zoonotic disease caused by the monkeypox virus, originally endemic in Central and West African regions [1]. In May 2022, an outbreak of mpox occurred, characterized by a rapid increase in cases reported in previously nonendemic countries [2]. In response to the global outbreak of mpox, the World Health Organization (WHO) declared a public health emergency of international concern on July 23, 2022 [3]. In May 2023, the WHO announced that mpox no longer constituted a public health emergency of international concern [4]. In contrast to the global trend, the number of reported mpox cases in China has increased rapidly, with cases mainly concentrated in economically developed regions [5]. As of August 2025, China has reported 3531 cases and ranks among the 10 most affected countries [6].

Mpox primarily spreads through person-to-person transmission via close contact, including sexual activity. It has disproportionately affected men who have sex with men (MSM), who account for 85.4% of confirmed cases worldwide [6,7]. In China, 93.8% of mpox cases were identified within the MSM population [8]. Mpox is characterized by a skin rash or mucosal lesions that progress through several stages. These lesions can appear anywhere on the body, commonly affecting the face; palms; soles; and mucosal surfaces such as the mouth, genitals, and anus [7]. Vaccination has been shown to provide protective effects [9]. However, effective control in China remains challenging due to multiple factors, including difficulties in tracing infection sources, managing close contacts, and addressing stigma toward MSM [10,11].

MSM are also a vulnerable group to HIV infection. Worldwide, high prevalence rates of HIV have been consistently reported among MSM [12-14]. In China, consecutive cross-sectional surveys in the Jiangsu province documented prevalence estimates ranging from 8% to 9.8% between 2016 and 2020 [15]. During the global mpox outbreak, a substantial proportion of cases occurred in people living with HIV [16]. Studies have consistently documented overlap between mpox and HIV [17,18], which may reflect multiple, non–mutually exclusive factors such as overlapping sexual networks, differences in testing and health care access, and immune compromise [19]. These findings underscore HIV as a critical factor in understanding vulnerability to mpox within MSM populations.

Beyond this overlap, HIV is strongly associated with a broader range of chronic conditions, particularly metabolic comorbidity [20]. A recent meta-analysis estimated that the prevalence of metabolic syndrome among HIV-positive individuals was 25.3%, with significantly higher odds compared with their HIV-negative counterparts [21]. Even in those with normal body weight, HIV has been linked to poorer metabolic health, including unfavorable blood pressure and lipid and glucose profiles [22]. Such metabolic dysfunction is associated with chronic immune dysregulation and impaired antiviral responses, providing biologically plausible pathways through which metabolic comorbidity may influence susceptibility to viral infections [23].

Building on these observations, the co-occurrence of HIV and metabolic comorbidity may confer excess risk beyond individual effects. MSM are disproportionately exposed to adverse social conditions, and syndemic theory highlights that co-occurring health conditions can interact to generate excessive disease burdens [24]. Evidence from other infectious diseases supports this concern. In the context of COVID-19, coexistence of HIV and metabolic disorders has been shown to exacerbate disease severity [25]. Evidence from tuberculosis research demonstrates that co-occurrence of HIV and diabetes is associated with elevated mortality and measurable biological interaction, indicating synergistic rather than additive effects [26,27]. Although HIV and metabolic conditions have each been associated with mpox individually [18,28], whether their combined presence could pose additional mpox risk remains unclear.

This study aimed to address this knowledge gap by investigating the relationship between HIV, metabolic comorbidity, and mpox among MSM in 6 regions of China. Specifically, our hypothesis was that (1) HIV and metabolic comorbidity would be interrelated and individually associated with mpox infection and (2) HIV and metabolic comorbidity may interact in a way associated with a greater likelihood of mpox infection.

Methods

Participants and Procedure

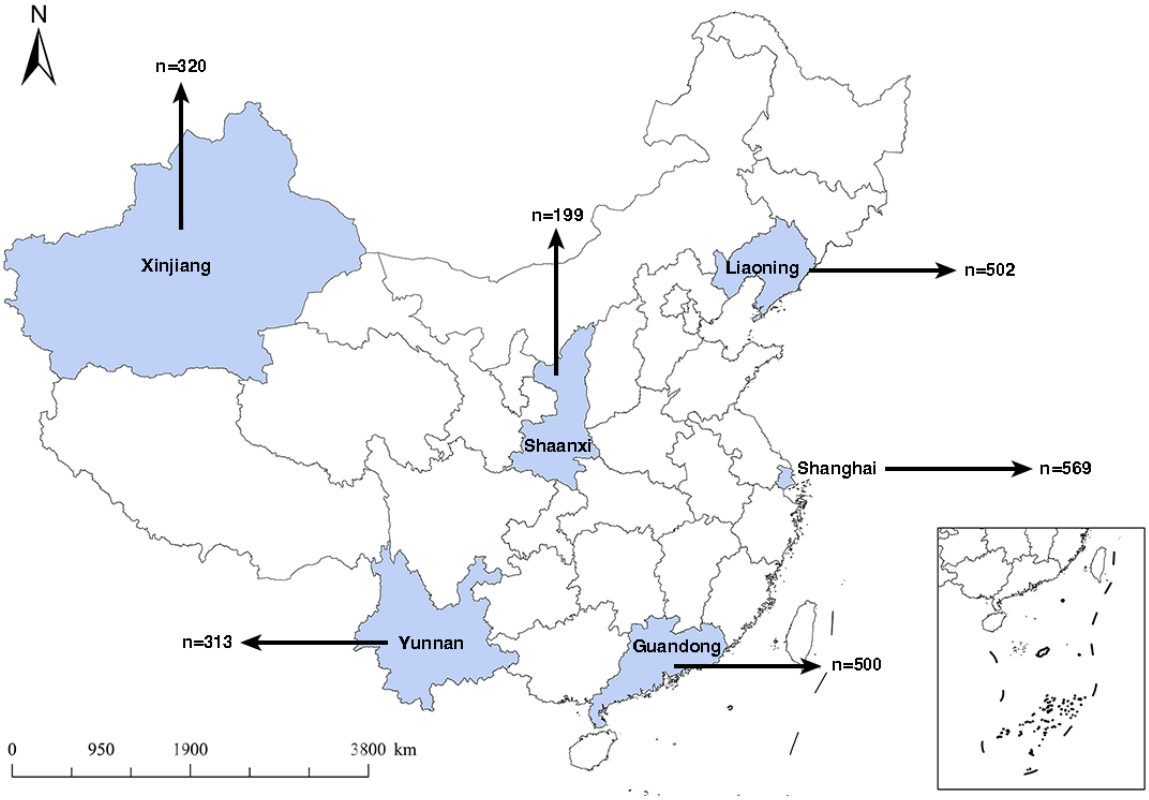
A nationwide cross-sectional study was conducted from October 2023 to March 2024 in 6 geographically representative provincial regions of China: Shanghai, Guangdong, Xinjiang, Shaanxi, Yunnan, and Liaoning. Given the relatively hidden nature of the MSM population, recruitment was conducted in partnership with nongovernmental organizations (NGOs) that provide services and outreach to MSM.

Before the survey started, NGO staff received standardized training on study protocols, informed consent, and quality control procedures. Relying on their established networks and trust within MSM communities, the trained staff promoted the study and invited participation. Recruitment channels included both offline venues (eg, community events and in-person outreach) and web-based platforms (eg, WeChat groups). Potential participants were informed of the study's objectives,

XSL•FO
RenderX

procedures, and potential benefits before completing the questionnaire.

The inclusion criteria were as follows: (1) male and aged ≥18 years, (2) reporting of engagement in sexual behavior with men within the previous 6 months, and (3) regular residence in one of the 6 selected provincial regions (primarily residing locally for most of the previous 6 months). The exclusion criteria were as follows: (1) completion of the questionnaire in <300 seconds, (2) incorrect answers to quality control questions, and (3) IP address indicating a location outside the surveyed provincial regions. All eligible participants provided electronic informed consent and then completed the anonymous questionnaire via the Wenjuanxing web-based survey platform (Changsha Ranxing Information Technology Co).



The sample size was calculated using the prevalence of mpox as the primary outcome. Based on previous literature, the prevalence in MSM is approximately 5.6% [29]. Setting the allowable error (δ) at 0.20, the following sample size formula for cross-sectional surveys was applied:

A sample size of 1619 was obtained. Considering a nonresponse rate of 15%, the final sample size for this survey was determined to be at least 1905 participants.

In this study, a total of 2481 questionnaires were collected, of which 2403 (96.86%) were valid. Figure 1 shows the geographic location and sample size of each surveyed area.

Figure 1. Distribution of the participants.

Measurements

HIV Infection

Participants were asked the following: *What was your recent voluntary HIV testing (VHT) result*? A response of *positive* was considered a self-reported HIV infection.

Metabolic Comorbidity

This study primarily focused on 3 common metabolic diseases: hypertension, diabetes mellitus, and hyperlipidemia. Participants were asked whether they had been diagnosed with any of these conditions. The presence of at least one of these conditions was defined as having a metabolic comorbidity, consistent with a previous study [30]. Participants with metabolic comorbidity were referred to as the metabolically unhealthy group, whereas those without these conditions were referred to as the metabolically healthy group.

Self-Reported Mpox Infection

Participants were asked the following: *Have you been diagnosed with mpox by a doctor*? A response of *yes* was classified as a self-reported diagnosis of mpox.

Covariates

Sociodemographic characteristics included age, educational level (junior high school and lower, senior high school, and college and higher), marital status (single, married, and divorced or widowed), employment status (mental labor, manual labor, student, freelance work, and unemployed), duration of residence in the surveyed area (local, <5 years, and >5 years), and sexual orientation (homosexual and others).

XSL•FO
RenderX

Behavioral and clinical factors included the self-reported number of male sexual partners in the previous 6 months (1 or none, 2, and ≥3), condom use during anal intercourse with men in the previous 6 months (never, rarely, mostly, and always), and current use of antiretroviral therapy (yes or no).

Statistical Analysis

Descriptive analyses were conducted to examine demographic characteristics and the prevalence of HIV and metabolic diseases. Chi-square tests were used to compare the distribution of categorical variables between the mpox infection and noninfection groups, whereas independent-sample 2-tailed *t* tests were used for continuous variables. Logistic regression models were constructed to investigate the bivariate associations among HIV, metabolic comorbidity, and mpox, as well as the associations between the number of health conditions and mpox infection while adjusting for demographic factors.

We examined the interaction between HIV and metabolic comorbidity in relation to mpox infection using logistic regression analyses [31], with 95% CIs estimated using the mover method as implemented in the *interactionR* R package (R Foundation for Statistical Computing) [32]. Interactions on both multiplicative and additive scales were assessed using interaction terms and indicator variables, including relative excess risk due to interaction (RERI), attributable proportion due to interaction (AP), and synergy index (SI) [33]. If the 95% CI of the AP or RERI contained 0 or the 95% CI of the SI contained 1, this indicated the absence of an interaction effect.

Sensitivity analyses were conducted to assess the robustness of our findings. Given the relatively small number of mpox cases, we performed Firth penalized logistic regression using the R package *logistf* to reduce small-sample bias and improve the stability of estimates [34]. In addition, to evaluate the potential impact of unmeasured confounding, we used the R package *EValue* to compute *E* values [35]. The *E* value quantifies the minimum strength of association that an unmeasured confounder would need to have with both the exposure and the outcome, conditional on the measured covariates, to fully explain the observed association.

Ethical Considerations

All procedures performed in studies involving human participants were in accordance with the 1964 Declaration of Helsinki. The study protocol was approved by the Ethics Committee of Shanghai University of Medicine and Health Sciences (2023-MSMMPOX-22-310222197604080237). Written informed consent was obtained from all participants. Participants were informed that participation was voluntary and that they could withdraw from the study at any time without consequences. All data were anonymized before analysis, and no personally identifiable information was collected. Participants received a ¥50 (approximately US $7) gift card as compensation for their time.

Results

Characteristics of the Participants

Table 1 presents the characteristics of the 2403 participants aged 18 to 76 years, with a mean age of 30.59 (SD 8.02) years. Most of the participants were unmarried (2148/2403, 89.38%) and employed (1973/2403, 82.11%), whereas 78.57% (1888/2403) had an educational level of college or higher. A total of 38.95% (936/2403) of the participants were locals, and 24.84% (597/2403) had lived in the surveyed area for over 5 years. The sexual orientation of most participants (1887/2403, 78.53%) was homosexual. A total of 2.33% (56/2403) self-reported an mpox infection, and 8.28% (199/2403) self-reported an HIV infection. The prevalence rates of hypertension, diabetes mellitus, hyperlipidemia, and metabolic comorbidity were 6.45% (155/2403), 2.87% (69/2403), 9.24% (222/2403), and 13.52% (325/2403), respectively. The prevalence was 9.57% (230/2403) for participants with 1 metabolic condition and 3.95% (95/2403) for those with 2 or more conditions.

Of the sociodemographic factors, age (*P*=.002) and marital status (*P*<.001) were associated with mpox infection. In addition, self-reported HIV (*P*<.001), hypertension (*P*=.003), hyperlipidemia (*P*=.02), and metabolic comorbidity (*P*=.003) were associated with higher odds of self-reported mpox infection.

Bivariate Associations Among HIV, Metabolic Comorbidity, and Mpox Infection

Table S1 in Multimedia Appendix 1 presents the results of the adjusted logistic regression examining bivariate associations among HIV, metabolic comorbidity, and mpox infection. After adjusting for covariates, HIV was positively associated with metabolic comorbidity (odds ratio [OR] 2.49, 95% CI 1.63-3.74). Both HIV (OR 4.81, 95% CI 2.29-9.64) and metabolic comorbidity (OR 2.62, 95% CI 1.27-5.14) were associated with higher odds of mpox infection.

Association Between Number of Health Conditions and Mpox Infection

Table 2 shows the results of the adjusted logistic regression examining the association between number of health conditions (ie, HIV and metabolic comorbidity) and mpox infection. After adjusting for covariates, an increase in the number of conditions was positively associated with mpox infection, suggesting a dose-response pattern (linear trend=3.03, 95% CI 1.86-4.83). Individuals with the simultaneous presence of HIV and metabolic comorbidity were associated with higher odds of mpox infection (OR 10.88, 95% CI 3.63-30.13).

Table 2. Association between number of health conditions (HIV and metabolic comorbidity) and self-reported mpox infection.

	Participants, n/N (%)	OR[a] (95% CI)	*P* value
Number of health conditions			
0	33/1927 (1.71)	Reference	Reference
1	15/428 (3.5)	2.16 (1.08-4.15)	.02
2	8/48 (17)	14.03 (4.64-39.59)	<.001
Linear trend	—[b]	3.03 (1.86-4.83)	<.001

No	48/2355 (2.04)	Reference	Reference
Yes	8/48 (17)	10.88 (3.63-30.13)	<.001

[a]OR: odds ratio; adjusting for age, educational level, marital status, employment status, duration of residence, sexual orientation, number of sexual partners, condom use, and antiretroviral therapy use.

[b]Not applicable.

Interaction Between HIV and Metabolic Comorbidity in Relation to Mpox Infection

Table 3 shows the results of the multivariable logistic regression examining interaction between HIV and metabolic comorbidity in relation to mpox infection. No statistically significant interaction was found between HIV and metabolic comorbidity (OR 2.98, 95% CI 0.68-13.70; *P*=.15). The RERI, AP, and SI for mpox infection resulting from HIV+metabolic comorbidity were 10.80 (95% CI 1.21-37.52), 0.74 (95% CI 0.07-0.87), and 4.99 (95% CI 1.19-20.86), respectively. The findings suggest a possible additive interaction between HIV and metabolic comorbidity. When examining each metabolic disease separately, HIV showed an interaction with hypertension in relation to mpox infection, whereas no interaction was observed with diabetes mellitus or hyperlipidemia (Table S2 in Multimedia Appendix 1).

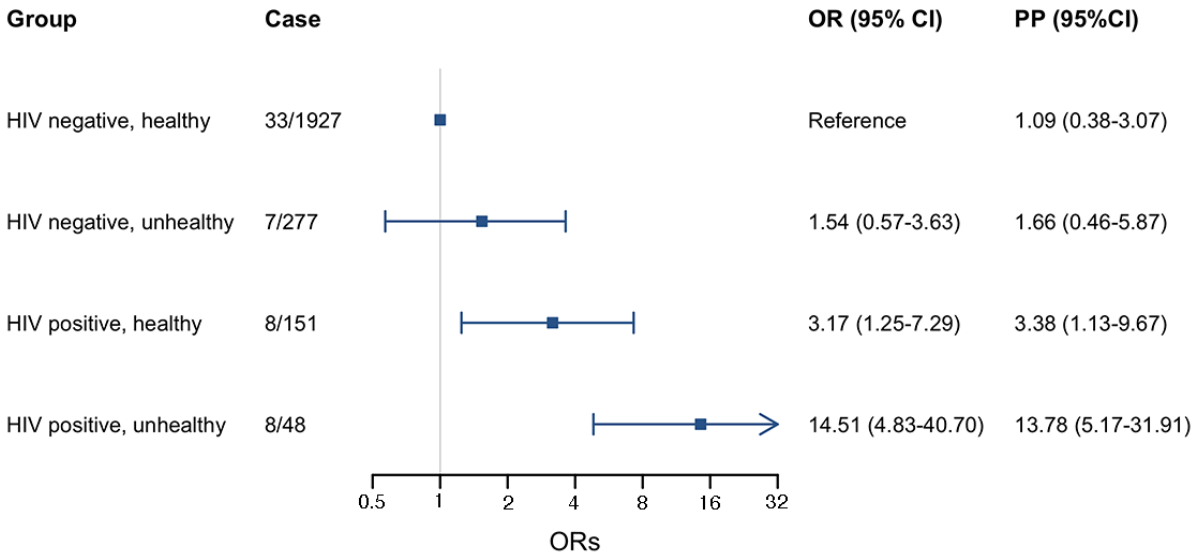
XSL•FO
RenderX

Table 3. Interaction between HIV and metabolic comorbidity in relation to mpox infection.

	OR[a] (95% CI)	*P* value
Interaction model		
Unhealthy versus healthy	1.54 (0.61-3.83)	.36
HIV positive versus HIV negative	3.17 (1.32-7.60)	.009
Interaction term	2.98 (0.68-13.70)	.15
Multiplicative scale	2.98 (0.67-13.21)	—[b]
RERI[c]	10.80 (1.21-37.52)	—
AP[d]	0.74 (0.07-0.87)	—
SI[e]	4.99 (1.19-20.86)	—

[a]OR: odds ratio, adjusting for age, educational level, marital status, employment status, duration of residence, sexual orientation, number of sexual partners, condom use, and antiretroviral therapy use.

[b]Not applicable.



[c]RERI: relative excess risk due to interaction.

[d]AP: attributable proportion due to interaction.

[e]SI: synergy index.

Figure 2 shows the relative odds of mpox infection by HIV infection and metabolic status. Compared to individuals without self-reported HIV and who were metabolically healthy, those with self-reported HIV but who were metabolically healthy (OR 3.17, 95% CI 1.25-7.29) and those with both self-reported HIV and metabolic comorbidity (OR 14.51, 95% CI 4.83-40.70) had higher odds of self-reported mpox infection.

Figure 2. Odds ratios of self-reported mpox infection by HIV infection and metabolic status. OR: odds ratio; PP: predicted probabilities (%).

Sensitivity Analysis

The estimates of the additive interaction between HIV and metabolic comorbidity obtained using the Firth penalized likelihood logistic regression were consistent with those from the main analysis. Specifically, the RERI was 9.56 (95% CI 1.16-30.90), the AP was 0.71 (95% CI 0.08-0.86), and the SI was 4.38 (95% CI 1.20-15.94), supporting a possible additive interaction. Penalized regression models assessing mpox infection by HIV infection and metabolic status produced results that were in line with the primary findings (Table S3 in Multimedia Appendix 1).

In the quantitative bias analysis, the group with self-reported HIV but who was metabolically healthy yielded an *E* value of 5.79 (lower 95% CI bound=1.81), suggesting that an unmeasured confounder would need to be associated with both exposure and outcome by an OR of at least 5.79 to fully account for the observed association. For the group with both self-reported HIV and metabolic comorbidity, the *E* value was 28.51 (lower 95% CI bound=9.13), indicating that only a strong unmeasured confounder could explain the observed association.

RenderX

Discussion

Principal Findings

This study offers valuable insights into the associations among HIV, metabolic comorbidity, and self-reported mpox. In our sample of MSM in China, we observed a clustering of HIV and metabolic comorbidity, both of which were individually associated with mpox infection. In addition, our exploratory analyses suggested a possible additive interaction between HIV and metabolic comorbidity in relation to mpox infection.

MSM, as a sexual minority population, often face social, economic, and environmental disadvantages, leading to a higher prevalence of adverse health conditions [36]. In this study among MSM, the prevalence rates of HIV and metabolic comorbidity were 8.28% (199/2403) and 13.52% (325/2403), respectively, with a positive correlation observed between the 2 health conditions. Consistent with previous findings that metabolic diseases tend to occur earlier in people living with HIV [20], we found that 24.1% (48/199) of MSM who were infected with HIV simultaneously exhibited metabolic comorbidity. The underlying factors contributing to these comorbidities are multifaceted and include antiretroviral therapy use, unhealthy lifestyle behaviors (ie, smoking and alcohol use), and chronic inflammation despite suppressed HIV replication [37].

Existing studies among MSM have predominantly examined the interplay of psychological, social, and structural factors using the syndemic framework [38-40], whereas relatively few have focused on HIV and co-occurring physical health conditions [41,42]. This study provides exploratory observations on the association between HIV and metabolic comorbidity in relation to mpox infection among MSM. While previous research has documented associations between both HIV and metabolic diseases and mpox infection individually [18,28], our analysis, through calculation of additive interaction measures (RERI, AP, and SI), suggests a previously unrecognized possibility of interaction between HIV and metabolic comorbidity. These findings suggest that MSM with both HIV and metabolic comorbidity may warrant further investigation in future research and consideration in the design of integrated health services.

In this study, we identified 2.33% (56/2403) of cases of mpox infection among MSM in China. This prevalence rate is notably higher than the 0.73% reported in a previous nationwide survey conducted in early August 2023 [43], primarily because a substantial number of confirmed mpox cases in China were reported after that [8]. In addition, despite the clear clustering of HIV with metabolic comorbidity, the prevalence rates of each metabolic condition, namely, hypertension (155/2403, 6.45%), diabetes mellitus (69/2403, 2.87%), and hyperlipidemia (222/2403, 9.24%), were relatively low in our sample. This may explain the nonsignificant interaction observed between HIV and each separate metabolic disease in this study.

Implications

Our findings suggest that HIV and metabolic health issues tend to cluster and interact, and exploratory analyses suggested a possible additive interaction in relation to mpox infection. Understanding the individual and contextual factors underlying these interactions—such as substance use, living conditions, and social networks—will be important for informing future research [41,44]. Although this study was conducted in China, the results may offer insights relevant to other low- and middle-income countries, where HIV and noncommunicable diseases are highly prevalent and health systems often underresourced [45,46]. Strengthening resilient health systems capable of delivering integrated care is crucial for advancing universal health coverage [47]. Previous research has shown that interventions focusing solely on individual conditions such as HIV have limited effectiveness in improving overall health [48,49]. Building on these lessons, global experiences from infectious disease emphasize the need for systematic health system redesign and stronger international collaboration [50]. In this context, MSM with multiple conditions may represent a subgroup warranting attention in future comprehensive health services. However, the design and evaluation of such interventions should be based on stronger empirical evidence from future studies.

Limitations

This study has several limitations. First, HIV status, mpox status, and metabolic comorbidity were self-reported, which may have introduced misclassification and reporting bias. Given that mpox-related stigma among MSM can discourage care-seeking behaviors [51], underreporting of previous diagnoses is plausible. In epidemiological studies, nondifferential misclassification due to underreporting typically reduces sensitivity while maintaining high specificity, which tends to bias effect estimates toward the null [52]. Therefore, our findings are likely conservative and should be interpreted as exploratory. Second, the sample was recruited through NGOs and web-based platforms, potentially overrepresenting MSM who are more engaged with health services and limiting generalizability to hidden or higher-risk subgroups. Third, the cross-sectional design precludes causal inference. As a result, the temporal sequence among HIV, metabolic comorbidity, and self-reported mpox cannot be established, and reverse causation remains possible.

Fourth, the number of mpox cases was relatively small, which limited statistical power and precision, especially for interaction analyses. The wide CIs for the interaction terms reflect this instability. Although we conducted sensitivity analyses using the Firth penalized likelihood logistic regression to mitigate sparse-data bias and found consistent results, the findings should still be interpreted as exploratory. Fifth, our study focused on 3 common metabolic diseases—hypertension, diabetes mellitus, and hyperlipidemia—potentially overlooking other important conditions such as obesity. Finally, while we adjusted for several behavioral and clinical covariates, other relevant factors such as sex work, history of other sexually transmitted diseases, viral load, and vaccination status were not collected, which may have led to residual confounding. However, our quantitative bias analysis indicated that only unmeasured confounders with very strong associations with both exposure and outcome could fully explain the observed results, suggesting that the main findings are relatively robust. Taken together, these limitations highlight

XSL•FO
RenderX

the need for future studies with larger and more representative samples; objective diagnostic measures; and more comprehensive assessments of biomedical, behavioral, and contextual factors.

Conclusions

Our findings suggest a potential clustering and additive interaction of HIV and metabolic comorbidity in relation to self-reported mpox infection among MSM. These exploratory results highlight the importance of considering co-occurring health conditions among MSM and may offer insights for similar populations in other settings with high burdens of HIV and noncommunicable diseases.

Abstract

Background: Hainan is a pilot free trade port in China and a multiethnic province. Catastrophic health expenditure (CHE) reflects health care inequity, particularly affecting vulnerable groups in rapidly developing multiethnic regions.

Objective: This study aims to analyze CHE prevalence and intensity and their influencing factors among residents in a Chinese multiethnic province.

Methods: Data from the 2023 Hainan Province Health Services Survey, conducted among 14,532 individuals aged 18 years or older, were used in a multistage stratified cluster sampling. CHE was defined as out-of-pocket health care payments exceeding 40% of the household's capacity to pay. The chi-square test and a logistic regression were used to identify influencing factors for CHE. Nonparametric tests and quantile regression were used to evaluate the influencing factors for CHE intensity.

Results: The prevalence of CHE in Hainan province was 8.37%, with a median intensity of 17.67% (IQR 8.31%-29.77%). Residents were more likely to experience CHE if they were older than 60 years (odds ratio [OR] 1.928, 95% CI 1.602-2.320; *P*<.001), unmarried (OR 1.241, 95% CI 1.075-1.433; *P*=.003), or had chronic illnesses (OR 2.214, 95% CI 1.930-2.540; *P*<.001). Ethnic minority groups (OR 0.774, 95% CI 0.679-0.883; *P*<.001) as well as middle-income (OR 0.722, 95% CI 0.600-0.869; *P*=.001), high-middle-income (OR 0.739; 95% CI 0.609-0.898; *P*=.002), and high-income (OR 0.591, 95% CI 0.474-0.738; *P*<.001) groups were less likely to experience CHE. At lower CHE intensity (20th percentile), individuals older than 60 years (β=1.935; *P*=.03) and middle-income (β=1.737; *P*=.04) and rural (β=2.202; *P*=.005) residents showed positive associations. At the 50th percentile, low-middle-income (β=–5.052; *P*=.005), high-middle-income (β=–4.203; *P*=.03), and high-income (β=–6.534; *P*=.004) groups showed negative associations. At the 80th percentile, high-middle-income (β=–7.143; *P*=.03) and rural (β=–6.241; *P*=.005) groups showed stronger financial protection.

Conclusions: Addressing CHE risks remains a critical challenge in Hainan province, highlighting structural inequities rooted in socioeconomic disparities and health vulnerabilities. Therefore, policy should prioritize primary prevention in the lowest-income populations while implementing enhanced insurance coverage for rural populations facing extreme costs to alleviate the most severe financial burdens.

Introduction

Universal health coverage (UHC) aims to provide everyone with quality health services while ensuring they do not incur financial hardship [1]. However, high out-of-pocket (OOP) health expenditures can hinder the achievement of UHC and create a vicious cycle of poverty and poor health [2]. Catastrophic health expenditure (CHE) is defined as annual OOP health care payments exceeding a predetermined percentage of the household capacity to pay, which serves as a critical indicator for monitoring UHC progress and health care inequity [3]. Globally, approximately 1.4 billion people experience CHE annually, with more than 60% residing in low- and middle-income countries [4]. As the world's largest middle-income country, China faces significant challenges in reducing CHE, with an incidence of 8.70% in 2018 [5]. Therefore, addressing CHE deserves heightened attention and strategic efforts, which are pivotal for reducing health inequalities and mitigating poverty.

Globally, efforts to mitigate CHE have focused on strengthening financial protection through UHC [6]. The World Health Organization advocates reducing financial barriers to health care access for vulnerable populations, adopting legislation to prevent medical impoverishment, and establishing health financing mechanisms [7]. In China, the health care reform that began in 2009 expanded basic medical insurance, which now covers more than 95% of the population [8]. The Healthy China 2030 plan further institutionalizes payment reforms and centralized procurement of drugs [9,10]. However, considering only the national achievements may mask regional disparities [11]. Existing studies have demonstrated significant variations in the prevalence of CHE across Chinese provinces, with the highest value differing by up to 2.5 times from the lowest [11,12].

CHE is influenced by multiple factors, such as economic condition, residence, ethnicity, chronic diseases, and age [13]. Among them, economic condition and ethnicity are important explanatory variables affecting CHE [14,15]. Most studies indicate that ethnic minority groups are one of the most vulnerable groups in terms of health and medical cost burden [16,17]. Among Native Americans, low health insurance coverage and high-cost diseases, such as diabetes, often make health expenditure a major financial burden [18]. In addition, studies highlight that rapid economic development has exacerbated CHE, particularly in emerging markets, such as Brazil, China, and India [14,19]. The rapid economic development brings many challenges, including the large income disparities, lagging social security system, and uneven distribution of medical resources, all of which have been proven to increase economic inequality in health care [20,21].

Existing research on CHE has focused on national-level insights, examining the economic burdens of older individuals, specific diseases, and rural regions [13,22,23]. Cross-national studies have also identified systemic drivers, notably insurance fragmentation [24,25]. Although some studies have examined provincial-level differences, few have investigated regions with specific economic and ethnic structures, especially those undergoing rapid economic development [11,15].

Hainan province, located in the southernmost part of China, is the only tropical island province in the country, with a relatively small and dispersed population. Ethnic minority groups account for 15.7% of the population, significantly higher than the national average (8.9%), with the Li ethnic group being the main ethnic minority group. Economically, this province ranks fourth from the bottom in terms of gross domestic product within the country. Region-specific results are crucial for shaping effective health care policies, as they enable the alignment of public health investments with localized needs. This study aims to analyze the prevalence and intensity of CHE as well as their influencing factors among residents in Hainan province, a free trade port with a multiethnic population. The findings of this research are expected to inform the design of targeted strategies, ultimately contributing to the reduction of health inequalities in multiethnic areas with rapid economic development.

Methods

Data Source

Data for this cross-sectional study were obtained from the 2023 Hainan Province Health Services Survey. The survey was organized by the Hainan Provincial Health Commission and was a part of the China National Health Services Survey, which has been conducted every 5 years since 1993. The data are representative of Hainan province in terms of geographic location, level of economic development, and population distribution characteristics. A multistage stratified cluster sampling method was used to conduct the survey. All cities, counties, and autonomous counties in Hainan province were included in the scope of this survey. A total of 24 districts and counties were sampled. Within each district or county, 2 to 5 towns (or streets) were randomly selected, and within each selected town (or street), 2 villages (or communities) were further randomly chosen. Subsequently, within each selected village (or community), 60 households were randomly selected. A standardized questionnaire was used to collect data from all residents in the sampled households. In total, 6485 households, with a population of 18,677, were surveyed.

Trained interviewers conducted household visits and face-to-face interviews with all household members using mobile phones or tablets equipped with an electronic survey system. Each resident was individually questioned according to the survey's electronic questionnaire. The questionnaire collected information on demographic and socioeconomic characteristics, household expenditures, health status, insurance coverage, and health service use. The study population consisted of residents of

XSL•FO
RenderX

Hainan province aged 18 years or older. After excluding missing value samples, 14,532 adult participants were included.

Ethical Considerations

The 2023 Hainan Province Health Services Survey (organized by the Hainan Provincial Health Commission) was approved by the institutional review board of the National Bureau of Statistics of China. This study is part of the National Health Service Survey (NHSS), a nationwide survey conducted across all 31 provinces of China under the authority of the National Bureau of Statistics (NBS). The 2023 Hainan Health Service Survey represents the province-level extension undertaken by the Hainan Health Commission within the framework of the NHSS. Ethical review for the NHSS is provided through the institutional review procedures of the NBS. As is standard for national statistical investigations in China, the internal approval reference numbers are not publicly disseminated, but the survey is widely recognized as a routine, government-mandated activity with established ethical oversight. Oral informed consent was obtained from all participants before the interview. The survey was conducted anonymously, and all data were deidentified and kept confidential. Participation was voluntary, and no compensation was provided to participants. All procedures were conducted in accordance with the Declaration of Helsinki and relevant ethical guidelines.

CHE Measurement

The threshold of CHE is calculated as the proportion of medical expenses to household income or expenditure (excluding food expenditure) [26]. The selection of thresholds for defining CHE varies from 2.5% to 60%, with the commonly used criterion in studies conducted in low- and middle-income countries being the 40% threshold recommended by the World Health Organization [27]. We adopted a threshold of CHE at 40% of a household's total nonfood expenditure for self-paid medical expenses in the year 2022. If the expenditure was below this threshold, it was considered that CHE had not occurred. The intensity of CHE was defined as the average extent to which households exceeded the catastrophic threshold, calculated among all households whose medical expenditure share surpassed the 40% cutoff. [28]. The total nonfood expenditure of a household is the difference between the total household expenditure and the household's food expenditure. In addition, we included individual participants in our analysis, rather than the households they belonged to, as this approach allowed us to consider the individual characteristics of the residents. OOP medical expenses were measured by asking "What was your household's expenditure on medical care in 2022?" The total household expenditure was measured by asking "What was your household's total consumption expenditure in 2022, approximately in yuan?" The household's food expenditure was measured by asking "How much did your household spend on food, tobacco, and alcohol in 2022?"

General Demographic Information

General demographic information included sex (male or female), ethnic group (Han ethnicity or ethnic minority groups), age (18-39 y, 40-59 y, or 60 y), marital status (married or unmarried), educational level (illiterate or semiliterate, primary school, junior school, senior high school, or above), residence (urban or rural), medical insurance (Urban Employee Basic Medical Insurance, Urban and Rural Residents' Basic Medical Insurance, or others), annual income quintiles (low, low middle, middle, high middle, or high), and chronic disease (no or yes). National civil servants, professionals, enterprise managers, and active military personnel were classified as senior practitioners based on their professional levels and required skills; clerks and workers were classified as midlevel practitioners; and farmers, freelancers, self-employed individuals, unemployed persons, and students were classified as general staff. The annual income quintile referred to the division of an individual's personal annual income or the per capita annual income of their household into 5 equal parts.

Statistical Analysis

We used frequencies (n) and percentages (%) to depict the sociodemographic and CHE-related characteristics of residents in Hainan province. The prevalence of CHE was calculated as the proportion of respondents who experienced CHE among all survey participants. On the basis of the chi-square test, we compared the categorical factors associated with CHE. Dummy variables were set for the categorical variables with more than 2 groups. In the multivariate analysis, binary logistic regression was performed to examine the factors associated with CHE, as the dependent variable, indicating whether the respondent experienced CHE, was dichotomous (yes or no). The odds ratios (ORs), 95% CIs, and *P* values were reported. The intensity of CHE showed a significantly skewed distribution; therefore, medians and IQRs were reported. The Mann-Whitney rank-sum test was used for 2-group comparisons, and the Kruskal-Wallis test was used for multiple comparisons. Quantile regression was used to explore the influencing factors of the intensity of CHE at different levels (20th, 50th, and 80th percentiles) among residents who had incurred CHE. All statistical analyses were conducted using Stata (version 16.0; StataCorp). The significance level for statistics was set at a 2-sided $P<.05$.

Results

Basic Characteristics of the Participants

The characteristics of the participants are shown in Table 1. A total of 14,532 participants were enrolled in this study, of whom 41.74% (n=6065) belonged to ethnic minority groups. The overwhelming majority of participants were male (n=7863, 54.11%), aged 40 to 59 years (n=6043, 41.58%), married (n=10,941, 75.29%), with junior school education (n=6030, 41.49%), were general staff (n=11,502, 79.15%), from rural areas (n=8876, 61.08%), had Urban and Rural Residents' Basic Medical Insurance (n=11,473, 78.95%), and did not have chronic disease (n=11,564, 79.58%). In addition, the annual income quintiles were divided into 5 groups from low to high.

Prevalence of CHE by Basic Characteristics

Table 1 shows the prevalence of CHE and disparities in basic characteristics among the residents of Hainan province. Among 14,532 participants, the prevalence of CHE was 8.37%. As the results of the chi-square test revealed, CHE was significantly associated with ethnic group (χ^2_1=10.2; *P*=.001), age (χ^2_2=275.3; *P*<.001), marital status (χ^2_1=4.5; *P*=.03), educational levels (χ^2_3=58.9; *P*<.001), careers (χ^2_2=16.9; *P*<.001), annual income (χ^2_4=38.3; *P*<.001), residence (χ^2_1=7.7; *P*=.005), medical insurance (χ^2_2=13.7; *P*=.001) and chronic disease status (χ^2_1=298.9; *P*<.001).

Determinants of CHE Identified by Logistic Regression

Table 2 shows the results of logistic regression analysis of the determinants of CHE. Ethnic minority residents were less likely to have experienced CHE than residents from the Han community (OR 0.774, 95% CI 0.679-0.883; *P*<.001). Compared to residents aged between 18 and 39 years, those aged 60 years and older were more prone to having experienced CHE (OR 1.928, 95% CI 1.602-2.320; *P*<.001). Unmarried residents were more likely to have faced CHE than married residents (OR 1.241, 95% CI 1.075-1.433; *P*=.003). In comparison to low-income groups, middle-income (OR 0.722, 95% CI 0.600-0.869; *P*=.001), high-middle-income (OR 0.739, 95% CI 0.609-0.898; *P*=.002), and high-income groups (OR 0.591, 95% CI 0.474-0.738; *P*<.001) were less likely to have encountered CHE. Residents with chronic diseases were more likely to have experienced CHE than those without chronic diseases (OR 2.214, 95% CI 1.930-2.540; *P*<.001).

Intensity of CHE by Baseline Characteristics

Table 3 shows the intensity of CHE and disparities in the basic characteristics of Hainan residents. Among 1216 participants with CHE, the median intensity of CHE was 17.67% (IQR 8.31%-29.77%). The Mann-Whitney rank-sum test and Kruskal-Wallis test results show that the intensity of CHE was significantly associated with age (H=7.813; *P*=.02), careers (H=6.350; *P*=.04), and annual income quintiles (H=11.460; *P*=.02).

Determinants of the Intensity of CHE Identified by Quantile Regression

Table 4 shows the results of quantile regression for the determinants of the intensity of CHE. The regression results at lower quantile points indicated that residents aged 60 years and older were associated with an increase in the intensity of CHE (β=1.935; *P*=.04). In the presented quantile regression results, annual income quintiles were factors influencing the intensity of CHE, except for varying directions of their impacts. At lower quantile points, the regression results showed that middle income was associated with an increase in the intensity of CHE (β=1.737; *P*=.05). The regression results at medium quantile points indicated that low-middle income (β=–5.052; *P*=.01), high-middle income (β=–4.203; *P*=.05), and high income (β=–6.534; *P*=.01) were all associated with a decrease in the intensity of CHE. The regression results at higher quantile points indicated that high-middle income was associated with a decrease in the intensity of CHE (β=–7.143; *P*=.03). Both the regression results at lower and higher quantile points indicated urban-rural differences as a factor influencing the intensity of CHE. Notably, in the regression at lower quantile points, residence in rural areas was associated with an increase in the intensity of CHE (β=2.202; *P*=.001), whereas at higher quantile points, it was associated with a decrease in the intensity of CHE (β=–6.241; *P*=.007).

Discussion

Principal Findings

This study found that the prevalence of CHE in Hainan province was 8.37%, indicating that nearly one-tenth of the residents experienced financial hardship when seeking health care. When using the same calculation method and threshold, this provincial prevalence aligns with China's national estimates of 8.70% in 2018 but exceeds reported figures from Malaysia (2.80% in 2016) and Pakistan (4.57% in 2019) [5,29,30]. The intensity of CHE in Hainan province (17.67%) further highlights the severe economic burden, surpassing the intensity in Iran (12.88% in 2015) and Bhutan (0.80% in 2017) [31,32]. The high prevalence and intensity of CHE in Hainan province may correlate with China's low overall welfare level, as nationwide OOP health care payments reach 28%, far exceeding the international benchmark of 20% [5,33]. Notably, the development of the Hainan Free Trade Port has greatly increased the risk of CHE. Tourism expansion and seasonal migrants may exacerbate the strain on health care resources, inflating service prices and increasing economic burdens [34]. Concurrently, the migrant population (eg, flexible workers) demonstrates heightened financial vulnerability due to interregional barriers to medical expense reimbursement [35]. Therefore, there is significant room for improvement in the control of health expenditures in Hainan province.

Contrary to previous evidence that minority groups are at higher risk of CHE (eg, the US Hispanic population), ethnic minority groups in Hainan province exhibit lower CHE prevalence than Han residents [18]. This phenomenon reflects a distinct sociocultural context in Hainan province. Ethnic minority groups benefit from preferential health care subsidies that are channeled to autonomous regions, directly lowering OOP medical costs [36]. Complementing this, traditional ethnic villages maintain mutual-aid financing systems that buffer against sudden health care expenses by pooling resources to share financial risks [37]. Meanwhile, ancestral medical practices, such as fire needle therapy and herbal poultices preserved by the Li and Miao ethnic groups, decrease reliance on costly modern treatments, further mitigating the likelihood of CHE [38]. In contrast, urbanized Han populations rely heavily on expensive fee-for-service tertiary hospitals, thereby exacerbating financial burdens [17]. In addition, given that ethnic minority groups generally have lower family costs compared to the Han population in China, it seems less likely that family cost is a major contributing factor to the lower prevalence of CHE in this population [39,40]. Therefore, special subsidy criteria for diseases prevalent among ethnic minority groups (such as areca oral cancer screening) should be refined. It is also important to accelerate the inclusion of Li and Miao traditional medicines in the insurance catalog.

This study revealed the subtle relationship between residence and CHE intensity in Hainan province. At the lower quantile, rural areas were associated with an increase in CHE intensity. Under the free trade policies, advanced medical resources are concentrated in urban centers, such as Haikou and Sanya [20]. Rural patients' cross-city medical care overlaps with hidden costs, such as transportation and missed work, triggering family financial collapse [41]. Paradoxically, at the higher quantile, rural residents showed a protective effect. Possible explanations suggest that rural residents, constrained by lower economic resilience, tend to delay medical consultations, reduce treatment frequency, and prefer low-cost alternatives when facing the high costs of critical illnesses [42]. This behavioral pattern potentially exacerbates health inequalities through untreated disease progression and accumulated complications. Therefore, priority should be given to strengthening rural primary health care capacity through 5G telemedicine, incentives for family physicians, and hierarchical medical systems while establishing targeted medical relief funds for rural families [43].

Consistent with previous studies [44], income was negatively associated with experiencing CHE. However, our study revealed a complex intensity gradient in Hainan province. Specifically, middle-income residents demonstrated higher CHE intensity at lower expenditure quantiles. The sandwich-class population, while exceeding the poverty threshold, demonstrated constrained financial resilience due to inadequate social safety nets and elevated living expenditures, such as mortgage obligations [45]. In contrast, the poorest population exhibited suppressed health care demand due to chronic poverty, weakening the CHE effect [42]. Upper-middle-income groups at higher quantiles effectively mitigate health risks through commercial insurance and precautionary savings [46]. These stratified patterns highlight limitations of uniform provincial insurance policies in addressing heterogeneous income gradients. It is recommended to strengthen critical illness risk pooling mechanisms for middle-income populations, broaden medical assistance for the most impoverished, and explore internationally aligned commercial health insurance services via the free trade port of Hainan province.

Research found that age, chronic diseases, and marital status significantly impacted the likelihood of experiencing CHE, consistent with previous studies [47,48]. Older adults with chronic diseases showed higher CHE prevalence. Aging often leads to declining physical functions, while chronic diseases require long-term treatment and multiple medications, increasing cumulative health care costs [49]. Unmarried individuals had higher CHE rates than their married counterparts. This discrepancy may stem from family risk-sharing mechanisms, where married people use household financing and mutual care to buffer medical shocks, whereas unmarried individuals rely more on personal savings [50]. To address these challenges, Hainan province pioneered the "2+3" health care package, implementing 5 high-burden chronic disease screening and management for early cost control. Meanwhile, vulnerable populations, such as older individuals living alone, receive dual teams of family physicians and social workers, preventing cost escalation from delayed care. This integrated strategy offers a replicable model for developing regions.

Limitations

This study has several limitations. First, despite our efforts to assist patients in their recall to minimize estimation error, self-reported expenditures on health care and food are subject to recall bias. Second, the data do not capture individuals who either did not seek treatment or abandoned it due to financial

XSL•FO
RenderX

constraints. This may cause the research findings to underestimate the prevalence and intensity of CHE to a certain extent. Finally, this study was exclusively conducted among residents in Hainan province, China. The applicability of the findings to other regions remains unsubstantiated and will necessitate further investigation in future research.

Conclusions

Addressing CHE risks remains a critical challenge for health systems in Hainan province. Residents aged 60 years and older, belonging to the Han ethnicity, in the lowest income quintile, who were unmarried, and with chronic conditions, exhibited a significantly higher likelihood of being confronted with CHE. Annual income, age, and residence were identified as factors influencing the intensity of CHE. It is worth noting that the direction of their influence was found to vary across the levels of the intensity of CHE. Policy should prioritize primary prevention to reduce CHE prevalence, such as chronic disease management and expanding financial protection for the older population and the poorest. Simultaneously, secondary measures, potentially through enhanced insurance coverage for specific rural populations or conditions leading to extreme costs, are needed to alleviate the highest levels of financial burden.

Acknowledgments

The authors are grateful to all participants in this study for their cooperation. This study was funded by the Shandong Provincial Natural Science Foundation (grant ZR2023MG007). The funder had no involvement in the study design; data collection, analysis, and interpretation; or writing of the manuscript.

Data Availability

The data are managed by the Statistical Information Center of the Hainan Provincial Health Commission and are not publicly available due to institutional restrictions. However, the data used and analyzed during the study are available from the corresponding author on reasonable request.

Abstract

Background: Emerging studies suggest that exposure to the COVID-19 pandemic may have heightened the risks of neurodevelopmental disorders in infants (0–1-year-old); however, population-based studies investigating these associations in Chinese contexts remain scarce, particularly including the postpandemic phase.

Objective: The aim of this study was to characterize the dynamic changes in neurodevelopment among infants in eastern China during distinct phases of the COVID-19 pandemic and to identify the critical risk factors associated with infant neurodevelopmental delays.

Methods: This cross-sectional study analyzes 17,621 Peabody Developmental Motor Scales-II (PDMS-II) assessments and 7877 Bayley Scales of Infant Development-Chinese Cities Revised (BSID-CR) scores of infants who visited a tertiary maternal and children hospital for routine neurodevelopment assessment from January 2019 to July 2023. Multivariate logistic regression models were used to evaluate the associations of COVID-19 pandemic phases (stage I: prepandemic, January 2, 2019, to January 22, 2020; stage II: pandemic, January 23, 2020, to December 18, 2022; and stage III: postpandemic, December 19, 2022, to July 31, 2023), seasonal variations, and perinatal variables (eg, delivery mode, birth weight, gender) with the neurodevelopmental outcomes.

Results: Infants assessed at stage II of the COVID-19 pandemic had a higher risk of neurodevelopmental delay compared to infants assessed at stage I (total motor quotient: odds ratio [OR] 2.84, 95% CI 2.17-3.72; fine motor quotient: OR 2.71, 95% CI 1.99-3.68) and stage III (total motor quotient, OR 2.52, 95% CI 1.79-3.55; gross motor quotient: OR 1.65, 95% CI 1.21-2.25; fine motor quotient: OR 3.40, 95% CI 2.36-4.92). Infants assessed at stage III had the highest risk of mental development delay (OR 2.54, 95% CI 1.91-3.36). In addition, cesarean delivery, male gender, and low birth weight were independent risk factors of neurodevelopmental delay (P<.05).

Conclusions: The COVID-19 pandemic exacerbated neurodevelopmental vulnerabilities in infants, persisting into the postpandemic period. Public health strategies should mitigate the long-term effects through early interventions.

KEYWORDS

neurodevelopment; infants; risk factor; COVID-19; cross-sectional study

Introduction

The early childhood period represents a critical window of heightened neuroplasticity. However, globally, 8%-15% of children younger than 5 years have neurodevelopmental delays, which has been increasing annually [1,2]. In the United States, the prevalence rate of neurodevelopmental delay increased from 16.2% to 17.8% between 2009 and 2017 [3], while in rural China, around 30% of the infants experienced motor delays, and approximately half of the children aged 0-3 years exhibited cognitive, language, and socioemotional delays [4]. Early neurodevelopmental delay constitutes a major global public health challenge, with profound lifelong consequences such as increased risks of academic underperformance and cognitive impairment during adolescence. Longitudinal studies demonstrate that 38% of the affected children exhibit reduced labor productivity in adulthood, contributing to 1.2%-2.6% annual gross domestic product loss in low- and middle-income countries [5]. Alarmingly, 34.7% of children younger than 5 years in low-income regions failed to attain developmental potential due to intersecting poverty and neurodevelopmental impairments [5].

Early neurodevelopmental screening is a crucial public health intervention, providing children with timely access to support services [6]. Previous research consistently demonstrates that early intervention, particularly before the age of 3 years, can significantly improve outcomes for children with developmental disorders [7,8]. Neurodevelopment is influenced by a complex interplay of genetic, environmental, and social factors [9], although some factors, including perinatal factors, are amenable to intervention [10-12]. In addition, emerging evidence from high-income countries suggests that the COVID-19 pandemic has had a significant macrosocial impact on early childhood development [13,14]. Large-scale population-based data from low-income countries are also necessary due to the differences in relevant epidemic prevention policies among various countries. However, although one study from Guangzhou, China, in 2021 has demonstrated that the COVID-19 pandemic adversely affected infant neurodevelopment [15], more evidence is needed to fully understand the pandemic's effects on children's neurodevelopment [16].

Since 2018, the city of Yiwu, located in Zhejiang Province, China, has rolled out a comprehensive, publicly funded neurodevelopmental screening program targeting all children aged 0-3 years. This initiative is remarkable because it provides free screening services to around 3000 children each year. Such a large-scale and long-running program presents a distinctive opportunity for conducting real-world research with extensive data. Therefore, we conducted this study by using the screening data as mentioned above and aimed to evaluate the trends and characteristics of infant neurodevelopment after the implementation of such a screening program. Moreover, we aimed to identify the key associated factors for infants' neurodevelopment and assess the influence of the COVID-19 pandemic. Findings from this study will contribute substantial evidence, which can be used to inform the formulation of public health policies and the design of interventions. These policies and interventions are crucial for promoting optimal child development in China.

Methods

Study Population

This cross-sectional study retrospectively analyzes infants who underwent routine neurodevelopmental assessments at Yiwu Maternity and Children's Hospital (a tertiary grade A hospital) between January 2019 and July 2023. Yiwu, a metropolitan hub in central Zhejiang province with 1.86 million residents, served as the study setting, representing urban populations in the high-income eastern area of China. Data were extracted from 2 electronic health systems: (1) Neurodevelopmental Assessment System—providing evaluation scores, assessment dates, and living address and (2) Child Healthcare System—containing sociodemographic (eg, parental age, education) and perinatal variables (delivery mode, birthweight, gestational age at birth, date of birth, and infant's sex).

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki [17] and was approved by the ethics committee of Yiwu Maternity and Children Hospital (approval 2024-Research-07). Because it utilizes a secondary analysis of pre-existing anonymized data, which had no privacy threats to individuals, and the unique ID used to link different data is actually deidentified, and the matching work was performed by the stall of data management department to ensure data security, the informed consent was waived. Given that the study did not include direct engagement with participants, no monetary compensation was offered.

Measurements of the General and Clinical Characteristics

We extracted children's demographic data (eg, infant's sex, date of birth, residence) and neurodevelopmental assessment data from the Neurodevelopmental Assessment System and linked it to the Child Healthcare System via a unique ID to obtain general parental characteristics (eg, age, educational level, parity) and child birth characteristics (eg, gestational age at birth, birth weight, delivery mode, date of birth).

Parental age when the child was born was determined by subtracting the parents' birthdays from the child's birthday. Given the limited sample size for parity exceeding 4 times, we grouped these cases as "4 times and above." Preterm birth was defined as the gestational age of less than 37 weeks at delivery. Birthweight was categorized into 3 groups: low birth weight (<2500 g), normal birth weight (2500-3999 g), and macrosomia (≥4000 g). Seasons were divided into spring (March, April, and May), summer (June, July, and August), autumn (September, October, and November), and winter (December, January, and February). Based on the living address, the residence of the

XSL•FO
RenderX

participants was categorized into urban and town/rural areas. We categorized the timeline into 3 stages of the COVID-19 pandemic in Zhejiang, China: stage I (prepandemic: January 2, 2019, to January 22, 2020), stage II (pandemic: January 23, 2020, to December 18, 2022), and stage III (postpandemic: December 19, 2022, to July 31, 2023).

Assessment of Neurodevelopment

In 2018, Yiwu was one the first municipalities in Zhejiang Province to implement a regional early childhood development screening program for infants aged 0-3 years, incorporating standardized developmental assessments into routine pediatric care at the Yiwu Maternity and Children's Hospital. Neurodevelopmental evaluations were routinely administered to infants starting from January 2019. Therefore, we included the data starting from January 2019. Two validated instruments were administered: Peabody Developmental Motor Scales-II (PDMS-II) and Bayley Scales of Infant Development-Chinese Cities Revised (BSID-CR). PDMS-II was employed to assess the gross motor quotient (GMQ) and fine motor quotient (FMQ) for infants aged 2-6 months. The total motor quotient (TMQ) is calculated as (GMQ + FMQ)/2. BSID-CR was applied to assess the development in infants aged 8-12 months, and it encompasses 2 subscales: mental development index (MDI) and psychomotor development index (PDI) to measure cognitive/language abilities and gross/fine motor skills, respectively. There were no data of repeated measurements for the same kind of assessment. All assessments followed standardized protocols: (1) being conducted in distraction-free rooms after 10-minute infant acclimation, (2) performed by pediatric professionals certified in developmental assessment tools (interrater reliability $\kappa>0.85$), (3) double-checked data entry to minimize recording errors, and (4) corrected age was used for preterm infants.

Developmental outcomes were classified using validated cutoff criteria aligned with Chinese norms for early childhood assessment, with scores below 90 on any indicator defined as neurodevelopmental delay [18]. For the PDMS-II, scores of TMQ<90 were classified as total motor delay, encompassing both gross motor delay (GMQ<90) and fine motor delay (FMQ<90). For the BSID-CR, scores of MDI<90 indicated below-average cognitive and language development, defined as mental development delay, and scores of PDI<90 signified motor skill deficits, particularly in coordination and object manipulation, defined as psychomotor development delay. Composite neurodevelopmental delay was defined as having either MDI or PDI below 90.

Statistical Analysis

First, we conducted a descriptive analysis. Continuous variables were assessed for normality by using Shapiro-Wilk tests. Normally distributed data were expressed as mean (SD), while nonnormally distributed data were summarized as median (IQR). Categorical variables were described using numbers and percentages. Second, we assessed the differences in the general characteristics between groups with and without neurodevelopmental delay. Two-sample independent *t* tests were applied for normally distributed data, while Mann-Whitney *U* tests were performed for nonnormally distributed data. Chi-square tests were used for categorical variables or Fisher exact tests when expected cell counts were <5. For multivariable analyses, variables showing significance indicated by $P<.01$ in univariate analyses were entered into logistic regression models. Lastly, we conducted multivariable logistic regression models to examine the potential risk factors associated with neurodevelopmental delay (defined as scores <90 on BSID-CR [MDI/PDI] or PDMS-II [TMQ]). All statistical analyses were performed using R software (version 4.2.3; The R Foundation). The statistical significance was set at $P<.05$ (2-tailed).

Results

Basic Characteristics of the Study Participants and Comparisons Between Groups

In this study, we included a total of 17,621 PDMS-II assessments and 7877 BSID-CR assessments. Table 1 presents the general characteristics of the parents and children. For infants assessed with the PDMS-II, 64.1% (11,294/17,621) were born during COVID-19 pandemic stage II. Among infants assessed with the BSID-CR, 64.4% (5074/7877) were born during COVID-19 pandemic stage II. Table S1 of Multimedia Appendix 1 shows the comparison of the general and clinical characteristics between infants with and without neurodevelopmental delay assessed by PDMS-II. There were statistically significant differences observed in the maternal age, paternal age, maternal education, assessment age, delivery mode, preterm status, birth season, COVID-19 pandemic stages, and residence between infants with or without neurodevelopmental delay when assessed by PDMS-II. Similarly, significant differences were found in maternal age, paternal age, assessment age, birthweight, gestational age, delivery mode, gender, preterm status, birth season, COVID-19 pandemic stages, and residence between infants with and without neurodevelopmental delay when assessed by BSID-CR (Table S2 in Multimedia Appendix 1).

Infant Neurodevelopment Trend From 2019 to 2023

As illustrated in Figure 1 and Figure 2, the neurodevelopmental levels of infants in Yiwu, assessed by BSID-CR and PDMS-II, exhibited fluctuations from January 2019 to July 2023. Specifically, TMQ, GMQ, and FMQ, evaluated by PDMS-II, demonstrated a downward trend from October 2019 to October 2020. Figure 1 shows that since January 2021, there has been a cyclical fluctuation with an approximate 1-year cycle, wherein TMQ showed lesser variability. Figure 2 shows that both boys and girls followed similar patterns. However, in terms of the mental and psychomotor development indices, as measured by BSID-CR, boys performed worse than girls.

Figure 3 shows the prevalence of neurodevelopment delay at different stages of the COVID-19 pandemic. Across all evaluation indices (TMQ, GMQ, FMQ, MDI, PDI), stage I showed the lowest prevalence of neurodevelopmental delay.

Factors Associated With Infant Neurodevelopment Delay

Table 2 and Table 3 present the results of logistic regression analyses in terms of the associated factors of infant neurodevelopmental delay assessed by PDMS-II and BSID-CR, respectively. Infants assessed at stage II had a higher risk of neurodevelopmental delay compared to infants assessed at stage I, even after adjusting for other variables (TMQ: odds ratio [OR] 2.84, 95% CI 2.17-3.72; FMQ: OR 2.71, 95% CI 1.99-3.68) and stage III (TMQ: OR 2.52, 95% CI 1.79-3.55; GMQ: OR 1.65, 95% CI 1.21-2.25; FMQ: OR 3.40, 95% CI 2.36-4.92). Infants assessed at stage III had the highest risk of mental development delay (OR 2.54, 95% CI 1.91-3.36). In addition, the results indicated that cesarean delivery, infant's sex as male, preterm birth, LBW, and residing in town/rural areas were significantly associated with neurodevelopmental delay (P<.05).

Discussion

Principal Findings

This study uses a large-scale, retrospective dataset of a publicly funded neurodevelopmental screening program among infants since 2019 in Yiwu, China, to evaluate the early childhood neurodevelopment after the implementation of this program. Our study reveals that the COVID-19 pandemic may have adverse effects on infant neurodevelopment, persisting into the postpandemic period. The scores obtained via BSID-CR and PDMS-II assessments among infants consistently demonstrated seasonal variations. Furthermore, infant's age, sex, birthweight, preterm birth, and mode of delivery were significantly associated with the infants' neurodevelopment. To the best of our knowledge, this study bridges a crucial evidence gap on factors influencing infant neurodevelopment by providing population-level, neurodevelopmental data spanning prepandemic, pandemic, and postpandemic periods.

This study shows that the levels of infant neurodevelopment fluctuated, especially in 2020, which might be related to the COVID-19 pandemic. Our study reveals that compared to infants in the stage I of the COVID-19 pandemic, those in stage II demonstrated significantly higher risks of motor and mental delay. One study from Guangzhou, China, in 2021 also demonstrated that the COVID-19 pandemic adversely affected infant neurodevelopment [15]. Another study conducted in New York also indicated that infants exposed and unexposed to the SARS-CoV-2 during the COVID-19 pandemic had considerably lower scores in gross motor, fine motor, and personal-social subdomains compared to historical cohorts born prior to the pandemic [19]. This adverse effect could be attributed to various factors. First, the COVID-19 pandemic and related restrictions likely limited infants' opportunities for environmental exploration and peer engagement, which could adversely impact their neurodevelopmental outcomes [15]. Second, prolonged mask-wearing may have reduced infants' exposure to facial expression recognition and other crucial social stimuli during critical developmental periods [20]. Notably, infants assessed at stage III continued to demonstrate significantly lower neurodevelopmental level compared to those in stage I. At present, there is a lack of relevant research to confirm. In our study, these infants at stage III were born to mothers who not only experienced pandemic-related stress during pregnancy but also had relatively high chance to be infected by the SARS-CoV-2. Related stress factors during pregnancy should be recognized as a potential contributing mechanism to these developmental delays [21,22]. Moreover, the infection itself might have played a role. A meta-analysis published in 2022, encompassing 8 studies with 21,419 infants, demonstrated that maternal SARS-CoV-2 infection was associated with an increased risk of fine motor impairment in offspring (OR 3.46, 95% CI 1.43-8.38) [23].

Even after adjusting for the effects of different stages of the COVID-19 pandemic on neurodevelopment, we still found several factors related to neurodevelopmental delay. In our study, we observed that boys exhibited poorer performance compared to girls not only on BSID-CR but also on PDMS-II. A cohort study conducted in Japan supported this finding, revealing a higher risk of developmental delay among boys younger than 2 years (OR 2.5, 95% CI 1.5-4.2) than girls [24]. Additionally, a 2024 review highlighted that boys are more prone to malnutrition and stunting—factors that could potentially impact neurodevelopment [25]. We hypothesized that these disparities may be linked to sex-based differences in utero exposure sensitivity. Guma and Chakravarty [26] also reported that exposure to inflammation in utero or early life can influence fetal neurodevelopment, with boys being more vulnerable than girls due to sex hormone differences. Furthermore, early language development exhibits sexual dimorphism due to genetic and hormonal factors, with girls typically developing faster than boys, leading to earlier social awareness and superior neurodevelopment levels in girls [27-29].

Our study indicates that infants with LBW exhibited poorer neurodevelopmental outcomes. This observation aligned with that reported by Wu et al [30] demonstrating infants with marginally LBW (ranging from 2000 to 2499 g) with a higher risk of neurodevelopmental delays. This may result from impaired brain connectivity and neuronal migration in LBW infants [31], where high-quality family environmental stimulation can partially mitigate the adverse neurodevelopmental impacts [32]. Consequently, timely parent-child interaction interventions should be prioritized for LBW infants to improve neurodevelopmental outcomes. Interestingly, our study shows that preterm birth appeared to be a protective factor for infant neurodevelopment. This might be a chance finding due to the limited sample size of infants with preterm birth, especially very preterm birth, in our study. Additionally, it was possible that the increased attention and care received by premature infants could have contributed to improved neurodevelopment by altering the methylation levels [33]. We recommend that future studies replicate our protocol to support or refute our findings.

We also identified cesarean delivery as a risk factor for infant neurodevelopmental delay, consistent with prior epidemiological evidence [34]. The potential harm associated with cesarean delivery may be linked to microbiome disturbances. A blinded randomized controlled trial revealed that cesarean-born infants who received vaginal microbiota transfer showed significantly better neurodevelopment at 6 months compared to those who received saline [35]. Therefore, we hypothesize that cesarean delivery may impact infant neurodevelopment by altering the microbiome disturbances.

Additionally, our study reveals seasonal variations in infants' neurodevelopment levels. We found that infants born in summer had a higher risk of mental and psychomotor development delay. This might be because most summer-born infants undergo the BSID-CR assessment in winter, when they receive less sunlight exposure. Similar to what we found, a comprehensive multi-center study encompassing Denmark, Finland, Norway, Sweden, and Western Australia has uncovered a seasonal trend in the occurrence of autism spectrum disorder [36]. This trend might be attributed to varying sunlight levels during early childhood [35]. Furthermore, recent research indicates a positive correlation between children's neurodevelopment and 25(OH)D levels [37,38]. This suggests that vitamin D, closely linked to

XSL•FO
RenderX

sunlight exposure, could be a crucial factor for explaining the seasonal disparity in the neurodevelopment of infants. Further research and exploration of the underlying mechanism relationships are still needed in the future.

Limitations

There are some limitations worthy of mention. First, as a cross-sectional design, this study could not establish causational relationships. We recommend future longitudinal follow-ups or birth cohort to replicate this study protocol in order to confirm or to refuse our findings. Second, our data, derived from a single city, may not comprehensively reflect the situation in China. It is worth noting that Yiwu serves as a pilot city for various projects, including the National Rural Early Childhood Development Project and the National Rural Revitalization Strategy-Grassroots Early Childhood Development Project, thereby possessing a certain degree of theoretical representativeness of areas with advanced child health care in China.

Conclusions

The COVID-19 pandemic exacerbated neurodevelopmental vulnerabilities in infants, with effects persisting into the postpandemic period. Public health strategies should focus on comprehensive developmental monitoring and timely interventions for all high-risk infants to mitigate the long-term impacts.

Acknowledgments

We thank Yiwu Maternity and Children Hospital for significant support in the citywide infant neurodevelopmental screening. We also appreciate the guidance from the Department of Children's and Adolescent Health, Public Health College of Harbin Medical University, during manuscript preparation. In addition, we thank all the members of the Pediatric Evidence-based Medical and Clinical Laboratory, Children’s Hospital, Zhejiang University School of Medicine (led by GB) for the interesting discussions and significant contributions to the methodology in this study.

Funding

We acknowledge support from the Zhejiang Provincial Medical and Health Science and Technology Plan Project (2022ZH066, 2024XY079) and the Social Development in Science and Technology Plan Project of Jinhua (2023-4-260).

Data Availability

The data presented in this study are available on request from the corresponding author. The data are not publicly available because they contain information that could compromise the privacy of research participants.

Abstract

Background: The long-term economic impact of frailty measured at the beginning of elderhood is unknown.

Objective: The objective of our study was to examine the association between an individual's frailty index at 66 years of age and their health care costs and utilization over 10 years.

Methods: This retrospective cohort study included 215,887 Koreans who participated in the National Screening Program for Transitional Ages at 66 years of age between 2007 - 2009. Frailty was categorized using a 39-item deficit accumulation frailty index: robust (<0.15), prefrail (0.15 - 0.24), and frail (≥0.25). The primary outcome was total health care cost, while the secondary outcomes were inpatient and outpatient health care costs, inpatient days, and number of outpatient visits. Generalized estimating equations with a gamma distribution and identity link function were used to investigate the association between the frailty index and health care costs and utilization until December 31, 2019.

Results: The study population included 53.3% (n=115,113) women, 32.9% (n=71,082) with prefrailty, and 9.7% (n=21,010) with frailty. The frailty level at 66 years of age was associated with higher cumulative total costs (robust to frail: $19,815 to $28.281; *P*<.001), inpatient costs (US $11,189 to US $16,627; *P*<.001), and outpatient costs (US $8,625 to US $11,654; *P*<.001) over the next 10 years. In the robust group, a one-year increase in age was associated with increased total health care costs (mean change per beneficiary per year: US $206.2; SE: $1.2; *P*<.001), inpatient costs (US $126.8; SE: $1.0; *P*<.001), and outpatient costs (US $74.4; SE: $0.4; *P*<.001). In the frail group, the increase in total health care costs was greater compared to the robust group (difference in mean cost per beneficiary per year: US $120.9; SE: $5.3; *P*<.001), inpatient costs (US $102.8; SE: $5.22; *P*<.001), and outpatient costs (US $15.6; SE: $1.5; *P*<.001). Similar results were observed for health care utilization (*P*<.001). Among the robust group, a one-year increase in age was associated with increased inpatient days (mean change per beneficiary per year: 0.9 d; *P*<.001) and outpatient visits (2.1 visits; *P*<.001). In the frail group, inpatient days increased annually compared to the robust group (difference in the mean inpatient days per beneficiary per year: 1.5 d; *P*<.001), while outpatient visits increased to a lesser extent (difference in the mean outpatient visits per beneficiary per year: −0.2 visits; *P*<.001).

Conclusions: Our study demonstrates the potential utility of assessing frailty at 66 years of age in identifying older adults who are more likely to incur high health care costs and utilize health care services over the subsequent 10 years. The long-term high health care costs and utilization associated with frailty and prefrailty warrants public health strategies to prevent and manage frailty in aging populations.

Introduction

Health care systems face the challenge of managing increasing health care costs in aging populations [1,2]. South Korea experiences one of the fastest rates of population aging in the world, with 40% of its population expected to be aged over 65 years by 2050 [3]. The country is already experiencing a deficit in health insurance budget [4]. Proactive identification of individuals who are likely to incur high health care costs and utilization is critical for developing strategies to control health care expenditures in the aging society.

Frailty is defined by a decline in physiological reserves across multiple organ systems, leading to increased susceptibility to poor health outcomes following stressors [5]. Previous studies have found that frailty was associated with increased health care costs and utilization [6-10]. Moreover, individuals with frailty accounted for 43.9% of preventable health care expenditures [11]. One of the established models for measuring frailty is the deficit accumulation frailty model, expressed as a frailty index (FI), which is calculated by dividing the number of deficits present by the total number of deficits considered [12,13]. The FI can range from 0 to 1, with higher scores indicating greater frailty [13]. It can be derived from an existing database that contains information on standardized health assessments.

Since 2007, all Koreans who turn 66 years old have been invited to participate in a comprehensive health evaluation as part of the National Screening Program for Transitional Ages at government-approved clinics, hospitals, and public health facilities [14]. This examination assesses lifestyle, medical history, functional status, and laboratory tests, providing data to quantify a deficit accumulation FI on a national level. We have recently shown that higher FI scores at age 66 were associated with faster development of age-related chronic diseases over the subsequent 10 years among nearly 1 million Koreans [15]. The availability of standardized health assessments through the National Screening Program for Transitional Ages provides a unique opportunity to identify the FI across a large cohort. However, it is uncertain whether the FI at age 66 can predict long-term health care costs and utilization.

We conducted a nationwide cohort study of Koreans who participated in the National Screening Program for Transitional Ages in 2007 - 2009 to examine the association between the FI at age 66 and subsequent health care costs and utilization over 10 years. South Korea offers a unique context for research in frailty due to its nationwide single-payer health insurance system, which ensures both universal coverage, and provides detailed and standardized claims data for the entire population. This system facilitates long-term follow-up of health care costs and utilization, enabling population-level analyses that are rarely feasible in other health care settings. In this study, we hypothesized that a higher FI at age 66 would be associated with a greater increase in health care costs and utilization over 10 years.

Methods

Data Sources

We accessed the National Screening Program for Transitional Ages database (2007 - 2009), which was linked to the Korean National Health Insurance database (2004 - 2019), through the Korean National Health Insurance Corporation research program. The dataset included a 35% (n=435,572) random sample of adults who reached the age of 66 years between 2007-2009. The screening program database includes information on lifestyle indicators, medical history, functional status, and laboratory measurements. The Korean National Health Insurance database includes ICD-10 diagnostic codes, sociodemographic variables, health service claims, health care utilization, and long-term care insurance claims [16].

Study Population

We included individuals with complete sociodemographic information who participated in the screening program (n=222,480) through the 435,572 enrollees of the Korean National Health Insurance aged 66 years between 2007 - 2009. We excluded those with (1) duplicate records (n=1460), (2) insufficient data (<80% of the necessary items) for calculating frailty (n=5119), or (3) death within the month of examination or the month following the examination (n=14). Our final cohort included 215,887 enrollees (Figure S1 in Multimedia Appendix 1). This cohort included both community-dwelling older adults and long-term care residents.

Measurement of Frailty and Other Characteristics

The detailed procedure for constructing the FI has been described previously [15]. Briefly, we followed the standard procedure established by Searle et al [17]. The variables were selected as health deficits if they met the following criteria: (1) associated with health status, (2) prevalence increased with age, (3) did not saturate too early, and (4) covered a range of organ systems. We calculated the FI (range: 0 to 1; higher scores indicated greater frailty) based on 39 health-deficit items in the following health domains: medical history (15 items), biometric or laboratory measures (8 items), physical health (2 items), psychological health (8 items), and disability (6 items) (the definition of each item is provided in Table S1 in Multimedia Appendix 1) [15]. Frailty categories were defined using the previously used cut off points [15,18,19]: robust (<0.15), prefrail (0.15 to <0.25), and frail (≥0.25). We also assessed the presence of chronic conditions using ICD-10 diagnosis codes (ie, 1 inpatient or 2 outpatient diagnoses) from the previous year. Additionally, the following characteristics were obtained from the screening examination: sex, annual income level (quantiles), insurance status (employee insurance, self-employed insurance, or medical aid for low income), residential area (capital,

XSL•FO
RenderX

metropolitan, or rural areas), and examination year (2007, 2008, or 2009).

Outcome Measurements and Follow Up

The primary outcome was total health care costs per beneficiary per year. These health care costs were the sum of reimbursements from the Korean National Health Insurance and beneficiaries' cost-sharing for inpatient and outpatient care. Secondary outcomes were inpatient costs, outpatient costs, inpatient days, and the number of outpatient visits per beneficiary per year. Follow up began on the day after the screening examination and lasted until the following, depending on whichever occurred earlier: date of death, 10 years from the screening examination, or December 31, 2019. To account for variations in inflation, we adjusted the costs to 2007 Korean Won (KRW) using an annual conversion factor (converted into US dollars at an exchange rate of 1 USD=1200 KRW). The extreme cost values were truncated at the 1st and 99th percentiles (ie, replacing values smaller than the 1st percentile with the 1st percentile value, and values larger than the 99th percentile with the 99th percentile).

Statistical Analysis

We used the χ^2 test to compare baseline characteristics by frailty category. The cumulative annual costs (total health care costs, inpatient costs, and outpatient costs) were compared using one-way ANOVA. Additionally, we compared the annual rates of health care utilization (inpatient days and number of outpatient visits) over 10 years, according to the frailty category. To investigate the association between the FI at age 66 years and health care costs and utilization over 10 years, generalized estimating equations were applied with a gamma distribution and the identity link function [20,21]. This was done to model right-skewed and over-dispersed health care cost and utilization data, accounting for repeated annual measures of costs and utilization within each beneficiary. Subgroup analyses were conducted by sex and by health insurance type. We tested the homogeneity of the interaction term between time and frailty categories across sex and health insurance type [22,23]. All models were adjusted for sex, annual income, insurance status, residential area, and examination years.

$$Y_{it}=\beta_0+\beta_1 Prefrail_{it}+\beta_2 Frail_{it}+\beta_3 Time_{it}+\beta_4 Time_{it}*Prefrail_{it}+\beta_5 Time_{it}*Frail_{it}+\beta_6 X_{it}+\varepsilon_{it}$$

- Y_{iT}: Dependent variable for an individual participant i observed for time T
- $T=t-c$; where time T is defined as year t minus the calendar year in which an individual participant i underwent a medical examination year C^i (2007, 2008, or 2009)
- $Time_t$: Time in years [0 (67 years), 1 (68 years), 2 (69 years),…, 9 (76 years)]
- $Prefrail_{iT}$: Dummy variable (1 for prefrail group, 0 otherwise)
- X_i: Independent variables

The analyses were performed using SAS Enterprise Guide (version 7.15; SAS Institute,) and STATA (version 15; Stata Corporation). A two-sided *P*-value <.05 was considered statistically significant.

Ethical Considerations

This study was exempted from review by the Institutional Review Board of Ajou University Health System (AJIRB-MED-EXP-20‐127) as the data used in this study were deidentified and secondary analysis was performed using public data. No compensation was provided to the participants.

Results

The study population included 123,795 (57.3%) women, 71,082 individuals with prefrailty (32.9%), and 21,010 individuals with frailty (9.7%) (Table 1). Individuals with greater frailty were more likely to be women (robust vs frail: 44.8% vs 68.6%) and medical aid recipients (robust vs frail: 1.8% vs 7.8%). Over the 10-years follow up, 20,189 (9.4%) individuals died. The survival rate to age 76 years was higher in the robust group than in the prefrail and frail groups (robust: 91.8%; pre-frail: 90.3%; frail: 85.2%) (Table S2 in Multimedia Appendix 1).

Figure 1 shows the cumulative health care costs over 10 years by frailty category in individuals aged 66. Individuals in the frail group incurred the highest cumulative total health care costs (US $28,281), followed by the prefrail (US $23,793), and robust groups (US $19,815; *P*<.001). Compared to the robust group, the frail group was associated with higher cumulative inpatient costs (US $11,189 vs US $16,627) and outpatient costs (US $8,625 vs US $11,654) for the subsequent 10 years.

[a]Frailty categories were defined as robust (frailty index <0.15, prefrail (0.15 to <0.25), and frail (≥0.25).

[b]P values were calculated using the χ^2 test for categorical variables.

Figure 1. Cumulative growth in total health care costs according to frailty index at age 66 years (A) Robust; (B) Prefrail; (C) Frail categories. The X-axis represents age (years) and the Y-axis represents cumulative total health care costs (US $). The pink area represents inpatient costs and blue area represents outpatient costs.

Over a period of 10 years, the annual growth in total health care costs, inpatient costs, and outpatient costs was greater in the frail group than in the prefrail and robust groups (Figure 2). Multivariable analyses (Table 2; Table S3 in Multimedia Appendix 1) showed that the frail group had higher mean total health care costs (difference: $827.2, SE: $20.0; *P*<.001), inpatient costs ($432.2, SE: $16.3; *P*<.001), and outpatient costs ($395.0, SE: $7.9; *P*<.001) than the robust group at baseline.

XSL•FO
RenderX

In the robust group, a one-year increase in age was associated with increased total health care costs (mean change per beneficiary per year: $206.2; SE: $1.2; *P*<.001), inpatient costs ($126.8; SE: $1.0; *P*<.001), and outpatient costs ($74.4; SE: $0.4; *P*<.001). In the frail group, there were greater increases in total health care costs each year compared to the robust group (difference in the mean cost per beneficiary per year: $120.9; SE: $5.3; *P*<.001), inpatient costs ($102.8; SE: $5.2; *P*<.001), and outpatient costs ($15.6; SE: $1.5; *P*<.001). The prefrail group had higher mean total health care costs, inpatient costs, and outpatient costs than the robust group at baseline, with the annual change per one-year increase in age falling between the robust and frail groups (Table 2).

Figure 2. Trends in annual health care costs per beneficiary per year according to frailty index at age 66 years. The X-axis represents age (years) and the Y-axis is annual health care costs per beneficiary per year (US dollar). The navy diamond line represents frail individuals, the blue triangle line represents pre-frail individuals, and the sky-blue square line represents robust individuals.

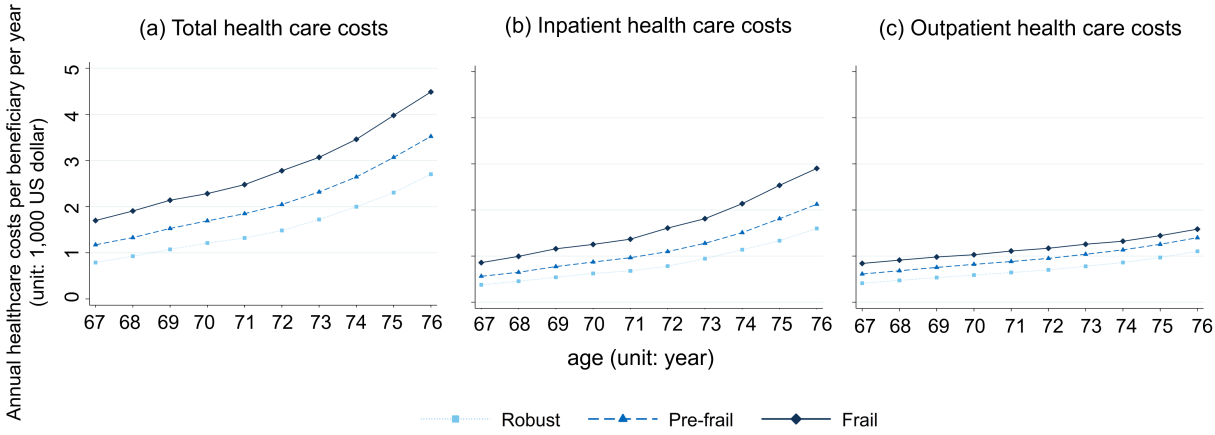

Table . Association between frailty at 66 years of age and annual health care costs and health care utilization over 10 years.[a] results of the generalized estimating equations models that examined the association between frailty at 66 years of age and annual health care costs and health care utilization over 10 years.

[a]Generalized estimation equation models were used for the analysis. The models were adjusted for the examination year, sex, annual income, insurance status, and residential area.

[b]β (SE) represents the regression co-efficient (β) and its standard error (SE).

[c]P values indicate the significance level of the comparisons.

[d]Frailty categories were defined as robust (frailty index<0.15), pre-frail (0.15 to <0.25), and frail (≥0.25).

[e]Ref. denotes the reference category used for comparisons.

XSL•FO
RenderX

The examination of health care utilization over 10 years showed that the frail group had a greater increase in inpatient days and the outpatient visits over 10 years than the prefrail or robust groups (Figure S2 and Figure S3 in Multimedia Appendix 1). The frail group had a greater mean number of inpatient days (5 d; SE: 0 d; *P*<.001) and outpatient visits (36 visits; SE: 0.1; *P*<.001) than the robust group at baseline (Table 2). In the robust group, a one-year increase in age was associated with increases in inpatient days (mean change per beneficiary per year: 0.9 d; SE: 0 d; *P*<.001) and outpatient visits (mean change per beneficiary per year: 2.1 visits; SE: 0 visits; *P*<.001). In the frail group, the number of inpatient days increased more each year compared to the robust group (difference in the mean inpatient days per beneficiary per year: 0.9 d; SE: 0 d; *P*<.001), whereas the number of outpatient visits increased to a lesser degree (difference in the mean outpatient visits per beneficiary per year: −0.2 visits; SE: 0 visits; *P*<.001). The prefrail group had a greater mean number of inpatient days and outpatient visits than the robust group at baseline, with more increases in both inpatient days and outpatient visits annually (Table 2).

In subgroup analyses, men with frailty had a greater increase in total health care costs than women with frailty (*P*-for-interaction:<.001) (Table S4 in Multimedia Appendix 1). Frail people with low-income medical aid were more likely to incur higher total health care costs than those with other insurance types and frailty groups; however, the observed difference was not significant (*P*-for-interaction: .74) (Table S5 in Multimedia Appendix 1).

Discussion

Principal Findings

Using a nationwide Korean cohort, we found that the frailty level at 66 years of age was associated with higher health care costs and health care utilization over the subsequent 10 years. The growth in annual health care costs and health care utilization, particularly inpatient days, was greater in individuals with frailty than in prefrail or robust individuals. Furthermore, prefrail individuals, who made up 32.9% of the population, had higher health care costs and utilization than robust individuals. Given the high prevalence of prefrailty and associated long-term health care costs and utilization, our findings suggest the importance of identifying frailty and prefrailty to control health care costs and utilization in aging populations.

Our findings are consistent with previous studies demonstrating that frailty is associated with increased use of health care resources [24-26]. A population-based cohort study showed that the association between frailty onset and increasing self-reported health care costs was prominent in inpatient care and informal nursing care [6]. A meta-analysis of 7 cohorts of community-dwelling older adults found that health care costs of prefrail and frail older adults were higher than robust individuals [27]. In addition, those who were frail faced a greater risk of hospitalization, skilled nursing facility stays [28,29], emergency department visits [30], and institutionalization [31], compared to robust individuals. Our study contributes to the existing literature by examining 10-year trajectories of health care costs and utilization in a nationally representative cohort of Koreans aged 66 years. The choice of this time point in the beginning of elderhood removes the effect of chronologic age and emphasizes the importance of early identification, prevention, and management of frailty and prefrailty. Early identification can provide the opportunity to proactively address the needs of these individuals to lower health care costs and utilization in the future [32,33]. Frailty may be prevented or delayed by interventions such as physical activity, nutrition, and comprehensive geriatric assessment [34]. Therefore, by linking frailty with long-term health care costs and utilization, our findings expand the understanding of frailty's economic impact beyond short-term or disease-specific analyses commonly found in the literature.

Previous research suggested that incorporating frailty into a diagnosis-based model, such as the hierarchical condition category method (which is used to predict Medicare health care costs), may improve the accuracy of cost projections [35]. However, most prediction models for health care costs used in Korea do not account for frailty [36]. Although health care cost prediction models have been developed using the National Screening Program for Transitional Ages database, they have been designed for the entire population rather than specifically for older adults [37]. Our findings suggest that frailty metrics could enhance existing health care cost prediction models, providing a more nuanced understanding of health care needs in aging populations.

In our study, the associations between frailty and health care costs and utilization were stronger in men than women. Li et al [38] and colleagues found that frailty or worsening frailty had a stronger association with increased hospitalization and outpatient costs in men than in women. However, other studies did not find an interaction between frailty and sex on catastrophic health expenditures [39] or health care utilization (outpatient visit, inpatient visit, and inpatient length of stay) [40]. There are several explanations for higher health care costs among frail men than among frail women in our study. Men are generally more likely to develop serious health conditions that can be costly to manage, such as coronary heart disease, cancer, cerebrovascular disease, emphysema, cirrhosis of the liver, kidney disease, and atherosclerosis [41]. In addition, men are more likely to engage in risky health behaviors such as smoking and drinking and may be less likely to seek health care services for health issues, leading to delayed treatment [42]. These findings suggest that taking into account the differences in health risks and needs between frail men and frail women may help to improve health outcomes and reduce costs in older adults.

Limitations

Our study had important limitations. First, we were unable to assess costs and utilization of noncovered services including the costs of outpatient prescription medications. Second, selection bias is possible due to nonparticipation of otherwise eligible individuals in the National Screening Program for Transitional Ages and deaths, which may affect the longitudinal cost trajectories. However, we previously reported no major differences in characteristics between nonparticipants and participants in the program [15]. Third, the association between frailty and health care costs and utilization may be subject to

XSL•FO
RenderX

the choice of frailty definitions. Both the deficit accumulation FI and frailty phenotype have been associated with increased health care costs in previous studies [8,43]. Fourth, causality may not be inferred from our observational data. Finally, our findings may not be generalizable to other countries with different health care systems and financing structures.

Conclusion

Our study demonstrates the potential utility of assessing frailty at 66 years of age to identify older adults who are more likely to incur high health care costs and utilize health care services in the subsequent 10 years. The long-term high health care costs and utilization associated with frailty and prefrailty call for public health approaches to prevent and manage frailty in aging populations.

Acknowledgments

This study used customized data provided by the Korean National Health Insurance Service and was supported by faculty research grant 6-2021-0112 from Yonsei University College of Medicine (JS), grant KSPM-2021-01 from the Korean Society for Preventive Medicine and the Korea Health Technology R&D Project through the Korea Health Industry Development Institute funded by grant HI21C1249 from the Ministry of Health & Welfare, Korea (JJ), and by Mid-Career Investigator Award K24AG073527 from the National Institute on Aging (DHK). The funding sources had no role in the design and conduct of the study; collection, management, analysis, and interpretation of the data; preparation, review, or approval of the manuscript; and decision to submit the manuscript for publication.

An earlier version of this study was presented at the Gerontological Society of America Annual Scientific Meeting on November 6, 2022 in Indianapolis, Indiana, and a poster was presented at the American Geriatrics Society Annual Scientific Meeting on May 4, 2022 in Long Beach, California.

Data Availability

The datasets generated and analyzed during this study are not publicly available. We obtained permission to use the datasets for the present study.

Abstract

Background: The National Essential Public Health Service Package (NEPHSP) was launched in 2009 to tackle poor blood pressure control in Chinese people with hypertension; however, it's effect is still unclear.

Objective: In a retrospective population-based longitudinal study, we aimed to evaluate effect of the NEPHSP on blood pressure control.

Methods: A total of 516,777 patients registered in the NEPHSP were included. The blood pressure control data were assessed based on the Residence Health Record System dataset. We longitudinally evaluated the effects of the NEPHSP on blood pressure control by analyzing changes in blood pressure at quarterly follow-ups. Both the degree and trend of the blood pressure changes were analyzed. We conducted stratified analysis to explore effects of the NEPHSP on blood pressure control among subgroups of participants with specific characteristics.

Results: The mean baseline systolic blood pressure (SBP) and diastolic blood pressure (DBP) were 147.12 (SD 19.88) mm Hg and 85.11 (SD 11.79) mm Hg, respectively. The control rates of baseline SBP and DBP were 39.79% (205,630/516,777) and 69.21% (357,685/516,777). Compared to baseline, the mean SBP decreased in each quarter by 5.06 mm Hg (95% CI −5.11 to −5.00; *P*<.001), 6.69 mm Hg (95% CI; −6.74 to −6.63; *P*<.001), 10.30 mm Hg (95% CI −10.34 to −10.23; *P*<.001), and 6.63 mm Hg (95% CI −6.68 to −6.57; *P*<.001). The SBP control rates increased in each quarter to 53.12% (274,493/516,777; β coefficient=0.60, 95% CI 0.59-0.61; *P*<.001), 56.61% (292,537/516,777; β coefficient=0.76, 95% CI 0.75-0.77; *P*<.001), 63.4% (327,648/516,777; β coefficient=1.08, 95% CI 1.07-1.09; *P*<.001), and 55.09% (284,711/516,777; β coefficient=0.69, 95% CI 0.68-0.70; *P*<.001). Compared to baseline, the mean DBP decreased in each quarter by 1.75 mm Hg (95% CI −1.79 to −1.72; *P*<.001), 2.64 mm Hg (95% CI −2.68 to −2.61; *P*<.001), 4.20 mm Hg (95% CI −4.23 to −4.16; *P*<.001), and 2.64 mm Hg (95% CI −2.68 to −2.61; *P*<.001). DBP control rates increased in each quarter to 78.11% (403,641/516,777; β coefficient=0.52, 95% CI 0.51-0.53; *P*<.001), 80.32% (415,062/516,777; β coefficient=0.67, 95% CI 0.66-0.68; *P*<.001), 83.17% (429,829/516,777; β coefficient=0.89, 95% CI 0.88-0.90; *P*<.001), and 79.47% (410,662/516,777; β coefficient=0.61, 95% CI 0.60-0.62; *P*<.001). The older age group had a larger decrease in their mean SBP (β coefficient=0.87, 95% CI 0.85-0.90; *P*<.001) and a larger increase in SBP control rates (β coefficient=0.054, 95% CI 0.051-0.058; *P*<.001). The participants with cardiovascular disease (CVD) had a smaller decrease in their mean SBP (β coefficient=−0.38, 95% CI −0.41 to −0.35; *P*<.001) and smaller increase in SBP control rates (β coefficient=−0.041, 95% CI −0.045 to −0.037; *P*<.001) compared to the blood pressure of participants without CVD.

Conclusions: The NEPHSP was effective in improving blood pressure control of Chinese people with hypertension. Blood pressure control of older individuals and those with CVD need to be intensified.

Introduction

The Global Burden of Disease Study reported that cardiovascular diseases (CVDs) are the leading noncommunicable disease contributing to the increase in disease-adjusted life years in China [1-3]. Hypertension, the major modifiable risk factor for CVDs, is prevalent in China [4-12]. According to the data of a recent survey conducted nationwide, the prevalence of hypertension was 54.7% among Chinese adults over 18 years old, and reportedly, merely 60.1% of Chinese adults with hypertension accepted antihypertensive treatments [13]. The low hypertension treatment rate has led to a suboptimal control of blood pressure among Chinese adults with hypertension [13]. Merely 7.2% of Chinese adults with hypertension had their blood pressures under control [13].

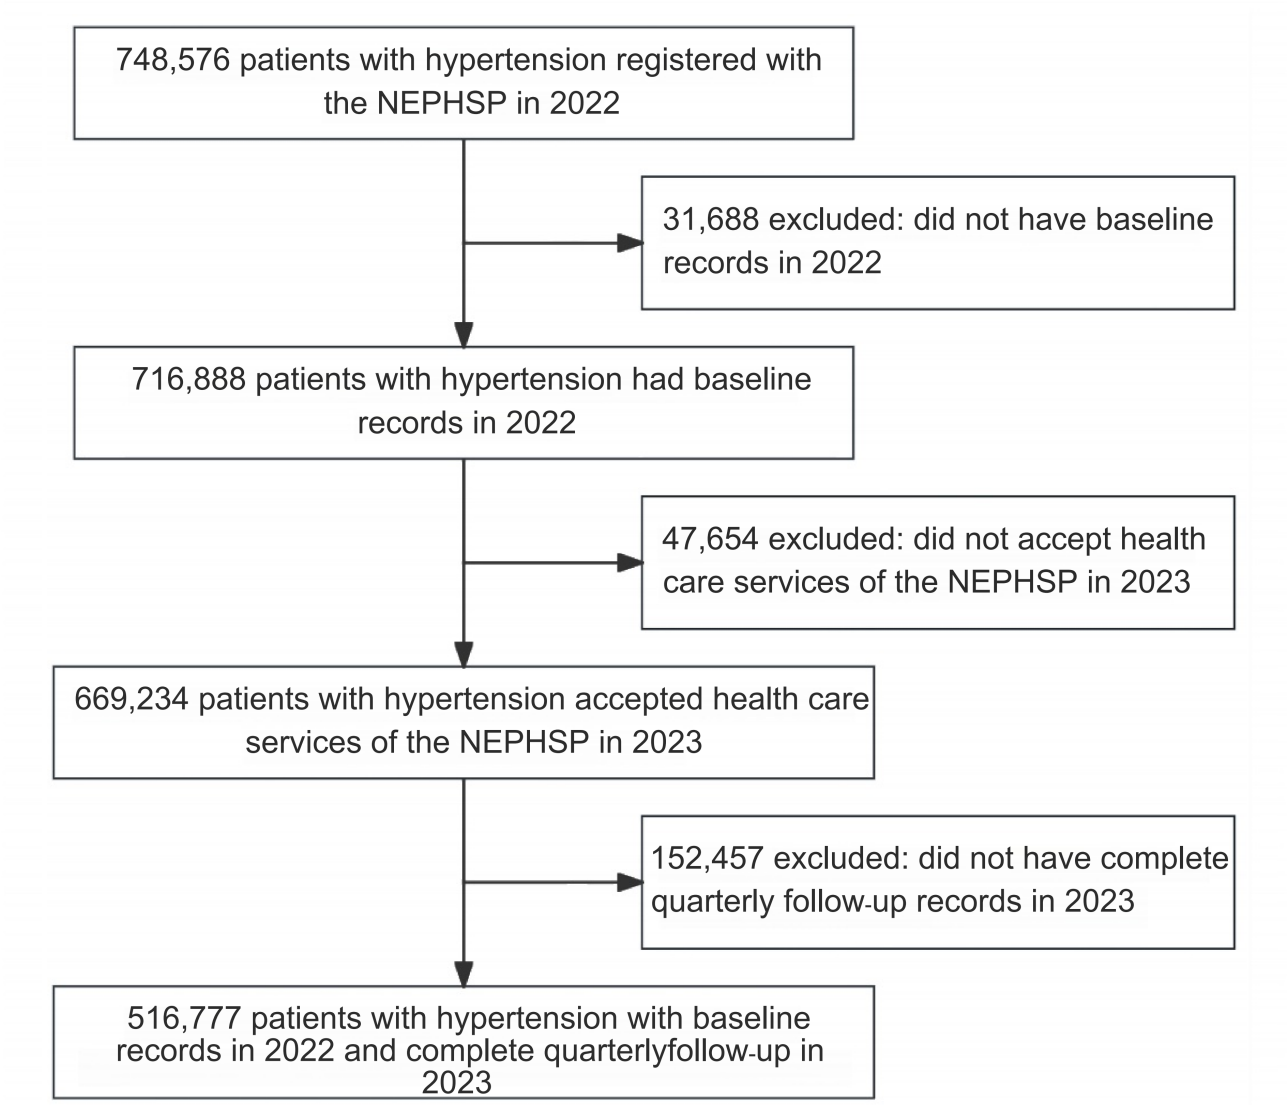
To tackle the poor hypertension control and growing burden of CVDs, the Chinese government launched the National Essential Public Health Service Package (NEPHSP) in 2009 [14]. The NEPHSP was a set of public health services which were available for all community-dwelling residents [14-18]. The public health services contain 4 modules, which are screening, monitoring, regular follow-up, and individualized interventions for hypertension control. The 4 modules were provided by primary health care professionals [14-18]. NEPHSP registration has been continuously expanded since it was launched in 2009 [14,18]. A total of 109 million Chinese adults diagnosed with hypertension registered with the NEPHSP from 2009 to 2019 [14]. The government investment increased from 15 to 84 RMB (US $2.05 to US $11.46) per person annually [15,18]. Because of the registration expansion and investment increase for the NEPHSP, the proportion of Chinese adult with hypertension who accepted antihypertensive treatment increased by 59.58% from 2009 to 2019 [14,18].

Although the registration expansion and investment increase for the NEPHSP improved the hypertension treatment rate, the NEPHSP lacks quality-oriented evaluations, which leads to an uncertainty whether the NEPHSP is effective for blood pressure control [14-18]. Furthermore, research demonstrating the effectiveness of the NEPHSP for blood pressure control in Chinese adults with hypertension is lacking [14-18]. To fulfill the research gap, this study aimed to explore effect of the NEPHSP on blood pressures control of Chinese adult with hypertension.

Methods

Study Design

This study was designed as longitudinal study to evaluate effect of the NEPHSP intervention on blood pressure control. The longitudinal study observed changes in the health status and clinical indicators of individuals who accepted treatment in a period of time, in order to explore the association between treatment and disease control [19-22]. Longitudinal studies have been commonly used in clinical research to evaluate the effects of treatment [19-22]. In this longitudinal study, we repetitively measured the blood pressure in participants who accepted hypertension care services offered by the NEPHSP in each quarter of 2023. All participants had a recorded blood pressure measurement prior to joining the NEPHSP in 2022. With the baseline outcomes in 2022 as the control, the degree and trend of the blood pressure changes after receiving NEPHSP in 2023 were analyzed longitudinally.



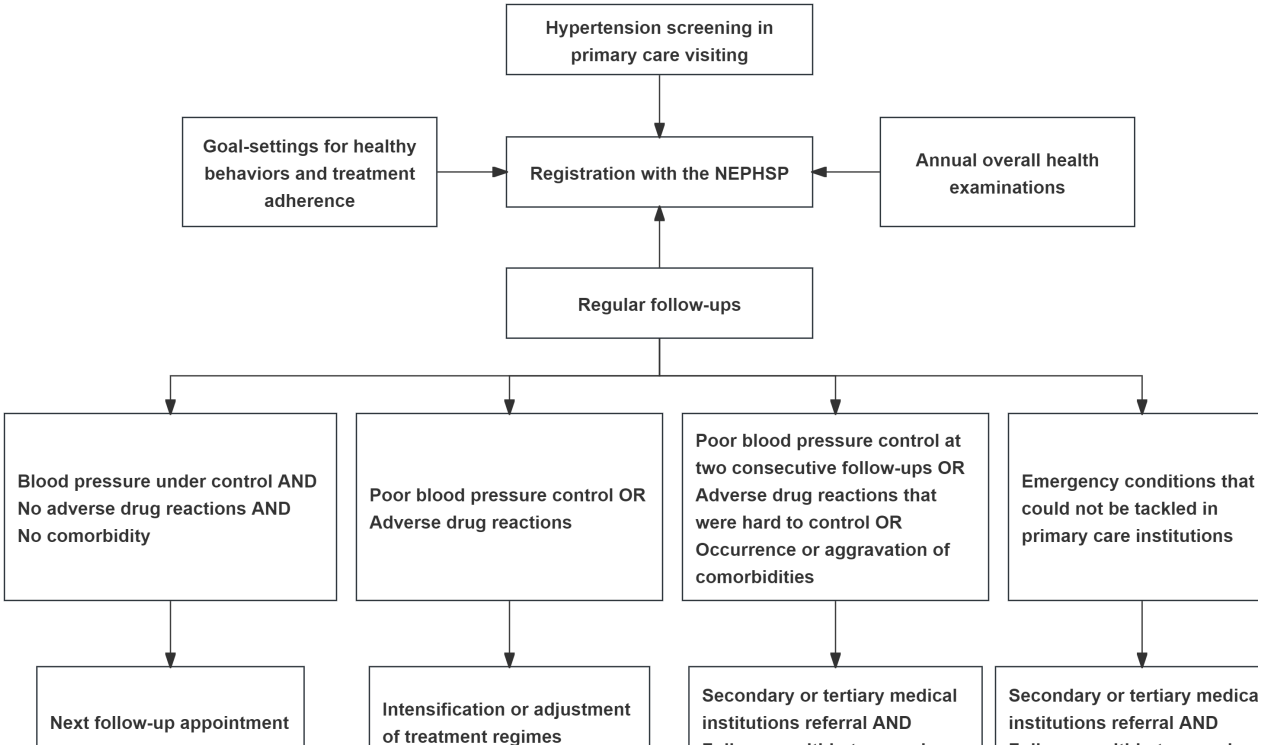
The data in this study were extracted from the Residence Health Record System, which is an electronic health record system built to recording demographic and health information of people registering with the NEPHSP [16,17]. This study used data of the Residence Health Record System built in Jining City, which is a national pilot city of the Chronic Disease Comprehensive Prevention and Control programs and is located in eastern China.

Study Participants

We analyzed data from the NEPHSP participants from 1593 primary care institutions in the 9 districts in Jining City. Eligibility criteria were (1) individuals registering with the NEPHSP as a patient with hypertension, (2) individuals who had baseline records of health examinations in 2022, (3) individuals who accepted health care services offered by the NEPHSP in 2023, and (4) individuals who had records for quarterly follow-ups conducted in 2023. The flowchart of participant inclusion is described in Figure 1.

XSL•FO
RenderX

Figure 1. The flowchart of the participant inclusion. NEPHSP: National Essential Public Health Service Package.



Intervention

The NEPHSP was divided into 4 dimensions: screening, routine follow-ups, individualized interventions, and annual health examinations. The explicit flowchart of the NEPHSP is described in Figure 2.

XSL•FO
RenderX

Figure 2. Flowchart of the NEPHSP. NEPHSP: National Essential Public Health Service Package.

The screening was conducted at primary care institutions when community residents had an appointment with primary health care professionals. The criteria for a hypertension diagnosis were a systolic blood pressure (SBP) over 140 mm Hg or a diastolic blood pressure (DBP) over 90 mm Hg for 3 separate measurements on different days. The residents were invited to register with the NEPHSP if they were diagnosed with hypertension.

The routine follow-up contained 5 facets: (1) assessing emergency conditions, (2) evaluating hypertensive symptoms, (3) measuring blood pressure, (4) evaluating healthy behaviors, and (5) evaluating medication treatment regimens and compliance. Assessing emergency conditions was the first part of the routine follow-up. The participants would be referred to secondary or tertiary care settings if there were emergency conditions that were hard to tackle in primary care institutions. If no emergency conditions were identified, the remaining parts would be conducted. The regular follow-ups were provided quarterly.

The individualized interventions contained 3 components: medication treatment adjustment, referral channel to superior medical institutions, and healthy behavior changes. According to health conditions that were evaluated in the regular follow-ups, primary care professionals would make decisions on medication treatment adjustments for the participants. If the health issues could not be handled in primary care settings, the primary care professionals would transfer the patient to superior medical institutions. The explicit processes and criteria of medication treatment adjustment and referral were divided into 3 dimensions. First, if blood pressure was under control, there were no adverse drug reactions, and there was not an occurrence of comorbidities or an aggravation of comorbidities, the next follow-up appointments were made for the participants. Second, if blood pressures were uncontrolled or adverse drug reactions were identified, the primary health care professionals would adjust the antihypertensive medication regimens. The conditions of the participants would be re-evaluated within 2 weeks. Third, if the patients had refractory uncontrolled blood pressure, adverse drug reactions that could not be tackled in primary care settings, or an occurrence and aggravation of comorbidities, the primary health care professionals would refer the participants to secondary or tertiary care settings. The conditions of the participants would be re-evaluated within 2 weeks.

Changes in health behavior were available for all participants, and goal-setting was used to formulate their health behaviors. The primary health care professionals developed shared goals with the participants. The targets for changes in health behavior included medication treatment compliance, dietary changes and weight control, control of smoking and alcohol drinking, and exercise engagement. The achievements of the health behavior changes were evaluated at the routine follow-ups. Annual health examinations were available for all patients. The health examinations contained overall physical and bioclinical examinations, as well as lifestyle and medication treatment evaluations.

Outcome Variables

We evaluated the impact of the NEPHSP on blood pressure control in Chinese patients with hypertension through changes in SBP and DBP and changes in the control rates of SBP and DBP. The control rates of SBP and DBP were the proportion of study participants whose SBP and DBP values were in the normal range, respectively. The normal range of SBP and DBP in the Chinese hypertension guideline is defined as <140 mm Hg and <90 mm Hg, respectively [23].

XSL•FO
RenderX

We used the mean blood pressure values at baseline in 2022 and at 4 quarterly follow-up visits in 2023 to depict trends in blood pressure for the patients before and after receiving the NEPHSP services. The baseline values of SBP and DBP were averaged by the blood pressure measurements of the health examinations in 2022. The mean follow-up values of SBP and DBP were averaged by blood pressure measurements of the routine follow-ups. We extracted the blood pressure data from the Residence Health Record System, which recorded the SBP and DBP values measured in the annual health examinations and the regular follow-ups of the NEPHSP participants.

Statistical Analysis

Baseline characteristics of the participants were statistically described. The quantitative variables were described as mean and SD, while categorical variables were described as counts and percentage. The generalized estimating equation (GEE) model was used to analyze the repetitively measured blood pressure data that contained a continuous time variable [24]. The GEE model was capable of analyzing numerical and categorical data that were repetitively measured [24]. Both the trend and degree of the blood pressure changes were analyzed. First, the variable of time was set as the continuous variable to analyze the trend of the blood pressure changes in the GEE models. Linear trend tests were conducted to examine whether the changes in the blood pressure values with the continuous time variation were linear. The linear trend test were reflected by *P* for trend [25,26]. If the changes in the blood pressure values for the continuous time variation were linear, we used the coefficients of GEE models to reflect linear trends of blood pressure changes. Second, we also set the variable of time as the categorical variable to analyze the degree of blood pressure changes in the GEE models. The baseline blood pressure values in 2022 were chosen as the reference group. All statistical analyses were carried out by R software version 4.0.4 (R Core Team). The analysis was performed with 2-tailed tests at an α level of .05.

The covariates were first selected based on evidence of previous studies that had proven the factors that could impact blood pressure [27-34]. Subsequently, we also conducted univariate analyses to confirm whether the covariates had an impact on blood pressure. The following participant characteristics were adjusted as covariates: age, sex, BMI, waist circumference, exercise engagement, alcohol drinking and smoking status, fasting plasma glucose, total cholesterol, triglycerides, low density lipoprotein, high density lipoprotein, baseline SBP and DBP values, diagnosis of cardiovascular and renal diseases, and duration since hypertension diagnosis. The results of univariate analyses and corresponding information of each covariate in the GEE models are described in Multimedia Appendix 1 and Multimedia Appendix 2.

Sensitivity and Stratified Analyses

A series of stratified and sensitivity analyses were conducted to identify whether the changes in blood pressure were different by subgroup. The subgroups were predefined as an older age group (≥65 years old) and younger age group (<65 years old), a male group and female group, a CVD diagnosis group and no CVD diagnosis group, and a baseline controlled SBP group and baseline uncontrolled SBP group. We fit GEE models to assess the changes in blood pressure separately for those subgroups. We then tested the interactive effects between the time variables (continuous time variable) and the subgroup indicators using the total sample, to formally evaluate whether the changes in blood pressure differed between the subgroups.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and approved by the Committee on Human Research of the Jining No. 1 People's Hospital (2023 Ethical Approval No. KYLL-204609‐176). The need for informed consent was waived due to the retrospective nature of this study.

Results

Baseline Characteristics

The baseline characteristics are accessible in Table 1. A total of 516,777 participants were involved in this study. The mean age was 68.59 (SD 9.57) years, 58.56% (n=302,109) of the participants were female, and 66.94% (n=345,923) of the participants were over 65 years old. The mean values for baseline SBP and DBP were 157.12 (SD 19.88) mm Hg and 85.11 (SD 11.79) mm Hg, respectively. The mean values of baseline SBP were above the normal criteria [19]. The control rates of baseline SBP and DBP were 39.79% (205,630/516,777) and 69.21% (357,685/516,777), respectively.

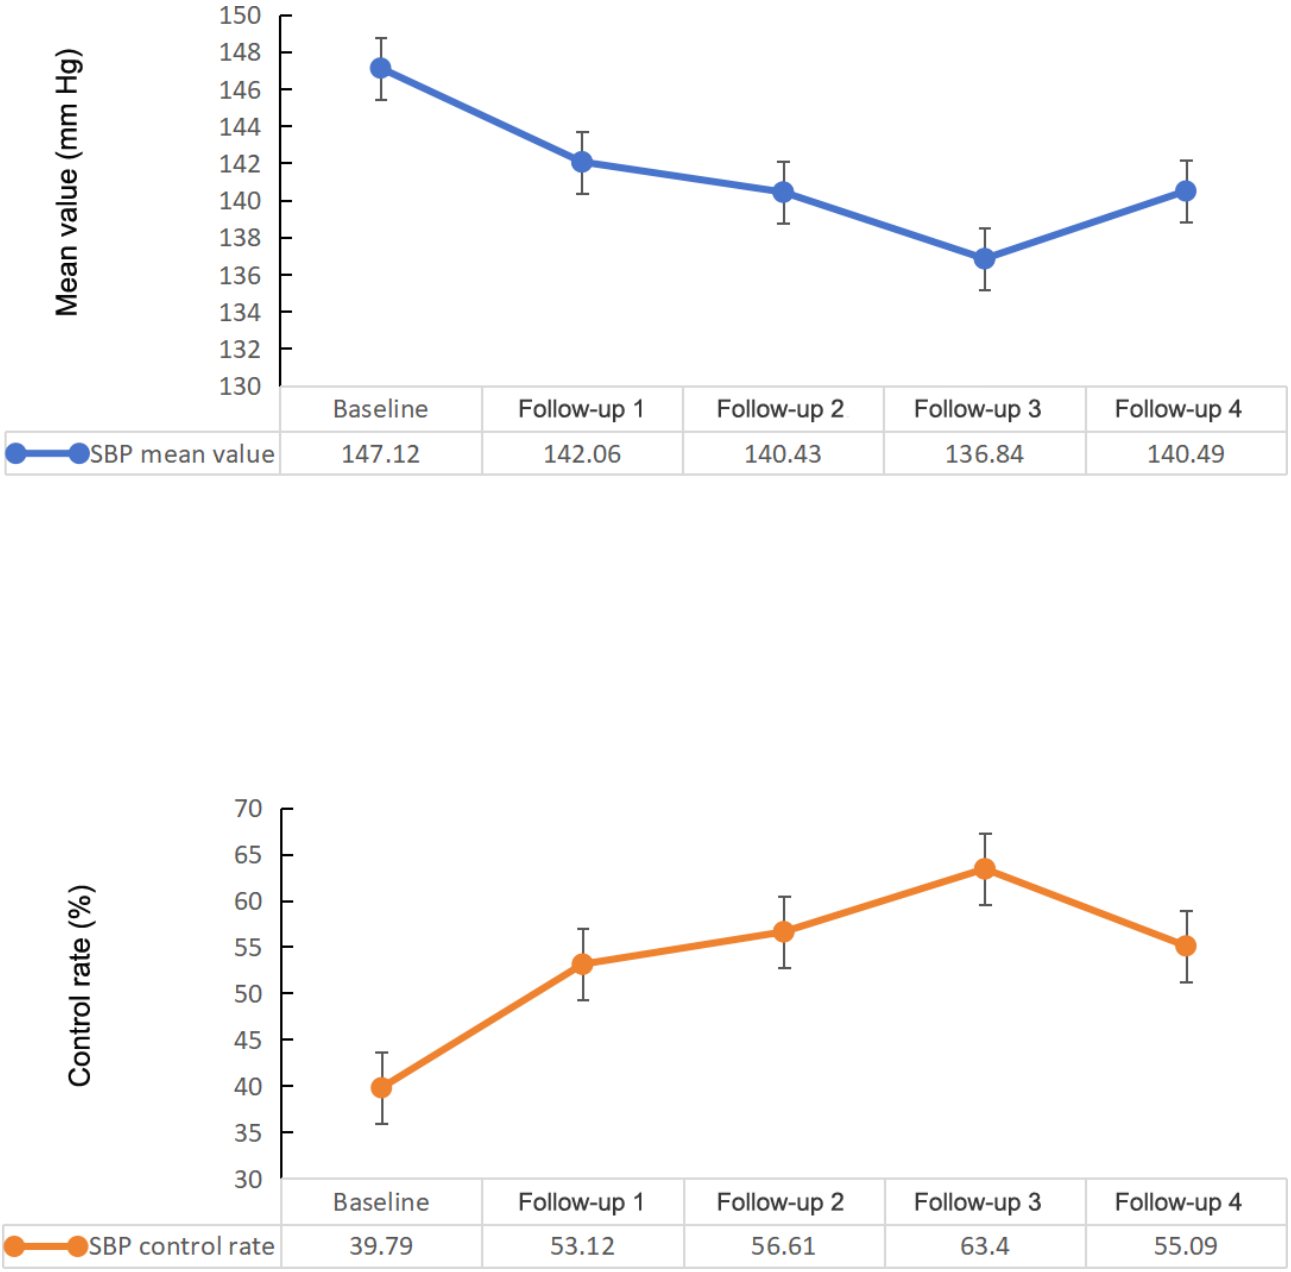
[a]DBP: diastolic blood pressure.



[b]SBP: systolic blood pressure.

Changes in SBP Control

The changes in SBP control are described in Figure 3. The SBP values had a linear change trend with continuous time variation (β coefficient=−1.85, 95% CI −1.86 to −1.93; *P*<.001).

XSL•FO
RenderX

Figure 3. Changes in SBP control. SBP: systolic blood pressure.

The SBP values showed a decreasing trend (Table 2, Figure 3). Compared to baseline, SBP decreased in each quarter by 5.06 mm Hg, 6.69 mm Hg, 10.60 mm Hg, and 6.63 mm Hg (Table 3).

Table . Slopes of the blood pressure changes from baseline to the fourth follow-up.

Variable	β coefficient (95% CI)	*P* value
SBP[a]	−1.85 (−1.86 to −1.93)	<.001
SBP control rate	0.185 (0.183-0.187)	<.001
DBP[b]	−0.77 (−0.78 to −0.76)	<.001
DBP control rate	0.169 (0.166-0.171)	<.001

[a]SBP: systolic blood pressure.

[b]DBP: diastolic blood pressure.

XSL•FO
RenderX

Table . Degree of change in systolic blood pressure (SBP) control.

Appointment	SBP		SBP control rate	
	β coefficient (95% CI)	*P* value	β coefficient (95% CI)	*P* value
Follow-up 1	−5.00 (−5.11 to −5.00)	<.001	0.18 (0.183-0.187)	<.001
Follow-up 2	−6.69 (−6.74 to −6.63)	<.001	0.60 (0.59-0.61)	<.001
Follow-up 3	−10.60 (−10.54 to −10.63)	<.001	0.76 (0.75-0.77)	<.001
Follow-up 4	−6.63 (−6.68 to −6.57)	<.001	1.08 (1.07-1.09)	<.001

SBP control rates for the NEPHSP participants showed an increasing trend (Figure 3, Table 2). Compared to baseline, SBP control rates increased in each quarter to 53.12% (274,493/516,777), 56.61% (292,537/516,777), 63.4% (327,648/516,777), and 55.09% (284,711/516,777; Table 3).

Changes in DBP Control

The changes in DBP control are described in Figure 4. The DBP values had a linear trend with continuous time variation (β coefficient=−1.85, 95% CI −1.86 to −1.93; *P*<.001). The DBP values of the NEPHSP participants showed a decreasing trend (Table 2, Figure 4). Compared to baseline DBP, DBP decreased in each quarter by 1.75 mm Hg, 2.64 mm Hg, 4.20 mm Hg, and 2.64 mm Hg (Table 4).

XSL•FO
RenderX

Figure 4. Changes in DBP control. DBP: diastolic blood pressure.

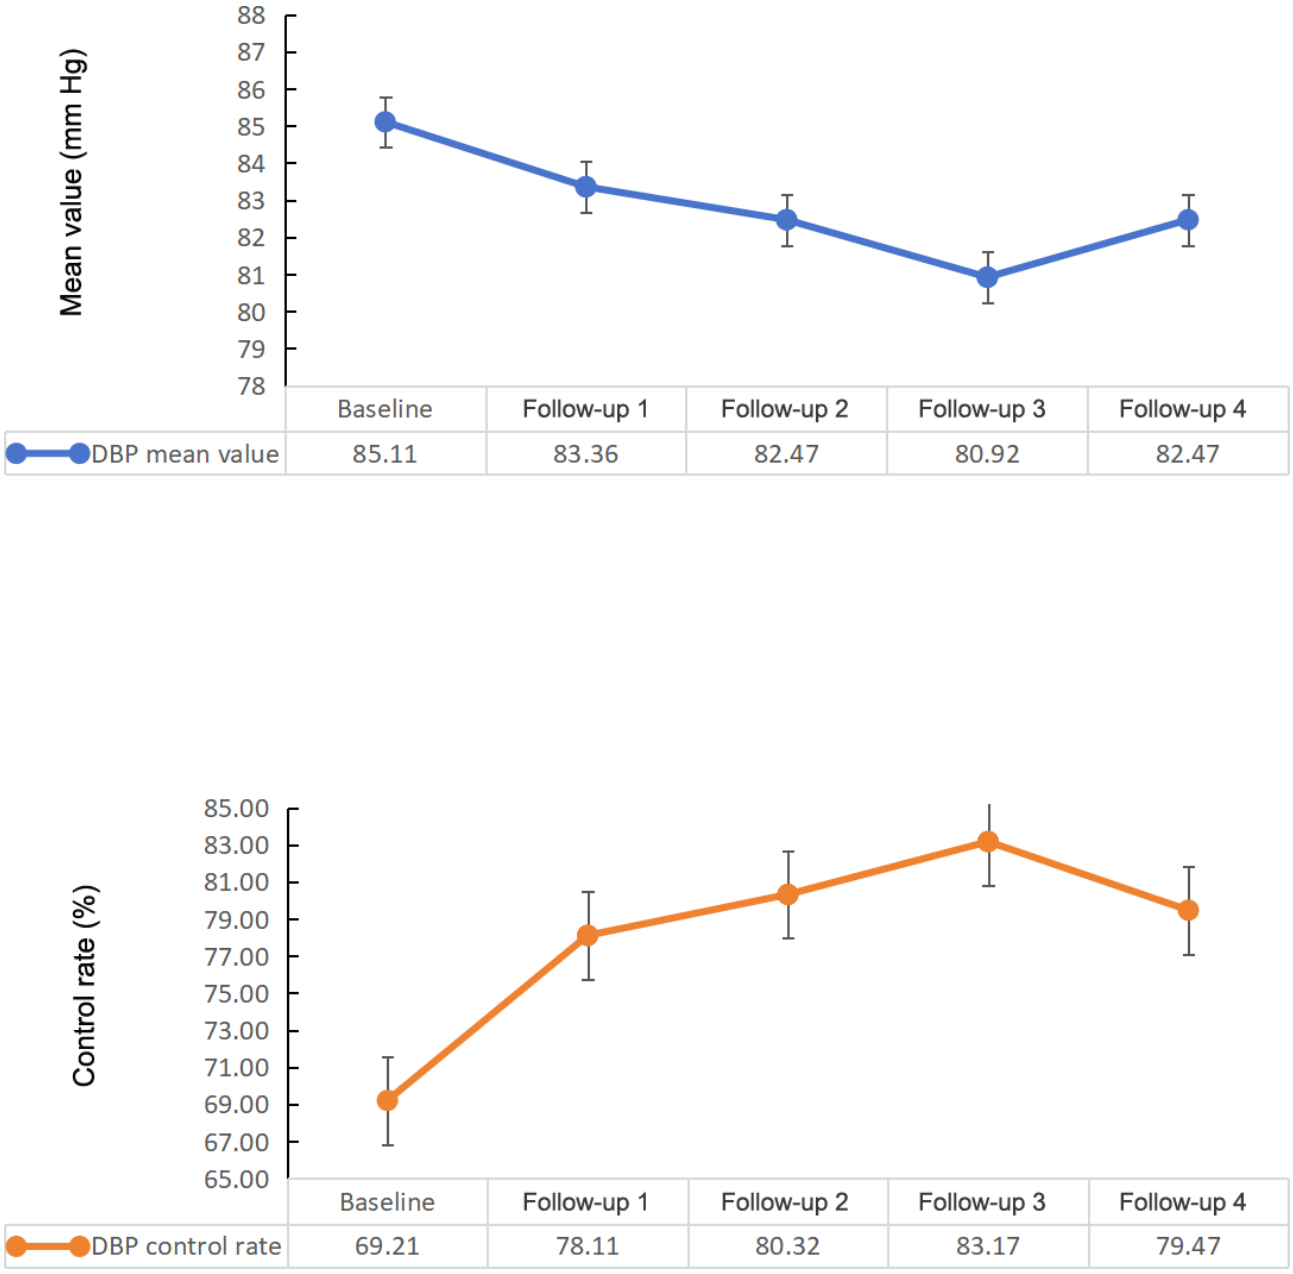


Table . Degree of change in diastolic blood pressure (DBP) control.

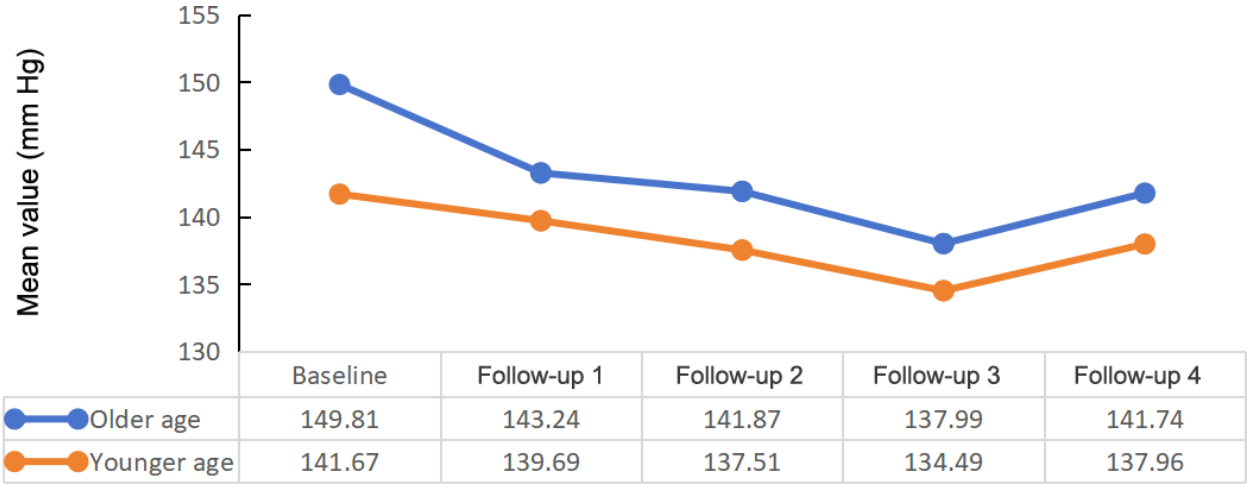
Appointment	DBP		DBP control rate	
	β coefficient (95% CI)	*P* value	β coefficient (95% CI)	*P* value
Follow-up 1	−1.75 (−1.79 to −1.72)	<.001	0.62 (0.61-0.63)	<.001
Follow-up 2	−2.64 (−2.68 to −2.61)	<.001	0.67 (0.66-0.68)	<.001
Follow-up 3	−4.20 (−4.63 to −4.16)	.01	0.89 (0.88-0.90)	<.001
Follow-up 4	−2.64 (−2.68 to −2.61)	<.001	0.61 (0.60-0.62)	<.001

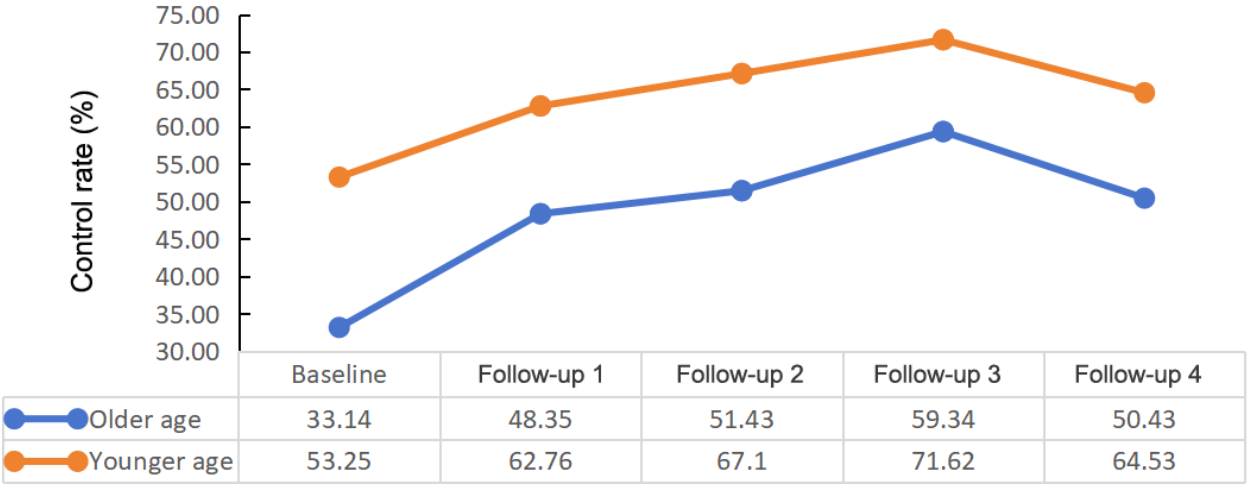
DBP control rates for the NEPHSP participants showed an increasing trend (Table 2, Figure 4). Compared to baseline, DBP control rates increased in each quarter to 78.11% (403,641/516,777), 80.32% (415,062/516,777), 83.17% (429,829/516,777), and 79.47% (410,662/516,777; Table 4).

Sensitivity and Stratified Analyses



Our sensitivity analysis stratified by the predefined subgroups showed that a decrease in blood pressure and an increase in blood pressure control rates were consistent across subgroups of age, sex, and a diagnosis of baseline CVD. The parameters of the sensitivity analysis are accessible in Multimedia Appendix 3. The changes in SBP were converse between the baseline

XSL•FO
RenderX



controlled SBP and uncontrolled SBP groups. The baseline controlled SBP group had an increased control of their SBP, while the baseline uncontrolled SBP group had a decreased control of their SBP. The SBP control rates decreased in the baseline controlled SBP group, while the SBP control rates increased in the baseline uncontrolled SBP group.

The changes in SBP control in the older and younger age groups are described in Figure 5. Compared with younger age group, the older age group showed a larger decrease in SBP and a larger increase in SBP control rates. The SBP of the older age group were higher than the younger age group. The SBP control rates of the older age group were significantly lower than the younger age group (P<.001).

Figure 5. Systolic blood pressure control of the age groups.

	Baseline	Follow-up 1	Follow-up 2	Follow-up 3	Follow-up 4
Older age	149.81	143.24	141.87	137.99	141.74
Younger age	141.67	139.69	137.51	134.49	137.96

	Baseline	Follow-up 1	Follow-up 2	Follow-up 3	Follow-up 4
Older age	33.14	48.35	51.43	59.34	50.43
Younger age	53.25	62.76	67.1	71.62	64.53

The changes in SBP control of the participants with and without CVD were described in Figure 6. The participants with CVD had a smaller decrease in SBP and smaller increase in SBP control rates than the participants without CVD. The SBP control rates of the participants with CVD were significantly lower than the participants without CVD (P<.001).

Figure 6. Systolic blood pressure control of the cardiovascular disease group.

	Baseline	Follow-up 1	Follow-up 2	Follow-up 3	Follow-up 4
Cardiovascular group	28.42	38.7	40.13	44.66	38.01
Non-Cardiovascular group	40.03	53.11	57.08	64.06	56.01

The stratified analysis by sex demonstrated that the decrease in SBP values and the increase in SBP control rates were greater in the female group than in male group; however, the differences were relatively small.

Discussion

Principal Findings

To our knowledge, this is the first study that longitudinally explored effect of the NEPHSP on blood pressure control. The study findings demonstrated that the NEPHSP was effective for improving SBP and DBP control. The NEPHSP decreased the values of SBP and DBP and increased the control rates of SBP and DBP.

The routine follow-up that monitored blood pressure and the individualized interventions of the NEPHSP might contribute to the improvement of SBP and DBP control. The routine follow-ups generated clinically crucial data that could recognize prioritization of the participant subgroups who had poorly controlled blood pressures [35]. Previous studies also reported that the regular population review that enables the formulation of customized interventions for improving blood pressure control is an effective strategy for hypertension management [35-48]. Individualized interventions were formulated according to the evaluations of routine follow-ups to identify appropriate strategies to improve blood pressure control in participants with poorly controlled blood pressure [35,36,47].

Although the NEPHSP improved the control of blood pressure, the mean values of SBP were still slightly higher than the normal criteria. This might be caused by therapeutic inertia [33]. Therapeutic inertia was defined as a failure of health care professionals to initiate or intensify treatment appropriately during visits [33,49]. Previous research demonstrated that the failure to appropriately initiate or intensify treatment was introduced by the perspective of health care professionals that near-target blood pressures were acceptable and the overconcern about adverse effects caused by treatment intensification [47,48,50,51]. Because of the doctor-related factors leading to therapeutic inertia, participants with near-target blood pressures might not accept intensification of antihypertensive treatments, which could contribute to the slightly higher values of blood pressure [47,48,50,51]. Although therapeutic inertia is associated with poor blood pressure control and cardiovascular events, therapeutic inertia is common in hypertension management in primary care settings [47,48,51]. Given this situation, interventions for handling therapeutic inertia are important for improving hypertension management in primary care settings [33,47,48,51]. However, in terms of the NEPHSP, no component for tackling therapeutic inertia were embedded. The relevant components addressing therapeutic inertia can be considered for inclusion in the NEPHSP [33].

The subgroup analysis showed that the older participants had greater blood pressure improvement compared to the younger participants. This finding might be relevant to the referral mechanism of the NEPHSP. Compared with younger patients with hypertension, older patients with hypertension have more complex health conditions, such as frailty, comorbidities, and polypharmacy [34,52-58]. These complex health conditions can introduce challenges for blood pressure control in primary care settings, which are positively associated with poor blood pressure control [34,52-58]. To improve poor blood pressure control in older patients with complex health conditions in primary care settings, a referral mechanism to superior medical institutions is important [34,46,47,57-59]. In terms of the NEPHSP, the older participants with complex health conditions and poor blood pressure control were recognized via the regular follow-up evaluations. Based on the health condition evaluations of the regular follow-ups, the older participants could accept more referrals to superior medical institutions than the younger participants. Through the referral to superior medical institutions, the older participants could receive more intensive antihypertensive treatments than the treatments in primary care settings [34,46,47,57-59]. Because of the intensive antihypertensive treatments provided in superior medical institutions, the older participants had more blood pressure control improvement than the younger participants [34,46,47,57-59].

Although older participants had a greater improvement in blood pressure control than younger participants, the SBP of the older participants were still higher than the younger participants.

XSL•FO
RenderX

Moreover, the SBP control rates for the older participants were significantly lower than the younger participants. These study findings might be associated with concerns about adverse events caused by blood pressure–lowering pharmacotherapy [33,34,45-58]. However, previous robust research evidence demonstrated that decreasing the blood pressures of older adults to normal range is safe and effective for reducing risks of cardiovascular events [59,60]. Consequently, older people with hypertension should have a similar attitude toward blood pressure control as younger people with hypertension [59,60]. Given this situation, strategies to intensify blood pressure control in older participants engaging in the NEPHSP are necessary [59,60].

The improvement in the blood pressure control for the participants with CVD was less than the participants without CVD, while blood pressure control for people with hypertension and CVD needs to be more intensive than people with hypertension but without CVD [60]. Similar to the older participants, the patients with hypertension with CVD also required more referrals to superior medical institutions to achieve optimal blood pressure control [61-66]. Compared to patients with hypertension without CVD, the patients with CVD demand more intensive blood pressure control to prevent cardiovascular events, and blood pressure control in patients with hypertension and CVD is challenging in primary care settings [61-66]. The main challenges are potential adverse drug effects caused by polypharmacy and emergent cardiovascular events caused by intensive antihypertensive treatments [61-66]. Given this situation, referral to superior medical institutions is necessary for patients with hypertension and CVD to achieve optimal blood pressure control via intensive and safe antihypertensive treatments [61-66].

Although the NEPHSP had the algorithm to evaluate health conditions of the participants with comorbidities and subsequent referral mechanism to superior medical settings, the improvement of blood pressure control in the participants with CVD was still less than the participants without CVD. The lesser improvement in blood pressure control in the participants with CVD could be caused by the health evaluations of the regular follow-ups. The health condition evaluations might fail to accurately assess the health conditions of the participants with CVD, as the evaluations did not have systematic tools such as checklists, which could lead to failure to refer the participants who needed referral [61-66]. Furthermore, no explicit criteria for referral of participants with CVD were predefined, which could lead to confusion for the primary health care professionals when making the decisions on referral [61-66]. Given that the blood pressure control in people with hypertension and CVD needs to be more intensive than people without CVD, strategies for intensifying blood pressure control in the NEPHSP participants with CVD should be considered [61-66].

The subgroup analysis showed that the participants with controlled SBP at baseline had an increase in SBP and a decrease in SBP control rates, which were converse to the SBP results of all study participants. These results could be associated with the health evaluation algorithm of the regular follow-ups of the NEPHSP. According to the health evaluation algorithm, the participants who had controlled blood pressures that were evaluated in the regular follow-ups would not accept specific interventions. Because specific interventions were not provided, the participants with controlled SBP at baseline could have an increase in SBP and a decrease in SBP control rates. Although SBP of the participants was controlled at baseline, the increase of SBP values within the normal range could also increase CVD events [58]. Given this situation, the health evaluation algorithm and interventions of the NEPHSP for the participants with controlled SBP at baseline were suggested to be reformulated [58-61].

Blood lipid and glucose control could impact hypertension management. Previous studies reported that the triglyceride-glucose index (TyG), which is calculated by multiplying fasting triglyceride by fasting glucose, had a positive relationship with blood pressure control [31,32,61,62]. The increase of the TyG could contribute to poor blood pressures control [31,32,61,63]. A linear dose-response relationship between changes in the TyG and the change in blood pressure was identified [31,32,62,63]. To achieve optimal blood pressure control, blood lipid and glucose should be concurrently managed in people with hypertension [31,32,62,63]. However, in terms of the NEPHSP, no treatment targets for blood lipid and glucose were predefined for the study participants, which might cause ignorance toward blood lipid and glucose control. The ignorance of blood lipid and glucose control might cause a high TyG, which could contribute to the near-target blood pressure levels in this study [31,32,62,63]. Given this situation, further studies are required to confirm whether blood lipid and glucose control impact blood pressure control of the NEPHSP participants, in order to clarify the target for improving blood pressure control in this population.

Limitations

This study had several limitations. Although the effects of the NEPHSP on blood pressure control were modest, this study could not confirm the factors impacting blood pressure control of the NEPHSP. The group divisions for subgroup analysis were general and not explicit. Further studies that include a gradient group division to explore factors impacting hypertension control of NEPHSP are needed. Randomization for group division was not applied in the subgroup analysis, which could lead to an uneven distribution of confounding factors. Further studies that use randomization or matched group division are need to confirm the factors impacting hypertension control of the NEPHSP. This study explored baseline characteristics that could impact hypertension control of the NEPHSP, and future studies exploring the impact of the factor trajectories on hypertension control are needed. In addition, this study evaluated NEPHSP in a pilot city, and further nationwide studies are needed.

The blood pressure data in this study were the clinical records obtained from routine blood pressure measurements that were conducted via the Riva-Rocci and Korotkoff techniques [64-66]. The Riva-Rocci and Korotkoff techniques are still considered a cornerstone in evaluation of blood pressure levels in clinical trials [64-66]. However, the techniques have limitations, including that they can provide only a limited number of blood pressure values and can not reflect blood pressure fluctuations over 24 hours [64-66]. As a result, potential influences of blood

XSL•FO
RenderX

pressure fluctuations over 24 hours in our study findings were uncertain [64-66]. Further studies that use advanced devices such as ambulatory blood pressure monitoring to explore impacts of 24-hour blood pressure fluctuations on effects of the NEPHSP on blood pressure control are required. Despite the uncertainty of impacts of 24-hour blood pressure fluctuations, our study findings also provide preliminary evidence for the control of blood pressure by the NEPHSP. First, our study was conducted at population level. The large scale of the study participants might reduce the impact of 24-hour blood pressure fluctuations on the changes in blood pressure levels to some degree. Second, the follow-up time was one year for this study, which could offset the impact of blood pressure fluctuations over 24 hours.

This study was designed as a self-controlled longitudinal study. We compared blood pressure levels before the participants accepted health services from the NEPHSP versus after accepting the health services. The changes in blood pressure levels could preliminarily reflect the effect of the NEPHSP on blood pressure control for the participants with hypertension. However, the data monitoring blood pressure changes were only available for the NEPHSP participants and were inaccessible for people with hypertension who did not register with the NEPHSP. Because of the inaccessibility of blood pressure monitoring data for this population, this study was unable to compare blood pressure control between the NEPHSP participants and people who did not register with the NEPHSP. Given this situation, further cohort and control trials are required to confirm advantages of the NEPHSP.

Conclusion

The NEPHSP was effective for improving blood pressure control of Chinese people with hypertension. However, the SBP of the study participants was near-target, which could imply therapy inertia in the NEPHSP participants. A suggested strategy to tackle potential therapy inertia was to intensify blood pressure control of the NEPHSP. The effects of the NEPHSP on blood pressure control in older participants and participants with CVD were modest. Embedding intensive treatment modules into the NEPHSP was suggested to improve blood pressure control of older participants and participants with CVD. Further studies confirming effects of the NEPHSP on blood pressure control for people with specific characteristics, such as older age and comorbidities, are required.

Acknowledgments

We are grateful to all the staff who participated in this research survey.

Abstract

Background: COVID-19 ended on May 5, 2023, and since then Hong Kong reported increased mental distress, which was speculated to be from the policies implemented during the pandemic. Despite this, longitudinal surveillance of deliberate self-harm (DSH) incidences throughout the pandemic in Hong Kong remained insufficient.

Objective: The objective of this study was to outline the changes in DSH incidences before and during the COVID-19 pandemic in Hong Kong, with respect to sex, age, and co-occurring mental health issues.

Methods: A quasi-experiment was conducted using an interrupted time series design to estimate the impact of the pandemic on DSH-related emergency department (ED) visits. This design enabled the estimation of DSH-related ED visits based on prepandemic data from 2016 to 2019, assuming the pandemic had not occurred, and allowed for a comparison with observed DSH-related ED visits during the pandemic. The descriptive results were reported as the observed monthly DSH-related ED visits and observed incidence ratios during the pandemic. Afterwards, a negative binomial model was fitted to the prepandemic data (2016 - 2019) and adjusted for temporal trends, seasonality, and population variation to estimate the expected monthly DSH-related ED visits and adjusted incidence ratios (aIRs).

Results: Between January 2016 and December 2022, a total of 31,893 DSH episodes were identified. Initial descriptive analysis showed a significant difference in demographic characteristics (sex) and clinical characteristics (death within 28 d, diagnoses of co-occurring mental health issues, public assistance pay code, and triage level). Subsequent interrupted time-series analysis demonstrated significantly increasing trends in comparison with the prepandemic period. As reported in the aIRs among young adult males (aIR in 2020=1.34, *P*=.002; 2021: aIR=1.94, *P*<.001; and 2022: aIR=2.53, *P*<.001), adult males (aIR in 2020=1.58, *P*<.001; 2021: aIR=2.64, *P*<.001; and 2022: aIR=3.13, *P*<.001), adult females (aIR in 2020=1.13, *P*=.01; 2021: aIR=1.52, *P*<.001; and 2022: aIR=1.64, *P*<.001), and older male adults (aIR in 2020=1.53, *P*<.001; 2021: aIR=2.37, *P*<.001; and 2022: aIR=3.01, *P*<.001).

XSL•FO
RenderX

Conclusions: The average annual DSH-related ED visits increased during the pandemic period. Therefore, there is a need to raise awareness for such vulnerable groups in Hong Kong to prepare for postpandemic spillover.

emergency department; COVID-19; deliberate self-harm; mental health; self-harm; self-injury; self-violence; Hong Kong; SARS-Cov-2

Introduction

During the early phase of COVID-19 pandemic, Hong Kong experienced a significant increase in mental health distress within the community [1-3]. Surveys indicated that an alarming 53.9% (299/555) of participants exhibited moderate to very high levels of psychological distress [4]. In response, the Hong Kong Chief Executive allocated HK $300 million (the conversion rate at the latest revision date of the Chief Executive's 2020 policy address [November 25, 2020] was US $0.129 per unit HKD) to raise mental health awareness [5]. An advisory committee subsequently developed a comprehensive, community-based initiative. This initiative included an education and health promotion program called "Shall We Talk," emotional support workshop training for school staff, mental health first aid training for service professionals, and the deployment of suicide bereavement liaison officers. Despite these efforts, there were ongoing concerns about the sustainability of these resources [6].

The association between stress and deliberate self-harm (DSH) was well-documented in the literature [7-11]. However, recent local studies on DSH risk factors, conducted before the pandemic, identified factors such as sex, age, social welfare status, and co-occurring mental health disorders (ie, depression, bipolar disorder, personality disorder, and substance misuse) [12]. The literature from other countries on this topic is limited and sometimes contradictory, with mixed definitions of self-harm and varying conclusions about youth as a risk factor [13-17]. This highlights the need for longitudinal surveillance to better understand the pre-existing risk factors of DSH.

One of the major challenges in emergency departments (EDs) is reducing waiting times without compromising the quality of health care, which includes preventing readmission and reducing health care costs. The Hospital Authority in Hong Kong has pledged to limit the waiting time for emergency (triage category 2) patients to 15 minutes, and for urgent (triage category 3) patients to 30 minutes [18]. However, by May 2022, over 1500 patients were still waiting for admissions in ED [19]. This underscores the necessity for effective health policies to manage DSH-related ED visits.

The aim of this study was to describe the impact of COVID-19 on DSH incidences in Hong Kong through a longitudinal analysis of DSH-related ED visits before and during the pandemic. This study was stratified by sex, age, and co-occurring mental health issues. The findings from this study justify the need for further surveillance to monitor a possible spill-over effect post the COVID-19 pandemic.

Methods

Study Overview and Settings

This territory-wide cohort study analyzed data from January 2020 to December 2022, which was further categorized into pandemic months (January 2020 to December 2022) and the prepandemic months (January 2016 to December 2019).

Data Sources and International Classification of Diseases, Ninth Revision, Clinical Modification Codes

Data were sourced from the Clinical Data Analysis and Reporting System (CDARS), an administrative clinical database managed by the Hospital Authority of the Hong Kong Special Administrative Region of China [20], encompassing ED data from 18 public hospitals.

DSH and mental health issues were identified using both nursing codes for self-inflicted injury and the *ICD-9-CM* (*International Classification of Diseases, Ninth Revision, Clinical Modification*) diagnosed by clinicians (Table S1 in Multimedia Appendix 1).

In addition, yearly and midyearly population counts for sex and age groups were obtained from the government in Hong Kong [21].

Outcome Measures

This study defined DSH according the National Institute for Clinical Excellence guidelines, which describe it as "self-poisoning or injury, irrespective of the apparent purpose of the act" [22]. This guideline was adopted due to the absence of patients' intent in the medical records from CDARS.

Other key definitions included age groups, public assistance pay codes, triage categories, and mental health issues. Age was categorized into teenagers (12 - 17 y), young adults (18 - 24 y), adults (25 - 64 y), and older adults (65 - 84 y). Public assistance pay codes referred to the recipients of the Hospital Authority medical fee waiver schemes (Residential Care Service Voucher, Comprehensive Social Security Assistance, and Old Age Living Allowance) [23]. Triage categories 1 to 3 were defined in Table S2 in Multimedia Appendix 1 [18]. Mental health issues included mood disorders, neurosis, alcohol and drug-associated mental health conditions, and other psychotic illnesses and developmental disorders. These diagnoses were identified by *ICD-9-CM* codes, as defined in Table S1 in Multimedia Appendix 1.

Data Analysis

First, a descriptive analysis of the outcome measures was conducted to identify statistical significance before and during

XSL•FO
RenderX

COVID-19. Fisher exact and Mann-Whitney *U* tests were used to compare DSH incidences, sex, age groups, and co-occurring mental health issues.

Next, a quasi-experiment was conducted using an interrupted time series (ITS) design to estimate the impact of the COVID-19 pandemic on DSH-related ED visits. Quasi-experiments estimate causal relationships between different factors and outcomes when random assignment is not possible. The ITS design enabled the estimation of DSH-related ED visits during the pandemic period (2020 to 2022) based on prepandemic data (2016 to 2019). This allowed for a comparison between the observed DSH-related ED visits and the expected DSH-related ED visits in the absence of the pandemic.

Segmented regression is a method commonly used in ITS, typically involves assuming linear trends and identifying significant break points. Given the complexity of COVID-19's impact on self-harm ED visits, a nonsegmented regression model was chosen, fitted with prepandemic data instead of a segmented-regression model fitted with all data. Self-harm–related ED visits were aggregated into monthly counts to ITS analysis for each group. This analysis was done by fitting prepandemic data to the negative binomial models, with a linear term for trend, and optionally with Fourier terms to account for seasonality, using population terms as an offset. The candidate models can be described by:

$$E[y]=\exp(\beta_0+\beta_{trend}x+\sum_{k=1}^{n}[\beta_{1,k}\sin(2\pi kxt/12)+\beta_{2,k}\cos(2\pi kxt/12)])population$$

Or

$$E[y]=\exp(\beta_0+\beta_{trend}\cdot xt)\cdot population$$

The dependent variable y represents the monthly count of self-harm incidents for a particular subgroup. Where xt is the number of months from the start of the study period, n is the highest degree of Fourier terms, $\beta_0\beta_{trend}$ is the prepandemic slope of incidence rate, $\beta_{1,k}\beta_{2,k}$ are coefficients for seasonality. The inclusion of the Fourier term and its degree n were guided by the Akaike Information Criterion (AIC). The final model is the one with the minimal AIC value, ensuring the best balance between model fit and complexity.

The findings from this study were presented as observed incidence ratio (oIR) and adjusted incidence ratio (aIR). The respective formulas were as follows:

$$oIR=\frac{Observed\ annual\ DSH\text{-}related\ ED\ visits}{Prepandemic\ annual\ DSH\text{-}related\ ED\ visits}$$

$$aIR=\frac{Observed\ annual\ DSH\text{-}related\ ED\ visits}{Expected\ annual\ DSH\text{-}related\ ED\ visits}$$

In the formulas, the expected annual DSH-related ED visits were estimated using negative binomial models and accounted for trends, seasonal variations, and population changes. Annual counts were estimated by summing monthly counts, assuming the population remained constant. The aIR compares the observed number of DSH-related ED visits during the pandemic to the expected number based on prepandemic data, providing an estimate of the COVID-19 pandemic's impact on DSH-related ED visits. Time series graphs were then generated to illustrate these trends. All *P* values less than .05 were considered statistically significant. All statistical analyses were performed using RStudio (version 4.1.0; R Foundation for Statistical Computing).

Ethical Considerations

The study protocol received approval from the institutional review board of the Hospital Authority, Hong Kong West Cluster (reference UW 20 - 112; Multimedia Appendix 2). Informed consent was waivered, and all the data were anonymized.

Results

Overview

A total of 31,893 cases of DSH-related ED visits were identified during the study period. Initial descriptive analysis compared demographic characteristics between the prepandemic and pandemic periods (Table 1). The total number of ED visits with DSH increased by 1175 out of 15,359 (7.7%) patients. There were significantly higher DSH-related ED visits in males (*P*<.001), co-occurring mental health issues diagnosis (*P*<.001), triage category 3 (urgent), and 4 (semiurgent) (*P*<.001) during the pandemic. Conversely, there were significantly less deaths within 28 days (*P*<.001) and less patients with public assistance pay code during the pandemic (*P*=.046). These trends were further explored with subgroup analysis using ITS models (Table 2, Figures 1-8). Further subgroup analysis of co-occurring mental health issues diagnoses were explored in Table S2 in Multimedia Appendix 1.

Teenagers

For teenage females, the oIRs and aIR showed no difference (2020: *P*=.98, 2021: *P*=.27, and 2022: *P*=.95), as reflected by the overlap of the expected and observed trends (Figure 1).

For teenage males, the aIRs showed no difference (2020: *P*=.70, 2021: *P*=.07, and 2022: *P*=.21), as highlighted by the overlap of the observed and expected trends during the study period (Figure 2). However, the aIRs among those with alcohol and drug-associated mental health conditions were significantly different and increased during the pandemic (2020: *P*=.01, 2021: *P*=.01, and 2022: *P*=.02).

Young Adults

For female young adults, the observed trend was higher than expected during the pandemic (Figure 3). The highest aIR were observed among those with alcohol and drug-associated mental health conditions, with significant difference (2020: *P*=.008, 2021: *P*=.001, and 2022: *P*=.001).

For male young adults, the aIRs between 2020 and 2022 all significantly increased during the pandemic (2020: *P*=.002, 2021: *P*<.001, and 2022: *P*<.001). Further illustrated when the observed trend was higher than the expected trend during the pandemic (Figure 4). Those with alcohol and drug associated mental health conditions had the highest aIRs with statistical significance (2020: *P*=.001, 2021: *P*<.001, and 2022: *P*<.001).

Adults

The aIRs among adult females significantly increased during the pandemic (2020: *P*=.01, 2021: *P*<.001, and 2022: *P*<.001). This was highlighted when the expected trend decreased while the observed trend increased during the pandemic (Figure 5). The highest aIRs were seen in patients with co-occurring alcohol and drug associated mental health conditions with statistical significance (2020: *P*<.001, 2021: *P*<.001, and 2022: *P*<.001).

For adult males, the aIRs significantly increased during the pandemic (2020: *P*<.001, 2021: *P*<.001, and 2022: *P*<.001). As illustrated when the expected trend decreased while the observed trend increased during the pandemic (Figure 6). Significantly highest aIRs were observed among those with co-occurring alcohol and drug associated mental health condition (2020: *P*<.001, 2021: *P*<.001, and 2022: *P*<.001).

XSL•FO
RenderX

Older Adults

During 2021 and 2022, older female adults with mental health issues exhibited significantly higher aIRs (2021: *P*=.02, 2022: *P*=.002). These rates were elevated compared with the expected levels during 2021 and 2022 but declined during 2020 (Figure 7).

For older male adults, the aIRs significantly increased throughout the pandemic period (2020: *P*<.001, 2021: *P*<.001, and 2022: *P*<.001). Further underscored by the divergence between the decreasing expected rates and the increasing observed rates during the pandemic (Figure 8). The most pronounced aIRs with statistical significance were among found in older male adults with co-occurring alcohol and drug associated mental health conditions (2020: *P*<.001, 2021: *P*<.001, and 2022: *P*<.001).

Discussion

Principal Results

The findings from this study revealed differences in DSH incidences before and during the pandemic, with a notable rise among males and individuals with co-occurring alcohol and drug-related mental health issues.

Previous studies conducted before the pandemic also reported higher rates of DSH among males, which contrasts with the trends observed during our study period [12,24]. This discrepancy may be influenced by cultural factors [12]. For instance, past research has shown that while Chinese males in Hong Kong demonstrate health-seeking behavior, they often hesitate to consult doctors, preferring over-the-counter medications instead [25]. Such tendencies could be exacerbated by the mental distress linked to the isolation policies, as noted in another Hong Kong-based study [26]. However, further research is essential to elucidate the impact of COVID-19 policies on the rising incidences of male DSH in Hong Kong.

In addition, the increased incidences of DSH among individuals with alcohol and drug-related mental health issues observed in this study align with local government reports. The Narcotics Division of the Security Bureau in Hong Kong reported a surge in the use of cocaine, cannabis, ketamine, and heroin combined with methamphetamine during the pandemic [27]. In April 2020, the Centre of Health Protection in Hong Kong also noted a 5.5% increase in alcoholic consumption since the outbreak [28]. This increase in substance use may have been fueled by misinformation circulated on social media, suggesting that alcohol or smoking could protect against COVID-19 [29]. Despite the well-established link between self-harm and substance misuse [30], further research is needed to determine the association between these behaviors and COVID-19 policies.

Several additional patterns emerged from this study. First, there was a decline in DSH-related ED visits in early 2020 and 2022 as well as peaking staying times (Multimedia Appendices 3-6), consistent with the findings from both local and international studies [31-33]. This decline may be attributed to the stigma surrounding mental health issues, which can complicate health-seeking behavior, delay necessary care, and result in more severe DSH presentation requiring readmission to the ED [32,34]. Second, a significant decrease in patients requiring social security suggests that patients performing DSH may come from higher socioeconomic backgrounds. However, socioeconomic profiles varied across epidemic waves [35], indicating the need for further research to validate these findings. Finally, patients performing DSH might have been triaged to less urgent categories due to the changes in ED policies aimed at managing overcrowded cases of infection. These additional findings suggest that patients performing DSH had reduced access to health care services during COVID-19, potentially leading to worsening conditions and long-term repercussions postpandemic.

Given the empirical evidence from this study and existing literature, continued surveillance post the COVID-19 pandemic is essential to determine whether a spillover effect occurred. This need is particularly pressing in light of recent changes in the Hong Kong government's policies such as the announcement of a liquor tax cut to promote trade in 2024 [36]. Ongoing research and surveillance will be crucial in developing targeted interventions, guiding policy-making, and enhancing mental health services. By closely monitoring these trends, we can better address the mental health challenges posed by the pandemic and its aftermath, ultimately improving outcomes for vulnerable populations.

Strengths and Limitations

This study has several strengths and limitations. A major strength was the large sample size, which enhances reliability of the findings. In addition, the trend, seasonal, and population factors were adjusted for in the ITS analysis. However, there are notable limitations as well. The absence of data from outpatient and private clinics may reduce the generalizability of our results. Furthermore, the use of *ICD-9-CM* codes to identify DSH cases could compromise the accuracy of our findings, as later versions of the *ICD* (*International Classification of Diseases*) included more specific codes for DSH, but only *ICD-9-CM* was available on CDARS. Also, the data captured patients who presented to the ED with DSH, but neglected those not admitted through the ED. Another limitation is the lack of consideration for other potential confounding variables, such as the changing social conditions in 2019. In addition, the use of linear interpolation to adjust population counts may introduce bias, as population changes during the pandemic could affect the results.

Conclusion

The results indicate increasing adjusted DSH incidence ratios among males and individuals with alcohol and drug-related mental health conditions. This underscores the need for continued surveillance beyond the COVID-19 pandemic to determine if there is a spill-over effect. Importantly, all stakeholders—including policy makers, psychiatrists, and health care professionals—should collaborate to raise awareness and provide support for these vulnerable groups in Hong Kong. Targeted interventions and policies are essential to address the mental health challenges exacerbated by the pandemic and ensure better outcomes for those affected.

Abstract

Background: Poor vision is a challenging public health problem among children and adolescents globally and in China. It is well-recognized that early onset of poor vision and progressing to moderate and severe poor vision will increase the risk of irreversible blinding complications. To achieve the national goal of poor vision control and prevention, it is essential to investigate and understand the development of poor vision among children and adolescents in China.

Objective: This study aims to investigate the progression of poor vision among children and adolescents in Wuhan, China, based on a prospective cohort and to provide scientific evidence for the development and implementation of effective poor vision prevention and control programs.

Methods: Data were derived from a 4-year prospective cohort (2016 - 2019) of primary and middle school students (N=108,585) in Wuhan, China. Vision condition was measured using the standard logarithmic visual acuity charts. A group-based trajectory model was used to identify trajectories of poor vision overall and by gender and region.

Results: The mean age of the study subjects was 11.13 (SD 3.33) years, 200,110 (53.91%) were male and the majority (354404, 95.48%) were from urban areas. The prevalence of poor vision was 58.51% in 2016, 58.95% in 2017, 53.83% in 2018, and 54.79% in 2019. Group-based trajectory model identified 3 groups, including normal vision group (NVG) (27.4%), vision decline group (VDG) (17.8%), and moderate poor vision group (MPVG) (54.8%). A higher proportion of girls (57.8%) were in the MPV group compared to boys (50.5%), and the VDG showed greater changes in girls compared to boys. Furthermore, urban students (55.3%) had a higher proportion of MPV compared to rural students (47.5%), while urban students (17.2%) had a smaller proportion in the VDG compared to rural students (24%). Further analyses showed that as age increased, the likelihood of being categorized in the NVG decreased (β=−.417, *P*<.001), while the likelihood of being in the VDG (β=.058, *P*<.001) increased. Compared with boys, girls were more likely to be categorized in the VDG (β=.597, *P*<.001) and MPV group (β=.362, *P*<.001). Rural students were less likely than urban students to be categorized in the VDG (β=−.311, *P*<.001).

Conclusions: The prevalence of poor vision among children and adolescents in Wuhan has remained high over the years, with a slight decrease in recent years. The study identified three groups: normal vision, vision decline, and moderate poor vision. Girls and students from urban areas were more likely to have moderate poor vision, while boys and rural students had a higher proportion of vision decline. These findings provide valuable information for implementing poor vision prevention and control policies in the region.

Introduction

With the increasing prevalence of poor vision among children and adolescents in recent years, vision problems have been recognized as a major public health challenge globally in the 21st century [1] and in China [2]. Childhood and adolescence are well-accepted as the most vulnerable periods for poor visual development. Visual acuity reaches its full development by approximately 8 years of age, while visual cortex plasticity begins to diminish from the age of 2 years onward [1]. Poor vision can exert significant psychological, educational, and social impacts on children and adolescents, including psychological distress [3], perceived barriers [4], and poor academic achievement [5]. One systematic review and meta-analysis indicated that approximately one-third of children and adolescents were affected by myopia worldwide, and the number was projected to 740 million by 2050 [6] . Another review reported the prevalence of poor vision in children and adolescents as 7.26%, 7.34%, and 2.91% based on uncorrected visual acuity, presenting visual acuity and best corrected visual acuity, respectively, with refractive errors being the most common cause [7].

Compared with other countries, children and adolescents in East Asia reported a higher prevalence of poor vision. For example, data from a literature review indicated that the estimated prevalence of myopia among adolescents in East Asia was 69%, far greater than 16.7% in White adolescents and 14.3% in Hispanic or Latino adolescents [8]. Further, it is well-known that children and adolescents in China experience a significant burden of poor vision. Findings from a systematic review showed that studies from China reported a much higher prevalence of poor vision than those from other countries (13.33% - 41.17% in China vs 1.34% - 29.42% in other countries) [7]. Data from Chinese government indicated that the myopia rate among children and adolescents was 53.6% in 2018,decreased to 50.2% in 2019, and reversed to 52.7% in 2020 [9]. Additionally, data from a review showed that the prevalence of vision impairment in China increased from 19% at age 6 years to 66.9% at age 17 years [10]. To achieve the national goal of controlling and preventing poor vision, it is essential to investigate and understand its development among children and adolescents in China.

It is well-recognized that progression to moderate and severe poor vision increases the risk of irreversible blinding complications, such as retinal detachment, glaucoma, and myopic maculopathy [11]. Previous studies have shown that individuals with early-onset poor vision are at a higher risk of progressing to severe poor vision and vision impairment [12-14]. Therefore, it is valuable to identify the trends of poor vision progression among children and adolescents. However, to the best of our knowledge, most studies among children and adolescents in China have been cross-sectional, limiting the ability to examine the incidence and progression of poor vision [15,16]. Based on a prospective cohort, this study aimed to investigate the progression of poor vision among children and adolescents in China. Findings of the study will provide evidence for the future design and implementation of effective interventions and prevention programs for poor vision.

Methods

Participants and Sampling

Study data were derived from a prospective cohort of students in primary and middle schools in Wuchang District, Wuhan City, China. The cohort was developed based on a screening project that included all primary and middle schools in the Wuchang District. All students who were currently studying in the selected schools, with oral or written informed consent collected from the parents or guardians, were recruited for the study. Students who were absent from school on the test day or had severe eye diseases or conditions that may influence the testing results (eg, infections, surgeries) were excluded. Enrollment proportions were 91.10% in 2016, 91.43% in 2017, 95% in 2018, and 96.88% in 2019. The screening team from the Physical Examination Center, Renmin Hospital of Wuhan University visited each primary or middle school on a scheduled day. Schools prepared a classroom for the testing in advance, and students in that school entered the room one class at a time until all students were tested. The screening team completed the screening test for all students in the primary or middle schools in Wuchang District; the process was repeated every year between 2016 and 2019. Wuhan is one of the largest metropolitan cities in central China, with a population of 15 million and a per capita GDP (gross domestic product) of $25,000. Wuchang District is one of the 13 districts of Wuhan and ranks among the largest, with a population of 1.27 million [17]. We aimed to investigate the vision status among students and provide evidence and recommendations for decision-makers. Data from 2016 to 2019 were used in this study, with 89,872, 91,060, 93,391, and 96,849 students enrolled in each year, respectively.

Ethical Considerations

The original study was a free governmental screening project for which the informed consent was waived from the parents or guardians. This study involved secondary data analysis of screening data and was approved by the Medical Ethics Committee at Wuhan University School of Medicine (WHU-LFMD-IRB2023031). Informed consent for the secondary data analysis was waived, and all data were was deidentified. No compensation was provided to the participants.

Measurements

Vision Status Assessment

Participants' visual acuity was measured by the standard logarithmic visual acuity charts, which has been widely used in poor vision screening in ophthalmology clinics and schools for over 20 years in China [18]. Participants were asked to stand at a distance of 5 m from the visual acuity chart and identify the direction of the "E optotype." Visual acuity was recorded using the 5-point method; this is an original visual acuity recording method in China, which stipulates normal vision as ≥5.0 and no light perception as 0. The participant's visual acuity is the recorded value of visual acuity corresponding to the smallest row for which they can correctly identify more than half the directions of the "E" optotype [18]. All inspectors received professional training.

XSL•FO
RenderX

The screening results were categorized based on the requirements of the technical standard for physical examination for students [19]; normal vision was defined as 5.0 in both left and right eyes. In cases where the visual acuity of left and right eyes differed, the lower value was used for classification. Mild poor vision was defined as a visual acuity of 4.9, moderate poor vision as <4.9 but >4.5, and severe poor vision as ≤4.5.

Demographic Variables

Demographic variables, including age (in years), sex (male or female), and place of origin (urban or rural), were provided by the schools where the children and adolescents were enrolled.

Statistical Analysis

Descriptive analyses (eg, frequency, proportion, mean, standard deviation) were used to summarize the sample characteristics. The group-based trajectory model (GBTM) was used to analyze the longitudinal data, explore the heterogeneity within the study sample, and further identify different developmental trajectories for poor vision. The underlying assumption of the GBTM is that the overall study sample consists of several latent subgroups with distinct developmental trajectories or patterns. Findings from the GBTM could help researchers and decision-makers to have a deeper understanding of the variability within the population and how different individuals progress over time. The GBTM has been widely used in various areas, including behaviors, mental health [20], and medical conditions [21]. It is an application of finite mixture modeling, which can approximate different developmental trajectories with a finite number of groups through maximum likelihood estimation [22]. The model accommodates missing data for certain time points, as demonstrated in previous studies [23,24]. Here, $Y_i=\{y_{i1},y_{i2},...,y_{it}\}$ denotes individual i's longitudinal sequence of the k^{th} measured over T=4 time periods, π_g denotes the probability that individual i belongs to g^{th} group, $P^g(Y_i)$ represents the conditional probability of Y_i for a given membership in group g. The probability of the individual i's longitudinal sequence is expressed by Equation 1.

(1)P(Yi)=∑g=1GπgPgYi

Furthermore, GBTM assumes that the random variables $y_{it}(t=1,2,...,T)$ are independent of each other when within groups. Therefore, we can use Equation 2 to definite $P^g(Y_i)$.

(2)PgYi=∏t=1TPgyit

We tested models with varying numbers of trajectory groups and orders of polynomial function, and then selected the best model based on four criteria [25-30] : (a) a lower absolute value of Bayesian Information Criteria , (b) the average posterior probability (Avepp) for class membership >0.7 for all groups, (c) all groups included at least 5% of the total sample, and (d) a simplified and rational model. Following the establishment of the foundational model, the incorporation of age as a time-dependent covariate, along with initial age, sex, and place of origin as independent covariates, was undertaken to ascertain the impact of these variables on the progression of visual acuity. All analyses were implemented using SAS (version 9.4; SAS Institute) and R software (version 4.2.1; R Foundation for Statistical Computing).

Results

Characteristics of the Study Sample

Results in Table 1 show that among the 89,872 children and adolescents in Wave 1 (2016), 48,431 (53.89%) were male, 83,102 (92.47%) were from urban areas, and the mean age of the sample was 11.24 (SD 3.33) years. Among the 91,060 participants in Wave 2 (2017), 49,056 (53.87%) were male, 85,826 (94.25%) were from urban areas, and the mean age of the sample was 11.16 (SD 3.32) years. Among the 93,391 participants in Wave 3 (2018), 50,350 (53.91%) were male, 90,503 (96.91%) were from urban areas, and the mean age of the sample was 11.09 (SD 3.33) years. In Wave 4 (2019), 52,273 (53.97%) were male, 94,973 (98.06%) were from urban areas, and the mean age of the sample was 11.04 (SD 3.33) years.

Region, n (%)				
Rural	6770 (7.53)	5234 (5.75)	2888 (3.09)	1876 (1.94)
Urban	83,102 (92.47)	85,826 (94.25)	90,503 (96.91)	94,973 (98.06)

Prevalence of Poor Vision

Results in Table 2 show that the prevalence of poor vision in the study sample was 58.51% in 2016, 58.95% in 2017, 53.83% in 2018, and 54.79% in 2019. The prevalence of poor vision from 2016 to 2019 ranged from 12.71% to 12.32% for mild poor vision, from 20.46% to 21.05% for moderate poor vision, and from 25.34% to 21.42% for severe poor vision. Additional information by gender and region is presented in Table 2.

Mild poor vision	382 (14.29)	219 (9.99)	122 (10.07)	104 (13.76)
Moderate poor vision	538 (20.12)	459 (20.93)	302 (24.94)	170 (22.49)
Severe poor vision	495 (18.51)	514 (23.44)	207 (17.09)	173 (22.88)

Trajectories of Poor Vision

Figure 1 shows the three distinct trajectories that were identified based on the lowest absolute Bayesian Information Criteria value (−361460.5). Group 1 (n=29752, 27.4%; Avepp=0.76) was characterized by a low degree of poor vision with a reduction in first 2 years and was named the normal vision group (NVG). Group 2 (n=19328, 17.8%; Avepp=0.72) was characterized by a rapid increase in poor vision and was named the vision decline group (VDG). Group 3 (n=59505, 54.8%; Avepp=0.93) was characterized by a stable level of moderate poor vision and was named the moderate poor vision group (MPV).

Figure 1. Trajectories of poor vision among children and adolescents in Wuhan, China, 2016 - 2019. Dotted lines represent the actual value, solid lines represent the predicted value. NVG: normal vision group, VDG: vision decline group, MPV: moderate poor vision group.

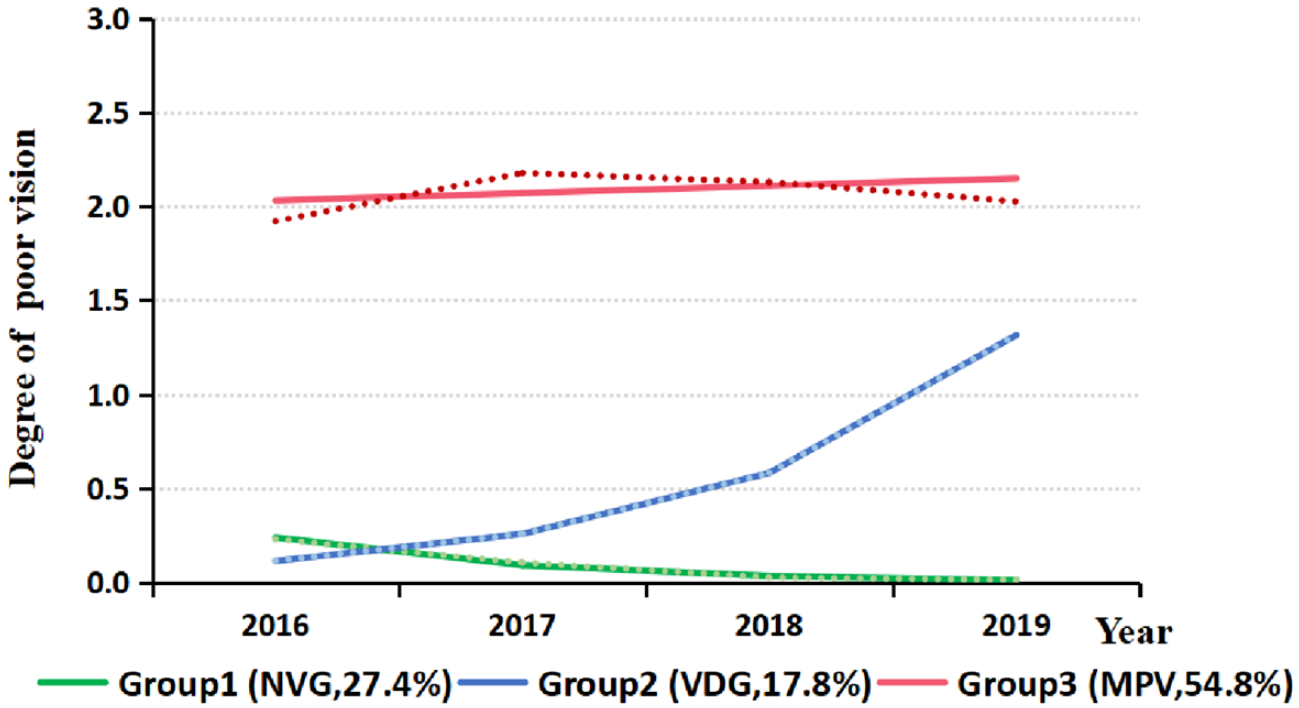

Figure 2 shows the trajectories of poor vision by sex and region, with a total of three trajectories identified. Compared to males, females had a higher proportion in Group 3 (57.8% vs 50.5%), and a lower proportion in Group 2 (17.8% vs 27.9%). Compared to rural areas, students in the urban areas had a higher proportion in Group 3 (55.3% vs 47.5%) and a lower proportion in Group 2 (17.2% vs 24.5%).

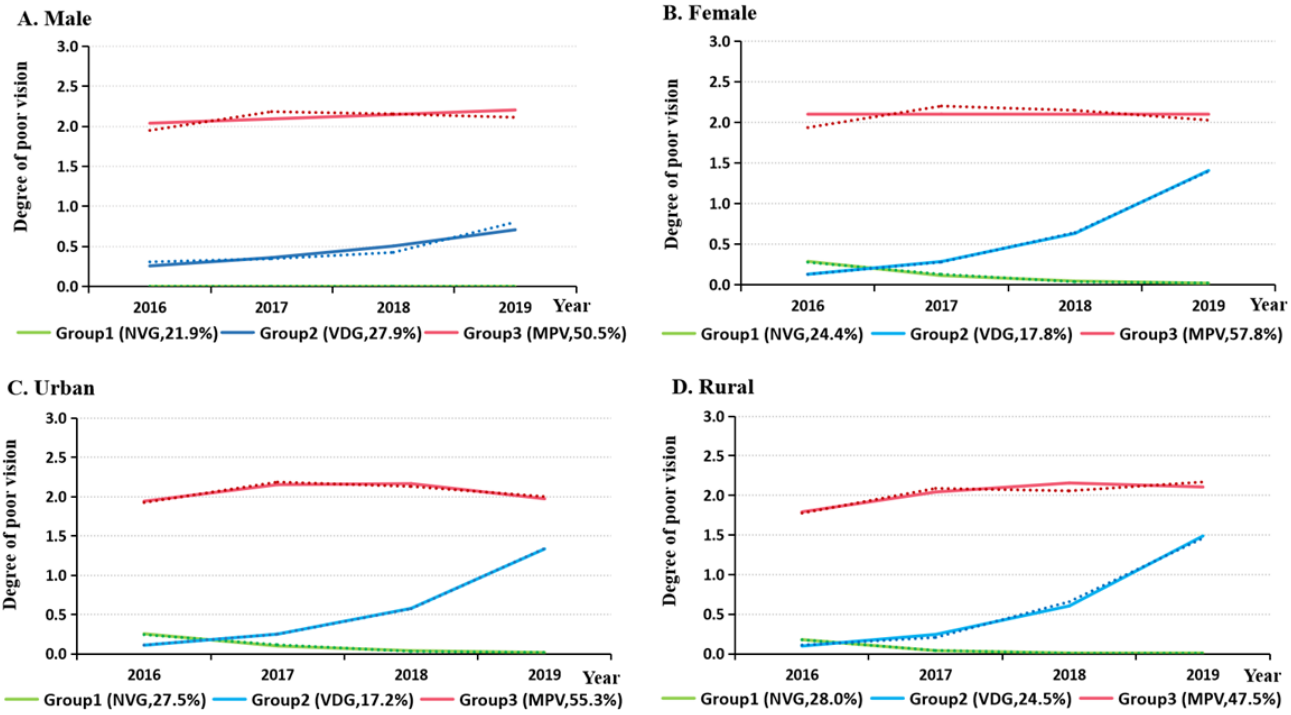
Figure 2. Trajectories of poor vision among children and adolescents in Wuhan, China, by sex and region between 2016-2019. Dotted lines represent the actual value, solid lines represent the predicted value. NVG: normal vision group; VDG: vision decline group; MPV: moderate poor vision group.



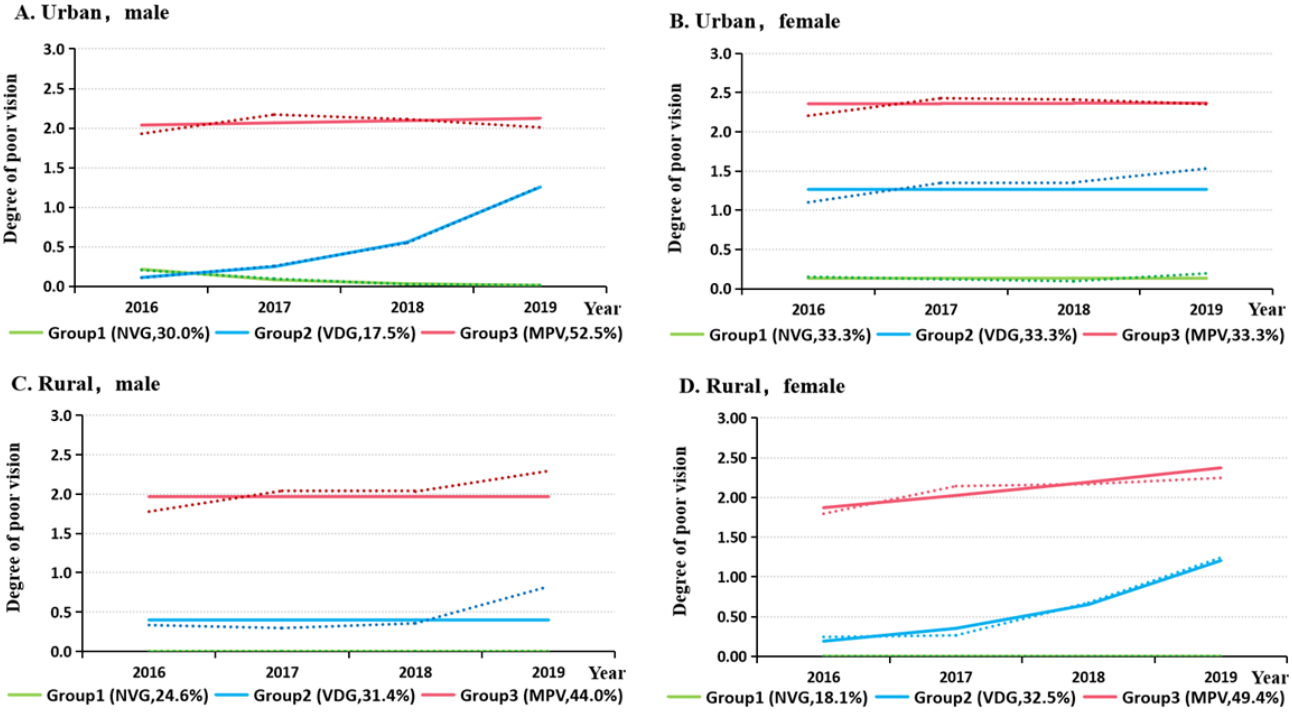


Figure 3 shows the trajectories of poor vision by the interaction of sex and region. The highest proportion in Group 3 was found among urban females (56.8%), while the lowest proportion was found in rural males (43.6%). The highest proportion in Group 2 was found among rural males (32.8%), followed by urban females (27.2%), rural females (25.8%), and urban males (17.5%).

Figure 3. Trajectories of poor vision among children and adolescents in Wuhan, China, 2016 - 2019, across sex and regions. Dotted lines represent the actual value, solid lines represent the predicted value. NVG: normal vision group, VDG: vision decline group, MPV: moderate poor vision group.

Factors Influencing Trajectory Membership and Progression

Data in Table 3 show that with increasing age, students were less likely to be categorized into Group 1 (β=−0.417, *P*<.001), and more likely to be categorized into Group 2 (β=.058,<.001). For group membership (Group 1 was used as reference), compared to boys, girls were more likely to be categorized into Group 2 (β=.597, *P*<.001) and Group 3 (β=.362, *P*<.001). Additionally, compared to urban students, students from rural

XSL•FO
RenderX

area were less likely to be categorized into Group 2 (β=−.311, *P*<.001). Further, with increasing initial enrollment age, students were more likely to be categorized into Group 1 (β=.369, *P*<.001) and Group 3 (β=.096, *P*<.001).

Table . Factors influencing trajectory membership and progression of poor vision among children and adolescents in Wuhan, China between 2016 and 2019.

Group	Variables	β	*t* test (*df*)[a]	*P* value
Trajectories progression				
Group 1[b]	Age	−.417	23.730 (85,820)	<.001
Group 2[c]	Age	.058	58.250 (85,820)	<.001
Group 3[d]	Age	.002	0.208 (85,820)	.84
Group membership (ref: Group 1)				
Group 2	Sex, (ref:Boys)			
	Girls	.597	22.709 (49,894)	<.001
	Region (ref:Urban)			
	Rural	−.311	−6.973 (5,092)	<.001
	Initial age	.369	33.711 (84,929)	<.001
Group 3	Sex (ref:Boys)			
	Females	.362	9.338 (49,994)	<.001
	Region (ref:Urban)			
	Rural	−.007	−0.113 (5,092)	.910
	Initial age	.096	5.391 (84,929)	<.001

[b]Group 1: normal vision group (NVG).

[c]Group 2: vision decline group (VDG).

[d]Group 3: moderate poor vision group (MPV).

Discussion

Principal Findings

This study investigated the progression of poor vision by analyzing data from a prospective cohort of primary and middle school students in Wuhan, China. To the best of our knowledge, this is the first study to use longitudinal data to identify the progression pattern of poor vision among children and adolescents. The findings of the study deepen our understanding of the development of poor vision and provide valuable evidence for devising and implementing intervention programs.

Population-based research indicates that poor vision in most school children results from uncorrected refractive errors [31,32]. Visual acuity has been widely used as a proxy measure for refractive error in children in previous studies [33-35] and is useful for estimating the prevalence of myopia in large populations that undergo vision screening when refraction is not feasible [36]. In this study, we found that the prevalence of poor vision among children and adolescents was 58.51% in 2016, 58.95% in 2017, 53.83% in 2018, and 54.79% in 2019, showing a decline in the latter two years. It is well-recognized that Chinese students are under greater academic pressure, spend more time on near-work activities and less time on outdoor activities, which may contribute to the high rates of poor vision [28]. The declines observed in the latter two years may be associated with the nationwide policy change regarding myopia prevention and control [29].

In this study, we identified 3 different development trajectories of poor vision among children and adolescents. Notably, more than half of the participants were categorized into the progression pattern of MPV during 2016 and 2019, amounting to 49,880 primary and middle school students in Wuchang district. If this pattern was applied to Wuhan City, approximately 589,135 primary and middle students would be fall into the MPV category. Meanwhile, our results show that 17.8% of the students enrolled were categorized into the VDG, which was characterized by a progression from normal vision to MPV. This finding suggests that the magnitude of vision loss is increasing every year. A study conducted by Ma et al [10] also showed that the prevalence rate of vision impairment was associated with grade and age in a nonlinear pattern. The underlying mechanisms of the rapid increasing pattern from normal to moderate poor vision may include high academic stress, long time of study, frequent use of electronic devices, lack of outdoor physical activities, among others [28,37-40]. These findings also highlight the urgent need for effective intervention and prevention programs to control poor vision development; potential actions include encouraging students to play outdoor sports, reducing their academic stress, and limiting time spent on electronic devices [41,42]. Further, we found that 27.4% of the participants maintained relatively normal vision

XSL•FO
RenderX

during the study period. Future studies should investigate the characteristics of this group and explore the potential protective factors against poor vision.

This study also suggests that being girls are at a higher risk of poor vision than boys, with the average poor vision rate being 59.61% in girls compared to 53.89% in boys, consistent with previous studies [26,43]. Moreover, a study on nationally representative samples conducted by Li and Mo [39] reported that 64.49% of girls were myopic while 54.44% of the boys. This trend was further confirmed in the trajectory analysis, where a greater proportion of females were classified into the MPV group compared to males. Although fewer girls belonged to the VDG, female children and adolescents experienced a greater decline in vision than males. The findings of this study indicated that girls had a greater risk of being assigned to both the VDG and the MPV than to the NVG; this result may be attributed to the fact that girls may spend less time on outdoor activities and more time on near-work tasks than boys [28,44,45].

Further, study findings suggest that urban students had a higher risk of poor vision than youth from rural areas, with a higher prevalence of poor vision and a greater proportion in the MPV category. Compared to urban students, rural children, and adolescents were less likely to be classified into the VDG than the NVG. Previous studies have similarly demonstrated higher rates of poor vision among urban students than those in rural areas [46]. This phenomenon could result from higher academic pressure, more time spent using electronic devices, and less outdoor activities among urban students [47,48].

Limitations

Although this study included a large population, it had several limitations. First, the results of the standard for logarithmic visual acuity charts were used as the sole criterion to determine the visual acuity of participants, and the cycloplegic refraction was not measured, which may have introduced measurement errors. We used the term poor vision instead of myopia throughout the paper to avoid the overestimation. Second, this study was only performed in a single district in Wuhan, and caution should be exercised when generalizing the findings to other areas. Third, there is a lack of data on demographic variables and risk factors for poor vision, that limited further analysis.

Conclusions

This study identified 3 groups with distinct poor vision progression patterns, including normal vision, visual decline, and MPV. Furthermore, the prevalence of poor vision was higher in girls than boys and higher in urban than rural students. Therefore, particular attention should be paid to girls and urban students for the prevention and control of poor vision among primary and secondary school students in the future.

Abstract

Background: Cervical cancer remains a major global health issue. Personalized, data-driven cervical cancer prevention (CCP) strategies tailored to phenotypic profiles may improve prevention and reduce disease burden.

Objective: This study aimed to identify subgroups with differential cervical precancer or cancer risks using machine learning, validate subgroup predictions across datasets, and propose a computational phenomapping strategy to enhance global CCP efforts.

Methods: We explored the data-driven CCP subgroups by applying unsupervised machine learning to a deeply phenotyped, population-based discovery cohort. We extracted CCP-specific risks of cervical intraepithelial neoplasia (CIN) and cervical cancer through weighted logistic regression analyses providing odds ratio (OR) estimates and 95% CIs. We trained a supervised machine learning model and developed pathways to classify individuals before evaluating its diagnostic validity and usability on an external cohort.

XSL•FO
RenderX

Results: This study included 551,934 women (median age, 49 years) in the discovery cohort and 47,130 women (median age, 37 years) in the external cohort. Phenotyping identified 5 CCP subgroups, with CCP4 showing the highest carcinoma prevalence. CCP2–4 had significantly higher risks of CIN2+ (CCP2: OR 2.07 [95% CI: 2.03 - 2.12], CCP3: 3.88 [3.78 - 3.97], and CCP4: 4.47 [4.33 - 4.63]) and CIN3+ (CCP2: 2.10 [2.05 - 2.14], CCP3: 3.92 [3.82 - 4.02], and CCP4: 4.45 [4.31 - 4.61]) compared to CCP1 (P<.001), consistent with the direction of results observed in the external cohort. The proposed triple strategy was validated as clinically relevant, prioritizing high-risk subgroups (CCP3-4) for colposcopies and scaling human papillomavirus screening for CCP1-2.

Conclusions: This study underscores the potential of leveraging machine learning algorithms and large-scale routine electronic health records to enhance CCP strategies. By identifying key determinants of CIN2+/CIN3+ risk and classifying 5 distinct subgroups, our study provides a robust, data-driven foundation for the proposed triple strategy. This approach prioritizes tailored prevention efforts for subgroups with varying risks, offering a novel and scalable tool to complement existing cervical cancer screening guidelines. Future work should focus on independent external and prospective validation to maximize the global impact of this strategy.

Introduction

Cervical cancer is the fourth most common cancer among women, with an estimated 660,000 new cases and 350,000 deaths globally in 2022 [1,2]. It is the most common cancer in 25 countries and the leading cause of cancer death in 37 countries. Despite being largely preventable through human papillomavirus (HPV) vaccination [3], the high incidence and persistence of high-risk HPV (hrHPV) remain the primary risk factors for cervical cancer [4] and related diseases [5-7]. In November 2020, the World Health Organization (WHO) launched a global initiative [8] to eliminate cervical cancer as a public health problem, emphasizing a triple intervention strategy: vaccinating at least 90% of girls against HPV by age 15 years, screening 70% of women with a high-performance test by ages 35 and 45 years, and treating at least 90% of detected precancerous lesions and invasive cancers. Yet, globally, an estimated 1.6 billion (67%) of 2.3 billion women aged 20 - 70 years have never been screened for cervical cancer [9], and in China, 5-year screening coverage among women aged 35 - 49 years was only 33%. Establishing high-quality, sustainable, and acceptable cervical cancer prevention (CCP) with broad coverage in resource-limited regions remains a critical challenge [10-12]. While HPV-based screening has demonstrated significant benefits [13-18], leading the WHO to recommend it as the primary method for CCP globally [19], its adoption in low- and middle-income countries (LMICs) is limited due to health inequities, resource constraints, and limited access to affordable, clinically validated HPV tests [9,20]. Addressing these barriers requires personalized CCP strategies.

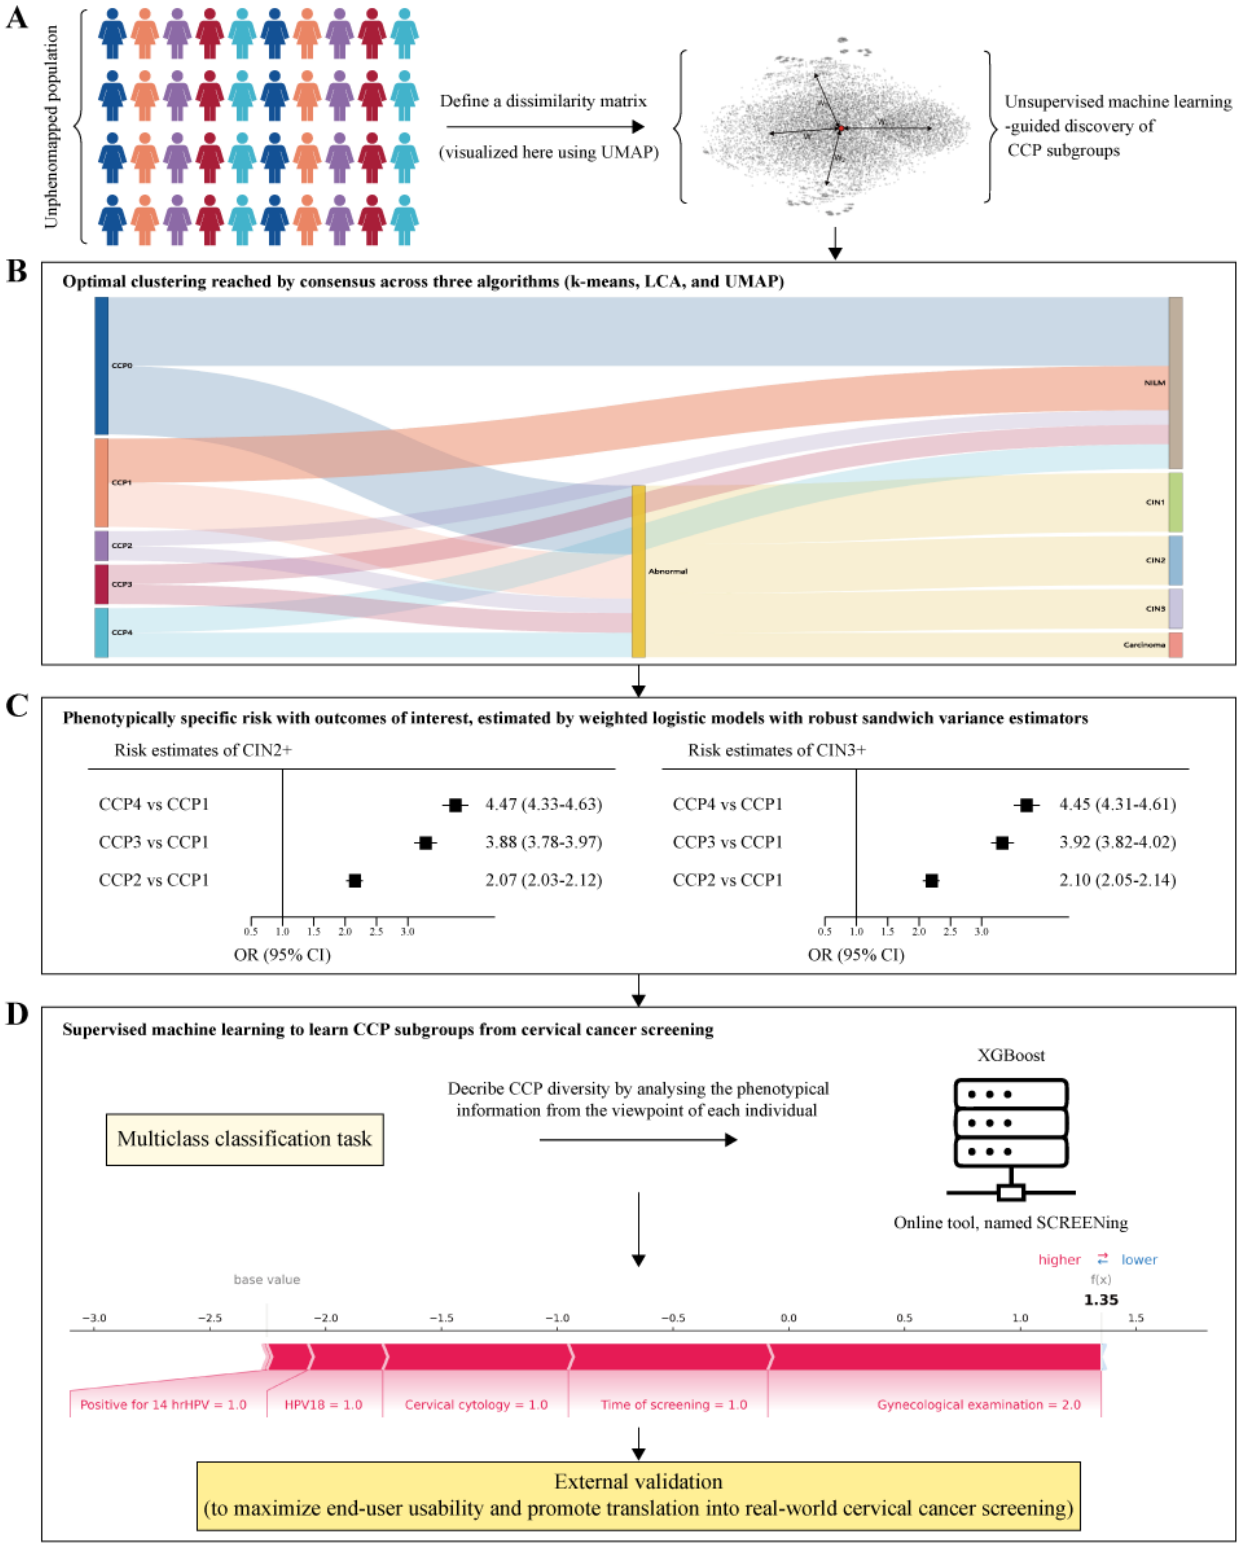
We hypothesize that data-driven CCP subgroups, identified using machine learning, can provide valuable insights into CCP, enabling personalized strategies to reduce the risk of cervical intraepithelial neoplasia (CIN) and cervical cancer. Personalized CCP strategies depend on the unique phenotypic profile of each individual. The population, with its varying phenotypic diversity, comprises heterogeneous subgroups that reflect multiple underlying behavior patterns and causes of disease. Clinical practice guidelines also recommend that cervical cancer screening should be tailored to an individual's risk profile of HPV infection [21,22]. Therefore, the discovery of CCP subgroups could inform and improve the development of new screening strategies, public health policies, and clinical decision-making, as well as contribute to trial design, despite the complex causal relationships among individual risk factors [4]. To date, no study has identified CCP subgroups. The incomplete understanding of these subgroups across large, diverse populations, coupled with insufficient validation through various methods, has hindered the implementation of the triple intervention strategy. Machine learning-based approaches allow for the phenotyping of entire populations based on individual characteristics, enabling the prediction of phenotypic clusters and disease onset [23,24]. Additionally, by defining a computational phenomap—a mathematical construct of individual phenotypes based on baseline measures [24]—computational methods can assess the heterogeneous risk effects of distinct subpopulations. This approach accounts for the phenotypic diversity within populations and their subsequent histopathological diagnoses.

As such, in this study, we aimed to: (1) test the hypothesis that distinct CCP subgroups exhibit differential risks of cervical precancer or cancer based on their complex phenotypic profiles (development); (2) demonstrate internal validity (within a dataset and across methods), as well as external and diagnostic validity (across datasets; validation); and (3) propose a computational phenomapping strategy with clinical relevance and pathways to improve global access to CCP (impact).

Methods

Data Source

Deidentified data were extracted from electronic health records (EHRs) of the national cervical cancer screening program in China. In summary, our study included eligible women aged



XSL•FO
RenderX

25‐65 years who participated in the cervical cancer screening. Data from Fujian Province (2014‐2023) were used to establish a discovery cohort to train the models. Additionally, EHR data from 5 other regions—Shenzhen City, Foshan City, Hubei Province, Gansu Province, and Guizhou Province—were employed as an external cohort to validate the generalizability of the models across diverse populations. Details on the study design, as illustrated in Figure 1, are available in Appendix S1 in Multimedia Appendix 1.

Figure 1. Study design. (**A**) We explored the data-driven cervical cancer prevention (CCP) subgroups by applying unsupervised machine learning to a deeply phenotyped, population-based discovery cohort. In this population-based, external, and diagnostic validation study, we aimed to use different machine learning methods to test our hypothesis (**B**) that individuals within distinct CCP subgroups exhibit differential risks of cervical precancer or cancer based on their complex phenotypic profiles. After identifying CCP subgroups, we extracted CCP-specific risks of outcomes of interest (**C**) conditionally on all predefined and algorithmically selected features through weighted logistic regression analyses providing average odds ratio (OR) estimates. Additionally, we stratified individuals based on their key features to conduct subgroup analyses. Finally, we trained a supervised machine learning model and developed pathways (**D**) to classify individuals using features most consistently linked to CCP subgroups before evaluating its diagnostic validity and usability on an external cohort. Pathologically abnormal diagnoses consisted of CIN1, CIN2, CIN3, and carcinoma. UMAP: uniform manifold approximation and projection; CCP: cervical cancer prevention; LCA: latent class analysis; NILM: negative for intraepithelial lesion or malignancy; CIN1: cervical intraepithelial neoplasia grade 1; CIN2: cervical intraepithelial neoplasia grade 2; CIN3: cervical intraepithelial neoplasia grade 3; CIN2+: cervical intraepithelial neoplasia grade 2 or worse; CIN3+: cervical intraepithelial neoplasia grade 3 or worse; OR: odds ratio; XGBoost: eXtreme gradient boosting; SCREENing: clinical Subgroups for CeRvical cancEr prEvention using computational phenomaps and machine learning; hrHPV: high-risk human papillomavirus; HPV: human papillomavirus.

Ethical Considerations

This study was approved by the Ethics Committee of Fujian Maternal and Child Health Hospital (2023KY141). No additional informed consent was required for this analysis. All participant data were deidentified prior to analysis. No images of identifiable individuals are included in the manuscript or supplementary materials.

Data Preprocessing

In line with the consensus that detecting and treating CIN2 or CIN3 [25,26], key premalignant cervical conditions, can prevent progression to invasive cervical cancer, our primary and secondary outcomes were CIN2+ and CIN3+, respectively. These outcomes were confirmed by histopathology and align with those commonly used in previous studies [26-29]. We selected features based on prior research [22,30-34] and input from clinical, biostatistical, and epidemiological experts. These included demographic characteristics, cervical cancer screening

XSL•FO
RenderX

history, HPV infection status, and medical examination results. Details on data preprocessing are provided in Appendix S1 in Multimedia Appendix 1.

Unsupervised Machine Learning

We calculated phenotypic distances between individuals using Gower's distance [35], a dissimilarity metric suitable for mixed continuous and categorical data. To visualize phenotypic variation in the population, we employed uniform manifold approximation and projection (UMAP) [36] to construct a phenomap. This approach enhances interpretability by presenting the distributions of individuals within a multidimensional phenotypic space, capturing the full range of baseline phenotypes. To identify and categorize the underlying CCP subgroups in which individuals exhibit phenotypic similarity, we employed and compared 3 methods to capture and validate CCP diversity: k-means [37], latent class analysis [38], and UMAP [39]. The final number of CCP subgroups was determined by reaching a consensus across all 3 approaches. Further details are provided in Appendix S1 in Multimedia Appendix 1.

Risk Estimates and an Algorithm to Identify Subgroups

To further explore the association between CCP subgroups and outcomes of interest, we calculated CCP-specific risk estimates (odds ratios, ORs) [40] and 95% CIs using inverse probability weights [41]. Additionally, we trained an eXtreme gradient boosting (XGBoost) algorithm [42] to predict 5 CCP subgroups with differential risks of outcomes, as described in our previous work [23]. Briefly, the model was trained and calibrated using an isotonic regression algorithm, and internally validated in the discovery cohort. The SHapley Additive exPlanations (SHAP) method was employed to identify each feature's relative contribution [23,43] and enhance the model's explainability. Model performance was evaluated using OVR AUROC (one-versus-rest area under the receiver operating characteristics curve, extended for multiple classes), Brier score, and calibration curves as primary metrics. In external validation, the model's diagnostic validity was assessed by comparing CCP-specific ORs between datasets to evaluate cross-cluster and cross-dataset risk differences. Further details are provided in Appendix S1 in Multimedia Appendix 1.

Developing Pathways to Improve Impact

We named our computational phenomapping strategy SCREENing (clinical Subgroups for CeRvical cancEr prEvention using computational pheNomaps and machine learnING). To assess real-world usability and effectiveness, we consulted 11 clinical experts and 3 epidemiologists on its clinical relevance, justification, result interpretability, and potential impact on screening strategies and public health policymaking.

Statistical Analysis

Given the importance of menopause in women, we specifically examined CCP-specific risks across age using spline analyses, with interaction tests to assess whether age modified these risks. Subgroup analyses were also performed by stratifying women based on key features. Details are provided in Appendix S1 in Multimedia Appendix 1. We followed the Guidelines for Developing and Reporting Machine Learning Predictive Models in Biomedical Research [44] and the Transparent Reporting of a multivariable prediction model for Individual Prognosis or Diagnosis statement [45]. Data management was performed using the lulab.utils R package [46]. All analyses [47] were conducted using Python (version 3.11.6), SAS Enterprise Guide (version 7.1), and R (version 4.3.2; R Foundation for Statistical Computing).

Results

Characteristics of Cohorts

The study included 551,934 women (median age 49 years [42,48]; 10% infected with hrHPV, 1.2% with HPV-16, and 0.6% with HPV-18) in the discovery cohort (Table 1) and 47,130 women (median age 37 years [32,45]; 16.6% with hrHPV, 3.9% with HPV-16, and 1.4% with HPV-18) in the external cohort (Table S3 in Multimedia Appendix 1). In the discovery cohort, 9932 were pathologically diagnosed with cervical abnormalities, including 533 with carcinoma. In contrast, the external cohort showed a higher prevalence of cervical abnormalities at 11.1% (5251).

[a]CCP: cervical cancer prevention.

[b]HPV: human papillomavirus.

[c]high-risk HPV: HPV-16/18/31/33/35/39/45/51/52/56/58/59/66/68.

[d]low-risk HPV: HPV-11/40/42/43/44/6/61/72/81.

[e]possible high-risk HPV: HPV-53/70/73/82/83.

[f]NILM: negative for intraepithelial lesion or malignancy.

[g]ASC-US: atypical squamous cells of undetermined significance.

[h]LSIL: low-grade squamous intraepithelial lesion.

[i]AGC: atypical glandular cells.

[j]ASC-H: atypical squamous cells, cannot exclude high-grade squamous intraepithelial lesion.

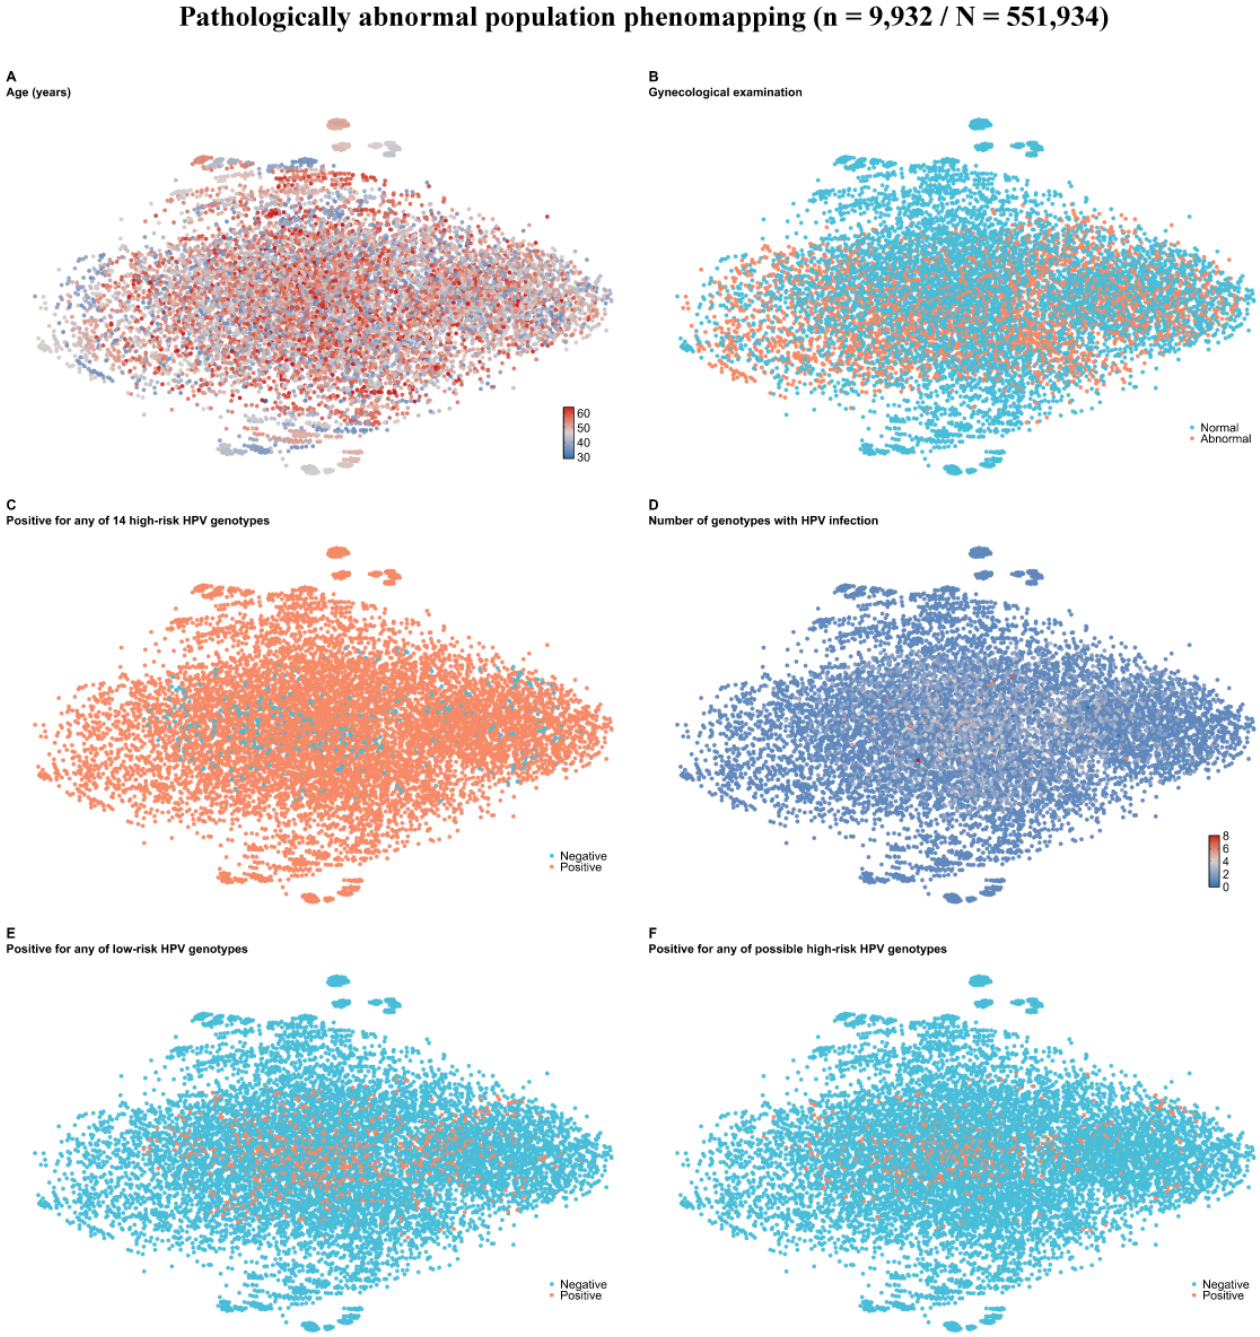
[k]AGC-FN: AGC-favor neoplastic.

[l]HSIL: high-grade squamous intraepithelial lesion.

[m]CIN1: cervical intraepithelial neoplasia grade 1.

[n]CIN2: cervical intraepithelial neoplasia grade 2.

[o]CIN2/3 is reflective of CIN2 or CIN3, i.e., HSIL; carcinoma consists of AIS (adenocarcinoma in situ) and cancer.



[p]CIN3: cervical intraepithelial neoplasia grade 3.

Data-Driven Subgroups

The discovery cohort was extensively phenotyped based on 31 features (Figure 2). Visual assessment of the risk phenomaps revealed that nearly all 6 features were heterogeneously distributed in the phenomic space to varying degrees, indicating distinct phenotypic neighborhoods. In the discovery cohort, the CCP subgroups identified across 3 algorithms and all metrics were stable (Figure 3A and Table S4 in Multimedia Appendix 1), with the optimal number of clusters being 4 in the subpopulation of 9932 women with cervical abnormalities. The distribution of cervical abnormalities across subgroups is presented in Figure 3B. Additionally, women with normal screening results were treated as another CCP subgroup (Table 1). Following a detailed analysis of each subgroup's features, we labeled the 5 identified subgroups as follows: (0) healthy, (1) early onset, (2) screening-targeted, (3) late onset, and (4) carcinoma-specific. CCP1 had the highest prevalence of CIN1, while CCP4 had the highest prevalence of carcinoma (Figure 3C). Most features were able to discriminate well between the subgroups. In the external cohort, the subgroups were consistent (Table S3 in Multimedia Appendix 1), though CCP1 was not identified due to missing information on previous screenings. The distribution of subgroups was similar across the discovery and external cohorts, with CCP0 being the most common subgroup and CCP4 having the highest prevalence of carcinoma.

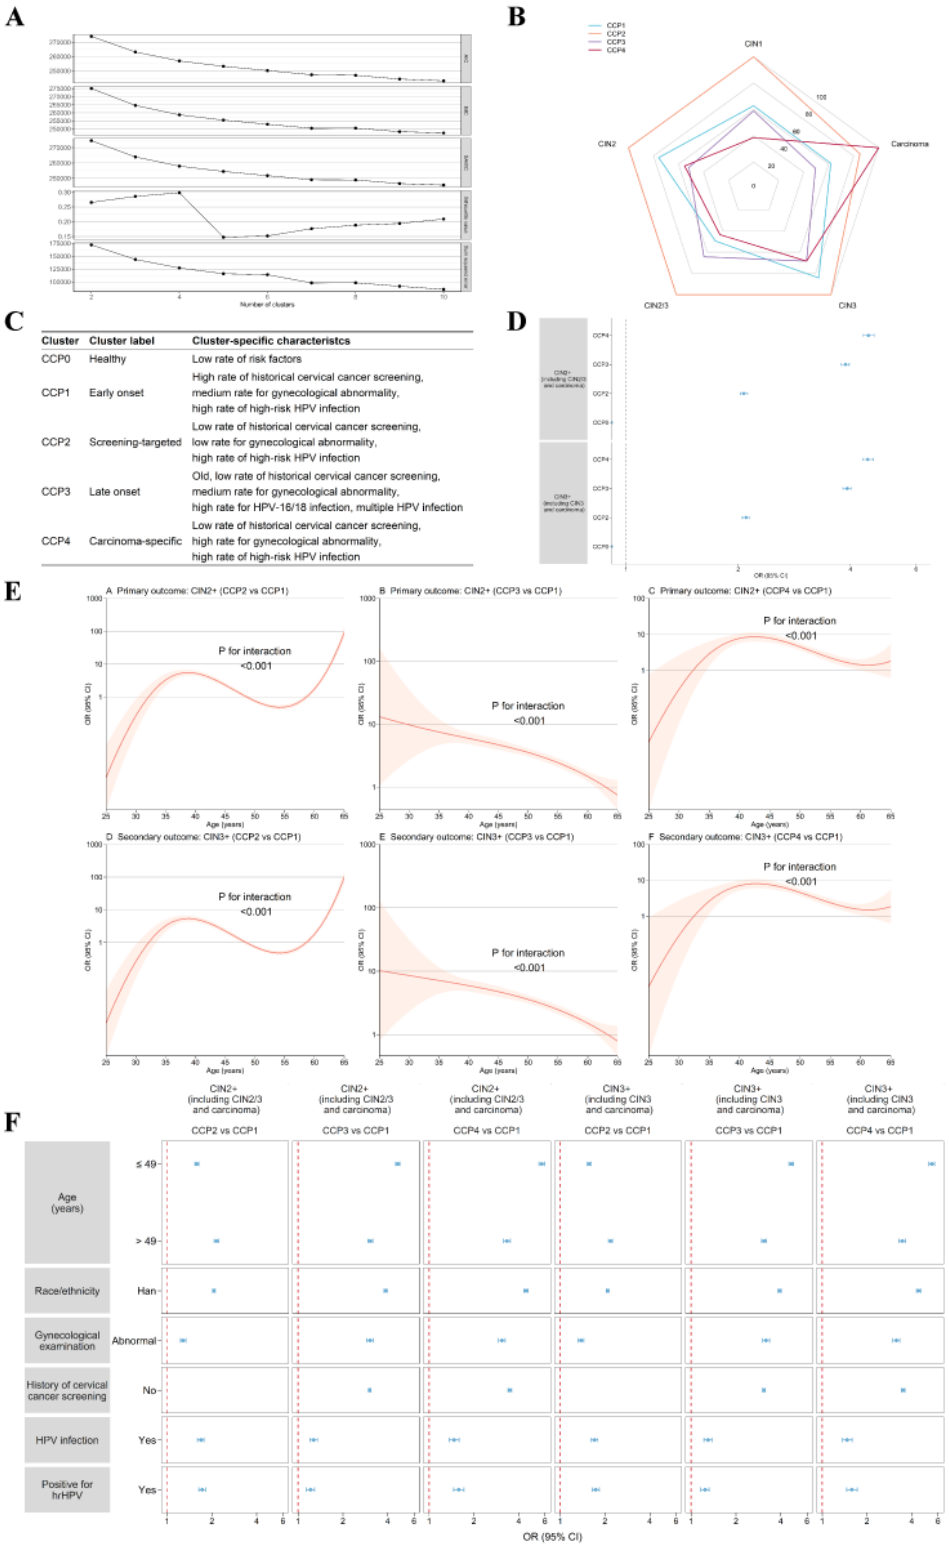

Figure 2. Manifold representations of the phenotypic architecture of 9932 individuals pathologically diagnosed with cervical abnormality from the discovery cohort (N=551,934). A total of 9932 individuals are embedded in the phenotypic space based on dissimilarity metrics (Gower's distance) derived from 31 included phenotypic features; thus, phenotypically similar women tend to be topologically closer. In the subfigures, each dot represents an individual, with coloring based on the value of features. Since the dimensionality reduction is nonlinear, axes have been omitted, and only the comparisons between distances are meaningful. Pathologically abnormal diagnoses consisted of CIN1, CIN2, CIN3, and carcinoma. 14 high-risk HPV: HPV-16/18/31/33/35/39/45/51/52/56/58/59/66/68; low-risk HPV: HPV-11/40/42/43/44/6/61/72/81; possible high-risk HPV: HPV- 53/70/73/82/83.

Figure 3. Determination of the 5 CCP subgroups with differential risks of CIN2+/CIN3+. (**A**) Elbow plot to determine the optimal number of clusters. Across 3 algorithms (k-means, LCA, and UMAP), identified CCP subgroups were stable, with the optimal number of clusters being 4 in 9932 women pathologically diagnosed with cervical abnormality. Women with normal screening test findings were considered as one independent CCP subgroup free of cervical cancer (Table 1). (**B**) Relative prevalence of pathologically abnormal diagnoses across CCP subgroups. For each pathologically abnormal diagnosis, the highest prevalence was designated as 100%, and the prevalence in each of the other CCP subgroups was relative to that prevalence (0 - 100). (**C**) Characteristics of CCP subgroups. (**D**) CCP-specific risk estimates of CIN2+/CIN3+ compared with the CCP1 subgroup. Adjusted ORs (dots) and 95% CIs (error bars) are presented. The dashed line marks an OR of 1.00; lower limits of 95% CIs with values greater than 1.00 indicate significantly increased risk. (**E**) The CCP-specific risks of CIN2+/CIN3+ across age compared with the CCP1 subgroup. Age was transformed into a restricted cubic spline function for the analyses. *P* value was based on 2-sided Chi-squared test on the interaction between age and CCP subgroups. A *P* value of <.05 suggests that age modifies the association between CCP subgroups and CIN2+/CIN3+. Light-colored bands represent 95% CIs. (**F**) Subgroup analyses of CCP-specific risk estimates of CIN2+/CIN3+ compared with the CCP1 subgroup. Adjusted ORs (dots) and 95% CIs (error bars) are presented. The dashed line marks an OR of 1.00; lower limits of 95% CIs with values greater than 1.00 indicate significantly increased risk. Empty subfigures suggest insufficient samples for the analysis. AIC: Akaike information criterion; BIC: Bayesian information criterion; SABIC: sample size-adjusted BIC; CCP: cervical cancer prevention; CIN1: cervical intraepithelial neoplasia grade 1; CIN2: cervical intraepithelial neoplasia grade 2; CIN3: cervical intraepithelial neoplasia grade 3; CIN2+: cervical intraepithelial neoplasia grade 2 or worse; CIN3+: cervical intraepithelial neoplasia grade 3 or worse; OR: odds ratio; hrHPV: high-risk human papillomavirus.

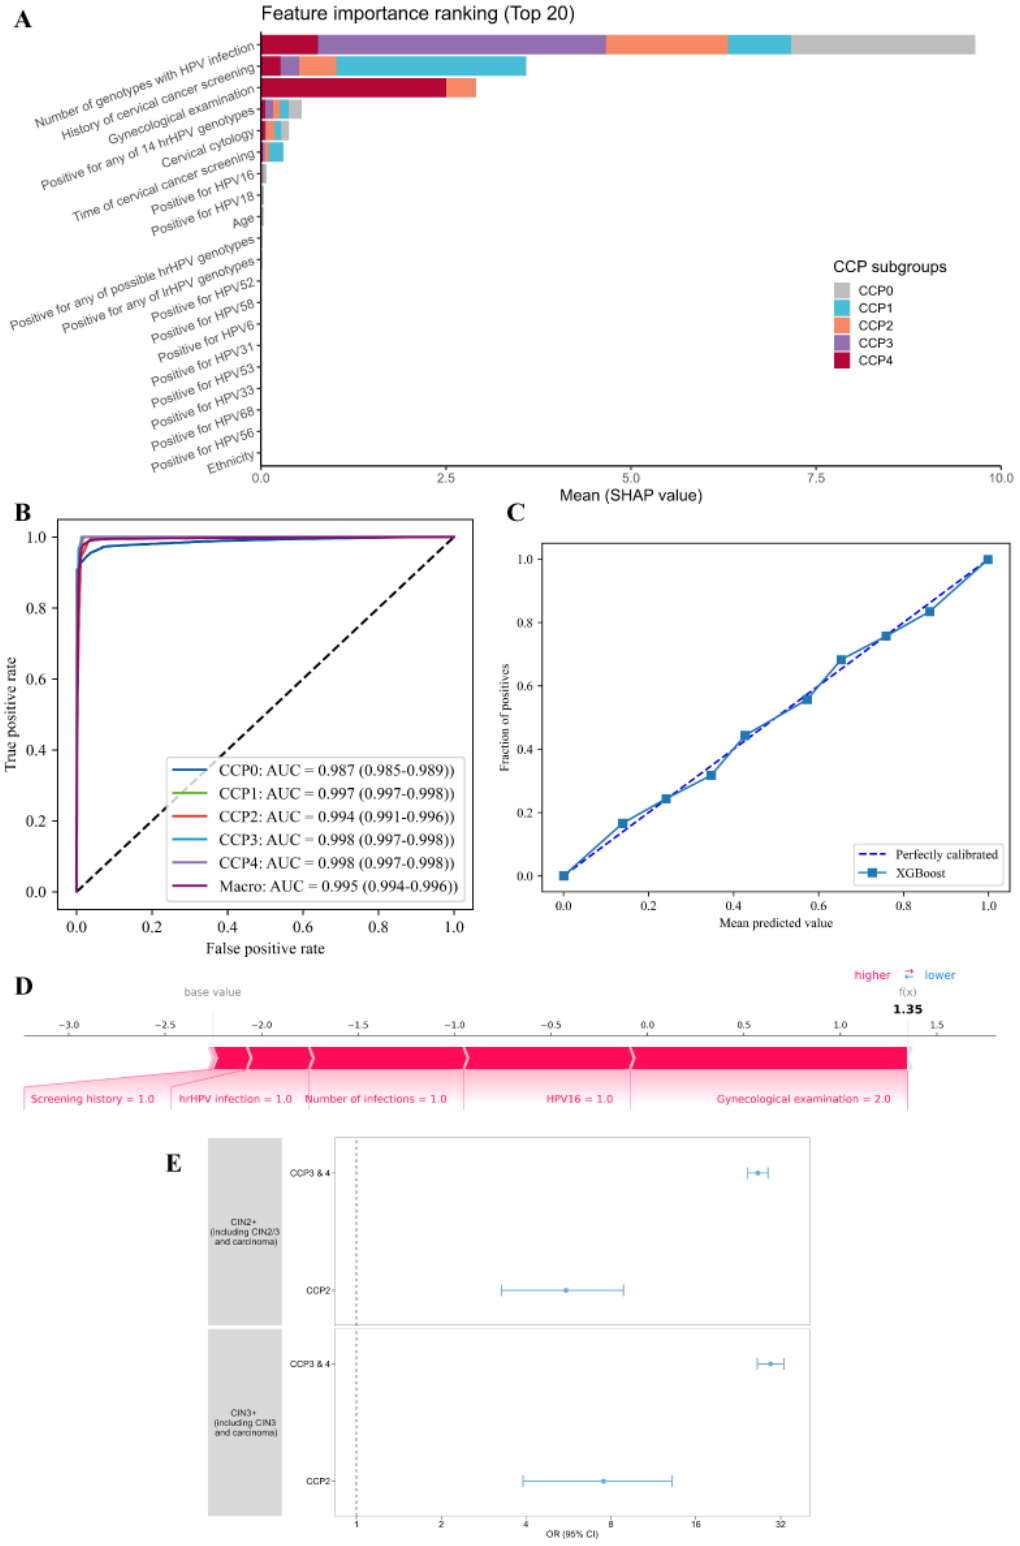
Risk Estimates and Diagnostic Validity

In the diagnostic validity analysis of the discovery cohort (Figure 3D), women in CCP2-4 exhibited a significantly increased risk of both CIN2+ (CCP2: OR 2.07, 95% CI [2.03 - 2.12]; CCP3: 3.88 [3.78 - 3.97]; CCP4: 4.47 [4.33 - 4.63]) and CIN3+ (2.10 [2.05 - 2.14]; 3.92 [3.82 - 4.02]; 4.45 [4.31 - 4.61]) compared to CCP1. Risk analysis across age groups showed that the risks for CIN2+/CIN3+ were evident in the age ranges of 34 - 47 and 60 - 65 in CCP2, 26 - 61 in CCP3, and 35 - 60 in CCP4, respectively (Figure 3E). Interaction analyses between age and subgroups revealed that the risks of CIN2+/CIN3+ increased with age in the 34 - 39 and 60 - 65 age ranges in CCP2, in the 35-43/44 age range in CCP4. Conversely, the risks decreased with age in CCP2 within the 40 - 47 age range and in CCP4 within the 45 - 60 age range (all *P* for interaction <.001). Subgroup analyses indicated that the risks for CIN2+/CIN3+ were present across nearly all subgroups, categorized by age, race, gynecological examination, screening history, hrHPV



XSL•FO
RenderX

infection, and number of infections (Figure 3F and Table S5 in Multimedia Appendix 1).

SHAP analysis identified the top 10 key features for prediction, including the number of infections, screening history, gynecological examination, hrHPV infection, cervical cytology, time since previous screening, HPV-16/18 infection, age, and possible hrHPV infection (Figure 4A). The final XGBoost model demonstrated excellent discrimination (OVR AUROC 0.995 [0.994 - 0.996]), with CCP0 showing the lowest AUROC of 0.987 [0.985 - 0.989], and strong calibration (Brier score 0.021 [0.020 - 0.022]) (Figure 4B–C and Table S6 in Multimedia Appendix 1). For the external diagnostic validity of the identified subgroups, women in CCP2-4 showed differential and increased risk for both CIN2+ (CCP2: 5.54 [3.27 - 8.86]; CCP3&4: 26.56 [24.44 - 28.88]) and CIN3+ (7.53 [3.90 - 13.18]; 29.47 [26.46 - 32.86]) compared to CCP0. The cross-cluster risk differences were consistent across the discovery and external cohorts. To illustrate the model's explainability, Figure 4D presents the SHAP plot for a woman in the CCP4 subgroup, who had no previous screening and tested positive for HPV-16 and CIN1 based on cervical cytology. Given this information, our model predicted an elevated risk of CCP4. Additionally, a screenshot of our browser-accessible tool based on the model developed in this study, to clarify how the model can be easily accessed via a browser in clinical settings, is shown in Figure S1 in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 4. Feature importance, discrimination, calibration, explainability, and external diagnostic validity. (**A**) The top 20 features for prediction of CCP subgroups with differential risks of CIN2+/CIN3+ are shown. The y-axis represents the features included in the model development (in descending order of importance), and the x-axis indicates the mean of SHAP values. The 10 most important features were selected to train the final parsimonious model. (**B**) ROC curves in the internal validation from the discovery cohort. The dark purple line represents the macro-average of all 5 CCP subgroups. (**C**) Calibration curve of the alignment between predicted and observed CCP subgroups for the final model. The solid line corresponds to the calibration curve, with the dashed line corresponding to a reference for perfect calibration (ie, perfect alignment between the predicted and observed probabilities). (**D**) Explanation of the SCREENing tool (ie, the inference process of the final model with a woman in the CCP4 subgroup). (**E**) In external validation, to assess cross-cluster and cross-dataset risk differences, the model was measured and compared by diagnostic validity (CCP-specific ORs) between datasets. CCP: cervical cancer prevention; hrHPV: high-risk human papillomavirus; lrHPV: low-risk human papillomavirus; SHAP: SHapley Additive exPlanations; AUC: area under receiver operating characteristics curve; XGBoost: eXtreme gradient boosting.

XSL•FO

Developed Pathways

Based on our analyses, we proposed a triple SCREENing strategy to prioritize CCP subgroups with varying CIN2+/CIN3+ risks: (1) top priority for colposcopy referrals to women in CCP3-4 in resource-constrained settings, (2) higher priority given for scaling up organized, population-based HPV screening programs (with adequate follow-up) for women in CCP1-2, and (3) lowest priority for CCP0 women, with large-scale screening limited to resource-rich settings. To assess its impact, we evaluated the real-world usability and effectiveness of SCREENing. Sample clinicians reported that the identified subgroups and included features were clinically relevant for risk-based cervical cancer management, particularly for colposcopy referrals in CCP3-4. They also found the strategy transparent, interpretable, and generalizable across clinical settings, with the browser-accessible model feasible and effective for indicating risk probabilities during consultations. Sample epidemiologists highlighted the strategy's potential to advance screening practices, public health policies, and trial design by enabling phenomapping, estimating subgroup-specific risk profiles, and establishing high-performance, cost-effective CCP for resource-limited regions. They noted its capability for testing effectiveness and cost-effectiveness in well-designed, prospective studies.

Discussion

This study represents one of the largest EHR analyses to date, employing diverse machine learning methods and robust validation approaches to classify subgroups and predict CIN2+/CIN3+ risk. By leveraging comprehensive and interconnected phenotypic features, our study identified 5 CCP subgroups with varying risks. CCP2–4 had significantly higher risks of CIN2+ (CCP2: OR 2.07 [95% CI: 2.03 - 2.12], CCP3: 3.88 [3.78 - 3.97], CCP4: 4.47 [4.33 - 4.63]) and CIN3+ (CCP2: 2.10 [2.05 - 2.14], CCP3: 3.92 [3.82 - 4.02], CCP4: 4.45 [4.31 - 4.61]) compared to CCP1 (P<.001), consistent with the direction of results observed in the external cohort. Our findings offer a robust foundation for the proposed triple SCREENing strategy. This tailored approach prioritizes high-risk subgroups, providing actionable insights for cervical cancer prevention, particularly in LMICs.

To this end, various approaches, including single-cell transcriptomic analysis [49], sequence and phylogenetic analysis [50,51], and cluster analysis [48,52-54], have been employed to define genetic and cellular heterogeneity [55] in cervical cancer. These studies suggest that distinct subpopulations exhibit heterogeneous risk effects, linking individual features to varying absolute cervical cancer risk. Our 5 CCP subgroups align with findings from 2 major population-based clustering studies [56,57]. One study used a Poisson regression–based CEM clustering algorithm [56] to identify clusters of Indian states with similar cervical cancer incidence patterns. However, due to its focus on approximating missing data on sexual behavior, HPV prevalence, or cervical cancer incidence [56], the clusters were not ideal for screening purposes. That study did not provide sufficient details to estimate cluster-specific risks, and its reliance on features not typically available in routine screening limited real-world applicability. Additionally, strict model assumptions and the inclusion of relatively few features further constrained its generalizability. Another study performed hierarchical clustering of HPV-related methylation sites to identify subgroups of patients with cervical cancer [57]. While informative for prognosis and clinical management, the 3 clusters were not designed for cervical cancer screening. Instead, they are more suitable for guiding prognosis assessment, refining risk stratification, and optimizing treatment strategies in clinical practice.

In contrast, our study, specifically designed for cervical cancer screening, identified complex interactions among factors such as the number of infections, screening history, gynecological examination, hrHPV and HPV-16/18 infections, cervical cytology, time since previous screening, age, and possible hrHPV infection as key determinants of the 5 CCP subgroups with varying CIN2+/CIN3+ risks. Compared to previous studies [56,57], our design and identified subgroups are more representative of real-world cervical cancer screening. Leveraging the comprehensive and interconnected phenotypic features from EHRs, our algorithm extracted CCP-specific risk estimates, providing a robust foundation for the proposed triple SCREENing strategy. This strategy prioritizes subgroups with differential CIN2+/CIN3+ risks, offering a tailored approach to CCP. We recommend implementing SCREENing as a supplemental tool to existing guidelines [58-60], while accounting for the unique priorities and constraints of LMICs. SCREENing enables clinicians to perform effective, risk-based screening, followed by adequate diagnosis, surveillance, and management, while empowering policy makers to optimize public health policies and resource allocation. This approach has the potential to mitigate resource shortages in LMICs, reduce delays in diagnosis and treatment, and enhance screening efficiency by focusing efforts on high-risk populations, ultimately maximizing population-level benefits. Additionally, our analysis highlights the modifying effect of age on CCP-specific CIN2+/CIN3+ risks, emphasizing the need for greater attention to menopause and age [61] in cervical cancer screening strategies.

Methodologically, our study advances the external validation of machine learning algorithms for identifying subgroups and predicting cervical precancer or cancer risk using large-scale routine EHRs—a rarity in previous studies, which have often been limited to small samples. Our robust, structured framework of internal, external, and diagnostic validation enhances the acceptability and generalizability of unsupervised and supervised machine learning approaches in routine CCP and is adaptable to other diseases. The identified subgroups demonstrated good accuracy and diagnostic validity for CIN2+/CIN3+ both within and across datasets, though performance was lower in scenarios with missing key features. Differences in diagnostic validity across datasets may reflect variations in HPV infection patterns and previous screening histories, which influence the distribution of risk factors. Our findings of 5 subgroups and the proposed strategy are novel, offering a framework for assessing validity in screening, follow-up surveillance, and treatment for cervical cancer. This study signals the potential for more effective and targeted approaches to CCP.

RenderX

This study represents one of the largest EHR analyses to date, employing multiple machine learning methods, datasets, and validation approaches to classify subgroups and predict CIN2+/CIN3+ risk. However, there are several limitations. First, a major limitation of this study is that our models were not externally validated beyond China. HPV infection patterns and the epidemiology of cervical abnormalities differ across countries and regions, which may impact the generalizability of our models. Given this variability, and although we used data from 5 distinct regions within China, we strongly recommend further validation of our models' performance before applying them in settings not included in this study. We acknowledge that externally validating the model in additional multicenter studies worldwide is crucial for assessing its transferability and applicability across different clinical settings. Additionally, the tool may face challenges in fully adapting to various real-world scenarios when implemented outside the controlled validation environment of this study. To address these concerns, we plan to conduct independent external and prospective validations, as well as pilot implementation across diverse clinical settings in future studies. These efforts will evaluate the model's effectiveness using a wider range of data, particularly in the context of real-world cervical cancer prevention across regions beyond those included in this study. We also encourage independent researchers to validate our model in their own settings, where feasible. While this study marks a significant step in the development of the SCREENing tool, we acknowledge that further research and validation are necessary to establish its effectiveness in real-world applications.

Second, we acknowledge that the use of retrospective EHR data may introduce biases and may not fully capture the real-time challenges of clinical practice. These challenges include issues such as missing data, data errors, and the heterogeneity of EHR systems across different settings. Although we made efforts to control for the quality of the EHR data, it remains inherently difficult to fully address these concerns without significant infrastructure changes, as well as ongoing monitoring and data validation. Therefore, we explicitly caution that the findings of this study should be interpreted with caution. In light of this limitation, future studies should aim to bridge the gap between retrospective analyses and the practical challenges of data collection in clinical settings. Third, while this study focused on routine EHR data, we acknowledge that incorporating multi-omics data—such as genomic, proteomic, and imaging data—could further enhance the model's robustness and performance, providing valuable new insights into cervical abnormalities. We propose this as an area for future research to better understand the progression of cervical cancer and to offer novel perspectives on controlling and eliminating cervical cancer. Fourth, due to the limitations of routinely collected EHR content, we were unable to include several key sexual behavior features, such as the number of sexual partners and oral contraceptive use [62], in our analyses. These factors are known to significantly influence HPV infection and cervical cancer risk. While the model in this study demonstrated high performance, the absence of such data constrained our ability to further analyze the impact of sexual behaviors on findings, such as subgroup characterization, which could provide valuable insights. We recommend that future studies incorporate these data to validate our findings and offer a more comprehensive understanding of this field.

In conclusion, this study underscores the potential of leveraging machine learning algorithms and large-scale routine EHRs to enhance cervical cancer prevention strategies. By identifying key determinants of CIN2+/CIN3+ risk and classifying 5 distinct subgroups, our study provides a robust, data-driven foundation for the proposed triple SCREENing strategy. This approach prioritizes tailored prevention efforts for subgroups with varying risks, offering a novel and scalable tool to complement existing cervical cancer screening guidelines. Future work should focus on independent external and prospective validation to maximize the global impact of this strategy.

Acknowledgments

We thank all the contributors for their efforts in this study. We also thank all funding sources for their funding. Abstract

Background: Colorectal cancer (CRC) and diabetes share many common lifestyle risk factors, such as obesity. However, it remains largely unknown how different factors interact to influence the risk of CRC development among patients with diabetes.

Objective: This study aimed to identify the interaction patterns among factors associated with the risk of CRC incidence among patients with diabetes.

Methods: This is a retrospective cohort study conducted using electronic health records from Hong Kong. Patients who were diagnosed with type 2 diabetes and received care in general outpatient clinics between 2010 and 2019 without cancer history were included and followed up until December 2019. A conditional inference survival tree was applied to examine the interaction patterns among factors associated with the risk of CRC.

Results: A total of 386,325 patients were included. During a median follow-up of 6.2 years (IQR 3.3-8.0), 4199 patients developed CRC. Patients were first partitioned into 4 age groups by increased levels of CRC risk (≤54 vs 55 to 61 vs 62 to 73 vs >73 years). Among patients aged more than 54 years, male sex was the dominant risk factor for CRC within each age stratum and the associations lessened with age. Abdominal obesity (waist-to-hip ratio >0.95) and longer duration of diabetes (median 12, IQR 7-18 vs median 4, IQR 1-11 years) were identified as key risk factor for CRC among men aged between 62 and 73 years and women aged more than 73 years, respectively.

Conclusions: This study suggests the interaction patterns among age, sex, waist-to-hip ratio, and duration of diabetes on the risk of CRC incidence among patients with diabetes. Findings of the study may help identify target groups for public health intervention strategies.

Introduction

Colorectal cancer (CRC) is the third most frequently diagnosed cancer worldwide [1]. Previous studies have shown that patients with diabetes are 1.3 times likely to develop CRC when compared with those without diabetes [2]. CRC and type 2 diabetes mellitus share many common lifestyle risk factors, such as obesity [3,4], smoking [5,6], heavy alcohol use [7,8], physical inactivity [9,10], Western dietary pattern [11-13], and processed meat [12-14].

While CRC and diabetes share many overlapping risk factors, little is known about how different risk factors interact in the presence of a pre-existing diabetes condition which may influence the risk of CRC development. For example, while older age and male sex are risk factors for many cancers including CRC, it remains less certain how the association differs by age and sex [15], and how to optimally separate patients with diabetes into subgroups by age and sex according to their risk levels. A previous meta-analysis [16] showed that men are 1.83 times likely to have CRC when compared with women. However, most CRC screening guidelines for average-risk individuals are age-based (mostly starting from 50 y [17], or 45 y at the earliest [18]). It remains largely unknown how the risk levels differentiate by age and sex within the population with diabetes. Several studies have incorporated

XSL•FO
RenderX

age-sex [19,20] and diabetes [19] into their proposed screening strategies. Furthermore, while adiposity is a common risk factor for diabetes and CRC [3,21], most studies focused on general obesity [3,22]. It is less clear whether general obesity may adequately represent abdominal obesity in predicting CRC risk [22-24], and whether adiposity becomes a predominant risk factor in certain subgroups of patients. A previous meta-analysis [22] found that when comparing highest with lowest categories of waist-to-hip ratio, men and women in the highest categories of waist-to-hip ratio are 1.47 and 1.3 times likely to have CRC respectively when compared with their same-sex counterparts in the lowest category. Furthermore, it is less understood whether duration of diabetes [15] or antidiabetic drug treatment [21] may influence the risk of CRC development, given the interactions between gut microbiota with obesity [25,26], insulin resistance [25,27], diabetes [25], antidiabetic drugs [25], diet [25,26], immunity [25,26], and CRC [26]. Previous studies [15,28-30] demonstrated mixed findings on the associations between duration of diabetes and CRC risk.

Previous research suggests type 2 diabetes as a heterogeneous disease [31-35], and various approaches such as clustering techniques [31-34] have been applied to explore the subtypes. For example, Ahlqvist et al [31] has used 6 variables (including age, BMI, and HbA_{1c}) to stratify patients with adult-onset diabetes into 5 distinct clusters, namely “severe autoimmune diabetes”, “severe insulin-deficient diabetes”, “severe insulin-resistant diabetes”, “mild obesity-related diabetes”, and “mild age-related diabetes”, where the latter 4 clusters may represent different subtypes within type 2 diabetes. Identifying subtypes of type 2 diabetes may help individualize most appropriate treatment to help improve clinical outcomes [31,33]. Furthermore, the interplay between genetic and environmental factors [36] may collectively contribute to the risk of diabetes and CRC. A previous meta-analysis on gene-environment interaction studies found insufficient evidence for the interaction effects between genetic and environmental factors [37]. However, a recent large-scale gene-environment interaction study [38] suggested that common genetic variants related to insulin signaling and immune function may potentially modify the association between diabetes and CRC risk. In addition, some medical conditions may share common pathophysiology with diabetes. For example, obesity, immune-mediated inflammatory bowel diseases, and metabolic disorders [39] are characterized by systematic low-grade inflammation, which may in turn promote CRC development.

Given the potential complex interplay among interrelated factors for diabetes and CRC, in this study, tree-structured survival analysis is applied to examine the potential interaction patterns among a set of covariates on CRC risk. Conditional inference survival tree [40] is a tree-structured (or recursive partitioning) algorithm embedded with statistical theory of conditional inference. Tree-structured algorithms are able to account for multicollinearity among the set of covariates, and explore the potential interactions among more than 2 covariates without an exhaustive search of all possible combinations. Compared with other tree-structured algorithms, conditional inference survival tree has the advantages of (1) incorporating a theoretical framework, (2) avoiding overfitting, (3) minimizing selection bias toward covariates with many possible values, and (4) not requiring explicit pruning [40].

This study aims to examine whether there are interaction patterns among factors associated with the risk of CRC incidence among patients with pre-existing type 2 diabetes using survival tree analysis.

Methods

Study Design and Study Population

This is a retrospective cohort study performed using territory-wide electronic health records of Hong Kong. The Hospital Authority (HA) is statutory body managing 43 public hospitals, 49 specialist outpatient clinics, and 74 general outpatient clinics over the territory. The HA maintains a centralized data repository that stores information on patients’ demographics, disease diagnoses, prescription records, laboratory measurements, as well as inpatient and outpatient visits. Since the HA provides approximately 90% specialist and inpatient care [41], most of the cancer cases were captured in the records system. Disease diagnoses were coded with the *International Classification of Diseases, Ninth Revision* (*ICD-9*) or *International Classification of Diseases, Tenth Revision* (*ICD-10*) or the *International Classification of Primary Care, Second Edition* (*ICPC-2*). Data were accessed through HA Data Collaboration Lab.

Patients

Patients who (1) were diagnosed with diabetes and (2) received a first diabetes complication screening assessment at any of the general outpatient clinics between 2010 and 2019 were initially included. Patients who (1) were diagnosed with non–type 2 diabetes, (2) had a missing date of diabetes diagnosis, (3) were diagnosed with diabetes below the age of 18 years, or (4) had a history of malignancy were excluded. Index date was defined as date of the first assessment. Patients were followed up until a cancer diagnosis, death, or December 31, 2019, whichever occurred earlier. Since the diagnosis of one cancer may influence the diagnosis of another cancer [42], those who received a cancer diagnosis at sites other than colon or rectum during follow-up were excluded. In addition, to minimize reverse causality, those who had less than 6 months of follow-up [42] were also excluded.

The diagnosis of type 2 diabetes was based on *ICPC-2* code (T90), and defined as a clinical diagnosis by clinicians, with 2 abnormal test results of plasma glucose and presentation of clinical symptoms. Type 2 diabetes is pharmaceutically treated by glucose lowering agents (most commonly used drugs are metformin, sulphonylurea, and insulin, since these drugs are less expensive options) [41]. HbA_{1c} is the primary measure used to monitor blood glucose control.

Outcome

The outcome of interest was diagnosis of CRC (*ICD-9*: 153 - 154; *ICD-10*: C18-21) during follow-up. Patients who presented with CRC symptoms (such as rectal bleeding or blood in stool) were recommended to take a fecal occult blood test. If the results were positive, patients would be referred for a

XSL•FO
RenderX

diagnostic colonoscopy procedure. For CRC diagnosis, gastroenterologists would perform a colonoscopy procedure to remove polyps and take biopsy samples for further examination by pathologists to provide a diagnosis. CRC are generally classified into 4 consensus molecular subtypes (CMSs), namely CMS1 (microsatellite instability immune), CMS2 (canonical), CMS3 (metabolic), and CMS4 (mesenchymal), with distinct characteristics and developmental pathways [43,44]. Possible treatment options include surgery, radiotherapy, chemotherapy, and targeted therapy.

Covariates

Information on input data was ascertained during the first assessment. Candidate split variables included demographics (age and sex), duration of diabetes, medical history (ischemic heart disease, cerebrovascular disease, heart failure, hypertension, chronic kidney disease, liver cirrhosis, chronic obstructive pulmonary disease, pneumonia, and family history of diabetes), medication use (antidiabetic drugs, aspirin, nonsteroidal anti-inflammatory drugs, anticoagulants, antiplatelets, antihypertensive drugs, and statins), lifestyle behaviors (alcohol use and smoking), anthropometric measurements (waist-to-hip ratio and BMI), and laboratory measurements (HbA_{1c}, fasting glucose, low-density lipoprotein cholesterol, high-density lipoprotein cholesterol, triglycerides, and serum creatinine). Duration of diabetes was the time difference between diabetes diagnosis and the first assessment. Medication use was defined as whether patients had been prescribed a drug at the time of the assessment. Antidiabetic drugs included were metformin, sulfonylurea, insulin, and dipeptidyl peptidase-4 inhibitors. Laboratory measurements were taken from most recent results to the assessment date.

Data Analysis

Conditional inference survival tree [40] was applied to examine the interaction patterns among factors associated with the risk of CRC incidence. At each split, a global null hypothesis of independence between any of the candidate split variables and the risk of CRC was first tested at a prespecified α level. If rejected, a set of partial null hypotheses of independence between each covariate and the risk of CRC were then tested, and the covariate with strongest association or smallest Bonferroni-corrected *P* value would be selected as split variable. The partitioning procedures were recursively conducted until the global null hypothesis cannot be rejected. For continuous variables, the cutoff point was the optimal value to maximize the between-node differences in survival probability. The statistical significance threshold α level and maximum depth of the survival tree were set at .01 and 4, respectively. Each path from the root node to a terminal node represents an interaction pattern [45]. The effects of a split variable are conditional on split variables chosen at its ancestor nodes. Patients were partitioned into mutually exclusive subgroups at terminal nodes with most homogenous within-group survival outcomes. The CRC-free survival of subgroups of patients with diabetes was examined using Kaplan–Meier method. Model performance was evaluated using area under the curve as metric. In post hoc analyses, the associations between identified important factors and the risk of CRC were estimated using Cox regression and reported in adjusted hazard ratio (aHR) with 95% CI. Data analyses were performed using R software (version 4.2.3; R Foundation for Statistical Computing).

Ethical Considerations

Ethics approval for secondary data analysis was provided by the Chinese University of Hong Kong – Survey and Behavioural Research Ethics Committee (SBRE-22-0386). Patient consent was waived since individuals were not identifiable in this study.

Results

Overview

Figure 1 shows the flowchart of patient selection. Of the 386,325 patients included, 4199 patients developed CRC during a median follow-up of 6.2 (IQR 3.3-8.0) years. The incidence rates among female and male patients aged more than 54 years were 1.90 and 2.94 per 1000 person-years, respectively. On the other hand, the incidence rate among patients aged ≤54 years across both sexes was 0.54 per 1000 person-years. The survival tree first partitioned patients into 4 age groups (≤54 vs 55 to 61 vs 62 to 73 vs >73 years) by increasing levels of CRC risk. Among patients aged more than 54 years, male sex was identified as most dominant risk factor for CRC within each age stratum. Waist-to-hip ratio and sulfonylurea use (characterized by long duration of diabetes) emerged as important factor in differentiating the risk of CRC among men aged between 62 and 73 years and women aged more than 73 years, respectively (Figure 2 and Tables 1 and 2).

Age and Sex

The optimal cutoffs identified to differentiate the increasing levels of CRC risk with age were 54, 61, and 73 years (Figure 2 and Figure 3) . Among patients aged more than 54 years, male sex was the most important risk factor for CRC within each age group (Figure 2). Men had an elevated risk of developing CRC when compared with women within each age stratum (for 55 to 61 years: aHR 1.81, 95% CI 1.54 - 2.12; for 62 to 73 years: aHR 1.70, 95% CI 1.54 - 1.87; and for >73 years: aHR 1.64, 95% CI 1.48 - 1.82), after controlling for age and duration of diabetes. On the other hand, among the youngest age group (≤54 years), no split variable was identified to have individually significant effects on the risk of CRC after adjusting for age, sex, and duration of diabetes (Table 3).

Age, Sex, and Waist-to-Hip Ratio

Among male patients aged between 62 and 73 years, elevated waist-to-hip ratio (>0.95) appeared as dominant risk factor for CRC (Figure 2). Those with a ratio of 0.95 above had an increased risk of developing CRC (aHR 1.82, 95% CI 1.61 - 2.05) when compared with those with a ratio ≤0.95, when controlling for age and duration of diabetes (Table 4). The corresponding mean waist-to-hip ratios of these 2 subgroups were 1.00 (SD 0.04) and 0.92 (SD 0.03).

[a]aHR: adjusted hazard ratio.

[b]Not available.

Age, Sex, and Duration of Diabetes

Among female patients aged more than 73 years, sulfonylurea use emerged as key factor in differentiating the risk of CRC (Figure 2). Those who had been prescribed sulfonylurea were characterized by long duration of diabetes when compared with those who were not prescribed with sulfonylurea (median 12, IQR 7-18 vs median 4, IQR 1-11 years). Among the oldest

XSL•FO
RenderX

female group, sulfonylurea users had a higher risk of developing CRC (aHR 1.19, 95% CI 1.02 - 1.39) when compared with sulfonylurea nonusers, controlling for age, duration of diabetes, HbA_{1c}, and fasting glucose (Table 4).

Model Performance

The areas under the curve of the tree model at 2, 5, and 7 years were 0.713, 0.696, and 0.685, respectively.

Discussion

Principal Findings

This study adopted a supervised learning algorithm approach, namely conditional inference survival tree embedded with statistical theory, to identifying key factors and their optimal cutoffs to differentiate the risk of CRC and separate patients with type 2 diabetes into mutually exclusive subgroups of most homogenous CRC risk. Age, sex, waist-to-hip ratio, and sulfonylurea use exhibited interaction patterns on the risk of CRC incidence among the study diabetes cohort. Despite older age, male sex, and obesity being established individual risk factors for CRC, the optimal cutoffs for age among the study cohort were identified to partition patients according to their CRC risk levels using a data-driven approach. Furthermore, while male sex emerged as most important risk factor among patients aged more than 54 years, abdominal obesity appeared as dominant risk factor among men aged 62 to 73 years. In addition, sulfonylurea use (as characterized by long duration of diabetes) was identified as key factor in differentiating CRC risk among oldest women aged more than 73 years.

This study found that male sex emerged as dominant risk factor for CRC among patients aged more than 54 years and the associations weakened with age, implying the potentially differential associations between male sex and CRC risk with age. A previous meta-analysis [16] found that the associations between male sex and CRC risk grew markedly from age 50 years but dropped gradually after reaching 60 years. A similar trend was observed in this study, where male sex was found to be an important risk factor from 55 years onwards, and the associations declined with age. In a more recent study performed among young adults who received colonoscopies in South Korea [46], male sex was only found to be a significant risk factor for overall colorectal neoplasia among patients aged 30 to 39 years, but not among those aged between 20 and 29 years. However, male sex was not associated with advanced colorectal neoplasia within each age group [46]. In another study conducted among patients who underwent colonoscopies in Korea [47], male sex was found to be a risk factor for colorectal adenoma among the overall cohort, but not younger patients aged less than 50 years. Furthermore, epigenomic evidence supports that the second period of abrupt changes in immunity occurs earlier in men than in women (early 60s vs late 60s), and the changes are more pronounced in men [48]. The discrepancy (5 to 6 years) in second period of accelerated aging coincides with life expectancy of men and women [48]. This change in immunity could partially explain the dominance of male sex on CRC risk starting from middle adulthood, and the effects decline over time as both sexes undergo rapid changes.

Furthermore, the survival tree model selected abdominal obesity (waist-to-hip ratio >0.95) over general obesity (BMI) as a dominant risk factor among middle-old men aged between 62 and 73 years. In a previous study conducted among patients who received colonoscopies in Korea [49], abdominal obesity was only found to be significantly associated with the risk of colorectal neoplasia in men but not women. Several reviews also summarized that obesity has a stronger effect on the risk of CRC among men than women [50-52], and weight gain later in life is a key risk factor for CRC among men [50,51]. Physiologically, men are predisposed to accumulating visceral fat than women [53], and this could account for the stronger link between obesity and CRC in men. The dominance of abdominal obesity as key risk factor among middle-old men could be due to decline in testosterone with age. Previous research has shown that lower testosterone in men is linked to abdominal obesity and metabolic abnormalities [51,53]. Furthermore, individuals tend to accumulate visceral fat and lose skeletal muscle with age, rendering general obesity being not sufficiently representative of abdominal obesity among older individuals [54].

In addition, oldest women aged more than 73 years who took sulfonylurea and had a longer duration of diabetes (median 12, IQR 7-18 years) appeared to have a greater risk of CRC risk than oldest women who did not take sulfonylurea and had a shorter duration of diabetes (median 4, IQR 1-11 years) in this study. It is unclear whether the elevated risk is due to longer duration of diabetes or sulfonylurea use. In the existing literature, the association between sulfonylurea use and cancer risk remains controversial. Previous studies generally reported a positive association [21] while some did not find any association [55,56]. In a study performed in Korea [57], sulfonylurea use was only found to be associated with an increased risk of CRC among patients aged 65 years or older, but not among those below the age of 65 years. In this study, sulfonylurea use only appeared to be a key factor associated with an increased risk of CRC among women aged more than 73 years. Given sulfonylurea users being characterized by long duration of diabetes, it is possible that changing gut microbiota over the course of diabetes progression [25,27] may eventually influence carcinogenesis of the colon and rectum [26].

This study identified the optimal cutoffs for age to partition patients with type 2 diabetes in the study cohort by their risk levels of CRC using a data-driven approach. While male sex is known to be a risk factor for many cancers, including CRC, the association between male sex and CRC appears to be more apparent among older patients with diabetes (aged more than 54 years). Nevertheless, the links become less strong with age. Furthermore, abdominal obesity becomes a dominant risk factor over general obesity among male patients with diabetes aged between 62 and 73 years. In addition, women aged more than 73 years with a long duration of diabetes could be potentially at greater risk of CRC than their counterparts with a shorter duration of diabetes. Findings of the study may offer valuable insights into identifying profiles of potential target groups for future public health interventions.

Strengths of this study include incorporation of a diabetes cohort with a relatively large sample size, regular follow-up, and

XSL•FO
RenderX

routine surveillance, availability of information from electronic health records, and adoption of a supervised learning algorithm such that selection of key factors is directly driven by outcome. However, several limitations may exist. First, information on some potential confounders such as dietary exposure, family history of CRC, insulin, or C-peptide was not available. Second, dosage and duration of medication use was not examined. Third, different types of sulfonylureas were not differentially evaluated in this study. Finally, the dominance of key factors and optimal cutoffs may vary across different populations. Future research is warranted to verify the findings. Examples include validation of optimal age-sex segmentation for CRC risk in a prospective cohort, incorporation of a comparison group without diabetes, exploration of the role of adiposity (general and abdominal) in CRC risk over the life course across sexes in a prospective cohort with a long-term follow-up, and new-user design in exploring drug effects (such as commonly used antidiabetic drugs and newer drugs including semaglutide) on CRC risk. Reproducible results of identified subtypes of type 2 diabetes associated with differential CRC risk may help guide public health intervention strategies and optimize clinical outcomes [33].

Conclusions

This study suggested the potential interaction patterns among age, sex, abdominal obesity, and duration of diabetes on the risk of CRC among patients with diabetes. While older age, male sex, and obesity are well-established risk factors for CRC, the combinations of risk factors may differentially contribute to different levels of CRC risk among patients with diabetes. Findings of the study may potentially help identify target groups for public health intervention strategies.

Acknowledgments

This study was supported by Hong Kong SAR government - Strategic Public Policy Research Funding Scheme (S2019.A4.015.19S).

Authors' Contributions

Conceptualization and methodology was contributed by STYY, EYML, and EKY. Data curation, formal analysis, and writing – original draft preparation was contributed by STYY. Abstract

Background: While survival among pediatric patients with cancer has advanced, disparities persist. Public health tools such as the Area Deprivation Index, the Child Opportunity Index (COI), and the Social Vulnerability Index (SVI) are potential proxies for social determinants of health and could help researchers, public health practitioners, and clinicians identify neighborhoods or populations most likely to experience adverse outcomes. However, evidence regarding their relationship with health care use, especially in the pediatric population with cancer, remains mixed.

Objective: We sought to evaluate the relationship between emergency department (ED) visits and hospitalizations with these area-level indices in our study population.

Methods: We conducted a cross-sectional study of pediatric patients with brain and central nervous system tumors in a single Midwestern state who were diagnosed between 2010 and 2020. We fitted zero-inflated Poisson models for counts of ED and inpatient visits to determine if any of these use measures were associated with our 3 area-level indices. Finally, we mapped index quintiles onto neighborhoods to visualize and compare how each index differentially ranks neighborhoods.

Results: Our study cohort consisted of 524 patients; 78.6% (n=412) of them had no recorded ED visit, and 39.7% (n=208) had no record of hospitalization. Moderate (coefficient=0.306; *P*=.01) and high (coefficient=0.315; *P*=.01) deprivation were associated with more ED visits. Both low child opportunity (coefficient=0.497; *P*<.001) and very high child opportunity (coefficient=0.328; *P*=.01) were associated with more ED visits. All quintiles of SVI were associated with ED visits, but the relationship was not dose-dependent. Low and very high deprivation were associated with hospitalizations, but COI and SVI were not. Additionally, by overlaying index quintiles onto census tracts and census block groups, we showed that most patients who had an ED visit lived in disadvantaged neighborhoods based on Area Deprivation Index rankings, but not necessarily COI or SVI rankings.

Conclusions: Although indices provide useful context about the environment in which our patient population resides in, we found little evidence that neighborhood conditions as measured by these indices consistently or reliably relate to health care use.

KEYWORDS

child opportunity; neighborhood deprivation; area deprivation; social vulnerability; health care use; social determinants of health; pediatrics; health disparities

Introduction

Extant research has attributed social determinants of health (SDOH) to differential health outcomes and health risks, sometimes more so than clinical care [1]. In pediatric populations with cancer, factors such as race, social deprivation, socioeconomic status, and insurance coverage are significantly associated with inequities in access to clinical trials and survival outcomes [2,3]. Even if pediatric patients with cancer do survive, they remain at higher risk than the general population for all-cause and health-related mortality [4]. Thus, mitigating these nonclinical factors may improve the life course of this vulnerable

XSL•FO
RenderX

population. However, to progress toward this goal, clinicians, public health professionals, health care organizations, payers, and policy makers must gather SDOH data. SDOH information can be collected in a variety of ways, including through aggregating individual responses to social risk assessments, using national databases (eg, Agency for Healthcare Research and Quality's SDOH Database), or relying on existing composite indices (or neighborhood indices) that rank or score geographic areas (eg, census tracts, census block groups, counties, or zip codes) on multiple sociodemographic and socioeconomic variables.

Using neighborhood indices as an approach to approximate SDOH affords several advantages. They offer convenience by operationalizing SDOH in the form of easy-to-interpret numeric rankings or scores and can be integrated into electronic health records or clinical data warehouses as clinical decision support tools [5,6]. The addition of neighborhood indices may also improve the performance risk prediction models when compared to models that only use patient- or individual-level characteristics [7-9]. Moreover, they may be valuable to investigators because their data are often publicly available and can be easily linked to patient data by matching geocodes—thus facilitating work in identifying nonclinical predictors of health outcomes, risk stratifying patient and patient populations by SDOH, and building prediction models. Finally, indices could serve as viable complements to screenings or substitutes when it is not feasible to assess patient populations' social needs, either due to workflow and time constraints, lack of training, or patients' uneasiness with revealing sensitive [10].

Researchers, clinicians, policy makers, and payors have access to numerous publicly available area-level indices. Three indices that have been linked to measures of health care use include the Area Deprivation Index (ADI), the Child Opportunity Index (COI), and the Social Vulnerability Index (SVI). The ADI was originally created by the US Health Resources and Services Administration and contains education, employment, housing, and poverty indicators [11,12]. Data used to build the ADI primarily come from the Census and the American Community Survey, and both sources have been demonstrated to underestimate foreign-born and noncitizen populations [13]. Some indices, such as the COI, are pediatric-specific. Investigators at Brandeis University and the Kirwan Institute at the Ohio State University collaborated to create and validate the COI, which ranks neighborhoods on health, socioeconomic, and education, and environmental indicators related to child health outcomes [14,15]. Not all indices were intended for research and clinical practice. For example, the Centers for Disease Control and Prevention and the Agency for Toxic Substances and Disease Registry originally created the SVI to help communities plan for and manage emergency responses to natural disasters and infectious disease outbreaks and include measures of socioeconomic status, household composition, minority status and language, housing, and transportation [16,17]. However, in recent years, investigators have used SVI scores to operationalize SDOH to determine associations between SDOH and health care access, surgical outcomes, and cancer screening [18-20].

Indices may be useful for informing clinical care, policy, and research; however, many publicly available indices exist without clear guidance or a gold standard for when or which index should be used. In many cases, investigators choose indices based on familiarity or available geographic information [21]. Our work seeks to examine the concordance of 3 indices by testing these indices on a single-state pediatric central nervous system (CNS) tumor cohort. We selected this cohort because brain and spinal cord tumors are the leading disease-related causes of death among children and teens and despite significant gains in survival outcomes, this population remains at elevated risk for poor health and higher health care use than the general pediatric population [22].

In this study, we raised and answered the following questions: do neighborhood indices correlate with emergency department (ED) use and hospitalizations, and is there discordance between these neighborhood indices? We hypothesize that neighborhood indices are correlated with downstream outcomes such as a higher likelihood of ED visits and hospitalizations, but effect sizes will be small. We also hypothesize that indices are discordant due to varying weighting techniques and input data used to construct the indices. Therefore, we hypothesize that indices also cannot be used interchangeably. Our study aims include determining whether indices are associated with health care use (ED visits and inpatient encounters).

Methods

Study Setting, Data, and Population

This cross-sectional analysis uses patient-level data from the Indiana Network for Patient Care research database, which includes most health care organizations throughout Indiana. We used data from this repository to identify pediatric patients with brain and CNS tumors. We then cross-referenced the patients with relevant diagnosis codes to state cancer registry data to exclude patients who might have had health care encounters in Indiana but were not Indiana residents or did not receive a plurality of care in Indiana. Our inclusion criteria were any patient diagnosed before the age of 21 years and any patient with an encounter between January 1, 2010, through December 31, 2020. We bounded the cutoff age at 21 years rather than 18 years to reflect the common practice in pediatric oncologists to treat patients up to 21 years and the *Bright Futures* guidelines from the American Academy of Pediatrics. We excluded any patients' missing sex, date of birth, or addresses. We then geocoded patients' addresses and assigned each patient a census block group or census tract. For patients with multiple addresses in their electronic health records, we geocoded the modal address. Data for the ADI, COI, and SVI were publicly available and downloadable as either text files or comma-delimited files. These indices were then linked to the patient cohort data by matching on census tracts for the COI and the SVI and census block groups for the ADI. The ADI is only validated at the census block group level; thus, we did not aggregate census block groups up to the census tract level.

Measures

We evaluated 2 visit types: inpatient encounters (hospitalizations) and ED. For each patient in our cohort, we

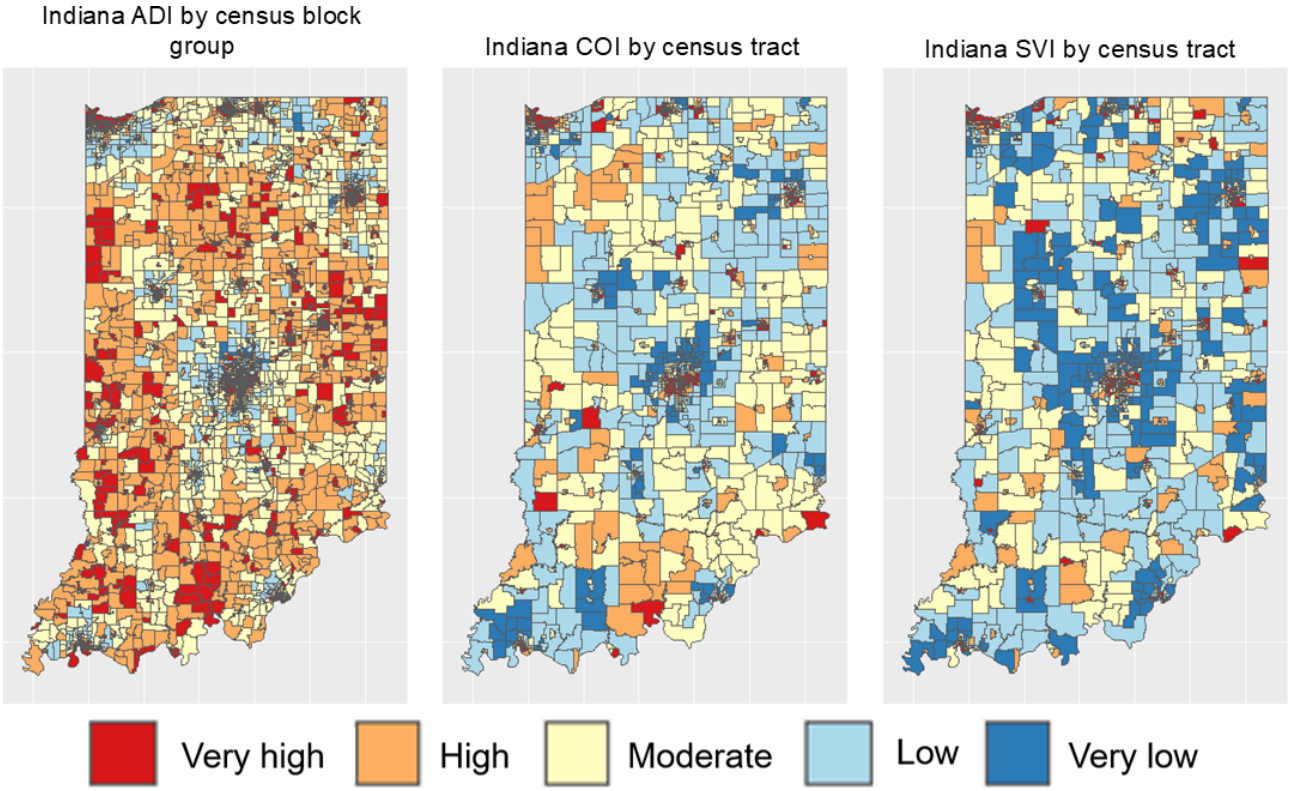
XSL•FO
RenderX

computed the number of ED encounters and hospitalizations. Our main analyses were count data for each visit type. We also created 2 binary measures for whether a patient had any ED visit or any hospitalization during our study period. Finally for each visit type, we computed a categorical measure (0 visits, at least 1 visit, and 2 or more visits).

Our main exposure variables were index quintiles, which we derived from raw scores for each index. The ADI and COI score neighborhoods numerically, from 1 to 100 based on deprivation or opportunity. For the ADI, higher scores mean more severe deprivation or disadvantage, while for the COI, higher scores mean greater opportunity. The SVI scores neighborhoods (census tracts) on a scale of 0 to 1, with values closer to 1 indicating higher vulnerability. Other controls and covariates included age at diagnosis, diagnosis category, sex, race as a binary indicator of "White" or "non-White," ethnicity (Hispanic or Latino vs not Hispanic or Latino), urbanicity (a binary indicator of urban or nonurban based on rural-urban codes), and distance (in kilometers) to the state's children's hospital where the patients were diagnosed or had at least 1 encounter.

Statistical Analysis

Descriptive analyses were first used to summarize the patient cohort's characteristics. For categorical variables, we presented frequencies and proportions. For continuous variables, we presented means and SDs. Next, we fitted a series of zero-inflated Poisson regression models for each of our outcome variables. In these models, we regressed visit type (ED visit counts or inpatient visit counts) on index quintiles and controlled for age at diagnosis, patient sex, diagnosis category, race, ethnicity, urbanicity, and visit year. We selected distance to the pediatric cancer center as our "inflate" variable based on the assumption that the farther away the patient is from the site of cancer treatment, the more likely the patient would rely on ED for some care. With regard to hospitalizations, patients closer to the pediatric cancer center might have their health better managed—reducing the possibility of being hospitalized. Alternatively, patients living far away from the pediatric cancer center, especially those in remote or rural areas, might use less care, therefore contributing excess zeros in our data. This approach addresses our overdispersion problem by accounting for an excess 0 ED visits and an excess number of patients with no hospitalizations in our data. We considered findings statistically significant at the α=.05 level. Statistical analyses were conducted in Stata SE (version 18; StataCorp LLC).



Supplemental Analyses

To test alternative specifications, we also fitted multivariable logit and ordered logit models for each visit type in additional analyses, which we report in Multimedia Appendix 1. In logit models, we regressed visit type as a binary indicator of "0" for never having a visit or "1" for having at least 1 visit on the index quintile and controlled for age at diagnosis, patient sex, diagnosis category, race, ethnicity, urbanicity, visit year, and distance to the pediatric cancer center. In our ordered logit models, we regressed visit type on the same set of explanatory variables and controls. However, our outcome variables were categorical variables with 3 levels ("never having a visit," "1 visit," and "more than 1 visit").

For each index, we overlaid index quintiles onto census tracts or census block groups to help readers visualize how indices classify or categorize neighborhoods in Indiana (Figure 1). All dataset assembly and visualizations were conducted using R (version 4.0.4; R Foundation for Statistical Computing) in the RStudio environment.

Ethical Considerations

This study received expedited approval from the Indiana University Institutional Review Board (IRB #13628) on December 3, 2021, and satisfied the waiver of authorization criteria in accordance with 45 CFR 164.512(i)(2)(ii). Because we analyzed deidentified secondary data, study participants did not receive compensation. All data were stored and analyzed in Health Insurance Portability and Accountability Act–compliant environments.

Results

Sample Characteristics

After applying our inclusion and exclusion criteria, our study cohort contained 524 patients. Table 1 presents sample characteristics. Of 524 eligible patients, 78.6% (n=412) had 0 ED visits, and 39.7% (n=208) had no hospitalizations. The average age at diagnosis was 7.9 (SD 5.4) years. Our patient cohort contained a higher proportion of male patients (n=297, 56.7%) to female patients (n=227, 43.3%). Additionally, the majority of our patient cohort was non-Hispanic White, urban-dwelling, and residing approximately 130 km from the local pediatric cancer center.

[a]Area Deprivation Index rankings were converted into quintiles in order of lowest to highest deprivation.

[b]Child Opportunity Index rankings were converted into quintiles in order of lowest to highest opportunity.

[c]Social Vulnerability Index rankings were converted into quintiles in order of lowest to highest vulnerability.

ED Visits

In comparing zero-inflated models for ED visits, we observed similarities and differences. Across all 3 models presented in Table 2, children who were diagnosed at an older age and male patients were less likely to have ED visits. Furthermore, urban-dwelling patients were more likely to have received care in an ED. However, we observed discordance among indices. Moderate (coefficient=0.306; *P*=.01) and high (coefficient=0.315; *P*=.01) deprivation were associated with more ED visits compared to very low deprivation. In contrast, both low child opportunity (coefficient=0.497; *P*<.001) and very high child opportunity (coefficient=0.328; *P*=.01) were associated with more ED visits compared to very low child opportunity. With regard to the SVI, all levels were associated with increased ED visits compared to very low social vulnerability.

Hospitalizations

In comparing zero-inflated model output among indices, we also find that indices do not produce similar estimates. Furthermore, we also do not observe a dose-dependent relationship between hospitalization and level of deprivation, opportunity, or vulnerability. Both low deprivation (coefficient=0.273; *P*=.003) and very high deprivation (coefficient=0.207; *P*=.03) appear to be associated with more hospitalization episodes. Meanwhile, models using the COI or the SVI produced null findings (Table 3). Across all zero-inflated models with hospitalization counts as the outcome variable, urbanicity was associated with fewer hospitalization episodes.

[a]Area Deprivation Index (ADI) rankings were converted into quintiles in order of lowest to highest deprivation.

[b]Child Opportunity Index (COI) rankings were converted into quintiles in order of lowest to highest opportunity.

[c]Social Vulnerability Index (SVI) rankings were converted into quintiles in order of lowest to highest vulnerability.

[d]Not available.

Supplemental Analyses

In our logit models, we did not find any relationship between index quintile and hospitalization (Tables S1-S3 in Multimedia Appendix 1). Moderate (adjusted odds ratio [aOR] 1.55, 95% CI 1.14-2.09; *P*=.005) and high deprivation (aOR 1.47, 95% CI 1.07-2.02; *P*=.02) were associated with increased odds of ED use compared to the reference category (very low area deprivation; Table S4 in Multimedia Appendix 1). Similarly, with the COI, we did not find a dose-dependent relationship. Low opportunity (aOR 1.46, 95% CI 1.09-1.96; *P*=.01) and moderate opportunity (aOR 1.72, 95% CI 1.29-2.30; *P*<.001) were associated with increased odds of ED visits compared to very low opportunity (Table S5 in Multimedia Appendix 1). When we regressed the binary indicator of any ED visit on the SVI quintile, we did observe that moderate to very high social vulnerability was significantly associated with higher odds of ED use but not low social vulnerability (Table S6 in Multimedia

XSL•FO
RenderX

Appendix 1). In ordered logit models, we also failed to uncover any concordance or consistency among indices in predicting ED use or hospitalization. Across the ordered logit models, we did consistently find that the farther patients are from the pediatric cancer center, the lower the odds of ED and inpatient visits (Tables S7-S12 in Multimedia Appendix 1).

Maps

For the most part, all 3 indices covered all neighborhoods in Indiana, except for the SVI, which lacked data for 1 census tract. After overlaying index quintiles onto neighborhoods, we found some differences and similarities in how indices rank or score neighborhoods. Although it was not fully possible to compare the ADI to the COI or SVI since the ADI is validated at the census block group level and the COI and SVI are validated at the census tract level, all 3 indices ranked neighborhoods in Central Indiana (near Indianapolis) less favorably due to higher deprivation, lower opportunity, or higher social vulnerability (Figure 1 and Table 4). Of all 3 indices, the ADI, which produces neighborhood estimates at a more granular geographic unit, ranked neighborhoods as highly or very highly deprived at 68% of the time compared to 42% for the COI and 37% for the SVI. Additionally, the ADI was more likely to classify neighborhoods' near state borders as highly or very highly deprived.

Table . Frequency table for index categories.

	ADI[a]	COI[b]	SVI[c],
Very low, n (%)	89 (1.7)	342 (22.7)	281 (18.7)
Low, n (%)	464 (8.9)	283 (18.8)	337 (22.4)
Moderate, n (%)	1128 (21.7)	379 (25.2)	328 (21.8)
High, n (%)	1612 (31)	345 (22.9)	310 (20.6)
Very high, n (%)	1909 (36.7)	156 (10.4)	248 (16.5)
Total census block group or census tracts, n	5202	1505	1504

[b]COI: Child Opportunity Index.

[c]SVI: Social Vulnerability Index.

Discussion

Principal Findings

In several of our models, we did find statistically significant associations between indices and ED visits or hospitalizations, but these findings were often isolated to specific quintiles of the indices. In other words, we did not observe evidence of dose-dependent or meaningful associations between these indices and ED or inpatient visits. Additionally, we also observed discordance between the indices in both our regression models and our maps. We expected to observe discordance due to the difference in input variables, data sources, and weighting decisions made by those who created and validated these indices. By demonstrating discordance in our findings, we contribute further evidence that indices are not interchangeable—that selection of index has implications for conclusions. Furthermore, while scholars in the pediatric cancer domain have incorporated indices into epidemiological and predictive modeling, our study is one of the first to compare multiple indices. Still, more research is needed to help establish a gold standard and an informative guide for researchers to reference in selecting which index to use, and many scholars have made significant progress toward qualitatively comparing the indices based on input variables, geographic nits, and study contexts [21,23].

Despite the lack of meaningful associations between indices and health care use measures, we found consistent associations between urbanicity and health care use as well as age and health care use. In our zero-inflated models, patients in urban settings had greater ED use and lower hospital use, which contradicts a corpus of studies showing that rural ED use often outpaces urban ED use [24,25]. Most hospitalizations are not predictable or planned events, and we lacked sufficient data to explain why we might see lower hospitalizations among urban-dwelling patients. However, it is possible that because physician or provider supply tends to be higher in urban areas, patients may have greater access to outpatient care and thus having health conditions and comorbidities better managed than nonurban-dwelling patients. The Indiana Network for Patient Care is one of the largest state health databases in the United States, so we believe that our data capture the majority (if not all) of a patient's encounters; however, it is possible that we may have missing use data from smaller, nonintegrated or independent EDs that do not contribute or share data with the Indiana Health Information Exchange. Furthermore, we may also have failed to capture out-of-state encounters among patients who live closer to the border of other Midwestern states (eg, Ohio, Illinois, or Kentucky). Consistent across our models, children diagnosed with a brain or CNS tumor later in childhood had lower health care use than children diagnosed at a younger age. We believe this might be because children undergoing cancer treatment have less developed organs, which may make them more vulnerable to adverse side effects of treatment [26]. This finding also contradicts some studies, showing that young adults or adolescents tend to have more ED visits because their treatment plan closely resembles treatment plans for adult patients with cancer—often resulting in a higher risk of toxicity from treatment [27]. Without additional context into what additional comorbidities or chronic conditions the patients might

XSL•FO
RenderX

have and their treatment plans, we cannot make any strong conclusions about why age matters.

Limitations

This study is not without several limitations. First, our findings are not generalizable to other patient populations, given that our cohort consisted of only pediatric patients with brain and CNS cancer found in one Midwest state's health information exchange. Consequently, our patient cohort was relatively small, containing 524 patients and over 30,000 encounters. Second, a plurality of our patient cohort was of non-Hispanic or Latino ethnicity and of White race, thus limiting our ability to detect racial and ethnic disparities. Third, we had limited information about patients' health status and health care use behaviors and could not stratify or adjust for the severity of cancer, the presence of comorbidities, or if any use was preventable. Fourth, comparing indices was complicated by the fact that indices were validated at different geographical levels. For example, the COI and SVI were validated at census tract levels, while the ADI was validated at the census block group level. Census block groups are more granular than census tracts and may be more sensitive or pick up more variation than indices validated at larger geographic units such as census tracts or counties. Finally, this study qualitatively and descriptively compared indices and did not use more complex quantitative approaches such as factor analyses.

Conclusions

This study contributes evidence to understanding how neighborhood indices can be used and when they might not have much utility. We found that even though the indices occasionally produced similar results in regression models, there was also much discordance among indices. More research is needed to understand how indices are used in clinical settings and whether the information provided by these indices is relevant to clinicians, patients, and patient outcomes. Although our work has limited generalizability outside of pediatric populations with cancer and our analyses should be tested on larger or more diverse patient cohorts, our work suggests that indices may not be useful for clinicians or other providers in helping them screen out or screen for patients who may need social services. Other methods or approaches such as household material hardship screening may yield more accurate patient-level information, with the tradeoff being low response rates to surveys, submission of incomplete surveys, or staff time needed to administer and analyze survey results [28]. Future work will consider qualitative and mixed method approaches to identify clinicians using these indices and to seek insight into how such clinicians interpret and make decisions with such information.

Abstract

Background: Converging evidence indicates an adolescent mental health crisis in Western societies that has developed and exacerbated over the past decade. The proposed driving factors of this trend include more screen time, physical inactivity, and social isolation, but their causal influence on mental health is insufficiently understood.

Objective: The objective of this study is to test whether and based on which predictor variables the development of mental health in adolescents in the last decade can be predicted and to better understand the causal chain of factors at work.

Methods: We implemented an interpretable machine learning pipeline based on gradient boosting regression with repeated cross-validation to assess the development of mental health throughout adolescence in members of 2 longitudinal cohort studies, the British Millenium cohort (MC; n=8599) and the German Health Interview and Examination Survey for Children and Adolescents (KiGGS) cohort (n=1212). In total, 144 (MC) and 102 (KiGGS) predictors assessed at the age of around 13.8 years (MC) and 11.6 years (KiGGS) were used to assess mental health at the ages of around 16.7 years (MC) and 16.4 years (KiGGS). Based on these predictive models, we used permutation-based feature importance analyses to identify relevant predictors and predictor domains. Moreover, we performed partial dependence analyses in a causal inference framework to determine the direct effects of physical inactivity, screen time, and peer problems on the development of mental health.

Results: The average cross-validated Pearson correlation coefficient (r) between predicted and true mental health in late adolescence was 0.614 (MC) and 0.466 (KiGGS). Feature importance analyses indicated a strong impact of preexisting mental health and weaker impacts of sex (female as a risk factor), physical health (chronic disease as a risk factor), lifestyle, and socioeconomic and family factors (eg, low parental education, income, and mental health as risk factors). Causal inference analyses suggested a strong direct effect of peer relationships, but only a small direct effect of physical inactivity and a very small direct effect of screen time.

Conclusions: Mental health development during adolescence can be assessed by a combination of variables from early adolescence. Peer problems represent an important direct cause of mental health development, and their deterioration may contribute to the current mental health crisis.

Introduction

Adolescence is a critical period of life when people explore, experiment, and are exposed to particular risk factors such as substance use, violence, bullying, and academic problems. It is when the course is set for health in adulthood [1]. The current debate about an adolescent and young adult mental health crisis in Western countries [2,3] is therefore all the more important, especially because it is substantiated by a number of recent

XSL•FO
RenderX

findings: a study comparing 2 UK birth cohorts found that while no difference was found during childhood, there were markedly more emotional problems during adolescence in individuals born 2000 - 2002 compared to individuals born 1991 - 1992 [4]. Consistently, a recent comparison of 2 methodologically standardized and comparable Dutch population surveys showed almost a doubling of affective disorders between the years around 2008 and around 2021, with the increase being particularly pronounced among young adults [5]. In the United States, after a years-long decline, rising depression among adolescents has been reported since about 2010 [6], accompanied by an increase in suicide rates in this age group [7]. While prevalence rates for externalizing mental health problems among children and adolescents in Germany were declining before the COVID-19 pandemic, emotional problems also increased here between 2003 - 2006 and 2014 - 2017, especially among girls [8]. These alarming results are in line with findings from other countries, although there is heterogeneity and effect sizes appear slightly smaller in meta-analytic summaries [9]. While reduced stigma and an increased readiness to report mental health problems might partly contribute to these trends, it is remarkable that rising prevalence rates are also reported in studies that used the same standardized and well-validated clinical interview over different time periods [5]. Moreover, investigations relating time trends of self-reported mental disorders to time trends of stigmatization of mental disorders in the same regions did not find evidence that reduced stigma explains the increase in self-reported mental health problems [10].

Summarizing the evidence suggests that since about 2010, there seems to be a marked cross-national increase in mental health problems of adolescents, particularly concerning internalizing or emotional problems and affective disorders. The causes for this increase are insufficiently understood [2]. Proposed risk factors cover rising screen time and social media consumption [11], worsened peer relationships with loneliness and social isolation [12], and physical inactivity [13]. However, the predictive strength and the causal interplay of these factors are still unclear and debated.

To address this research gap, we used multivariable machine learning models to assess the development of mental health from early to late adolescence in members of longitudinal cohort studies. This allows us to model nonlinear relationships between numerous predictors in early adolescence and the future development of mental health, as well as to test the quality of the resulting predictions by means of cross-validation. We investigated 2 large independent population-based cohort studies of adolescents, the UK Millennium Cohort (MC) study [14] and the German Health Interview and Examination Survey for Children and Adolescents (KiGGS) [15]. This approach allows a robust comparison of results between 2 independent cohorts from different countries.

The analyzed cohort studies were conducted in countries affected by the mental health crisis, and the investigated time period covers exactly the "critical period" of the crisis development from 2010 onwards. Thus, the developed models can also be used to add further evidence to the debate on driving factors of this deterioration. More specifically, it can be examined which simulated changes in risk factors that have been implicated in the ongoing mental health crisis actually led to worse predicted mental health. However, assessing beyond pure predictive relationships the causal impact of these risk factors on the development of mental health involves stronger assumptions and challenges interpretation [16]. In this work, we draw on our multivariable models in conjunction with recent research on the causal interpretation of predictive models [17] and on the appropriate selection of covariates [18]. Based on this approach, we assess the independent effect of proposed driving factors for the adolescent mental health crisis (increased screen time, less physical activity, and worsened peer relationships).

We aimed to answer 3 related research questions. (1) How well can mental health in late adolescence be assessed based on assessments in early adolescence? (2) Which assessments in early adolescence are important for these assessments? (3) What are the independent impacts of physical activity, screen time, and peer relationships on unfavorable mental health trajectories of adolescents in the years after 2010?

Methods

Analyzed Cohort Studies

For reciprocal validation, analogous analyses were conducted in 2 European cohort studies of child and adolescent health. The first one was the MC study investigates the development of children born in 2000-2002 in the United Kingdom [19]. For this study, we assessed the participants' mental health at the age of around 17 (hereafter referred to as "follow-up acquisition") based on assessments at the age of around 14 ("baseline acquisition"). The second one was the KiGGS, a population-based study for German children and adolescents with 3 longitudinal assessment waves [15]. In KiGGS, we used participants' assessments at the age of around 12 years ("Baseline acquisition") to assess their mental health at the age of around 16 years ("Follow-up acquisition"). A participant flowchart for both cohorts is shown in Figure S1 in Multimedia Appendix 1, and the final sample is described in Table 1.

[a]KiGGS: German Health Interview and Examination Survey for Children and Adolescents.

Ethical Considerations

All MC waves were approved by medical research ethics committees, specifically by the National Research Ethics Service Research Ethics Committee London—Central for the baseline acquisition (approval 13/LO/1786) and by the National Research Ethics Service Research Ethics Committee North East—York for the follow-up acquisition (approval 17/NE/0341). The ethics committee of the Charité – Universitätsmedizin Berlin has approved the KiGGS baseline study (approval 101/2000) and KiGGS Wave 1 (approval EA2/058/09), and the ethics committee of the Hannover Medical School has approved KiGGS Wave 2 (approval 2275 - 2014).

Outcome, Predictors, and Sample Weights

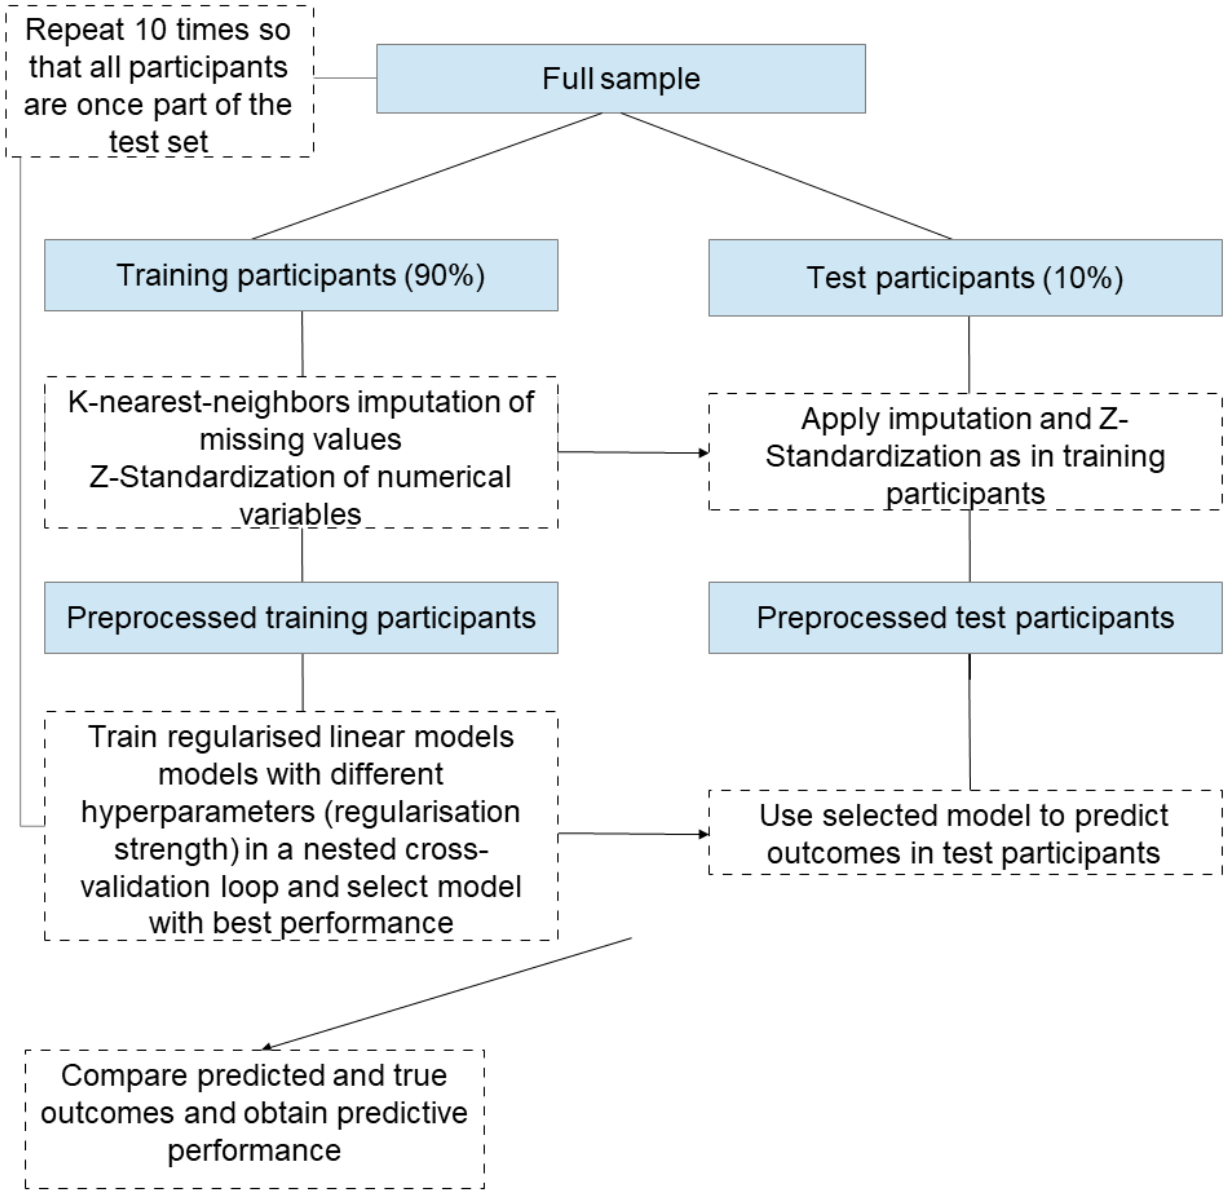
Consistent with previous studies [4] and because of its availability in both cohorts at both examination times, we used the emotional symptoms sum score of the parents-reported Strength and Difficulties Questionnaire (SDQ) as the outcome measure in both cohorts. The SDQ is among the most established assessment tools for mental health in children and adolescents [20]. Its emotional symptoms subscale (SDQ-E) consists of 5 items on a 0 - 2 Likert scale, which are summed to give a total score ranging from 0 to 10. It has demonstrated a high accuracy in detecting depressive and anxiety disorders [21].

Based on consultations with experts in adolescent mental health (RS, URS), the study assessments were systematically screened and a broad set of predictors of future mental health was included and assigned to the domains of mental health and well-being (eg, questions on depressive and anxiety symptoms, history of self-harm [22]), physical health (chronic diseases, BMI [23]), psychological and cognitive testing (school grades, cognitive assessments, moral attitudes), socioeconomic and family factors (family climate, socioeconomic status, and mental health problems of the parents [24,25]), lifestyle and peer relationships (substance use, media consumption, activities [11,26,27]), and others (sex [28]). A complete list of selected predictors, domain assignments, and the percentage of missing values can be found in Tables S1 and S2 in Multimedia Appendix 1. The analysis of predictor domains in addition to individual predictors aimed to simplify the interpretation of the feature importance analyses and to stabilize the results against the inclusion or exclusion of individual predictors. Hence, in contrast to data-driven dimension reduction techniques, the focus here was not on an explanation of the highest possible variance of the predictors by the factors but on their conceptual interpretability. However, post-hoc tests showed that these content-based domain assignments significantly better captured the latent factor structure of the data as compared to random assignments (Text S1 in Multimedia Appendix 1).

Both investigated cohort studies aimed for representativeness for the total population of the surveyed country. However, because individuals with certain sociodemographic criteria were underrepresented in the sampled cohort compared with the total population, both cohorts provide weight variables to give individuals from underrepresented groups more weight in the analyses. To further increase the generalizability of our results to the overall country population, we used these weights (GOVWT2 variable for the MC, wQSpop variable for KiGGS) in all univariable and multivariable analyses.

Univariable Comparisons

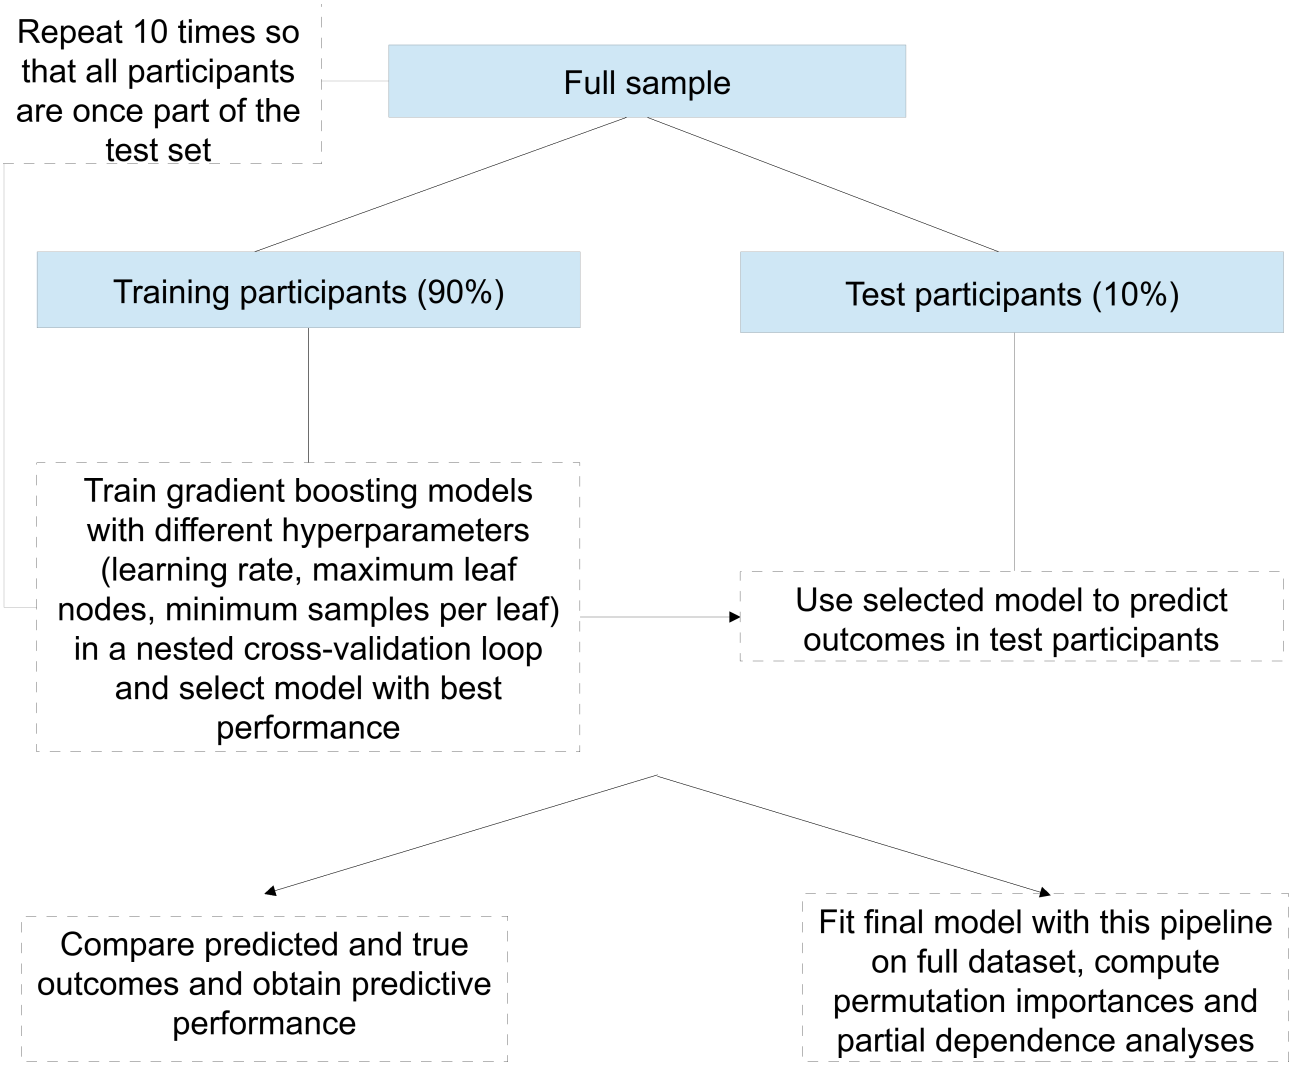
To obtain unadjusted associations between individual predictors and outcomes, we calculated linear models with each predictor as the only independent variable, based on data completed using K-nearest neighbors imputation (KNNImputer class of the scikit-learn toolbox for Python [29] with default parameters) and weighted with population sample weights. Exploratory tests on the quality of the values imputed in this way revealed highly significant correlations between imputed and actual values, which would not be achievable with univariate imputation methods such as mean or median imputation (Text S2 in Multimedia Appendix 1). Here, numerical predictors were z-standardized (so that the resulting coefficient values are identical to Pearson correlation coefficients). These analyses make it possible to assess correlative (uncorrected) relationships between the individual predictors of interest and mental health in later adolescence.



Multivariable Machine Learning Pipelines

Separately for both cohorts, we computed multivariable models that assess mental health at follow-up with all predictors combined. We used 10-fold cross-validation for a regularized linear and a nonlinear pipeline within the scikit-learn environment (Figures 1 and 2 for details). To correct for chance effects, the analyses were repeated 10 times with different random number generator seeds, and the results were averaged (so that the validation altogether amounts to a 10 times repeated 10-fold cross-validation). Nonlinear regression can improve the accuracy of predictions by modeling nonlinear relationships between predictors and outcomes, for example, in the form of interactions (ie, the effect of social media consumption on future

XSL•FO
RenderX



mental health might depend on gender) or nonlinear effects of single predictors (ie, very low or very high BMI values might both predict worse mental health). We used gradient boosting models (GBM [30]), which are currently considered the most accurate predictive tools for tabular datasets [31]. Specifically, we applied histogram-based GBMs as implemented in the HistGradientBoosting classes of scikit-learn for Python, which can automatically handle categorical and missing data. Hence, no imputation and encoding of categorical variables was performed as preprocessing in the nonlinear pipeline. The predictive performance was assessed with Pearson correlation coefficients and the mean squared error between predicted and true SDQ-E scores at follow-up in test set participants.

Figure 1. The linear pipeline comprised one-hot encoding of categorical variables, K-nearest neighbor imputation of missing values (as implemented in the scikit-learn KNNImputer class with default parameters), Z-standardization of numerical variables, and fitting of a linear model to predict the outcomes. To improve the predictive performance through mitigation of overfitting, we performed L2 regularization of the model's regression coefficients (Ridge regression), where the optimal regularization strength was determined in a nested 5-fold cross-validation loop in each training set.

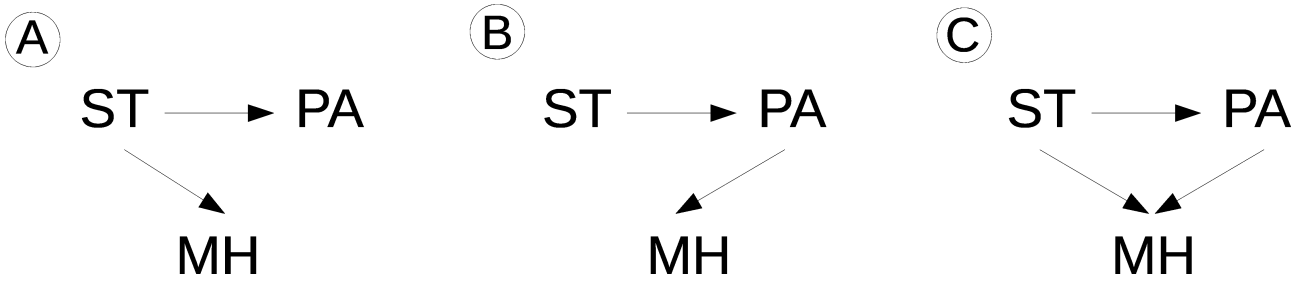
XSL•FO
RenderX

Figure 2. The nonlinear pipeline comprised fitting of a gradient boosting regression model to predict the outcomes, where the optimum value of crucial hyperparameters was determined in a nested 5-fold cross-validation loop in each training set. Iterations (adding of new trees to the predictor) were stopped when the predictor's performance did not improve over the last 10 iterations. Due to the model's native ability to handle missing values and categorical variables, no such preprocessing (imputation and encoding) was necessary.

Predictor Importance Estimation

To obtain a measure of the importance of individual predictors in the multivariable models, we calculated permutation-based feature importances as implemented in the PermutationImportance class of the Alibi explain toolbox for Python [32]. This technique assesses the decline in a model's performance when the associations between predictor and outcome are removed by randomly interchanging the values of 1 feature. The magnitude of decline in the model's performance afforded by this permutation quantifies the extent to which the model relies on that specific predictor [33]. Here, we report the percentage change in performance when the predictor is intact compared to when it is perturbed.

Since the importance of individual predictors in multivariable models with many predictors is difficult to interpret (ie, the importance of a predictor decreases when a correlated predictor is added), we, moreover, applied a variant of this algorithm, which calculated the importance of a priori defined domains of predictors (Tables S1 and S2 in Multimedia Appendix 1) domains of predictors. The procedure here was identical to that for individual predictors (the predictors belonging to a domain are permuted together, and the associated decline in predictive performance is determined). To correct for potential chance effects, we fitted 10 GBMs with different random generators and averaged the predictor importances over these 10 models.



Causal Effects of Predictor Changes

We assessed the causal effect of factors whose change is discussed as the cause of the observed adolescent mental health crisis (physical inactivity, screen time, peer problems). In contrast to linear models, nonlinear regressors such as GBMs do not have simple coefficients that capture the adjusted influence of a predictor on the outcome. Hence, we artificially changed the baseline values of the relevant predictors for all participants to estimate the adjusted effects of these factors on mental health development during adolescence. All other predictors were kept unchanged, and we assessed mental health with these changed predictor values. This approach is similar to partial dependence plots [34] and can yield causal estimates when "backdoor paths" [35] between changed predictor and outcome are closed through appropriate inclusion of covariate predictors in the model [17]. However, ensuring that all

XSL•FO
RenderX

backdoor paths are closed would require complete knowledge of the real causal graph, which is hardly possible in practice. Therefore, heuristics were developed for the best possible selection of predictor covariates to isolate causal effects, which can be applied with incomplete knowledge of the causal graph [18]. In line with this approach, we included available assessments of causes of mental health and of the factors investigated for causal effects on mental health into the predictive models. It should be noted that since this approach might lead to the inclusion of variables on the causal path from predictor to outcome (ie, effect mediators), the total causal effect (ie, the direct effect plus the effect indirectly mediated by mediators) of the predictors cannot be determined in this way [17,18]. Thus, the influence of the calculated predictors calculated is not an answer to the question, "How would mental health change in late adolescence if this predictor had a different value in early adolescence and the values of all other variables affected by this predictor also changed accordingly?" but rather to the question, "How would mental health change in late adolescence if this predictor had a different value in early adolescence but all other variables (including those potentially affected by the changed predictor) remained the same?" (Figure 3). This means that if an effect is found for a predictor in such an analysis, it represents a direct (ie, not conveyed via other mediators included in the model) cause of the further development of mental health.

Figure 3. Exemplary possible causal relationships between screen time (ST), physical activity (PA), and mental health (MH). (**A**) Screen time could reduce physical activity and worsen mental health. Screen time thus generates a statistical relationship between physical activity and mental health, although a causal relationship is missing in this example. In this case, a partial dependence analysis would falsely show an improvement in mental health due to an increase in physical activity if screen time is not included in the model. The inclusion of screen time in the model closes this "backdoor path," and conditional on screen time, physical activity and mental health become independent. A partial dependence analysis in this case (ie, with inclusion of screen time in the model) would correctly show an improvement in mental health through a reduction in screen time but not through an increase in physical activity. (**B**) High screen time could reduce physical activity and (only) thereby worsen mental health. In this case, without including physical activity in the model, there would be a statistical relationship between screen time and mental health. Conditioned on physical activity (by including this predictor in the model), screen time and mental health become statistically independent. If physical activity is not included in the model, a partial dependence analysis would show an improvement in mental health afforded by a reduction in screen time. However, if physical activity is included, a partial dependence analysis would show no effect of a reduction in screen time, but only of an increase in physical activity. (**C**) High screen time could have a direct negative effect on mental health and an additional indirect (mediated) effect by reducing physical activity. Without including physical activity in the model, in this case both the direct and the indirect (mediated by physical activity) effect on mental health would be "attributed" to screen time, and a partial dependence analysis would accordingly show the total effect (direct plus indirect effect) of a reduction in screen time. Including physical activity in the model would "attribute" the effect of screen time mediated by physical activity to physical activity. In this case, a partial dependence analysis would only show the direct effect of screen time on mental health.

Specifically, we tested the effect of screen time in both cohorts by setting all questions relating to time spent with media consumption to the minimum value (lowest), the 1/3 percentile (low), the 2/3 percentile (high), and the maximum value (highest). In both cohorts, these were questions about the hours spent using TV, computers, cell phones, and social media per day (details on all items in Tables S1 and S2 in Multimedia Appendix 1). Similarly, we set the values for questions on physical inactivity in both cohorts to minimum, 1/3 percentile, 2/3 percentile, and maximum and tested the impact on predicted mental health in late adolescence. These were questions on the number of days spent last week doing moderate to vigorous physical activity and the total minutes in moderate to vigorous physical activity as objectively recorded by the accelerometer in the MC and questions about the total hours of sports per week and the number of days physically active in the last 7 days in the KiGGS cohort (Tables S1 and S2 in Multimedia Appendix 1 for details). For peer problems, we changed parent-reported peer problems (as assessed in the SDQ with items like "The child has at least one good friend" or "The child is generally liked by other children"), the assessment of happiness with friendships, the feeling that "there is no one I feel close to," and that "there is someone I trust whom I would turn to if I had problems" in the MC. Similarly, we changed the parent- and self-reported peer problems in the SDQ and the social support scale sum score value in the KiGGS cohort. Again, details on the items used to measure peer problems can be found in Tables S1 and S2 in Multimedia Appendix 1.

Similar to the feature importance estimation, we fitted 10 GBMs with different random generators and averaged the predicted mental health under all predictor changes over these 10 models to compensate for random calculations during model training.

Data and Code Availability and Adherence to Reporting Guidelines

The analysis code used to generate the study results is freely available at the GitHub page of the authors[36]. For privacy reasons, the data cannot be made public, but data access can be requested at the institutes implementing the cohort studies (MC: Center for Longitudinal Studies of the University College London; KiGGS cohort: Department of Epidemiology and Health Monitoring of the Robert Koch Institute). The reporting of the model development and validation followed the Transparent Reporting of a multivariable prediction model for

XSL•FO

Individual Prognosis Or Diagnosis (TRIPOD [37]) guidelines (Table S4 in Multimedia Appendix 1).

Results

Univariable Relationships Between Baseline Predictors and Future Mental Health

The strongest statistically significant unadjusted linear relationships between baseline predictors and mental health at follow-up are shown in Figure 4 and coefficients of all predictors can be found in Tables S1 and S2 in Multimedia Appendix 1. Previous mental health problems, mental health problems of the parents, conduct problems, physical health problems and pain, low socioeconomic status, female sex, victimization, and potential exposure to marginalization and discrimination were related to worse future mental health in both cohorts.

Figure 4. Univariable (unadjusted) linear relationships and 95% confidence intervals between predictors assessed at baseline and mental health (Strength and Difficulties Questionnaire—Emotional [SDQ-E]) at follow-up for the Millennium Cohort (upper row) and the KiGGS cohort (lower row). For reasons of conciseness, only the 20 most important predictors with statistical significance are shown and sorted in descending order of absolute coefficients. A complete overview of all predictors, including their univariable coefficients and their assignment to predictor domains, can be found in Tables S1 and S2 in Multimedia Appendix 1. For binary predictors, a "yes"-response was generally coded as 1, meaning that a negative value indicates less future mental health problems when the question was answered with "yes." Ordinal-scaled items were ordered so that higher values indicated stronger agreement with a question.

Predictive Performance of Multivariable Models

The average cross-validated predictive performance of the multivariable linear and nonlinear models is summarized in Table 2 (Pearson correlation coefficients between predicted and true SDQ-E scores as well as mean squared error). In both cohorts, the nonlinear model performed better on average and was hence used for further analyses.

XSL•FO

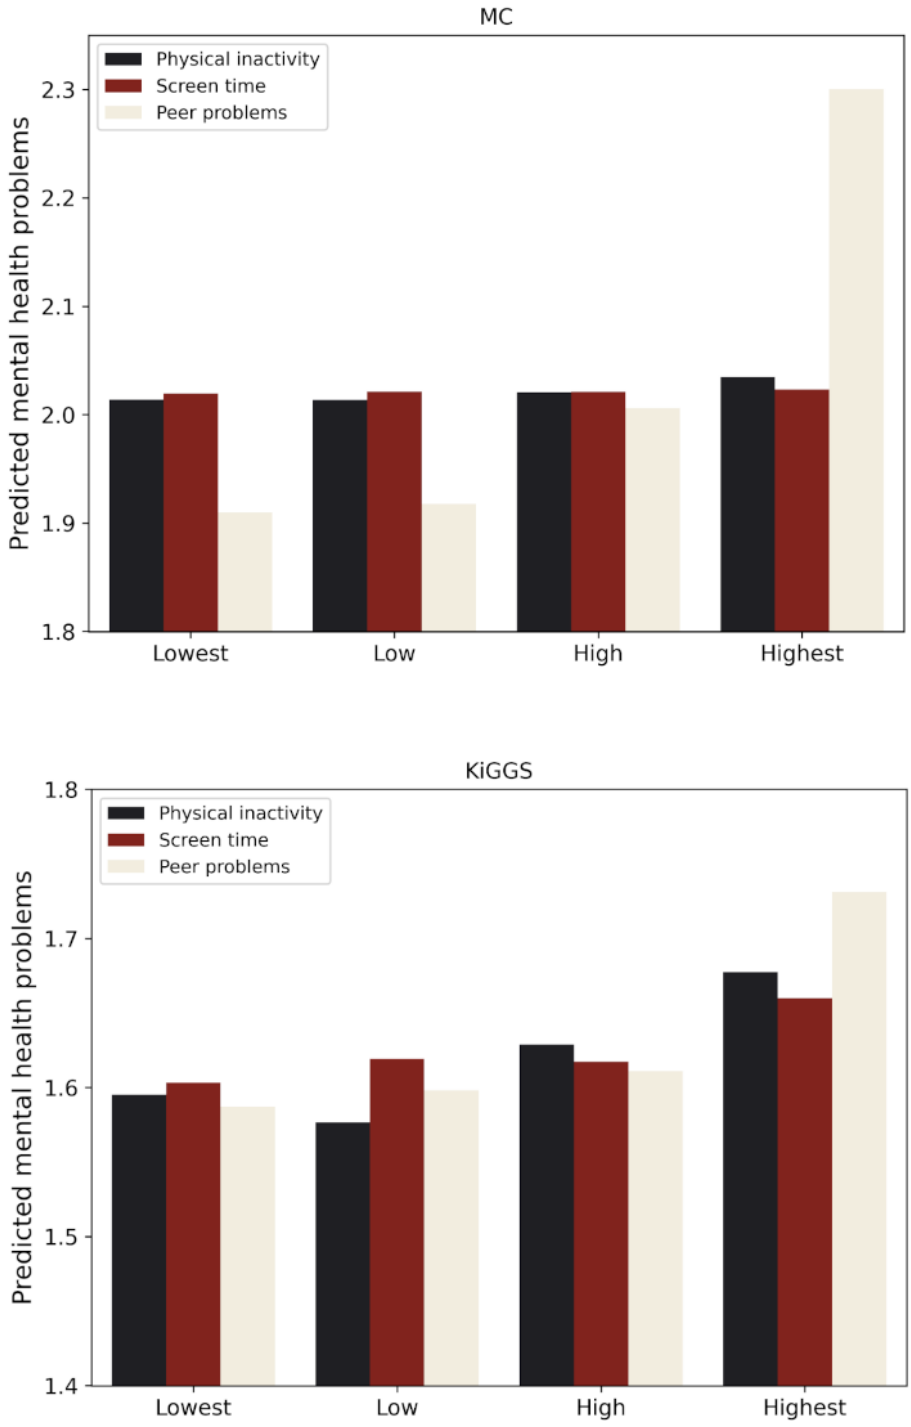
[c]MSE: mean squared error.

Predictor Importance

The permutation-based importance of defined predictor domains is shown in Figure 5. Mental health assessments at baseline were the most important domain in both cohorts, but other predictors (participants sex, physical health such as chronic diseases, sociodemographic factors such as parental education and mental health, and lifestyle factors such as physical activity) also contributed to the predictions. The importance of each individual predictor as well as their assignments to predictor domains can be found in Tables S1 and S2 in Multimedia Appendix 1.

Figure 5. Permutation-based feature importance of predictor domains (percentage improvement by keeping the predictor domain intact compared to perturbing it).

Direct Effects of Screen Time, Physical Activity, and Peer Relationships



The direct causal effects of physical inactivity, screen time, and peer problems in early adolescence on mental health in late adolescence are summarized in Figure 6. It can be seen that in both cohorts, predicted mental health problems in late adolescence increased with growing peer problems. Both cohorts also showed more predicted mental health problems for high levels of physical inactivity, although this effect was small in the Millennium Cohort. Increased screen time did not change predictions in the MC, while in KiGGS, predictions with the

XSL•FO
RenderX

highest screen time levels showed slightly more mental health problems compared to lower levels. These results show that, independent of changes in other predictors, a deterioration in peer relationships in particular leads to a worse development of mental health in both cohorts.

XSL•FO
RenderX

Figure 6. Direct effect of setting the value of predictors pertaining to screen time, physical activity, and peer relationships in early adolescence to minimum (lowest), 1/3 percentile (low), 2/3 percentile (high), and maximum (highest) on predicted mental health in late adolescence (keeping all other predictors constant). Screen time variables comprised all questions relating to time spent with media consumption (TV, computer, cell phone, and social media). Physical inactivity variables comprised days last week spent doing moderate to vigorous physical activity and total minutes in moderate to vigorous physical activity as objectively recorded by the accelerometer in the MC and total hours of sports per week and number of days physically active in the last 7 days in the KiGGS cohort. Peer problems variables comprised parent-reported peer problems (in the SDQ), the assessment of happiness with friendships, the feeling that "there is no one I feel close to," and that "there is someone I trust whom I would turn to if I had problems" in the MC and parent- and self-reported peer problems and the social support scale sum score value in the KiGGS cohort. In Tables S1 and S2 in Multimedia Appendix 1, the corresponding variables are color-coded in accordance with the figure.

Discussion

In this study, we used interpretable machine learning pipelines on 2 large European cohort studies for 2 related goals: First, we tested how well and based on which assessments the development of mental health during adolescence can be assessed. Second, we assessed the causal effects that high screen time, low physical activity, and worsened peer relationships had on an unfavorable development of mental health. Because the analyzed time period lies in the critical years after 2010, we thereby added evidence to the discussion on reasons for the mental health crisis unfolding during that time period.

Using cross-validation, we showed that multivariable models had medium to high predictive accuracy with Pearson correlations between predicted and actual mental health in late adolescence between 0.38 and 0.61. Although direct comparisons are complicated by differences in the study design and outcome measures, this predictive accuracy is in the upper range of the few studies published to date on the prediction of mental health problems in adolescents using comprehensive multivariable models [38,39]. Predictive performance was improved with nonlinear GBMs, which are known to perform well for medium-sized tabular datasets [31]. However, these figures also make it clear that the calculations of the models should be interpreted as assessments and not as absolutely accurate predictions. The relative superiority of the nonlinear model compared with the linear model suggests that at least some relationships between the investigated predictors and the development of mental health are not optimally modeled in a linear and additive fashion. This is also reflected, for example, in the disproportionately strong increase in predicted mental health problems with very severe peer problems.

We used univariable and multivariable feature importance analyses to identify predictive factors. Here, we were able to replicate and extend previously described risk and resilience factors. As expected and consistently demonstrated in previous studies [40,41], mental health problems in early adolescence were the strongest predictors of mental health problems in late adolescence. This result captures a certain stability of mental health problems during adolescence, but the contribution of other factors to the predictions shows that the development of adolescent mental health depends on multiple determinants that go beyond a mere “autoregressive” continuation of baseline mental health problems. Among family factors, mental health problems of the parents were strongly related to mental health problems in their adolescent children. For preventive strategies, it is important to understand the mechanisms of this intergenerational transmission of risk and to develop targeted interventions based on this understanding [42]. Indicators of physical health problems (chronic health conditions, self-reported pain, and impairments in general health) were also associated with future mental health problems. This finding substantiates current evidence that physical health problems in early life predict a worsening of mental health in adolescence and that children with chronic conditions might hence be particularly in need of support [23]. Low socioeconomic status (ie, income and education) of the parents predicted an unfavorable development of their children’s mental health during adolescence, which corroborates previous findings with different cohorts [43,44]. In both cohorts, we moreover found that female sex predicted worse mental health in late adolescence also when statistically correcting for baseline mental health symptoms in young adolescence. This finding is in accordance with a well-established gender gap in depressive symptoms, which starts to manifest during puberty, increases until adulthood, and has multifaceted reasons [28].

We leveraged recent advances in covariate selection and causal interpretation of predictive models [17,18] to approach the causal impacts of factors implicated in the deterioration of adolescent mental health in the past decade (less physical activity, more screen time, and worse peer relationships). This analysis revealed improved predicted mental health in late adolescence when more physical activity was assumed in early adolescence. However, the direct effect was small, particularly in the MC. We found that, except small effects of very much screen time in the KiGGS cohort, reducing screen time alone did not directly entail meaningful improvements in the predicted development of mental health in both cohorts. Conversely, good peer relationships predicted better mental health trajectories in both cohorts even when all other factors were held constant.

What do these results suggest in the context of current debates on the causes of the youth mental health crisis?

First, according to these analyses, adolescents would have had a more favorable mental health trajectory during the period of the observed deterioration in adolescent mental health if they had better peer relationships at ages 12-14 years, even if a wide range of other determinants of mental health had remained unchanged. It is noteworthy in this context that an overall deterioration in peer relationships of adolescents was observed across countries during the same period as the deterioration of mental health [45] and that proposed influencing factors such as increased screen time were shown to potentially have a detrimental impact on peer relationships [46]. It thus seems plausible that increased peer problems, themselves the result of a complex change in behavioral patterns of adolescents, represent an important direct cause of the deterioration of mental health. Given the growing evidence for the effectiveness of general prevention programs (such as antibullying school interventions) and individual therapeutic strategies (such as social skills training or self-esteem reflections) to improve peer relationships [47], it appears that a combination of these interventions would be a promising public health approach to the adolescent mental health crisis.

Second, adolescents would not have altered mental health trajectories if they had less screen time at ages 12-14 years when the other determinants of mental health had remained unchanged. This finding ties well with a recent panel network analysis showing that when multiple determinants of mental health were taken into account, social media use only had a very small influence on the development of mental health [48]. There is an intense debate around relationships between screen time, particularly social media use, and mental health in adolescents and young adults. The debate is fueled by a remarkable coincidence between the mass spread of social media and the deterioration of adolescent mental health around 2010 [49].

XSL•FO
RenderX

However, longitudinal studies could not prove a clear association between social media use and adolescent mental health [50,51]. It seems plausible that heavy social media use overall is part of a complex change in adolescent behaviors that might, potentially mediated through increased peer problems, contribute to mental health problems [11]. As illustrated in Figure 3, the absence of a direct effect in our study would be compatible with a model in which screen time exerts a negative effect on mental health via other downstream factors (eg, factors impacted by screen time and themselves impacting mental health, such as time spent with friends, body dissatisfaction, and sleep problems). Such modifiable factors on the causal pathway between exposures such as screen time and mental health outcomes could be targets for intervention strategies. Characterizing them more precisely would be an important undertaking for future research, which could use causal inference in combination with higher frequency surveys [18].

Third, adolescents would have a slightly improved mental health trajectory if they had been more physically active at ages 12-14 years, even when the other determinants of mental health had remained unchanged, especially those with very low levels of physical activity. In line with this finding, exercise interventions were shown to have small beneficial effects on adolescent mental health [52], and a recent review of reviews concluded that there is only "partial evidence" for a causal impact of physical activity on adolescent mental health [53]. Interestingly, the authors of this review discuss the possibility that the association between physical activity and adolescent mental health "may be linear, curvilinear, or contain a threshold, after which no further gains in mental health are made" [53], which would be consistent with our findings that increases in physical activity only have a beneficial direct effect in the case of low baseline levels. However, the small effect strengths, together with meta-studies that used aggregate data to demonstrate that the level of physical activity in adolescents has not relevantly decreased in Western countries between 2001 and 2016 [54], render it unlikely that the observed substantial worsening of adolescent mental in the past decade is due to decreased physical activity.

Some limitations of our study are relevant when interpreting the study results. First, causal inference from observational data is challenging, and results can depend on assumptions that are hard to test empirically. If the research questions cannot be investigated in a randomized controlled manner and one has to resort to observational data (as in our case), the best possible selection of covariates must be undertaken to approach causal interpretations. We applied principles developed for this purpose in our study [18]. Nevertheless, it should be kept in mind that the evidence for causal relationships in observational studies is generally lower compared to randomized controlled trials [55]. The results should therefore be interpreted in conjunction with other research work (eg, cohort studies, clinical observations, and analysis of aggregated time series) in order to gain a comprehensive picture of the factors contributing to the deterioration of young people's mental health. Moreover, the inability to reliably distinguish confounders from mediators only allows for the calculation of direct effects, and it is possible that the factors under investigation have additional effects through the modification of mediator variables. To characterize such mediating relationships more precisely, future research could explore multiple-wave longitudinal studies in conjunction with causal inference [18]. Second, although the mutual validation of results in 2 independent cohorts is a strength, both cohorts differed in some design features, which reduces the comparability. In particular, the MC is age-homogenous, whilst in the age-heterogeneous KiGGS cohort, participants with an age similar to the MC participants were selected, leading to a smaller case number. Due to a longer interval between baseline and follow-up examination, participants in the KiGGS cohort were younger at baseline. This could contribute to observed discrepancies, for example, to the result that the direct effect of physical activity was more pronounced in the KiGGS cohort. In addition, predictors were only partially overlapping between the 2 studies. Despite these differences, it is noteworthy that key predictors of future mental health, such as the parents' mental health, the participants' baseline mental health, sex, peer problems, and physical activity, were found in both cohorts and there was a qualitative agreement on the estimated direct causal effects. The robustness of these results would be further strengthened by an analysis of additional cohorts from other countries. Third, not all proposed driving factors of the observed adolescent mental health deterioration could be investigated with our study. For instance, factors affecting society as a whole, such as growing social inequality and pressure to perform in education, have also been suggested [56,57] but could not be analyzed with our research design, which leveraged interindividual differences in risk factors to assess their impact on mental health development. Relatedly, the influence of new stressors such as the COVID pandemic, the war in Ukraine, and the increasingly noticeable effects of climate change could not be examined due to the time period under study. However, once appropriate data are available, our ML pipeline could be readily adapted in future work to predict the risk for mental health problems in the face of societal crises and identify its determining factors.

In summary, we showed that the development of adolescent mental health can be assessed by a combination of variables from early adolescence. Our analyses suggest a strong influence of peer relationships, and a deterioration of these through different reasons may contribute as a causal factor to the observed adolescent mental health crisis. Interventions to improve social relationships with peers could be explored as countermeasures against further deterioration of adolescent mental health.

Abstract

Background: In China, the "8+2" stroke risk score has been widely used to identify individuals at high risk of stroke, despite insufficient evidence confirming its predictive ability for stroke events.

Objective: We aimed to validate the risk score's ability to predict the risk of stroke within a 10-year timeframe in community cohort populations and to optimize the scoring method to improve its predictive accuracy.

Methods: By reviewing previous literature to obtain the parameters for constructing the logistic regression model and the Rothman-Keller model, the risk threshold points of the models were determined using a sample of 100,000 participants. For this population-based cohort study, 22,259 community residents were recruited in 2013 from one urban and rural monitoring site in Ningxia, China. The occurrence of stroke was established by a combination of self-reporting and review of hospitalization electronic records (the *International Statistical Classification of Diseases and Related Health Problems 10th Revision*: I60-63). A logistic regression model and a Rothman-Keller model were used to refine the 8-factor stroke risk score to predict the 10-year stroke risk. The performance of the model was assessed by the area under the receiver operating characteristic curve and net reclassification improvement.

Results: The threshold points for low and medium risk in the logistic regression model and the Rothman-Keller model are risk scores of 0.062 and 0.002, respectively. The threshold points for medium and high risk are risk scores of 0.165 and 0.005, respectively. A total of 11,692 community residents aged 40 years or older who met the inclusion criteria completed the 10-year follow-up. According to the "8+2" stroke risk score, the stroke incidence in the low-risk (n=8908), medium-risk (n=1074), and high-risk groups (n=1710) was 4.5%, 14.7%, and 12.3%, respectively. The logistic regression model and the Rothman-Keller model demonstrated significant differences in area under the receiver operating characteristic curve values when compared to the "8+2" stroke risk score (Z=2.60, *P*=.001; Z=3.47, *P*=.009, respectively). However, no significant difference was observed between the logistic regression model and the Rothman-Keller model (Z=0.688, *P*=.49). Relative to the risk score, the absolute net reclassification improvement of the Rothman-Keller model was 0.051 (*P*=.01) and of the logistic regression model was 0.010 (*P*=.62).

Conclusions: Our study confirmed that the "8+2" stroke risk score does not effectively predict stroke events. But the Rothman-Keller model may enhance the ability to identify individuals at high risk for stroke. Future research should incorporate more specific biomarkers and multimodal imaging features to develop more accurate risk prediction models.

Introduction

The Global Burden of Disease (GBD) 2021 study found that the number of new cases of stroke increased by 70.2% from 1990 to 2021 [1], highlighting a relatively insufficient emphasis on prevention, particularly in low-income countries. The number of patients with stroke in China is currently the highest in the world. Stroke is the leading cause of death and disability among adults in the country [2]. China has the highest risk of stroke globally, with an overall lifetime risk of 39.9% [3]. Consequently, China has implemented a series of measures to address the increasing burden of stroke, advocating for an integrated approach to stroke prevention, treatment, management, and rehabilitation [4].

The National Ministry of Health of China launched a significant national project called the "China National Stroke Screening Survey (CNSSS)" in 2009 to tackle the challenge posed by stroke. The China Stroke Prevention Project Committee (CSPPC) was established in April 2011. Volunteers aged 40 years and older were recruited through structured face-to-face questionnaires, and the "8+2" risk scorecard is used to screen participants and to identify high-risk groups [5]. The "8" refers to 8 risk factors (hypertension, heart disease, smoking, dyslipidemia, diabetes, physical inactivity, overweight, and family history of stroke [FHS]), and the "2" refers to transient ischemic attacks (TIAs) and previous strokes. According to the judging criteria, respondents are categorized into low-risk, medium-risk, and high-risk groups. In 2020, a total of 268,000 individuals in the high-risk group for stroke were identified across more than 240 project areas across the country [6].

Risk assessment is an effective tool for identifying prevention priorities [7]. The Framingham Stroke Risk Profile is recognized as one of the earliest and most widely used simple stroke risk assessment tools. However, validation studies in domestic populations have found that it tends to overestimate the actual stroke incidence to some extent [8]. Since its publication, the pooled cohort risk assessment equations have also been controversial, as some external validation studies suggest that this risk assessment model may overestimate the risk of atherosclerotic cardiovascular disease [9]. A study compared the performance of the Framingham cardiovascular risk equation, the pooled cohort equations, and the China-Population Attributable Risk equations in predicting the 5-year risk of atherosclerotic cardiovascular disease, including ischemic stroke. In the Uyghur and Kazakh populations, all 3 risk assessment equations consistently underestimated the risk [10]. Furthermore, although the "8+2" risk score tool has been widely used, its predictive ability remains unclear.

Therefore, we aimed to validate the "8+2" stroke risk score for predicting the 10-year risk of stroke in community cohort populations, and to optimize the scoring method to improve predictive accuracy.

Methods

Data Source

This study was a cohort study. This study followed the Transparent reporting of multivariable prediction model for Individual Prognosis or Diagnosis (TRIPOD) guidelines.

The cohort was part of the China Stroke High-risk Population Screening and Intervention Program (CSHPSIP), an ongoing nationwide population-based program [5,11]. The study participants were recruited from the screening site in the Jinfeng District of Yinchuan City, Ningxia Hui Autonomous Region. A total of 22,259 community residents were enrolled in 2013 from one urban and rural monitoring site, and the outcome ascertainment was completed in 2023. The inclusion criteria for the screening participants are individuals who are aged 40 or older, permanent residents (those who have lived in the area for 6 months or more), and those who voluntarily participate by signing an informed consent form [12]. Patients younger than 40 years, those with a history of stroke or TIA, or individuals recruited after 2014 were excluded from the study cohort. The data quality control process is detailed in the Multimedia Appendix 1.

Risk Factors Measurement

Based on the "Stroke Screening and Prevention Technical Specifications" promulgated by the National Health and Family Planning Commission's Stroke Screening and Prevention Engineering Committee, the following risk factors were assessed: hypertension, heart disease, smoking, dyslipidemia, diabetes, physical inactivity, overweight, and FHS. The detailed criteria for each risk factor are shown in Table S1 in Multimedia Appendix 1 which is also available on the China Stroke and Cardiovascular Disease website.

The criteria for classifying individuals into high-, medium-, and low-risk stroke groups were as follows: the high-risk group was defined as having 3 or more risk factors; the medium-risk group was characterized by 3 or less risk factors along with a history of chronic diseases (such as hypertension, diabetes, and heart disease); and the low-risk group was defined as having 3 or less risk factors without any history of chronic diseases (Table S1 in Multimedia Appendix 1) [13]. For high-risk individuals, follow-up visits are conducted by primary health care institutions at 6 months and 12 months after the initial assessment. For moderate-risk populations, primary health care institutions conduct a single follow-up visit at 12 months to evaluate and address their associated risk factors.

Outcome

We recorded stroke as an endpoint event by searching electronic hospitalization records in Ningxia in June 2023. Stroke was identified using the diagnostic code I60-63 from the *International Statistical Classification of Diseases and Related Health Problems 10th Revision* (*ICD-10*).

Logistic Regression Model

Logistic regression was used to determine the odds ratios (ORs) of every risk factor for incident stroke [14]. The basic equation for regression with multiple independent variables is:

XSL•FO
RenderX

$$Y=\ln(P1-P)=\alpha+\beta1X1++\beta2X2+ +\beta iXi$$

Y is the estimated continuous outcome; α is the intercept. This is considered a constant value; β is the beta coefficients; and X_i is each risk factor.

Rothman-Keller Model

The Rothman-Keller model, initially developed by Kenneth J. Rothman and David B. Keller in the early 1970s, was designed to assess the combined impact of tobacco and alcohol consumption on the risk of oral and pharyngeal cancers [15]. This model provides a statistical framework that enables researchers to quantify both the independent and joint contributions of various risk factors to disease risk. It has been adapted and applied to a wide range of health conditions and diseases, including early-onset colorectal cancer and mild cognitive impairment [16,17]. Its flexibility in considering both additive and multiplicative effects of risk factors makes it a valuable tool for public health research and individual risk prediction.

The Rothman-Keller model uses the binomial distribution function method for risk classification. It calculates the benchmark proportion of incidence and risk scores based on the population exposure rate and OR of each risk factor. In addition, it estimates an individual's relative risk of developing a disease by calculating their combined risk scores. The parameters of the Rothman-Keller model are calculated as follows:

1. Baseline morbidity ratio ( ): $\rho=1\sum i=1nORi\times Pi=1-PAR\%$
   P_i: the exposure rate of individuals exposed to a risk factor in the whole population; OR_i: the odds ratios of exposure to a risk factor; and *PAR*%: population attributable risk percentage.
2. Risk score ( ): $S=\rho\times ORi$
3. Total risk score ( ):
   Pi: risk factor scores for S≥1, q_i: risk factor scores for S<1.
4. Individual risk prediction score: Individual risk of stroke=the incidence of stroke × . This expected risk of stroke is a relative value because it is measured against the overall incidence rate in the population. It can help us understand whether the individual's likelihood of developing a stroke is higher or lower than the average level of the population.

The population exposure rate of every risk factor was derived from the literature [18]. The OR of exposure to a risk factor was sourced from the logistic regression model. Data for 100,000 participants were randomly generated by the binomial distribution functions of risk factors collected from the literature to identify nodes of high, medium, and low risk in models. The exposure rate of a risk factor in the study population was P_0. We generate 100,000 random P values of 0: 1, $P<P_0$ was recorded as 1 (ie, exposure), and $P>P_0$ was recorded as 0 (ie, nonexposure). Each risk factor simulates a column of data, summarizing the exposure of 100,000 community residents to each risk factor.

Statistical Analysis

Missing Data Interpolation

Among 11,692 participants, 1 individual did not have information on hypertension, and 2556 individuals lacked information on blood lipid levels. In accordance with previous studies [12,19,20], the incomplete data for hypertension and dyslipidemia were imputed simultaneously by multiple imputations (n=25) using the R package MICE (Stef van Buuren) [21]. Based on the Akaike information criterion value, 2 of the interpolation datasets were selected and the same analysis was performed on the selected interpolation dataset to identify results that were likely to be robust. The detailed data report of the other interpolation set is presented in the Tables S2-S5 in Multimedia Appendix 1.

Model Evaluation

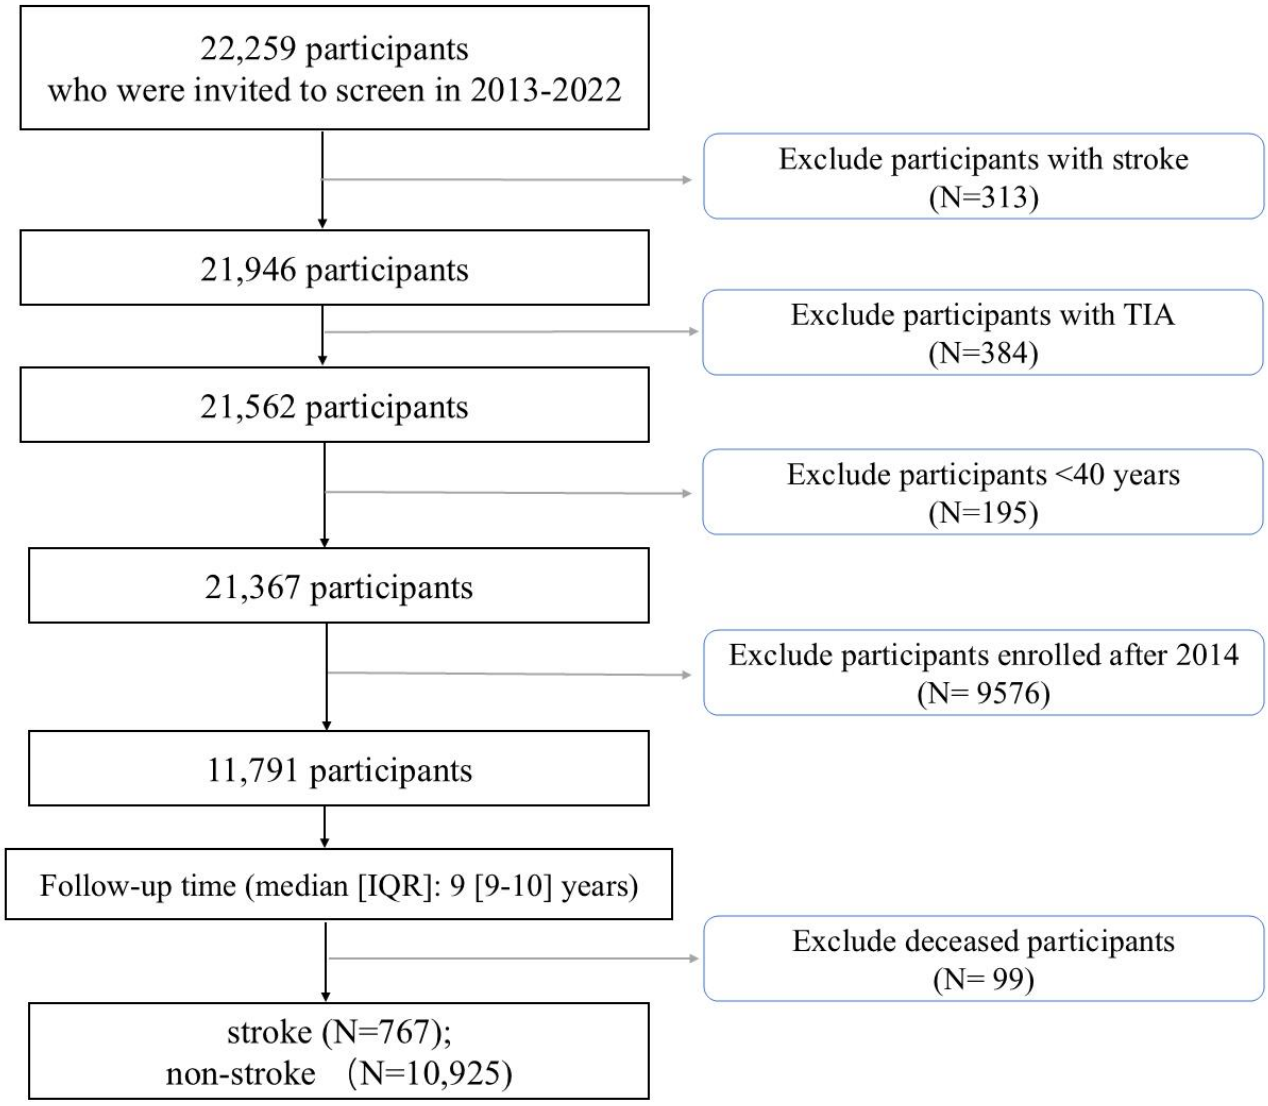
First, we assessed the discrimination for the Rothman-Keller model and the logistic regression model using the area under the receiver operating characteristic curve (AUC). Our primary objective was to determine whether the predictive capability of the Rothman-Keller model surpassed that of the conventional logistic regression model, particularly in a multiclassification situation. When the increase in AUC is not statistically significant, its interpretation can become challenging [22-24]. Therefore, in addition to the AUC, we incorporated the absolute net reclassification improvement (NRI) to evaluate the relative performance of the 2 models. If the absolute NRI is greater than 0 or less than or equal to 1, it indicates a positive improvement, showing that the predictive ability of the new index has improved compared to the old index for stroke events. Conversely, if absolute NRI is less than 0 or greater than or equal to −1, it signifies a negative change, suggesting an improvement in the predictive ability of the new model for no stroke events. If the absolute NRI is equal to 0, it means that the new model shows no improvement. In our study, we analyzed the reclassification and absolute NRI for individuals who experienced a stroke event and those who did not. For individuals who have had a stroke, being reclassified into a higher-risk group was deemed an improvement in classification, whereas being reclassified into a lower-risk group was considered a failure.

A P value less than .05 was considered to indicate statistical significance. The statistical analyses were performed using R 4.2 software (R Core Team).

Ethical Considerations

The ethics review committee of The People's Hospital of Ningxia Hui Autonomous Region approved this study (approval number: 2020-KY-053). Patients provided informed consent for using the data. Data were deidentified. No compensation was provided.

Results



Characteristics of the Study Cohort

A total of 22,259 community residents were recruited in 2013. After excluding individuals with a history of stroke (n=313), and TIA (n=384), as well as participants younger than 40 years

XSL•FO
RenderX

old (n=195) and those recruited after 2014 (n=9576), 11,791 participants were included in the follow-up cohort. After a 10-year follow-up period, 99 participants were lost to follow-up. Finally, a total of 11,692 eligible participants were included in the final analysis (Figure 1). A total of 767 participants (6.6%) had a stroke by the end of the follow-up period. Based on the "8+2" stroke risk score, the 10-year stroke incidence among the 3 stroke risk groups of the community residents was as follows: low-risk group 4.47% (n=8908, 398 stroke cases); medium-risk group 14.71% (n=1074, 158 stroke cases); and high-risk group 12.34% (n=1710, 211 stroke cases) (Table 1). Kaplan-Meier survival curves are shown in Figure S1 in Multimedia Appendix 1.

Model Construction

The baseline incidence ratio (ρ) of 8 factors was obtained to calculate the population attributable risk percentage (PAR%) through a previous study [18]. The OR values of these factors were assessed using a logistic regression model. The parameters of the logistic model and the Rothman-Keller model are shown in Table 2.

XSL•FO

[a]P_i: the exposure rate of individuals exposed to a risk factor in the whole population

[b]OR_i: the odds ratios of exposure to a risk factor;

[c] β_i is the beta coefficient

[d] PAR%: population attributed risk percentage

[e]ρ: baseline morbidity ratio

[f]S: risk score

After ranking the stroke incidence risk based on a dataset of 100,000 random entries, 2 nodes were selected for subdividing the risk groups into low-risk, medium-risk, and high-risk categories using the logistic regression model: node a (ID=25844, risk prediction score=0.06168760) and node b (ID=77778, risk prediction score=0.16451650). In addition, for the Rothman-Keller model, 2 other nodes were chosen for the same purpose: node A (ID=25426, risk prediction score=0.0021993391) and node B (ID=64553, risk prediction score =0.0047898060) (Figure S2 in Multimedia Appendix 1).

Evaluation of the Model

The sensitivity, specificity, and AUC of the “8+2” stroke risk score, the Rothman-Keller model, and the logistic regression model are presented in Table 3. The logistic regression model and the Rothman-Keller model demonstrated significant differences in AUC values compared to the “8+2” stroke risk score (Z=2.60, $P<.05$; Z=3.47, $P<.05$, respectively). However, no difference was observed between the logistic regression model and the Rothman-Keller model (Z=0.688, $P>.05$). The comparison of receiver operating characteristic curve is shown in Figure S3 in Multimedia Appendix 1.

Table . The discrimination of "8+2" stroke risk score, logistic and Rothman-Keller model.

	Sensitivity	Specificity	AUC[a] (95% CI)	Z value (*P*) [b]	Z value (*P*)[c]
"8+2" stroke risk score	0.48	0.79	0.627 (0.619 - 0.636)		
Logistic model	0.41	0.85	0.649 (0.641 - 0.658)	3.47 (*P*=.001)	
Rothman-Keller model	0.52	0.74	0.646 (0.637 - 0.654)	2.60 (*P*=.009)	0.688 (*P*=.492)

[a]AUC: area under the curve

[b]:Versus "8+2" stroke risk score;

[c]:Versus logistic model

From the NRI, we found that the majority of participants remained at the same level of risk for developing a stroke as predicted by the "8+2" stroke risk score, the logistic regression model, and the Rothman-Keller model (ie, along the diagonal from the lower left to the upper right). However, some community residents were reclassified as having a different level of risk for developing stroke (Figure S4 in Multimedia Appendix 1). According to the "8+2" stroke risk score, the NRI for reclassification of stroke events by the Rothman-Keller model was 7.8%, while the NRI for nonstroke events was −2.7%. The absolute NRI was then estimated to be 0.051 (*P*=.01), calculated using the sum of the net estimated for individuals who developed a stroke and those who did not. The NRI for the logistic regression model was 1.7% for stroke events and −0.7% for nonstroke events, resulting in an absolute NRI of 0.010 (*P*=.62) .

Discussion

Principal Findings

This cohort study followed 11,692 individuals aged 40 years and older for a duration of 10 years. According to the "8+2" stroke risk score, the stroke incidence in the low-risk (n=8908), medium-risk (n=1074), and high-risk groups (n=1710) was 4.5%, 14.7%, and 12.3%, respectively. We developed a logistic regression model and a Rothman-Keller model to validate and optimize the risk score. Through a comparative analysis of the performance of the 3 models, we found that the Rothman-Keller model exhibited the best performance.

We verified the efficacy of the model using an actual database. There was no significant difference in the AUC values between the logistic regression model and the Rothman-Keller model. To evaluate model performance more accurately, we used the NRI for a more in-depth analysis. The NRI assesses the effects of low-, medium-, and high-risk reclassification for both stroke and nonstroke events, resulting in a net reclassification that provides a more accurate estimate than that obtained with other approaches [23]. Positive values of the stroke NRI indicate that the model effectively identifies patients with stroke, enabling physicians to initiate targeted detection or treatment to prevent stroke events. In contrast, a decrease in the NRI for nonstroke events suggests that community residents with a low or medium risk as determined by the "8+2" stroke risk score may actually be at a higher risk of having a stroke. Based on the overall NRI, we conclude that the Rothman-Keller model enhances the reclassification of both stroke and nonstroke events [25]. This finding aligns with the results of previous studies. Researchers used the Rothman-Keller model to predict the likelihood of mild cognitive impairment in older Chinese individuals. Upon validation with actual population data, it was found that the model had appropriate accuracy and performed well in terms of predictive efficacy [16,26]. The model can be adjusted and optimized based on new research data and epidemiological changes, thereby maintaining its predictive power in a timely manner. Its methodology can be applied to risk assessments for other populations and chronic diseases, demonstrating significant universality.

There are many model studies aimed at predicting stroke risk [27-30]. For instance, SCORE2 is a risk assessment tool developed using extensive data from a large number of European populations. It is designed to evaluate the risk of cardiovascular disease in both men and women across 4 distinct risk areas in Europe within a 10-year period [31]. While this tool is widely applied, it has limitations in terms of ethnicity and geography. Significant prediction errors may occur when applying it to populations with considerable differences [9,32]. A study estimated the 10-year risk of stroke based on a cohort analysis and found that factors such as age, systolic blood pressure, diastolic blood pressure, FHS, atrial fibrillation, diabetes, and others can significantly predict the incidence of stroke [27]. Compared with other models, this study developed a Rothman-Keller model based on questionnaire information to identify new risk nodes through simulation datasets, which provided a basis for stroke prevention. Furthermore, the model's predictive power and accuracy were verified using real-world data. Logistic regression analysis indicated that smoking, heart disease, dyslipidemia, and physical inactivity were not related to stroke, which may be attributed to variations in demographic and stroke subtypes differences. This result was consistent with the results of previous Mendelian randomization studies [33-37].

The limitations of this study are as follows: first, the dataset used for verification only included participants from only one region. Studies in other provinces are necessary to evaluate the efficacy of our model. When research results are extrapolated to other populations with significant differences, it may be essential to consider the exposure rates of risk factors and OR or RR values for those populations in order to update and optimize the model. This process enhances the predictive accuracy and applicability of the Rothman-Keller model. Second, we were unable to perform a subgroup analysis on the various types of stroke. The primary objective of the program is to identify and intervene with high-risk populations to prevent the occurrence of stroke or reduce its risk, rather than focusing on the subtypes of ischemic stroke and hemorrhagic stroke.

XSL•FO
RenderX

Furthermore, given the limitations of medical resources and the acceptability of screening, the program may prioritize the implementation of more accessible and universal preventive measures. These measures include controlling blood pressure, quitting smoking, and increasing physical activity, all of which are effective in preventing both ischemic stroke and hemorrhagic stroke [38,39]. Third, during the decade, participants may have received lifestyle interventions, pharmaceutical treatments, and early clinical treatment that influenced the incidence of stroke events. However, in the medium- and high-risk groups for stroke, these patients represent a certain proportion. Our model primarily assesses the variations in the initial screening judgments, and the outcome events remain consistent across different models, making it unlikely to influence the study results. Finally, the low sensitivity observed in this study may be attributed to the lack of several important stroke prediction factors from the risk scoring scale, thereby limiting its predictive ability. In 2021, the Guidelines for Stroke Prevention and Treatment in China recommended including homocysteine testing in routine screening and conducting carotid artery examinations for high-risk populations when conditions permit. Our research findings further support this recommendation. Although this study has some limitations, it also presents several advantages. The diagnostic criteria for risk factors in this project are based on relevant guidelines and standards established by the China Health Commission. Staff members undergo standardized training and assessment, and only those who pass the assessment are qualified to conduct screening tasks. Therefore, the identification of risk factors in this study had high accuracy and credibility. We used the binomial distribution of risk factors to construct a random dataset of 100,000 community residents, which allowed us to determine the high-, medium-, and low-risk boundary values of the models. The variables in the model were easily obtained and predicted estimates could be derived through straightforward calculations. We included a substantial number of community residences from the CSHPSIP over a decade for external validation, which exhibited good discrimination and calibration.

Conclusions

In conclusion, the Rothman-Keller model may improve the predictive efficacy of stroke screening models. In the future, verification will need to be carried out in a wider population and combined with more risk factors. The Rothman-Keller model for assessing individualized stroke risk, combined with interactive information platforms for health education, is beneficial for decreasing the incidence of stroke among high-risk groups.

Abstract

Background: School-based immunization programs (SBIPs) have been widely used to efficiently deliver vaccines to children and adolescents, achieving higher and more equitable coverage than community-based approaches, though implementation varies across regions. However, the COVID-19 pandemic disrupted SBIPs, leading to significant declines in vaccine coverage and highlighting the need for long-term assessments to determine the effectiveness of recovery efforts, especially as current research has largely overlooked SBIPs or focused narrowly on select vaccines.

Objective: This study aimed to assess the impact of the COVID-19 pandemic and ongoing catch-up immunization efforts on vaccine coverage and administration volume among school-aged children in the Canadian province of Alberta. We also sought to determine the magnitude of any remaining vaccine deficits and estimate the duration of additional catch-up efforts required to address those deficits.

Methods: In this retrospective cohort study, we used population-wide administrative health data to calculate monthly cumulative vaccine coverage among Grade 1, 6, and 9 cohorts, comparing four pandemic cohorts (2019 - 2020, 2020 - 2021, 2021 - 2022, and 2022 - 2023 grade-years) to a prepandemic cohort for each grade. We also calculated vaccine administration rates as monthly count of vaccines delivered, stratified by routine (ie, received during the school year as scheduled) and catch-up (ie, received after the regularly scheduled school year) doses. For each vaccine, we calculated vaccine coverage deficits remaining at the end of the study period and estimated time to clear those deficits based on observed catch-up uptake rates.

Results: All Grade 6 pandemic cohorts had lower human papillomavirus (HPV) and hepatitis B vaccine coverage at the end of the school year (2.6 - 60 percentage points lower and 1.2 - 41.7 percentage points lower, respectively), though coverage had increased to near prepandemic levels after approximately 3 years of follow-up. Coverage among the Grade 1 and 9 cohorts remained below prepandemic levels at study end; the largest deficits were noted in the 2022 - 2023 Grade 1 cohort (7.87 percentage points lower for measles-containing vaccines, 4.64 percentage points lower for pertussis-containing vaccines) and the 2020 - 2021 cohort for Grade 9 (14.0 percentage points lower for meningococcal conjugate ACYW-135 vaccine, 12.9 percentage points lower for pertussis-containing vaccines). The additional catch-up time required to reach prepandemic coverage levels for all cohorts was estimated to be less than 1 year for Grade 6 cohorts, 5.6 years for Grade 1 cohorts, and 4.8 years for Grade 9 cohorts.

Conclusions: Partial recovery of vaccine coverage was found for cohorts impacted by interruptions to school-based programming during the COVID-19 pandemic. Further efforts to alleviate coverage deficits among Grade 1 cohorts may be addressed in routine Grade 6 programs, while targeted efforts in postsecondary institutions may be required to address delays in Grade 9 immunizations.

vaccination; measles-mumps-rubella; human papillomavirus; hepatitis B; meningococcal conjugate ACYW-135; Tdap

Introduction

School settings have been used in varying capacities around the world to administer vaccines to children and adolescents. Worldwide, the first grade is most frequently targeted for school-based immunization programs (SBIPs), though delivery to preadolescents and adolescents is increasing [1]. SBIPs are attractive, largely due to the ability to allow rapid delivery to a large portion of the target population [2], and have been shown to achieve higher and more equitable vaccine coverage than community-based delivery alone [1,3,4]. SBIPs have been used to support vaccine delivery across Canada for decades, though

XSL•FO
RenderX

there is regional variation in the grades and vaccines offered, as well as how these settings are used for catch-up immunization and implementation of mandatory immunization policies [5].

Despite previous successes, school closures and social distancing measures implemented during the COVID-19 pandemic resulted in significant decreases in vaccine coverage among those routinely immunized through SBIPs [6]. These critical drops in vaccine coverage raised concerns about possible resurgences of vaccine-preventable diseases [7] and left immunization programs with the added challenge of identifying and vaccinating those who missed the recommended doses. In addition, increased parental vaccine hesitancy in some areas of the world [8] has led to concerns that decreases in vaccine coverage may persist or become more pronounced [9].

Research exploring pandemic-related disruptions to routine childhood immunization programs has focused mainly on children aged 5 years and younger [10,11] or adolescent coverage outside of SBIPs [12-15], with minimal attention paid to SBIPs to date [16]. Those evaluating coverage among children eligible for immunization through SBIPs have limited their analysis to select vaccines (human papillomavirus [HPV] vaccine only [17]; HPV and meningococcal conjugate ACYW-135 [MenC-ACYW] only [6]), providing a limited picture of the full extent and impact of catch-up activities. In addition, current evidence points to immunization deficits that have persisted past the initial months of pandemic-related health care and school disruptions [14,15,18]. Assessment of vaccine coverage over the longer term is needed to determine whether recovery efforts have been effective or additional strategies are needed.

The aim of this study was to assess the impact of the COVID-19 pandemic and ongoing catch-up immunization efforts on vaccine coverage and administration volume among school-aged children in the Canadian province of Alberta, using more than four years of observation since the pandemic. We also sought to determine the magnitude of any remaining vaccine deficits and estimate the duration of additional catch-up efforts required to address those deficits.

Methods

Study Design and Setting

This retrospective observational cohort study was conducted in Alberta, which has a population of 4.8 million people. Almost 99% of Albertans are registered with the universal, publicly funded Alberta Health Care Insurance Plan (AHCIP), which provides access to all vaccines included in the provincial routine immunization schedule free of charge. With the exception of travel and seasonal vaccines (for example, influenza and COVID-19), all vaccines for school-aged children are provided exclusively by public health nurses through community-based public health centers and SBIPs, which includes screening and vaccinating children in Grade 1, Grade 6, and Grade 9. The Grade 1 program acts as a catch-up opportunity for those who missed preschool immunizations, while the Grades 6 and 9 programs are the main touchpoints for offering scheduled adolescent vaccines [19]. While schools are used to offer and provide vaccines, no vaccines are mandatory for school attendance in Alberta. The province's routine immunization schedule is provided in Multimedia Appendix 1. This study is reported in accordance with the STrengthening the Reporting of OBservational studies in Epidemiology (STROBE) cohort reporting guidelines [20].

Data Sources and Population

The data set was created by linking the Provincial School Immunization Record (PSIR), which contains individual-level records of student enrollment for each year, including grade, age, and sex, with the Immunization and Adverse Reaction to Immunization (Imm/ARI) repository, which includes a record of all publicly-funded vaccines provided in the province. We excluded those who lived in the city of Lloydminster (as vaccines are delivered by a neighboring province), and those who died or left the province before the study end date. To focus on institutions with SBIPs, we excluded schools that offer online or distance education only, as well as postsecondary, continuing education, summer, or evening or weekend schools. Schools on First Nations reserves were also excluded, as immunization data is not consistently submitted to the Imm/ARI repository. To align with the standard ages of assessment in the province, we also restricted cohorts based on individual age as of September 01 of the school year, including only those 5 - 7 years of age for Grade 1, 9 - 11 years of age for Grade 5, 10 - 12 years of age for Grade 6, and 13 - 15 years of age for Grade 9.

We examined 5 annual cohorts for each grade targeted for SBIPs, including 4 pandemic cohorts (2019 - 2020, 2020 - 2021, 2021 - 2022, and 2022 - 2023) and 1 prepandemic cohort. For Grades 1 and 9, the prepandemic cohort was defined as the cohort eligible for immunization during the 2018 - 2019 school year. For Grade 6, we used the 2017 - 2018 Grade 5 group as the prepandemic cohort, as the target grade for vaccine delivery changed from Grade 5 to Grade 6 in 2018 - 2019, resulting in no SBIP for Grade 5 or 6 in 2018 - 2019.

For each grade, we focused on the vaccines routinely delivered through SBIPs, including a second dose of measles-mumps-rubella (MMR) or measles-mumps-rubella—varicella (MMRV), and fifth dose of diphtheria, tetanus, acellular pertussis, polio (DTap-IPV) in Grade 1; the 2-dose HPV and hepatitis B series in Grade 6; and, the single dose of MenC-ACYW and tetanus, diphtheria, and acellular pertussis (Tdap) series in Grade 9. We included all pertussis-containing vaccines in the DTaP-IPV (Grade 1) and Tdap (Grade 9) analyses.

Data Analysis

For each vaccine, stratified by grade-year cohort, we calculated cumulative vaccine coverage, that is, the proportion of the grade-year cohort who had received the vaccine dose of interest, calculated for each month of observation. We determined cumulative coverage for each cohort from the end of their respective school year (eg, July 2020 for the 2019 - 2020 cohorts) to the end of the study period (July 2024), aiming to capture the impact of both the intensive and routine catch-up activities. As the Grade 1 immunization program is a routine catch-up opportunity (ie, children would have had the

XSL•FO
RenderX

opportunity to receive the vaccines of interest before entering their Grade 1 year), we included monthly cumulative coverage from the start of each cohort's Grade 1 year (eg, September 2019 for the 2019 - 2020 cohorts). For the Grade 6 HPV and hepatitis B series, we calculated both complete (2 dose) and 1+ dose coverage, given recent recommendations that 1 dose of HPV vaccine may confer immunity. During the prepandemic (2017 - 2018) school year, a 3-dose program for both HPV and hepatitis B was in place, which subsequently switched to a 2-dose program; thus, complete coverage was defined as receipt of 3 doses for the 2017 - 2018 cohort, and at least 2 doses for all subsequent cohorts. To estimate pandemic impacts, we calculated three measures of comparison for each vaccine of interest, using the prepandemic cohort as the counterfactual for pandemic cohorts: (1) cumulative coverage difference, (2) vaccine administration volume, and (3) cumulative immunization deficits.

To determine cumulative coverage differences, cumulative monthly coverage for each pandemic cohort was compared to the analogous month for the prepandemic cohort. For example, the July 2021 coverage for the 2019 - 2020 pandemic cohort represents coverage at 12 months from end of grade year and thus was compared to the coverage for the prepandemic cohort at 12 months from the end of grade year. We calculated 95% CI for binomial proportions, for both coverage and difference in coverage.

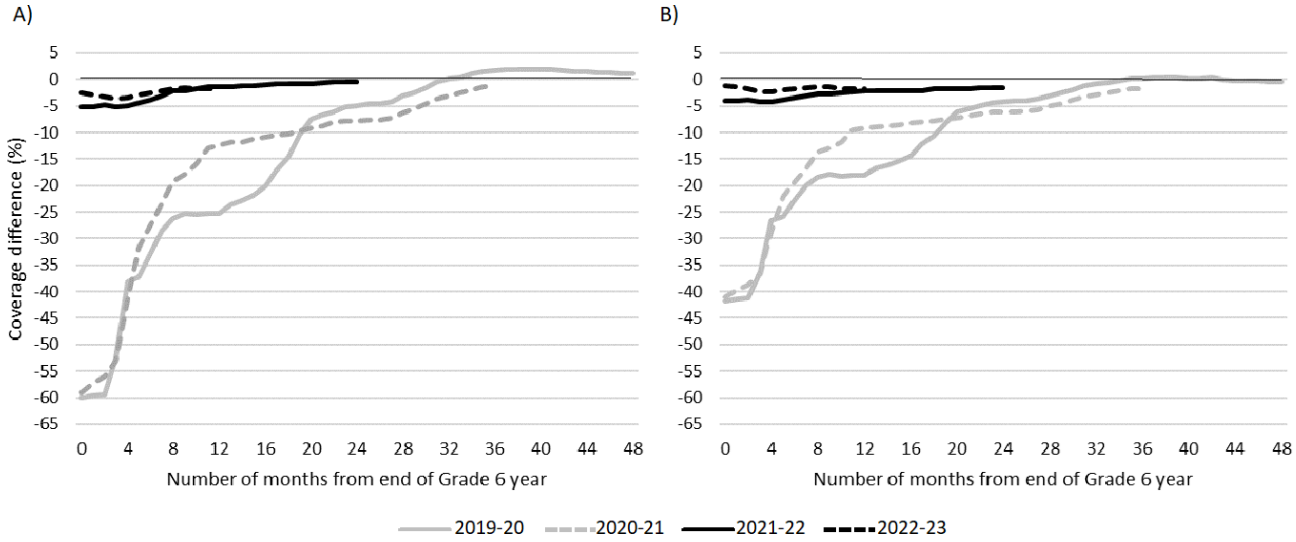
Vaccine administration, that is, a count of the number of vaccine doses delivered, was assessed for each grade-year cohort for each month of observation, collapsed into "school year" (from September to June) and "summer" (July and August) for each study year. We calculated administration for 1 vaccine for each grade: for Grade 6 and 9, we chose the vaccine with the highest administration volume (HPV and MenC-ACYW, respectively); for Grade 1, we chose to assess MMR or MMRV administration, given currently ongoing measles outbreaks globally. Administration counts were stratified by "routine" (ie, received during the school year as scheduled) and "catch-up" (ie, received after the regularly scheduled school year) immunization. We used dose count rather than calculating a delivery rate, which would correct for differences in cohort sizes, as we were interested in the magnitude and persistence of changes to vaccine administration volume associated with catch-up efforts.

We calculated the cumulative deficits for each vaccine at the end of the study period by comparing the observed number of individuals vaccinated for all pandemic cohorts to an expected number of individuals, estimated based on vaccine coverage for the prepandemic cohort at the end of the study period. For each pandemic cohort, the expected number of individuals vaccinated at the end of the study period was calculated by multiplying the observed cohort vaccine coverage at the end of the study period by the number of individuals in the pandemic cohort. We then summed the expected numbers of individuals vaccinated for all pandemic cohorts and calculated the difference from the observed number vaccinated at the end of the study period. Finally, we compared this calculated difference to observed maximum and average annual catch-up vaccine uptake, that is, number of individuals vaccinated [21], to estimate time to clear any accumulated deficits in coverage. All analyses were completed using SAS (version 9.4; SAS Institute Inc), and Microsoft Excel (version 1808).

Ethical Considerations

This study received approval from the Health Research Ethics Board (HREB) at the University of Alberta (Pro00134011). Informed consent to participate was waived by the HREB. All study data were deidentified.

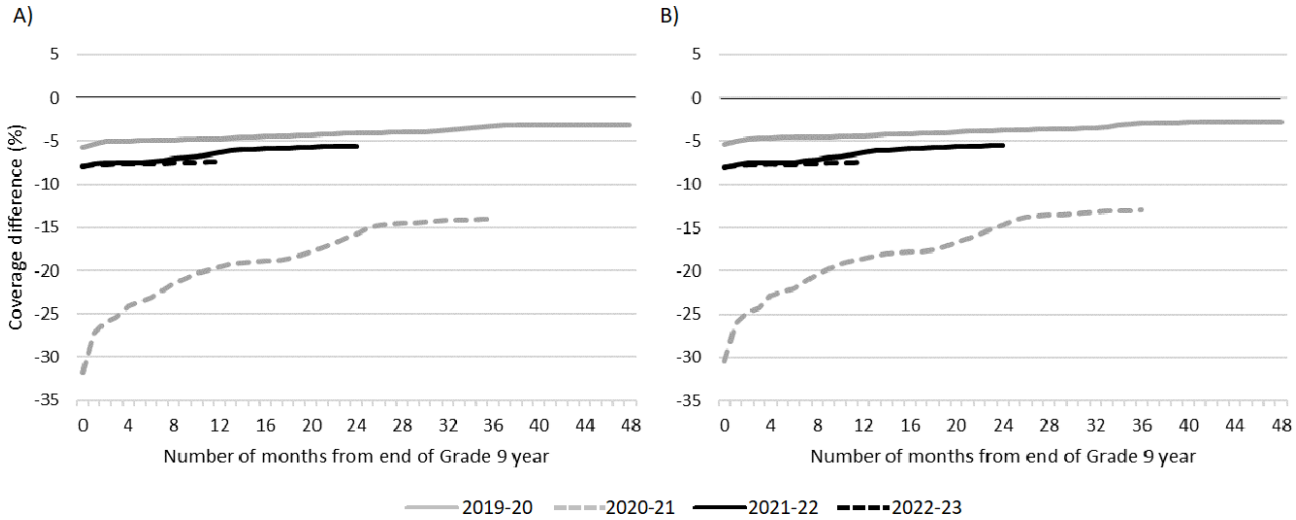
Results



A total of 799,961 children were included in our study cohorts; 270,603 were in the Grade 1 cohorts, 273,163 in Grade 6, and 256,195 in Grade 9. The total number in each grade-year cohort is provided in Multimedia Appendix 1.

Cumulative Coverage Difference

Cumulative vaccine coverage for the Grade 6 pandemic cohorts was lower than prepandemic levels at the end of each school year, although they reached at or near prepandemic coverage by the end of the observation period (see Figure 1). The 2019 - 2020 and 2020 - 2021 cohorts finished their school years with the largest deficits: 60 and 59 percentage points lower for HPV (see Figure 1A and Table S2 in Multimedia Appendix 1); and 41.7 and 41.0 percentage points lower for hepatitis B (see Figure 1B and Table S3 in Multimedia Appendix 1). For the 2019 - 2020 cohort, coverage levels were at or above prepandemic levels by February (HPV) and May (hepatitis B) of 2023. Another cohort, the 2021 - 2022 cohort, reached prepandemic levels for HPV by the end of the study period. For all other cohorts, coverage levels were less than 2 percentage points lower than prepandemic levels by the end of the observation period for both vaccines. For comparison, coverage for the prepandemic cohort ranged from 65.6% (end of Grade 6 year) to 75.4% (at 48 months of follow-up) for HPV (see Table S2 in Multimedia Appendix 1), and 73.7% (end of Grade 6 year) to 83% (at 48 months of follow-up) for hepatitis B (see Table S3 in Multimedia Appendix 1). HPV vaccine coverage remained below hepatitis B coverage levels throughout the study period, for all cohorts. Cumulative 1+ dose coverage for the most impacted cohort (2020 - 21) was approximately 15 percentage points lower than prepandemic levels at the end of the school year for both vaccines, recovering to within 2 percentage points of prepandemic levels within 31 (HPV) and 36 (hepatitis B) months of observation (see Figure S1 in Multimedia Appendix 1).

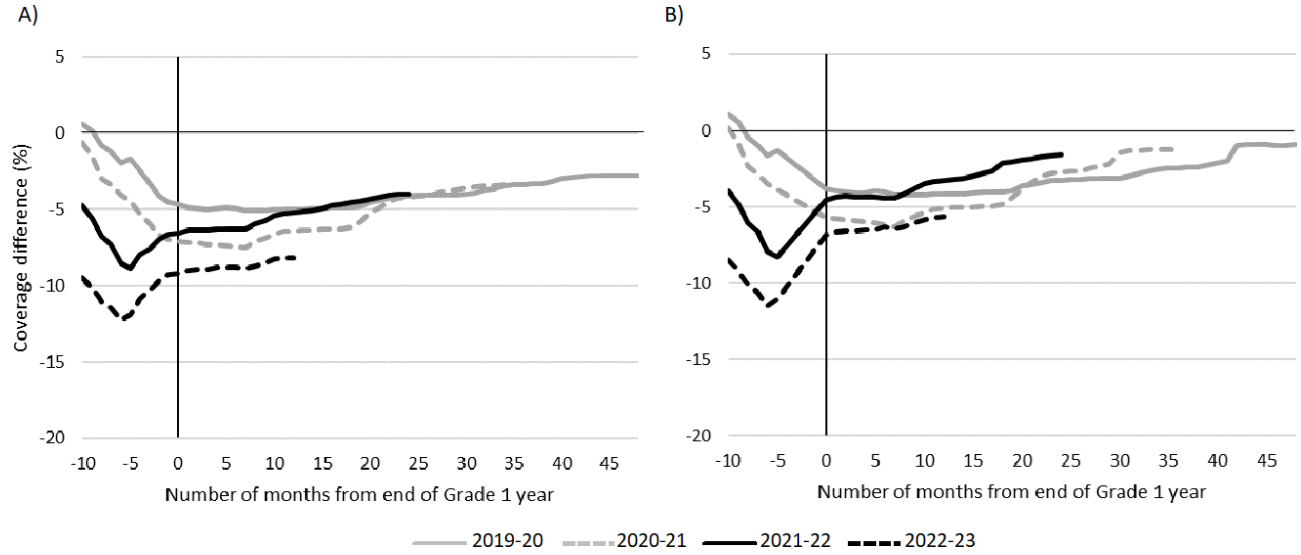


XSL•FO
RenderX

Figure 1. Differences in monthly complete (2 dose) coverage compared to prepandemic school year (2017 - 2018) for each Grade 6 cohort for: (A) human papillomavirus (HPV) and (B) hepatitis B. Differences were calculated by comparing the cumulative monthly coverage for each pandemic cohort to the cumulative coverage in the analogous month for the prepandemic cohort.

Cumulative coverage for all Grade 9 pandemic cohorts remained below prepandemic coverage throughout the study period (see Figure 2). The largest deficits in coverage were observed for the 2020 - 2021 Grade 9 cohort, with coverage for both vaccines more than 30 percentage points lower than prepandemic at the end of the school year, with deficits persisting through to the end of observation: 14 percentage points (95% CI 13.5 - 14.5) lower for MenC-ACYW coverage (see Figure 2A and Table S4 in Multimedia Appendix 1) and 12.9 percentage points (12.4 - 13.4) lower for Tdap (see Figure 2B and Table S5 in Multimedia Appendix 1). Coverage for the prepandemic cohort ranged from 84.9% (at end of Grade 9 year) to 86.6% (after 48 months of follow-up) for MenC-ACYW (see Table S4 in Multimedia Appendix 1), and from 85.6% (at end of Grade 9 year) to 88.2% (at 48 months of follow-up) for Tdap (see Table S5 in Multimedia Appendix 1).

Figure 2. Differences in monthly complete coverage compared to prepandemic school year (2018 - 19) for each Grade 9 cohort for: (A) Meningococcal conjugate ACYW-135 (MenC-ACYW; 1 dose), and (B) Tetanus, diphtheria, and acellular pertussis (Tdap; 1 dose). Differences were calculated by comparing the cumulative monthly coverage for each pandemic cohort to the cumulative coverage in the analogous month for the prepandemic cohort.

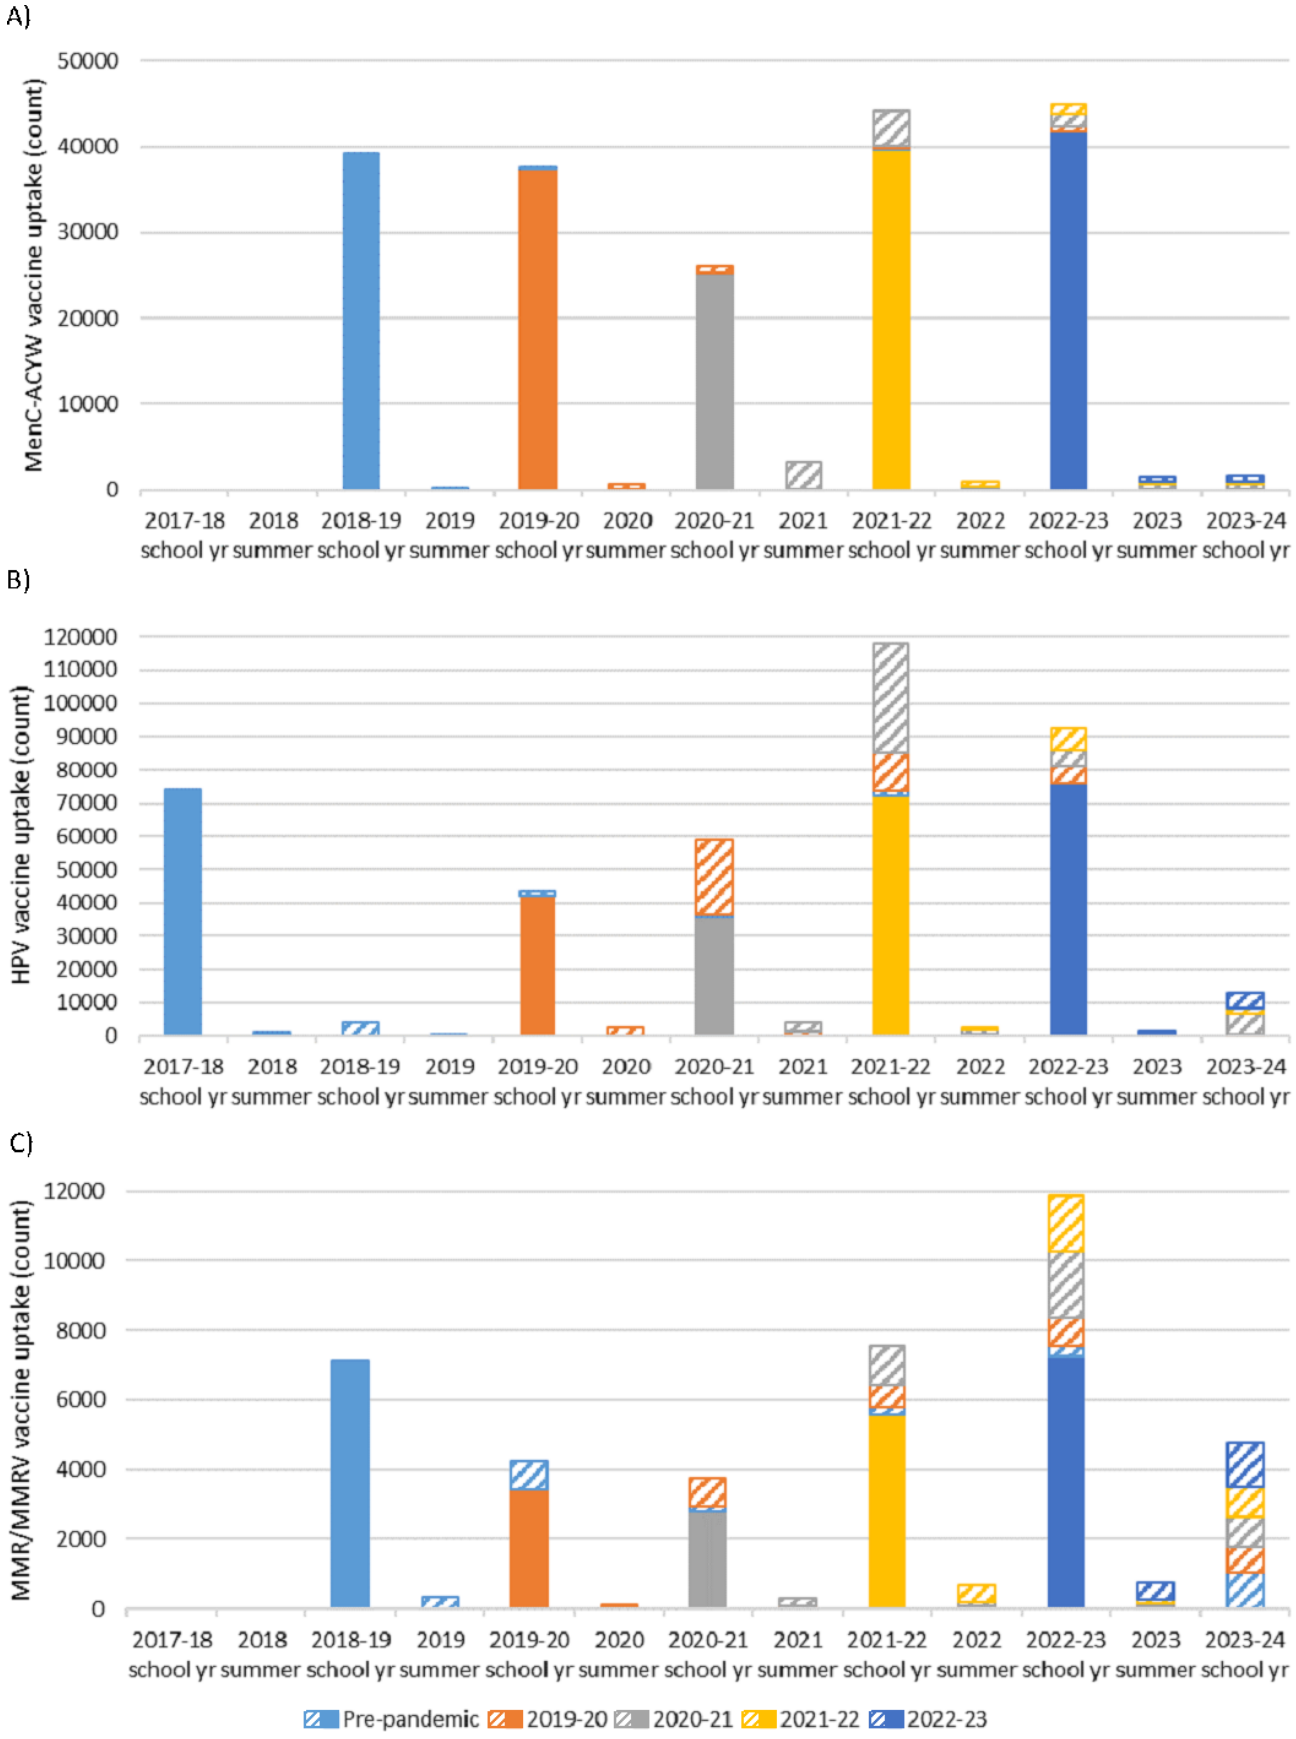


For all Grade 1 pandemic cohorts, cumulative coverage remained below prepandemic levels throughout the observation period, for both MMR or MMRV and DTaP-IPV (see Figure 3). For both vaccines, coverage at the start of the Grade 1 year was similar to prepandemic levels for the 2019 - 2020 and 2020 - 2021 cohorts, but significantly lower for the 2021 - 2022 and 2022 - 2023 cohorts. During the school year, coverage for the 2019 - 2020 and 2020 - 2021 cohorts continued to decline relative to prepandemic levels. In contrast, the 2021 - 2022 and 2022 - 2023 cohorts ended their Grade 1 years with coverage deficits similar to the start of the school year. For all cohorts, coverage deficits gradually decreased during the remaining period of observation. MMR or MMRV coverage for all cohorts remained significantly below prepandemic levels at the end of the study period, ranging from 3.06 percentage points lower (2.69 - 3.44) for the 2019 - 2020 cohort, to 7.87 percentage points lower (7.46 - 8.28) for the 2022 - 2023 cohort (see Figure 3A and Table S7 in Multimedia Appendix 1). Smaller deficits were observed for DTaP-IPV coverage, ranging from 0.5 percentage points lower (0.11 - 0.92) in the 2019 - 2020 cohort to 4.64 percentage points lower (4.20 - 5.08) in the 2022 - 2023 cohort (see Figure 3B and Table S6 in Multimedia Appendix

XSL•FO
RenderX

1). Coverage for the prepandemic cohort increased during the period of comparison: from 76.6% (76.3% - 77%; September 2018) to 90.5% (90.2% - 90.7%; July 2023) for MMR or MMRV (see Table S7 in Multimedia Appendix 1); from 74.3% (74% - 74.7%; September 2018) to 87.1% (86.8% - 87.4%; July 2023) for DTap-IPV (see Table S6 in Multimedia Appendix 1). Compared to DTaP-IPV, generally larger deficits in MMR or MMRV coverage were observed in all pandemic Grade 1 cohorts; MMR or MMRV coverage remained higher than DTaP-IPV in the 2019 - 2020, 2020 - 2021, and 2021 - 2022 cohorts, but was lower in the 2022 - 2023 cohort.

Figure 3. Differences in monthly complete coverage compared to prepandemic school year (2018 - 19) for each Grade 1 cohort for: (A) Measles-mumps-rubella (MMR) or measles-mumps-rubella—varicella (MMRV; 2 doses), and (B) Diphtheria, tetanus, acellular pertussis, and polio (DTap-IPV; 5 doses). Differences were calculated by comparing the cumulative monthly coverage for each pandemic cohort to the cumulative coverage in the analogous month for the prepandemic cohort.



Vaccine Administration

Drops in vaccine administration (ie, count of the number of vaccine doses delivered) were observed during the 2019 - 2020 and 2020 - 2021 school years, with volume increasing to above prepandemic levels during the 2021 - 2022 and 2022 - 2023 school years (see Figure 4). For Grade 1, the largest volume of catch-up immunization occurred during the 2023-2024 year (2023 summer and 2023 - 2024 school year [from July 2023 to June 2024], total of 5521 MMR or MMRV doses delivered). For both Grade 6 and Grade 9, the largest volume of catch-up immunization was completed during the 2021-2022 year (from July 2021 to June 2022), with totals of 50,290 (HPV) and 7780 (MenC-ACYW) doses delivered, respectively. Immunization of the prepandemic cohort continued throughout the study period for all vaccines, with vaccine delivery observed during each summer and school year included. While generally higher vaccine administration volumes were noted during the school years, we are unable to identify whether those doses were delivered through SBIPs or through other public health vaccination efforts.

Cumulative Immunization Deficits

The cumulative deficits of unimmunized or incompletely immunized individuals for each vaccine, aggregated for all years, are presented in Table 1. The estimated time to clear these deficits is also presented, including the minimum time required (based on maximum effort observed in the previous years) and average time required (based on the average effort observed in the previous years). Deficits were highest for the Grade 1 and Grade 9 cohorts, with correspondingly greater time estimated to clear these deficits.

Table . Cumulative vaccine deficits among pandemic cohorts at the end of the study period (July 2024), relative to maximum vaccine coverage for prepandemic grade cohorts, and estimated time to clear deficit.

Grade and vaccine	Number of individuals vaccinated		Cumulative deficit	Estimated remaining catch-up time (years)	
	Expected[a]	Observed		Minimum[b]	Average[c]
Grade 1					
DTaP-IPV[d]	198,332	183,132	−15,200	3.1	5.6
MMR[e] or MMRV[f]	199,198	184,409	−14,789	3.0	5.4
Grade 6					
HPV[g]	167,633	161,700	−5933	0.14	0.37
Hepatitis B	186,029	176,768	−9261	0.22	0.78
Grade 9					
MenC-ACYW[h]	180,871	164,436	−16,435	2.1	4.8
Tdap[i]	185,057	167,623	−17,434	2.2	4.7

[a]Estimated number of individuals vaccinated in pandemic cohorts to achieve coverage equivalent to maximum coverage observed in pre-pandemic cohort.

[b]Calculated using maximum annual catch-up uptake observed for each grade.

[c]Calculated using average annual catch-up uptake observed for each grade.

[d]DTaP-IPV: diphtheria, tetanus, acellular pertussis, and polio.

[e]MMR: measles-mumps-rubella.

[f]MMRV: measles-mumps-rubella—varicella.

[g]HPV: human papillomavirus.

[h]MenC-ACYW: meningococcal conjugate ACYW-135.

[i]Tdap: tetanus, diphtheria, and acellular pertussis.

Discussion

Principal Findings

We explored the cumulative impact of immunization program interruptions and subsequent catch-up efforts that have occurred since the COVID-19 pandemic on vaccine coverage and administration among school-aged children. Our results indicate that catch-up efforts resulted in significant recovery of vaccine coverage levels; however, important gaps remain. HPV and hepatitis B vaccine coverage levels had reached or were near prepandemic levels in all pandemic Grade 6 cohorts by the end of follow-up, though recovery took approximately 36 months for cohorts with the most significant relative deficits in coverage (2019 - 20 and 2020 - 21 grade-year). Our findings regarding persistent coverage deficits among Grade 1 and Grade 9 cohorts, more than 3 school years after pandemic-related school closures, are particularly concerning, given the recent elevation in pertussis [22] and measles [23] cases recorded in Canada. Both programs face unique challenges, with vaccine delivery to Grade 1 cohorts deprioritized early in the pandemic, and limited access to Grade 9 cohorts as they age out of routine SBIPs. While the routine SBIPs provide additional opportunities to catch up Grade 1 cohorts, efforts outside of secondary schools will be required to reach Grade 9 students who remain undervaccinated.

We found significant, though largely temporary, drops in HPV and hepatitis B vaccine coverage among Grade 6 cohorts. These results indicate that potential changes in immunization attitudes had little to no impact on uptake for these vaccines. This is particularly important to note for the HPV vaccine, which has historically been subject to large drops in uptake due to changes in public sentiment [24]. Similar to our findings, a largely temporary drop in HPV and hepatitis B vaccine coverage was observed in the province of Quebec, which also has a well-established SBIP [17]. However, that study observed a return to near prepandemic 1+ dose coverage levels after only one year of catch-up efforts for the most impacted cohort (2020 - 2021 school year), after experiencing drops in coverage larger than reported here, highlighting the importance of contextualizing findings within regional strategies used for intensive catch-up programs. While results from Alberta indicate that catch-up efforts were successful at returning coverage to prepandemic levels, coverage of both HPV and hepatitis B remains significantly below national vaccine coverage goals of 90% [25].

XSL•FO
RenderX

We found catch-up immunization efforts for Grade 1 cohorts were delayed relative to the Grade 6 and 9 cohorts, confirming that primary vaccine series were prioritized in catch-up efforts [26]. Concerningly, the most recent (2022 - 2023) Grade 1 cohort in our study showed the largest coverage deficit compared to prepandemic levels. This cohort would have been scheduled to receive their preschool vaccines during the initial stages of the pandemic, when access to immunization services was limited and infant vaccines were prioritized [27]. Other studies also noted relatively larger declines in immunization for this age group compared to infants [13,15,28,29]. While the Grade 1 SBIP coverage improvements for this cohort were similar to the SBIP in the prepandemic cohort, deficit levels from the preschool program remain. It will be important to understand whether the limited catch-up during the Grade 1 program is due to individual (eg, increased vaccine refusal, decreased school attendance) or programmatic (eg, staff capacity, school access) factors.

Our results indicate that catch-up efforts impacted coverage for all cohorts, across all vaccines, throughout the study period, demonstrating the importance of maximizing opportunities for immunization. While intensive catch-up in different grades was prioritized at different times, these efforts represent notable increases in vaccine delivery workload. In addition, these numbers do not capture unseen efforts related to mitigating potentially increased student stress [30], and heightened school collaboration required to implement catch-up immunization efforts. It is unclear whether it is feasible for providers to sustain this level of catch-up efforts for the estimated additional time required to address outstanding deficits. Finally, while ongoing catch-up efforts can simplify vaccine access and prompt vaccine uptake, they also have the potential to contribute to vaccine fatigue. Vaccine fatigue, described as individual "inertia or inaction towards vaccine information or instruction due to perceived burden and burnout" [31], has the potential to lead to ongoing decreases in vaccine uptake. More information on the impact of repeat offering is needed to determine whether those subsequently vaccinated simply missed previous opportunities, or their willingness to be vaccinated changed due to programmatic (eg, removing COVID-19 immunization from schools) or contextual (eg, infectious disease outbreaks) factors. While ongoing monitoring of vaccine-specific coverage deficits can help appropriately direct program efforts, optimizing the use of schools for catch-up programs will require careful consideration of the impact of these efforts on providers, children and their parents or caregivers, and schools.

Strengths and Limitations

This study provides a comprehensive summary of how vaccine coverage among children targeted through routine SBIPs was impacted by the COVID-19 pandemic and subsequent catch-up immunization efforts. Rather than evaluating a 1-time measure of vaccine coverage at a set age, we followed each cohort after grade completion to study end (July 2024). As a result, total cumulative vaccine coverage for our prepandemic comparison cohorts reflects vaccine activity that occurred before (ie, routine) and during the pandemic (ie, catch-up). Thus, the observed catch-up vaccination for this cohort may also reflect pandemic-related decreases in vaccination activity, causing an underestimation of pandemic impacts by the end of our study period.

Our work benefited from a population-based vaccine repository with information on all vaccines provided in the province, as well as complete denominator data. However, it is possible that vaccines received outside of the province were not completely captured in the vaccine repository, which could lead to underestimations in coverage. We also did not capture prepandemic trends that may have inflated or deflated coverage differences noted for the pandemic cohorts. Our HPV and hepatitis B prepandemic comparison year reflected coverage for the 3-dose series offered to Grade 5 students, which we compared to cohorts exposed to the 2-dose series offered in Grade 6. The decrease in series doses could have contributed to lower coverage deficits noted in the pandemic cohorts. We were also unable to identify whether catch-up vaccines were delivered through school programs or through other efforts (eg, outreach programs and community clinic visits). Future work should consider the impact of catch-up efforts on inequities in vaccine coverage.

Conclusions

We found coverage deficits that occurred during and after the COVID-19 pandemic persisted for at least 3 years after the pandemic-related school and health facility closures were initiated in March 2020. While we noted recovery to prepandemic vaccine coverage levels for vaccines scheduled in Grade 6, deficits remain in those targeted for delivery in Grades 1 and 9. Existing Grade 6 and 9 routine programs may provide additional opportunities to address immunization gaps among younger cohorts; strengthening these should be a priority. However, reaching those who missed Grade 9 vaccines will require targeted efforts in high school and post-secondary educational institutions. A better understanding of the approaches used for successful catch-up, in the context of routine delivery approaches, is required to ensure intensive and routine catch-up programs are optimized.

Abstract

Background: The association between social media usage and the risk of depressive symptoms has attracted increasing attention. WeChat is a popular social media software in China. The impact of using WeChat and posting WeChat moments on the risk of developing depressive symptoms among community-based middle-aged and older adults in China is unknown.

Objective: The objective was to assess the association between using WeChat and posting WeChat moments and the risk of depressive symptoms among middle-aged and older adults in China.

Methods: A prospective national cohort study was designed based on the data obtained from the fourth and fifth waves of the China Health and Retirement Longitudinal Study (CHARLS). The strength of association between using WeChat and posting WeChat moments and the risk of depressive symptoms was estimated by modified Poisson regressions. Depressive symptoms were determined using the 10-item Center for Epidemiologic Studies Depression Scale. Meanwhile, the heterogeneity of the associations was explored through multiple subgroup analyses. Moreover, multiple sensitivity analyses were performed to verify the robustness of the associations between the exposures and depressive symptoms.

Results: A total of 9670 eligible participants were included in the cohort study, and the incidence rate of depressive symptoms was 19.08% (1845/9670, 95% CI 19.07% - 19.09%) from the fourth to fifth waves of the CHARLS. Using WeChat (adjusted relative risk [aRR] 0.691, 95% CI 0.582 - 0.520) and posting WeChat moments (aRR 0.673, 95% CI 0.552 - 0.821) reduced the risk of depressive symptoms among middle-aged and older Chinese adults. The association between the exposures and depressive symptoms was robust, proved through multiple sensitivity analyses (all P<.05). However, the associations were heterogeneous in certain subgroup catagories, such as solitude, duration of sleep at night, nap after lunch, physical activity, and having multiple chronic conditions.

Conclusions: Using WeChat and especially posting WeChat moments can mitigate the risk of depressive symptoms among community-based middle-aged and older Chinese adults. However, there is likely a need for a longer follow-up period to explore the impact of the exposures on the risk of long-term depressive outcomes.

Introduction

Depression is a common emotional disorder [1-4] resulting in limited psychosocial functioning and a decreased quality of life [5] and is also an independent risk factor of all-cause mortality and other chronic conditions [6-8]. A meta-analysis [3] reported that the prevalence of depressive symptoms among older adults in mainland China was 20% (95% CI 17.5% - 22.8%), and Chen et al [9] reported an unweighted incidence rate of depressive symptoms of 34.77% based on the China Health and Retirement Longitudinal Study (CHARLS). These findings highlight the need for an increased attention to depressive symptoms in China. Therefore, understanding modifiable factors associated with depressive symptoms is essential for developing effective public health strategies to prevent them. Multiple well-known factors associated with depressive symptoms include genetic factors, psychosocial stress, changes in the hypothalamic-pituitary-adrenal axis, inflammation, and others [5,10,11].

In terms of psychosocial factors, there has been a growing body of studies on the association or correlation between social media usage (SMU) and depression in recent years. Studies conducted by Lin et al [12], Primack et al [13] and Perlis et al [14] demonstrated that SMU, particularly on Facebook, TikTok (known as Douyin in China) and Snapchat, was associated with an increased risk of depression among US adults. However, Cotten et al [15] analyzed the data from 6 waves of the National Health and Aging Trends Study and suggested that SMU may not be related to depression in older adults. Based on the above studies, the association between SMU and depression could be attributed to problematic SMU [16,17], while moderate and reasonable use of social media may not cause harm to mental health.

WeChat (known as Weixin in China) is a popular social media software in China, which had 1.04 billion monthly active users according to Tencent [18]. The primary functions of WeChat include texting, voice and video calling, and browsing and posting moments that encompass both positive and negative events happening among friends or oneself, as well as facilitating financial management. From the perspective of these functionalities, WeChat distinguishes itself from platforms like Facebook or TikTok, which focus on interests and preferences that can foster addiction or problematic SMU.

It is hypothesized that using WeChat and posting WeChat moments would not result in an increased risk of depressive symptoms among community-based middle-aged and older Chinese adults, but rather potentially mitigate the risk of developing depressive symptoms. In fact, two cross-sectional studies using data from the fourth wave of the CHARLS and the fifth wave of the China Family Panel Study reported an association between WeChat usage and a decreased risk of depressive symptoms among middle-aged and older Chinese adults [19,20]. However, the two studies were unable to determine a temporal relationship between WeChat usage and depressive symptoms, thus precluding any causal inferences regarding the relationship between the observed exposures and depressive symptoms. Additionally, findings from the study conducted by Qu et al [19] indicated that participants who posted WeChat moments did not exhibit a decreased risk of depressive symptoms, which contradicted the findings of Zhang and Liang [20].

In response to these conflicting findings, a national, prospective cohort study was designed, leveraging data from both the fourth and fifth waves of the CHARLS. The aim of this study was to elucidate the relationship between the use of WeChat—with particular emphasis on posting WeChat moments—and the risk of depressive symptoms.

Methods

Study Design and Study Population

The study was characterized as a national, prospective cohort study, deriving its data from the fourth and fifth waves of the CHARLS. Initiated in 2011, the CHARLS represents a longitudinal national survey aimed at collecting extensive data pertinent to community-based middle-aged and older adults in China. The scope of the CHARLS encompasses high-quality, representative panel data covering a broad spectrum of topics. These topics include demographic variables, socioeconomic status, familial relationships, health status, health care usage, and others. More information about the CHARLS is accessible at their official website [21].

The intersection of the following 3 datasets from the CHARLS were compiled for the raw dataset: demographic backgrounds from the fourth wave, health status and functioning from the fourth wave, and the 10-item Center for Epidemiologic Studies Depression Scale (CESD-10) from the fifth wave. Participants from the raw dataset that (1) were aged <45 years, (2) were missing scores for the CESD-10 in the fourth wave, (3) had a CESD-10 score ≥10 in the fourth wave, or (4) were missing scores for the CESD-10 in the fifth wave were excluded.

Assessment of Exposures

In the fourth wave of the CHARLS, participants were asked, “Do you use WeChat?” with possible responses being yes or no. Participants who answered yes were categorized as WeChat users; otherwise, they were categorized as non-WeChat users. Subsequently, the participants using WeChat were further asked, “Do you post WeChat moments?” with possible responses being yes or no. Participants who answered yes were categorized as WeChat moments users; otherwise, they were categorized as non-WeChat moments users.

Therefore, according to whether or not they used WeChat, the participants were stratified into 2 groups: WeChat users and non-WeChat users. Furthermore, according to whether or not the participant posted WeChat moments, they were stratified into 3 groups: non-WeChat users, non-WeChat moments users and WeChat moments users. In this study, we first focused on the comparison between the incidence of depressive symptoms among the WeChat users and non-WeChat users, then that among non-WeChat users, non-WeChat moments users and WeChat moments users.

XSL•FO
RenderX

Assessment of the Outcome

The outcome of this study was depressive symptoms, which were measured using the CESD-10 scores from the fifth wave of the CHARLS as a dichotomous variable (yes or no). Each item of the CESD-10 was rated on a 4-point Likert scale ranging from 0 to 3, corresponding to the frequency of the symptoms (0=rarely or not at all; 1=some or a little of the time; 2=occasionally or a moderate amount of time; 3=most or all of the time). The aggregate score, which was the sum of the responses to all items, thus ranged from 0 to 30. A cumulative score of 10 or above was used as a threshold for identifying participants with depressive symptoms, whereas scores below this threshold indicated the absence of such symptoms. Additionally, for sensitivity analysis, alternative cutoff points of 11 and 12 on the CESD-10 were also employed to further ascertain the presence of depressive symptoms.

Assessment of Covariates

The following characteristics obtained from the fourth wave of the CHARLS were considered as covariates: age, sex (male or female), race (Han or minority), faith (yes or no), type of community (village or city/town), marital status (married and cohabiting, married and separated, or others), education (illiterate, not finished primary school/home school/primary school, junior high school, or senior high school and above), smoking habits (currently, ever, or never), alcohol consumption (yes or no), duration of sleep at night (<6 hours, ≥6 hours to <8 hours, or ≥8 hours), nap after lunch (yes or no), and physical activity (none, mild, moderate, or vigorous). Additionally, the social activity score was a covariate [22], which was the frequency of 11 kinds of activities rated as never (score=0), not regularly (score=1), almost every week (score=2), or almost daily (score=3). These activities were assembled to a sum score based on the frequency level, and the total scores for social activities could range from 0-33 points.

The basic activities of daily living (BADL) score was also a covariate [23], which included items for dressing, bathing, feeding, moving from a bed to a chair, using the toilet, and maintaining continence. All items had 4 potential answers, including (1) do it without difficulty, (2) do it but with difficulty, (3) do it with difficulty and need help, or (4) cannot do it, which were rated as 0, 1, 2, or 3 points, respectively. BADL scores were the sum of points for all items. Another covariate was life satisfaction. This question had 5 alternative answers: completely satisfied, very satisfied, somewhat satisfied, not very satisfied, or not at all satisfied. The responses were then stratified into 3 categories: completely/very satisfied, somewhat satisfied, or not very/not at all satisfied. Last, the number of chronic conditions (5 categories: no chronic conditions, 1 chronic condition, 2 chronic conditions, 3 chronic conditions, and ≥4 chronic conditions) and the number of parts with body pain were covariates.

Statistical Methods

Descriptive analyses and differential comparisons were conducted on the characteristics of the eligible participants. The quantitative variables with a normal distribution were described using mean and SD, and a 2-tailed *t* test or one-way ANOVA was used for comparing the difference between two groups or among three groups, respectively. Quantitative variables with skewed distributions were described using the median and IQR, and a Wilcoxon rank sum test or Kruskal-Wallis H test was used for the comparison. Disordered multinomial variables were described by the number of cases and percentage, and a χ^2 test or Fisher exact test was used for the comparison. Ordinal multinomial variables were described by the frequency and percentage, and a Wilcoxon rank sum test or Kruskal-Wallis H test was used for comparison.

For all eligible participants, univariable modified Poisson regressions were used to analyze the association between using WeChat and posting moments with the risk of depressive symptoms. Next, variables with $P<.05$ from between-group comparisons, along with adjusted variables in previous studies [19,20], were included as confounders in the multivariable modified Poisson regressions to analyze the association between the exposures and depressive symptoms. Meanwhile, the generalized variance-inflation factor of covariates in the multivariable regressions were calculated to test for collinearity (Table S1 in Multimedia Appendix 1).

For subgroup analyses, all eligible participants were divided into different subgroups according to sex (male or female), age (<60 years old or ≥60 years old), type of community (village or city/town), solitude (living with a heterosexual partner or not), education (primary school and below or junior high school and above), alcohol consumption (yes or no), duration of sleep at night (<6 hours, 6 - 8 hours, or ≥8 hours), nap after lunch (yes or no), physical activity (vigorous, moderate, mild, or none), and chronic conditions (≥2 chronic conditions or not). In the same way, multivariable modified Poisson regressions with the confounders, except the grouping variable, were performed to estimate the strength of association between the exposures and depressive symptoms.

There were missing values in variables for smoking habits, alcohol consumption, duration of sleep at night, nap after lunch, physical activity, social activity score, BADL score, and the number of body parts with pain, of which the proportions of missing values are shown in the Table S2 in Multimedia Appendix 1. Hot deck imputation was used to impute the missing values, and all statistical analyses were based on that data. Smoking habits, social activity score, BADL score, and the number of body parts with pain were not considered as confounders in the main analysis, due to the proportion of missing values being >40%. However, the above variables were adjusted for in the sensitivity analyses.

Multiple sensitivity analyses were conducted to validate the robustness of the association between the exposures and the outcome. First, the outcome of depressive symptoms was redefined as a CEDS-10 score of ≥11 or 12 in the multivariable modified Poisson regressions. Second, eligible participants diagnosed with emotional, nervous, or psychiatric problems in the fourth wave of the CHARLS were excluded. Third, to improve the comparability of the exposed groups with the control group, eligible participants aged >83 years in the non-WeChat users group were excluded since the oldest user in the WeChat users group was 83 years old (Table S3 in

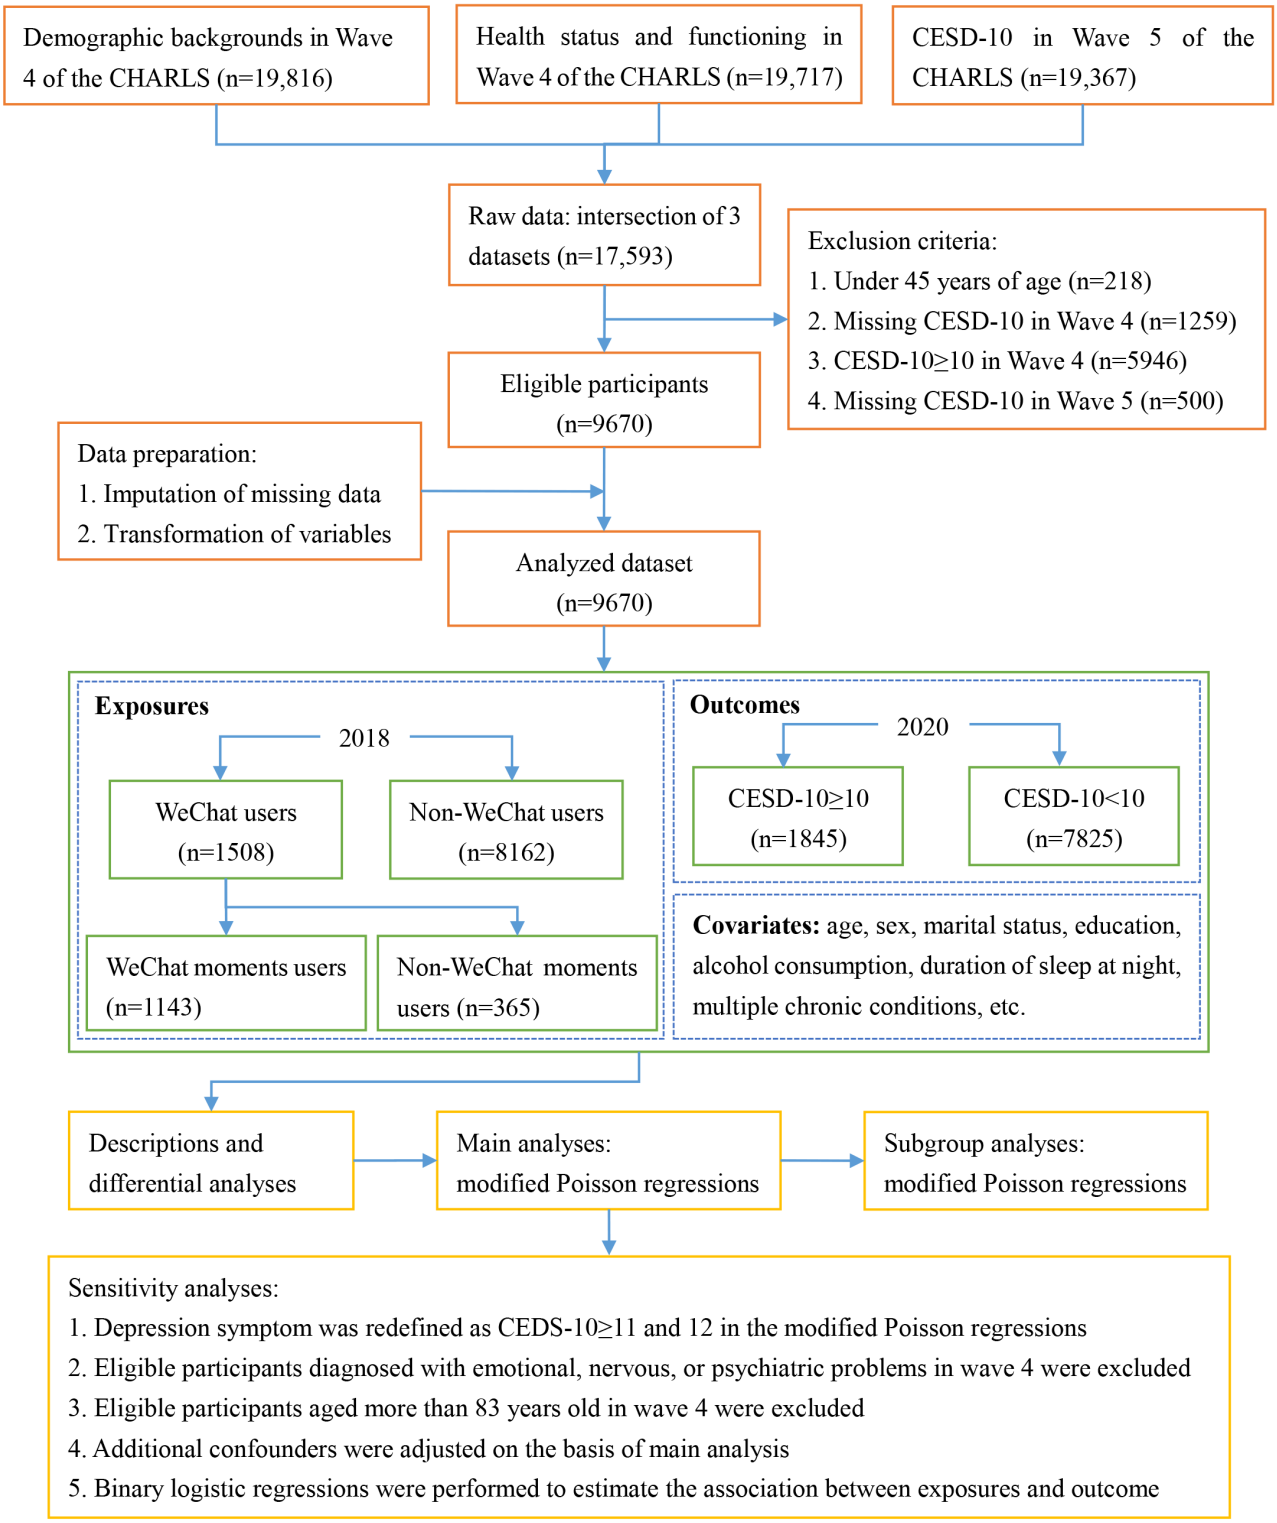
XSL•FO
RenderX

Multimedia Appendix 1). Fourth, additional confounders (smoking habits, BADL score, social activity score, and the number of body parts with pain) were adjusted for in the main analysis. Last, multivariable binary logistic regressions were performed to estimate the association between exposures and depressive symptoms.

All statistical analyses were completed by R 4.3.3 (R Core Team) with R packages *VIM*, *rqlm*, *car* and *forestploter* and the Mengte Cloud version 1.0 statistics platform (Wuxi Mengte Yi Shu Tong Co, Ltd). A 2-sided hypothesis test was used, and the significance level was set at α=.05.

Ethical Considerations

The ethical approval for the CHARLS was approved by the Ethics Review Committee of Peking University (IRB00001052-11015). Prior to participation, all study participants were required to sign an informed consent form, thereby confirming their voluntary engagement in the survey process. The study data were anonymous. China's Health Commission, Ministry of Science and Technology, and other departments jointly issued the Ethical Review Measures for Life Science and Medical Research involving Human Beings in February 2023, in which Article 32 mentioned 4 situations of exemption from ethical review. The secondary analysis of this public database CHARLS satisfied the first 2 of these: the data were free and publicly available and were available through a web-based application. Importantly, the data obtained from the platform were anonymous, and the identity information of all respondents was unknown. In addition, the study did not use biological samples from the survey subjects. Regarding compensation and informed consent, because this study was a secondary analysis, along with the subjects being anonymous, the respondents did not receive secondary compensation or sign a new informed consent form.



Results

The Characteristics of Eligible Participants

The process for screening participants is shown in Figure 1. A total of 9670 eligible participants were included in the final analysis. The mean age of these participants was 61.01 (SD 9.35) years. Of all eligible participants, 47.55% (n=4598) were female. A majority (n=6733, 69.63%) resided in villages, and 82.99% (n=8025) reported being married or cohabiting. Alcohol consumption was reported by 38.73% (n=3745) of participants, and 62.79% (n=6072) indicated they took a nap after lunch. A total of 92.84% (n=8978) engaged in physical activity, and 74.96% (n=7249) had been diagnosed with chronic conditions. The median scores of the CESD-10 were 4 (IQR 2-7) in the fourth wave and 6 (IQR 3-9) in the fifth wave. The incidence rate of depressive symptoms was 19.08% (95% CI 19.07% - 19.09%) from the fourth to fifth waves of the CHARLS (Table 1). Participants who used WeChat, regardless of whether they posted on WeChat moments, tended to be younger, male, non-religious, urban residents, or have a higher level of education. They were also more likely to be married or cohabiting, be current or former smokers, be alcohol consumers, sleep less than 8 hours at night, take afternoon naps, engage in physical activity, have high social activity scores, have low BADL scores, have fewer body parts in pain, and have no chronic conditions (Table 1 and S4 in Multimedia Appendix 1).

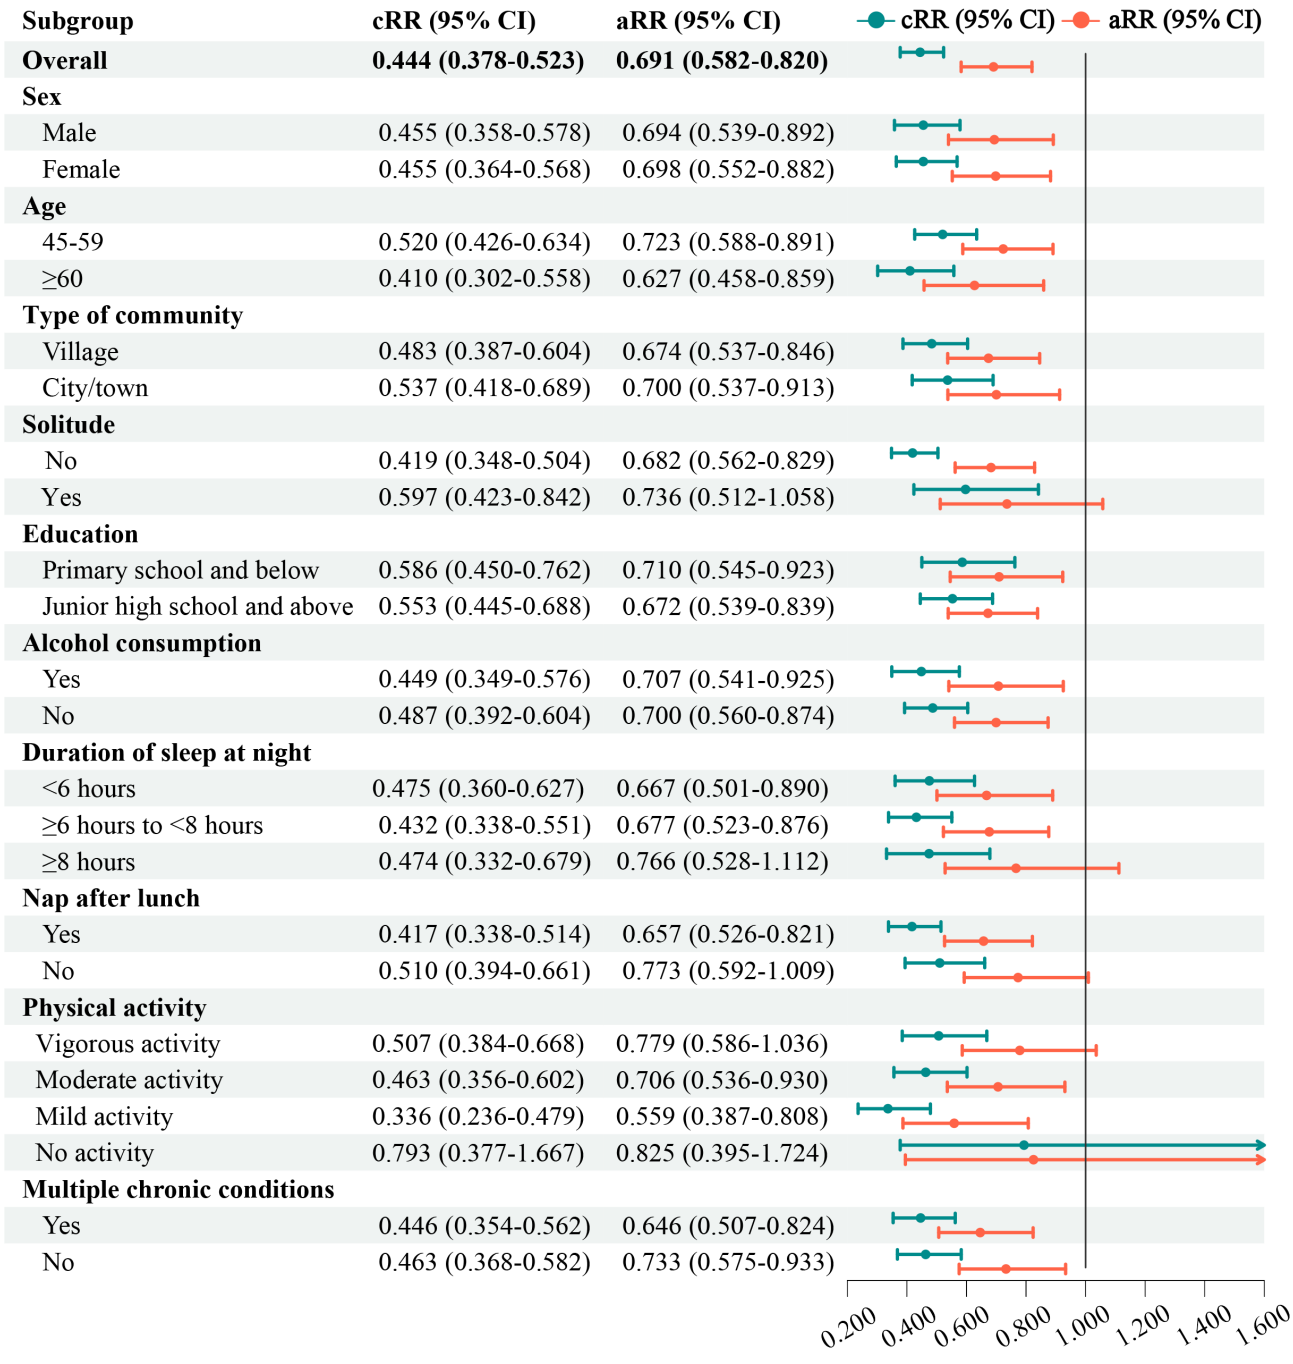
Association Between Exposures and Depressive Symptoms

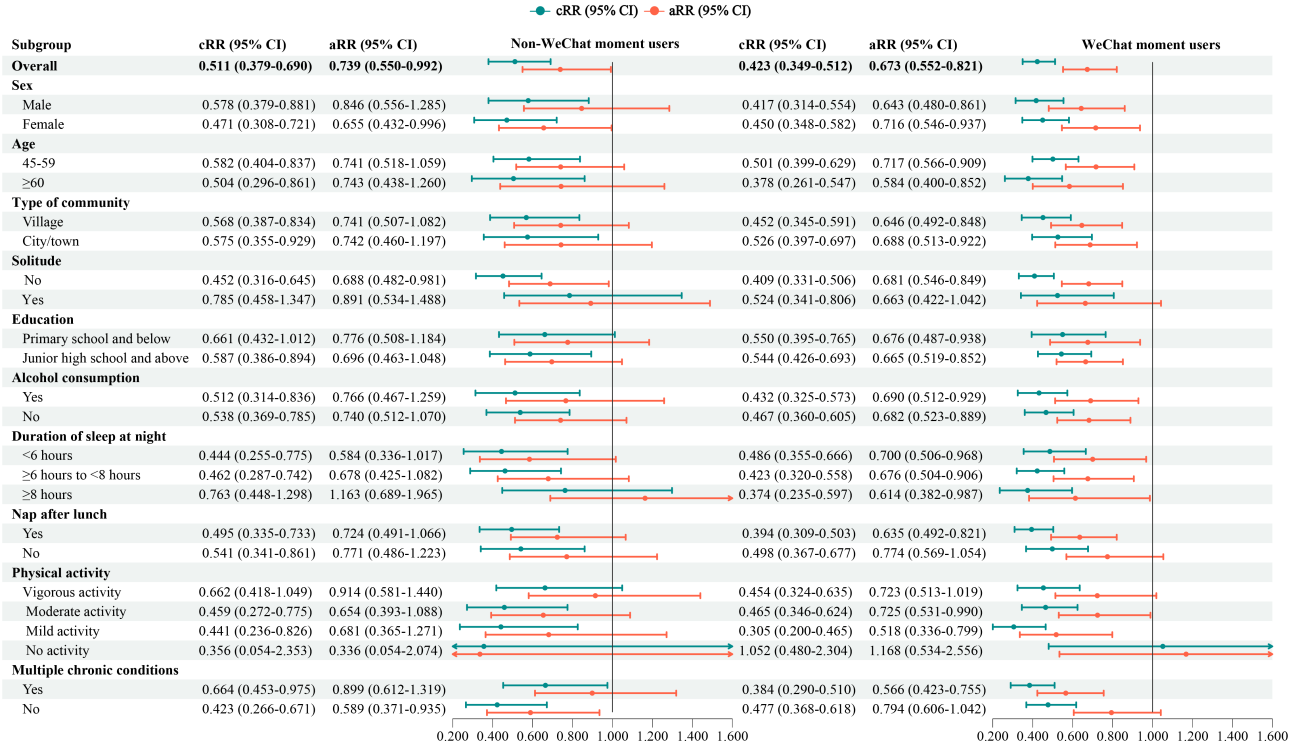
As shown in Figure 2 and Table S5 in Multimedia Appendix 1, among all eligible participants, the risk of depressive symptoms in the WeChat users group was 0.556 times lower than that in the non-WeChat users group, as indicated by the crude relative risk (cRR) of 0.444 (95% CI 0.378 - 0.523; *P*<.001) using a univariable modified Poisson regression. Furthermore, after adjusting for potential confounders in the multivariable modified Poisson regression models, the risk of depressive symptoms in the WeChat users group was 0.309 times lower than that in the non-WeChat users group (adjusted relative risk [aRR] 0.691, 95% CI 0.582 - 0.820; *P*<.001). These results suggested a significant association between WeChat usage and a decreased risk of depressive symptoms, implying that WeChat may serve as a protective factor against depressive symptoms in community-based middle-aged and older Chinese adults.



Subgroup analyses showed that WeChat usage did not reduce the risk of depressive symptoms among those who were solitary, had a sleep duration of ≥8 hours at night, did not have nap after lunch, engaged in vigorous physical activity, or did not engage in any physical activity. However, in other subgroups, the result indicated that WeChat usage was associated with a lower risk of depressive symptoms.

As depicted in Figure 3 and Table S6 in Multimedia Appendix 1, compared to non-WeChat users, both the non-WeChat moments users (aRR 0.739, 95% CI 0.550 - 0.992; *P*=.044) and WeChat moments users (aRR 0.673, 95% CI 0.552 - 0.821; *P*<.001) exhibited a lower risk of depressive symptoms. In the subgroups of females (aRR 0.655, 95% CI 0.432 - 0.996) and those without multiple chronic conditions (aRR 0.589, 95% CI

XSL•FO
RenderX



0.371–0.935), non-WeChat moments users had a lower risk of depressive symptoms compared to non-WeChat users. Additionally, with the exception of individuals who did not live with a spouse or opposite sex, did not nap after lunch, engaged in vigorous physical activity, did not engage in any physical activity, or did not have multiple chronic conditions, results from the subgroup analyses suggested that posting WeChat moments was associated with a reduced risk of depressive symptoms.

RenderX

Figure 3. The association between using WeChat with or without posting WeChat moments and risk of depressive symptoms among middle-aged and older Chinese adults in the cohort study based on CHARLS. aRR: adjusted relative risk; cRR: crude relative risk.

Sensitivity Analyses

The results of sensitivity analyses are presented in Table 2. (1) When depressive symptoms were redefined as CESD-10 scores of ≥11 or 12, the multivariable Poisson regressions indicated that WeChat usage reduced the risk of depressive symptoms in middle-aged and older individuals, regardless of whether they posted WeChat moments. (2) The multivariable Poisson regression was performed again after excluding participants who had emotional, nervous, or psychiatric problems in the fourth wave of the CHARLS, and results were consistent with the main analysis. (3) Given that none of the WeChat users were over 83 years old, another multivariable Poisson regression was performed after excluding non-WeChat users over 83 years old, which yielded results similar to the main analysis. (4) Additional adjustments were made for smoking habits, social activity score, BADL score, and the number of body parts with pain. The outcome of depressive symptoms remained consistent with those of the main analysis. (5) Odds ratios from multivariable binary logistic regressions were used to estimate the associations, and the results demonstrated the robustness of the main analysis.

Discussion

Principal Findings

This prospective national cohort study confirmed that using WeChat and posting WeChat moments was a protective factor for depressive symptoms among community based middle-aged and older adults in China. In terms of the absolute magnitude of the aRR, participants who post WeChat moments had a lower risk of depressive symptoms than those who do not post WeChat moments. The results of multiple sensitivity analysis also illustrated the robustness of the association between the exposures and depressive symptoms. In addition, the associations were heterogeneous across several subgroups. For example, irrespective of posting WeChat moments, the association between WeChat usage and the risk of depression was not significant among participants whose duration of sleep at night was more than or equal to 8 hours, while the association was statistically significant in the other two subgroups for the duration of sleep. Also, only in the subgroups where participants engaged in mild and moderate physical activity did using WeChat and posting WeChat moments mitigate the risk of depressive symptoms.

First, this study demonstrated that WeChat usage mitigated the risk of future depressive symptoms, which was consistent with the conclusions of 3 existing cross-sectional studies carried out by Qu et al [19], Wang et al [24], and Zhang and Liang [20]. Second, the study further suggested that posting WeChat moments was significantly associated with a decreased risk of depressive symptoms, and that was consistent with the finding of the cross-sectional study conducted by Zhang and Liang [20], but it was inconsistent with the finding of the cross-sectional study conducted by Qu et al [19]. The results from this prospective cohort study are more convincing because it meets a necessary and inarguable criterion for causal inference: the temporality of cause and effect [25]. Last, multiple subgroup analyses were performed to explore the heterogeneity of the associations for the different characteristics of the participants, which were not conducted in previous studies about WeChat usage and depression.

Many studies have shown that loneliness, social isolation, lack of family and social support, and lack of social activity are risk factors for anxiety and depression in adults [26-30]. On the one hand, WeChat is an instant message platform where WeChat users can communicate with family and friends to relieve the feeling of loneliness, especially for older adults whose children or relatives are not around them [31]. Importantly, a video call on WeChat allows users to see each other, which is more convenient for emotional expression and perception and users can obtain emotional support. WeChat users not only can maintain and improve existing social relationships through WeChat, but they can also expand their social circle to make more like-minded friends and engage in more social activity [32].

WeChat moments is another common and primary function of WeChat, which is an emotional space composed of words, pictures, and short videos posted by users. Users of WeChat moments can post what is happening around them or express their feelings by text or video, browse the content posted or reproduced by their WeChat friends, and interact with their friends through the act of liking and commenting on posts and short videos. Similarly, users can obtain emotional support and emotional communication, as well as release negative emotions by posting WeChat moments. Therefore, the results of Nan et al [33] were supported, which found that internet usage, including WeChat usage, could directly or indirectly reduce the risk of depression through improving interpersonal relationships. Since solitude, a longer sleep duration, and no physical activity are all risk factors for depressive symptoms, it is difficult to offset the negative impact of these factors by using WeChat or posting WeChat moments. Therefore, the heterogeneity of the associations among certain subgroups was observed. Importantly, the heterogeneity of the associations shown in the subgroup analysis suggested that a one-size-fits-all model should be used with caution, and recommendations for individualization or stratified treatment are necessary, especially when research is used to inform policy and clinicians' decisions [34-36].

Strengths and Limitations

There are several strengths of this study. First, this study is a prospective national cohort study, of which the sample sizes are large and the participants are representative. Second, modified Poisson regressions were used to precisely estimate the strength of the associations, which is a statistical approach more appropriate for this scenario given the high incidence of depressive symptoms. Third, multiple subgroups analyses were performed to explore the heterogeneity of the associations between the exposures and depressive symptoms among participants with different characteristics. Last, multiple sensitivity analyses were performed to validate the robustness of the associations between the exposures and depressive symptoms based on the main analysis.

Meanwhile, there are several limitations of this study. First, as the questions about WeChat usage and WeChat moments usage were only collected in the 2018 and 2020 surveys in the CHARLS database, the data for only these two surveys were used in this study. The corresponding follow-up period in this study was short, and a longer follow-up is needed to further confirm our conclusion. Second, the use of subgroups and more exposure groups (WeChat users were further divided into WeChat moments users and non-WeChat moments users) reduced the sample size and statistical power of the regression analyses. In particular, fewer participants used WeChat but did not post moments, which may have resulted in wide CIs for the associations and heterogeneity of the associations that are not easily explained. Third, some studies have suggested that excessive SMU or problematic SMU may increase the risk of depression [16,37,38]. However, the CHARLS database lacks relevant information on the frequency or duration of WeChat and WeChat moments usage, so this study cannot analyze the association between the frequency of WeChat use and depressive symptoms. Fourth, limited by the information collected in the database, other factors behind the use of WeChat and WeChat moments that may influence depressive symptoms were not considered in this study, such as the personality of participants (ie, outgoing or introverted). These factors can relate to whether participants post moments and affect the risk of depressive

XSL•FO
RenderX

symptoms. Last, WeChat is only one of many social media software, and the participants may also use other social media software in addition to WeChat. Also, limited by the relevant information provided by CHARLS, this study was unable to investigate the effects of other social media and the joint use of them on mental health.

Conclusion

In summary, the prevention of depression in community-based middle-aged and older adults calls for the joint efforts of individuals, families, and society. On the one hand, middle-aged and older adults are recommended to moderately use social media and the internet to learn more about new things or keep in touch with family and friends [39]. At the same time, middle-aged and older adults are recommended to participate in offline social activities and physical activity, if their physical capacity allows. On the other hand, it is suggested that children should actively contact their older family members, both electronically and offline, to provide them with emotional and material support. In addition, especially for older adults, it is recommended that the government and community organizations provide more community support [40], such as group recreational activities, which can also be important for the prevention of depression. In addition, the next waves of the CHARLS data will be obtained to determine the impact of using WeChat and posting WeChat moments on the long-term risk of depressive symptoms.

Acknowledgments

This work was supported by Preventive Medicine Scientific Research Project of Jiangsu Province in 2023 (Ym2023103), Medical Research Program of Health Commission of Jiangsu Province (M2021001), Natural Science Foundation of Nanjing University of Traditional Chinese Medicine (XZR2021005), and Academic Promotion Special Project of Department Director in 2022 (Y2022ZR14). All funding organizations had no role in the study design, implementation, analysis, or interpretation of the data. All authors thank the CHARLS team of Peking University for its excellent contribution and all participants surveyed for their efforts.

Data Availability

The data used in the cohort study can be accessed through the official website of the CHARLS [21].

Authors' Contributions

WW and HW are credited as cofirst authors for their significant contributions. XW is recognized as the corresponding author. WW, HW, and XW jointly worked on the study's concept and design. WW and HW also took on the analysis and interpretation of data. The drafting of the manuscript was a joint effort by WW and HW, with guidance from XW and with additional support from XH, QY, and FC who concentrated on assessing the results, especially focusing on the methods and analytics. All authors participated in critically revising the manuscript for important intellectual content, had full access to all the study's data, reviewed and revised the manuscript drafts, and gave their final approval for the version to be published.

Conflicts of Interest

None declared.

Abstract

Background: The effects of physical activity (PA) across different domains and intensities on depressive symptoms remain inconclusive. Incorporating the community-built environment (CBE) into longitudinal analyses of PA's impact on depressive symptoms is crucial.

Objective: This study aims to examine the effects of PA at different intensities—low-intensity PA (eg, walking activities) and moderate-to-vigorous-intensity PA (eg, activities requiring substantial effort and causing faster breathing or shortness of breath)—across leisure-time and occupational domains on depressive symptom trajectories among middle-aged and older adults. Additionally, it investigated how CBEs influence depressive symptoms and PA trajectories.

Methods: This longitudinal study included 6865 middle-aged and older adults from the China Health and Retirement Longitudinal Survey. A CBE variable system was developed using a community questionnaire to assess attributes of the physical built environment. Depressive symptoms were measured using the Center for Epidemiologic Studies Depression Scale. Latent growth curve modeling was applied to analyze 3 waves of the cohort data (2015, 2018, and 2020) to explore the differential effects of PA on depressive symptoms and the role of the CBE.

Results: In the 2015 and 2018 waves, higher low-intensity leisure-time physical activity (LTPA) was associated with lower depressive symptoms (β=–.025, *P*=.01 and β=–.027, *P*=.005, respectively). Across all waves, moderate-to-vigorous-intensity LTPA showed no significant predictive effects (*P*=.21 in 2015, *P*=.57 in 2018, and *P*=.85 in 2020, respectively). However, higher occupational physical activity (OPA), particularly at moderate-to-vigorous intensities, was consistently associated with higher depressive symptoms. Parallel process latent growth curve modeling revealed that the initial level of total LTPA negatively predicted the initial level of depressive symptoms (β=–.076, *P*=.01). OPA exhibited dual effects, positively predicting the initial level of depressive symptoms (β=.108, *P*<.001) but negatively predicting their upward trajectory (β=–.136, *P*=.009). Among CBE variables, better infrastructure conditions (β=–.082, *P*<.001) and greater accessibility to public facilities (β=–.036, *P*=.045) negatively predicted the initial level of depressive symptoms. However, greater accessibility to public facilities positively predicted the upward trajectory of depressive symptoms (β=.083, *P*=.04). Better infrastructure conditions (β=.100, *P*=.002) and greater accessibility to public transport (β=.060, *P*=.01) positively predicted the initial level of total LTPA. Meanwhile, better infrastructure conditions (β=–.281, *P*<.001) and greater accessibility to public facilities (β=–.073, *P*<.001) negatively predicted the initial level of total OPA. Better infrastructure conditions positively predicted the declining trajectory of total OPA (β=.100, *P*=.004).

XSL•FO
RenderX

Conclusions: This study underscores the importance of considering the differential effects of PA across domains and intensities on depressive symptoms in public policies and guidelines. Given the influence of the environment on PA and depressive symptoms, targeted community measures should be implemented.

Introduction

In communities, the physical built environment and health behaviors, such as physical activity (PA), can significantly influence residents' mental health [1]. Overall, well-designed community-built environments (CBEs)—including factors such as walkability, appropriate density, and safety—are beneficial in reducing depressive symptoms. By contrast, unfavorable built environments, such as poor-quality housing and insufficient green spaces, may exacerbate depressive symptoms [2]. Exercise and PA have been shown to be as effective as some antidepressant medications in improving depressive symptoms [3].

With the acceleration of the global aging process [4], depression among middle-aged and older adults has become a significant public health issue worldwide. The World Health Organization (WHO) estimates that the prevalence of depression in the global aging population ranges from 10% to 20% [5]. In China, the pooled prevalence of depressive symptoms among seniors aged 60 years and older is approximately 22.7% [6]. Depression poses a serious threat to the mental health of middle-aged and older adults and can also lead to physical illness and an increased risk of death [7].

In all studies examining factors influencing depressive symptoms, PA has become a focal point. PA can be easily incorporated into the daily context of a community, whether in a living or work environment, making it a universally accessible and straightforward intervention. Its practicality and ease of implementation have made PA a key topic in discussions about improving mental health [8]. The beneficial effects of PA on alleviating depressive symptoms are well-documented. Physically inactive individuals are more likely to experience depressive symptoms compared with those who engage in regular PA [9]. Recent studies have shown that this effect is not influenced by age [10]. Middle-aged and older adults are particularly susceptible to depressive disorders due to factors such as the gradual decline in physical function, an increase in chronic illnesses, and the potential for significant life changes, including widowhood, retirement, and living alone after middle age [11]. Older adults who engage in insufficient PA are at a higher risk of depression compared with those who maintain adequate levels of PA [12].

Many studies exploring the relationship between PA and depressive symptoms have primarily focused on exercise-based PA [13]. However, PA can also occur in occupational settings or outside structured exercise programs. PA shows different health outcomes depending on the context, such as work versus leisure settings [14]. Recently, researchers have begun to examine the "PA paradox"—the concept that leisure-time physical activity (LTPA), such as sports and recreational activities, has positive effects on health, while PA in occupational settings may have negative consequences for both physical and mental health [15]. LTPA, regardless of intensity, is associated with a lower risk of depressive symptoms. By contrast, occupational PA (OPA) or transportation-related PA does not show a similar reduction in the risk of depressive symptoms [16]. Workers who engage in work-related physical activities tend to report higher levels of depressive symptoms [17], and individuals with the highest levels of OPA are more likely to experience depressive symptoms [18]. Globally, a significant proportion of people continue to engage in manual labor, particularly in many developing countries. Therefore, it is important to distinguish between different domains or motivations when examining the effect of PA on depressive symptoms, as this distinction may lead to entirely different results. However, only a small number of studies have made such distinctions to examine the effects of various PA domains on depressive symptoms [19].

There are still several limitations and gaps in the existing research on the effects of PA on depressive symptoms. First, while the beneficial effects of exercise on depressive symptoms are well-established, the complex impacts of different domains (such as exercise and work) or PA intensity remain inconclusive [20]. There is still a lack of basic evidence, particularly for middle-aged and older adults, and further research is urgently needed to provide clearer insights. Second, most studies on the effect of PA on depressive symptoms offer only a cross-sectional perspective, with few utilizing cohort data to explore the longitudinal impact. By focusing on individual trajectories and patterns over time, longitudinal studies can provide valuable insights into the developmental continuum, help determine the stability of the association between PA and depressive symptoms, and analyze the dynamics of these interactions [21].

Furthermore, the CBE is an important factor influencing mental health, including depressive symptoms and mental health inequalities [22]. Depressive symptoms are associated with the built environment, and different physical attributes of the community may impact them through various behavioral or social pathways [23]. Many characteristics of the CBE may expose residents to environmental stressors—such as poor housing quality, uncomfortable population densities, low safety, and poor accessibility to amenities—that can negatively affect their mental health [24]. As for built environment measures, the most common ones are related to the "5D" elements: density, diversity, design, destination accessibility, and distance to transit

XSL•FO
RenderX

[25]. These elements are often evaluated individually or together.

Despite the growing body of literature on the effects of CBE on depressive symptoms, there is still limited evidence concerning middle-aged and older adults. Few studies have highlighted that improving community walkability, particularly the accessibility and safety of public transportation, is crucial for middle-aged individuals with depression [2]. Higher levels of residential greenery have been significantly associated with lower odds of depressive symptoms among older adults living in the community [26]. Additionally, high population density and proximity to destinations contribute to better mental health, while walkable environments are linked to reduced depression, particularly among Asian women [27]. Conversely, the availability of local retail stores has been associated with an increased likelihood of depressive symptoms in older men [28]. Thus, inconsistent results may arise in different contexts or regions. Therefore, it is crucial to consider the local community context when assessing the effects of CBE on depressive symptoms and PA. Furthermore, among longitudinal studies exploring the relationship between PA and depressive symptoms, few have taken CBE into account [29]. Therefore, providing insights into how CBE influences the trajectories of depressive symptoms and PA is invaluable.

To address these gaps, this study focused on middle-aged and older adults aged 45 years and older in China, using data from 3 waves of repeated measurements to identify the trajectory of depressive symptoms, various types of PA, and the built environment of communities. The study aimed to answer the following 2 research questions: (1) What are the longitudinal effects of LTPA and OPA on depressive symptoms among middle-aged and older adults? (2) How does the CBE influence the trajectory of depressive symptoms and the 2 domains of PA in this population?

Methods

Data Source and Study Sample

The data for this study were obtained from the latest 3 waves of tracking data (2015, 2018, and 2020) from the China Health and Retirement Longitudinal Survey (CHARLS), a large microsurvey database. CHARLS covers 450 communities across 28 provinces in China, using a multistage stratified probability proportional to size sampling method to conduct the survey. A detailed description can be found in Appendix S1 in Multimedia Appendix 1 (see also [30-32]). As part of the International Survey of Health in Aging, CHARLS has been extensively utilized in interdisciplinary studies focusing on aging and health issues [33].

Figure S1 in Multimedia Appendix 1 illustrates the sample screening process. For each wave of data, this study excluded samples with missing PA data (missing PA data were randomly absent: participants were randomly selected to answer PA-related questions, and the absence of available records indicated that they did not respond to PA-related questions) and missing depressive symptom scores (individuals who left more than 2 questions unanswered on the scale were considered invalid for the depressive symptom measure. Among the respondents excluded from the analysis, approximately 80% had missing data for all 10 items on the scale in each wave). Additionally, samples lost due to attrition or participant death were excluded. After matching data across the 3 waves, participants younger than 45 years were also excluded. This resulted in a final sample of 6865 respondents, with 20,595 observation points. For samples with missing values for sex and education level, data from adjacent waves were used.

Ethics Approval

The original data collection was approved by the Biomedical Ethics Review Committee of Peking University (IRB00001052-11015). All data used in this study were fully anonymized, and participants provided informed consent. The data for this study were registered and obtained through the official CHARLS website [34].

Depressive Symptoms

Depressive symptoms were assessed using the Center for Epidemiologic Studies Depression Scale (CES-D), as provided by CHARLS. Respondents answered 10 questions reflecting feelings and behaviors associated with depression [35]. The total score, which ranged from 0 to 30, was calculated by summing the responses to these 10 questions, with reverse scoring applied to the 2 positive questions. Higher CES-D scores indicated more severe depressive symptoms. The Cronbach α coefficients for the CES-D scale in this study were 0.794, 0.800, and 0.796 in 2015, 2018, and 2020, respectively. In the descriptive statistical analysis, a CES-D score of ≥10 was classified as indicative of depression [36]. Additionally, we calculated the Reliable Change Index (RCI) for the CES-D scores across waves to assess whether changes in participants' depressive symptom scores over multiple waves were statistically significant (|RCI|>1.96) [37].

Physical Activity Level

The CHARLS used items similar to those in the International Physical Activity Questionnaire (short form) to assess respondents' levels of PA. It collected data on the duration and weekly frequency of each type of PA: low intensity (walking activities), moderate intensity (activities that cause faster breathing than usual, such as cycling, playing table tennis, and practicing yoga), and high intensity (activities that cause shortness of breath, such as fast running and playing basketball) [38]. This study used the metabolic equivalent (MET) method to calculate PA levels. To determine an individual's weekly MET for each PA intensity, we multiplied the corresponding duration, frequency, and coefficient for each activity. Following previous studies [30,31], we performed data organization and calculations for the 3 intensity levels of PA, including data cleaning, outlier elimination, and data truncation. Details regarding the CHARLS Questionnaire on PA, as well as the data processing and calculation methods used in this study, are provided in Appendix S1 in Multimedia Appendix 1. We scaled all PA data by a factor of 100 to meet the data requirements for statistical analysis before inputting them into the model calculation. As a result, the actual unit of MET reported in the models was 100 MET minutes per week.

XSL•FO
RenderX

The CHARLS database collected information on the purpose of each PA (4 categories: work, exercise, recreation, and others), allowing for the examination of the differential effects of various PA domains on depressive symptoms. Activities labeled as "other" in CHARLS were not explicitly defined and included a mix of multiple purposes, so they were excluded from the calculations for this study. PA data were categorized into 2 domains: LTPA and OPA. Within each domain, PA was further classified by intensity: low intensity (walking activities) and moderate-to-vigorous intensity (activities that require significant effort and lead to faster breathing or shortness of breath). The corresponding MET values were calculated and aggregated.

Construction of the Community-Built Environment Variables System

In this study, a set of variables was developed to assess the physical built environments of communities based on the community questionnaire data set provided by CHARLS. This data set was released in a single issue as part of the national baseline survey, updated in December 2013, with no subsequent updates in later waves. Based on the concepts of 3D, 5D, and other typical indicator systems and their extensions [25,39], and considering data availability and the characteristics of middle-aged and older adults, this study selected 7 core variables to evaluate the CBE attributes of each community: residential density, density of public facilities, diversity of sports venues, diversity of senior care facilities, accessibility of public facilities, accessibility of public transport, and infrastructure conditions. These variables are outlined in Table 1.

Table 1. Community-built environment variable system constructed from the community questionnaire of the China Health and Retirement Longitudinal Survey.

Built environment element	Variable	Calculation method: unit (weight)
Density	• Residential density • Density of public facilities	• Community population/total area of the community: pieces/km2 (N/A[a]) • The total number of basic public facilities in the community/total area of the community: pieces/km2 (N/A)
Diversity	• Diversity of sports venues • Diversity of senior care facilities	• Whether or not the community has any of the 8 sports venues: a "yes" answer will be scored as 1 point for that venue, a "no" answer will be scored as 0 points for that venue, and the total values will be added up. The maximum score is 8: points (N/A) • Whether or not the community has any of the 7 senior care facilities; diversity levels were calculated as described above.
Destination accessibility	• Accessibility of public facilities	• The average distance from the community office to the most commonly used type of each facility (if this facility is located within the community, the answer is 0): km (N/A).
Distance to transit	• Accessibility of public transport	• The actual distance from the community office to the most commonly used bus stop: km (43.86%). • The total number of actual bus lines accessible to the community: pieces (56.14%).
Infrastructure	• Infrastructure conditions	• Pavement quality of the main roads, where pathway/dirt/unpaved road=1 point, sandstone road=2 points, and paved road=3 points: points (13.62%) • The total number of days roads are impassable: days (12.31%) • The proportion of households that use purified tap water: percentage (18.30%) • Availability of sewer system in the community. yes=1 point and no=0 points: points (17.56%) • The level of waste disposal, where moved away by truck=5 points, buried in the village=4 points, burn away=3 points, put into nearby river=2 points, and do not manage=1 point: points (17.13%) • The proportion of households that use electricity: percentage (17.07%) • The condition of community toilets, where inside toilet with water=5, inside toilet without water=4, outside toilet with water=3, outside public toilet without water=2, and open air=1: points (4.00%)

[a]N/A: not applicable.

Among the variables, the accessibility of public transport and infrastructure conditions were assessed by calculating multiple subvariables. The CRITIC weighting method was used to determine the weight of each subvariable. Detailed information on the content of the facilities and the source of the question numbers can be found in Table S1 in Multimedia Appendix 1. Furthermore, due to limitations in the survey data, this study could not include variables such as green spaces and road network connectivity, despite their recognized importance [40,41]. All CBE variables were normalized using the min-max normalization method, resulting in a processed data range of 0-1, before being included in the model calculations. Further details can be found in Appendix S1 in Multimedia Appendix 1.

XSL•FO
RenderX

Covariates

Three types of variables were used as control variables: demographic and socioeconomic status, health behavior and status, and housing characteristics. These variables were selected due to their association with mental health levels or their potential impact on depressive symptoms [42]. Baseline data were chosen as covariates for inclusion in the model calculations. Specifically, demographic and socioeconomic status included age, sex (male or female), education level (categorized into 4 groups: illiteracy; primary and lower; middle, high, and vocational school; and 3-year college/bachelor's degree and higher), marital status (married or other), cohabiting status (with or without a cohabiting partner), and personal annual income. Personal annual income encompasses salaries and transfer income, such as pensions, benefits, and subsidies.

Health behavior and status included smoking (current smoker or nonsmoker), drinking (categorized into 3 groups: drinking more than once a month, drinking less than once a month, and nondrinker), the number of chronic diseases (total of 10, as outlined in Appendix S2 and Table S2 in Multimedia Appendix 1), and disability status (disabled or nondisabled). Housing characteristics were assessed based on the presence of various amenities: elevator, barrier-free facilities, toilet flushing, electricity, running water, bathing facility, gas/natural gas, heating, broadband, air purifier, and tidiness, for a total of 11 items. One point was assigned for each present characteristic or amenity, and the total score was calculated. Higher scores indicate better housing quality.

Statistical Analysis

This study utilized latent growth curve modeling (LGCM) to analyze the trajectories and longitudinal associations among the variables. LGCM, a variant of structural equation modeling, is a statistical method commonly used in longitudinal studies with latent variables [43]. It uses the intercept to represent the initial level and the slope to capture the rate of change. First, an unconditional linear LGCM was applied to each of the 3 measures of PA and depressive symptoms to examine their trajectories in middle-aged and older adults. In the second step, all control variables were incorporated into a linear growth model to construct a conditional linear LGCM for depressive symptoms. PA was included as a time-varying covariate to examine the effect of each wave of PA on depressive symptoms. To test whether these effects remained stable over time (2015-2018-2020), equality constraints were applied to the effects at each wave, and likelihood ratio tests (LRTs) were conducted to assess the statistical equivalence of these effects. In the third step, an LGCM was constructed for both depressive symptoms and PA, with 7 categories of built environment (CBE) as time-invariant covariates. A parallel process LGCM was used to examine the dynamic associations among CBE, PA, and depressive symptoms. The study also incorporated the adjusted individual weights provided by CHARLS for each wave of data in all models to minimize representational bias due to response differences. The acceptable thresholds for model fit indices were as follows: Comparative Fit Index>0.90, Tucker-Lewis Index>0.90, root mean square error of approximation<0.08, and standardized root mean square residual<0.08 [44]. Additionally, the Harman single-factor test was conducted to examine the data for common method bias. The total variance explained by the first common factor was 19.76% (<40%), indicating that the study was not significantly affected by common method bias [45]. Data cleaning was performed using Stata 18.0 (StataCorp), all LGCM analyses were conducted with Mplus 8.10 (Muthén and Muthén), and the Harman single-factor test was executed using IBM SPSS 26.

Results

Characteristics of the Sample at Baseline

A total of 6865 participants were included in the study sample, with the detailed statistical characteristics presented in Table S2 in Multimedia Appendix 1. The male-to-female ratio in the sample was 0.88, indicating a nearly balanced distribution. The respondents' education levels were relatively low: of the 6865 participants, 4652 (67.76%) did not receive education beyond secondary school, reflecting the social context of the middle-aged and older adult generation in China. The marriage rate in the sample was very high (6836/6865, 99.58%), and a majority of respondents (5767/6865, 84%) lived with a cohabiting partner. The mean annual personal income of participants was 15,712.63 Chinese yuan (1 yuan=US $0.14). Among the respondents, the majority were nonsmokers (4986/6865, 72.63%) and nondrinkers (4400/6865, 64.09%). On average, participants reported having 2.10 chronic diseases, and the average score for housing characteristics was 4.06. Additionally, 872 (12.70%) participants reported having a disability.

Developmental Trajectories of Physical Activity and Depressive Symptoms

The statistics for depressive symptoms and various types of PA among middle-aged and older adults across the 3 data waves are presented in Table 2. The proportion of participants with depression (CES-D scores≥10) ranged from approximately 30% to 40% over the study period (2178/6865, 31.73%, in 2015; 2469/6865, 35.97%, in 2018; and 2666/6865, 38.83%, in 2020). Additionally, in each wave, participants consistently reported higher levels of OPA than LTPA. The amount of moderate-to-vigorous-intensity OPA was greater than that of low-intensity OPA, while low-intensity LTPA was more prevalent than moderate-to-vigorous-intensity LTPA.

Unconditional LGCM was used to examine the developmental trends of each variable. The model fit indices, along with the mean intercepts and slopes for the 3 models, are presented in Table 3. Overall, the models demonstrated a good fit. Depressive symptoms and LTPA levels showed a linear upward trend across the 3 measurement waves (with positive and significant slopes), while OPA levels displayed a linear downward trend. Furthermore, based on the RCI statistics for changes in depressive symptoms (Appendix S2 and Table S3 in Multimedia Appendix 1), despite the overall increasing trend in depressive symptoms, most participants did not show significant changes across waves (–1.96≤RCI≤1.96). Specifically, 5506 of 6865 (80.20%) individuals from 2015 to 2018, 5483 of 6865 (79.87%) individuals from 2018 to 2020, and 5391 of 6865 (78.53%)

XSL•FO
RenderX

individuals from 2015 to 2020 showed no significant changes (–1.96≤RCI≤1.96). Over the longer period from 2015 to 2020, 948 of 6865 (13.81%) participants experienced a significant increase (RCI>1.96) in depressive symptoms, while 526 of 6865 (7.66%) participants experienced a significant decrease (RCI<–1.96).

Table 2. Statistical characteristics of depressive symptoms and physical activity among middle-aged and older adults across three waves of data.[a]

Variable	Wave 2015	Wave 2018	Wave 2020
Depressive symptoms, mean (SD)	7.81 (6.27)	8.46 (6.32)	8.85 (6.46)
Number of depression, n/N (%)	2178/6865 (31.73)	2469/6865 (35.97)	2666/6865 (38.83)
Number of nondepression, n/N (%)	4687/6865 (68.27)	4396/6865 (64.03)	4199/6865 (61.17)
Total LTPA[b], mean (SD)	974.38 (2130.84)	1248.28 (2412.47)	1590.66 (2748.37)
Low-intensity LTPA, mean (SD)	593.47 (1198.14)	792.45 (1356.73)	902.70 (1356.9)
Moderate-to-vigorous-intensity LTPA, mean (SD)	380.91 (1514.96)	455.83 (1719.31)	687.96 (2140.36)
Total OPA[c], mean (SD)	5529.50 (6988.45)	4834.27 (6593.79)	3745.39 (5744.90)
Low-intensity OPA, mean (SD)	1234.15 (1907.24)	1190.91 (1925.46)	719.76 (1570.59)
Moderate-to-vigorous-intensity OPA, mean (SD)	4295.35 (5985.89)	3643.36 (5600.78)	3025.63 (5064.63)

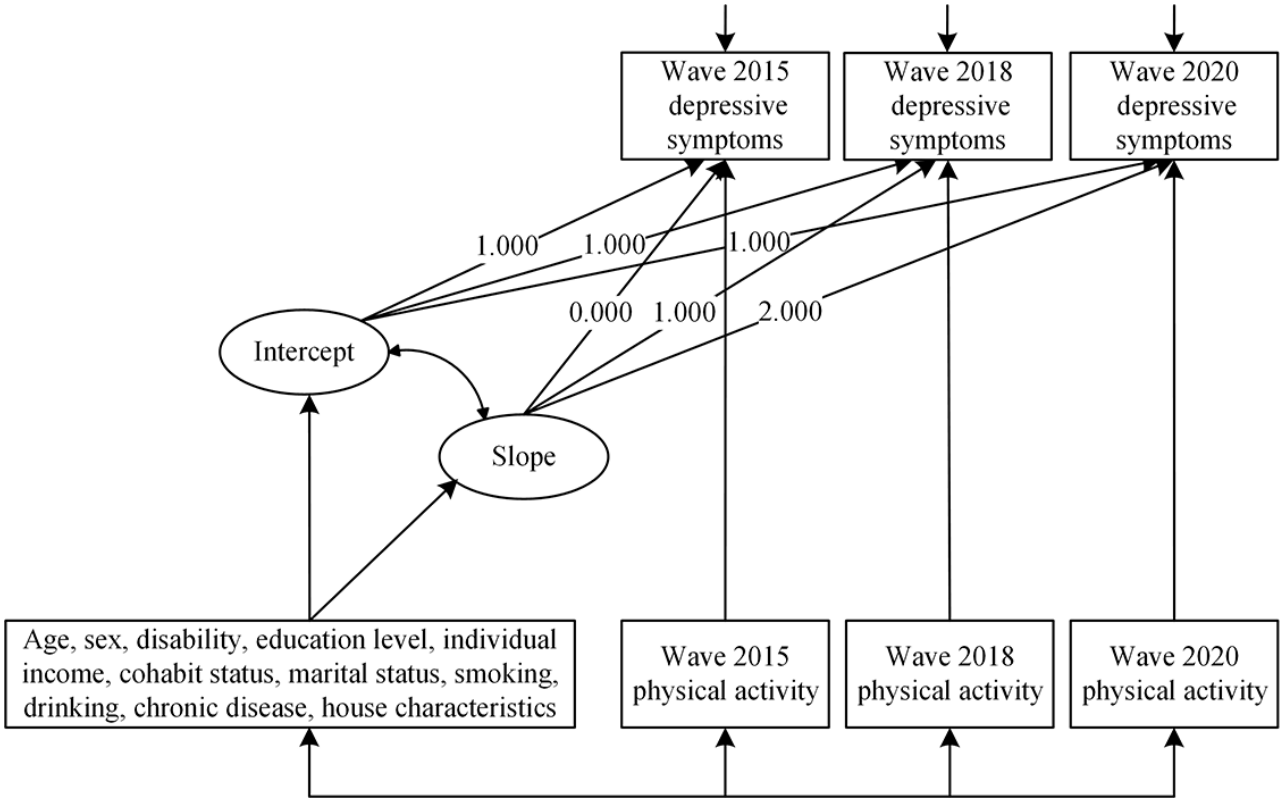
Effects of Leisure-Time and Occupational Physical Activity on Depressive Symptoms



Based on the time-varying covariate LGCM specified in Figure 1, the direct effects of all types of PA on depressive symptoms were calculated for each wave, and equality constraints were tested. The results are presented in Table 4. The model fit for all pathways was satisfactory (Appendix S2 and Table S4 in Multimedia Appendix 1). In both 2015 and 2018, total LTPA (β=–.023, *P*=.02 and β=–.025, *P*=.01, respectively) and low-intensity LTPA (β=–.025, *P*=.01 and β=–.027, *P*=.005, respectively) negatively predicted depressive symptoms.

XSL•FO
RenderX

However, this effect was not statistically significant in 2020 (*P*=.51). No significant differences were observed in the pathways across multiple waves, as the LRT results were not significant (*P*=.31 in 2015, *P*=.65 in 2018, and *P*=.14 in 2020, respectively). Moderate-to-vigorous-intensity LTPA did not show a significant predictive effect on depressive symptoms in any wave (*P*=.21 in 2015, *P*=.57 in 2018, and *P*=.85 in 2020, respectively).

By contrast, in waves 2015, 2018, and 2020, both total OPA (β=.041, *P*<.001; β=.022, *P*=.02; and β=.027, *P*=.03, respectively) and moderate-to-vigorous-intensity OPA (β=.036, *P*<.001; β=.020, *P*=.04; and β=.019, *P*=.049, respectively) positively predicted depressive symptoms. The positive predictive effect of low-intensity OPA on depressive symptoms was significant only in wave 2015 (β=.030, *P*=.003). Furthermore, the LRT results indicated that the effect of low-intensity OPA on depressive symptoms differed significantly between waves 2015 and 2018 (*P*=.048) and between waves 2015 and 2020 (*P*=.02). Across the 3 waves of data, the effects of both total OPA (*P*=.27 in 2015; *P*=.98 in 2018; and *P*=.33 in 2020, respectively) and moderate-to-vigorous-intensity OPA on depressive symptoms remained stable with no significant differences observed (*P*=.27 in 2015, *P*=.87 in 2018, and *P*=.41 in 2020, respectively). Given the representativeness, statistical significance, and stability of the effects across waves, this study proceeded with the inclusion of total LTPA and total OPA for further analysis.

Figure 1. Graphical representation of the time-varying covariate latent growth curve modeling with the depressive symptoms and physical activity as time-varying variables. The 11 covariates as time-invariant covariates were plotted in a box for mapping simplicity. They were calculated concurrently in each latent growth curve model analysis.

Longitudinal Associations Among Community-Built Environment, Physical Activity, and Depressive Symptoms

This study further used a parallel process LGCM to analyze the dynamic associations between CBE, the 2 domains of PA, and depressive symptoms (Figure 2). The models demonstrate a good fit (Appendix S2 and Table S4 in Multimedia Appendix 1). First, the intercept (initial level) of total LTPA negatively predicted the initial level of depressive symptoms (β=–.076, *P*=.003). The initial level of total OPA positively predicted the initial level of depressive symptoms (β=.108, *P*<.001) and negatively predicted the rate of increase in depressive symptoms (β=–.136, *P*=.009).

Regarding the effect of CBE on the trajectory of depressive symptoms, infrastructure conditions and accessibility of public facilities negatively predicted the initial level of depressive symptoms (β=–.082, *P*<.001 and β=–.036, *P*=.045, respectively). However, accessibility to public facilities positively predicted the rate of increase in depressive symptoms (β=.083, *P*=.04). Additionally, infrastructure conditions (β=.100, *P*=.002) and accessibility of public transport (β=.060, *P*=.01) positively predicted the intercept of total LTPA. By contrast, infrastructure conditions (β=–.281, *P*<.001) and accessibility of public facilities (β=–.073, *P*<.001) negatively predicted the initial level of total OPA. Infrastructure conditions also positively predicted the declining trend of total OPA over time (β=.100, *P*=.004).

Discussion

Longitudinal Effect of Physical Activity on Depressive Symptoms Among Middle-Aged and Older Adults

First, the analysis based on the linear unconditional LGCM revealed an upward trend in depressive symptoms among middle-aged and older adults from 2015 to 2020. This finding aligns with previous studies using CHARLS data [33], suggesting that depressive symptoms may be influenced by the aging process. However, further analysis using the RCI indicated that while depressive symptoms showed an upward trend, this change appeared to occur primarily at the group level. At the

XSL•FO
RenderX

individual level, fluctuations in depressive symptoms were relatively small for most participants, with only a minority experiencing significant increases. For the majority, changes did not reach statistically significant levels (Table S3 in Multimedia Appendix 1). Additionally, the average levels of depressive symptoms across the 3 waves were slightly below the CES-D clinical screening threshold (Table 2) [36], indicating that most participants exhibited mild or subclinical depressive symptoms. Therefore, the core focus of this study is to understand and explore the potential effects of CBE and PA on changes in depressive symptoms. These changes should not be overly simplified as the onset of clinical depression or an increase in its severity.

Existing studies examining the effects of PA on depressive symptoms often focus on a single domain or intensity level. However, given that PA across different intensities and domains may have varying effects on depressive symptoms [46], our study contributes to the literature by further categorizing PA into low- and moderate-to-high-intensity levels within the domains of LTPA and OPA. These results highlight the importance of the differences observed. By analyzing data from 3 waves of repeated measurements, we found that LTPA, particularly low-intensity LTPA, consistently served as a negative predictor of depressive symptoms among middle-aged and older adults in China. This suggests that greater participation in low-intensity LTPA was associated with fewer depressive symptoms in this population (Table 4). Our findings are consistent with previous studies that emphasize the benefits of moderate and light exercise over vigorous exercise for middle-aged and older adults [47]. Engaging in lower-intensity activities, such as walking, may also help prevent depression [48], with lower LTPA levels being associated with fewer depressive symptoms [20].

However, in all waves of the analysis, we did not observe a significant association between moderate-to-vigorous-intensity LTPA and depressive symptoms. This finding is inconsistent with some existing literature. For example, certain cross-sectional studies have suggested that both low- and moderate-to-vigorous-intensity PA positively impact the mental health of middle-aged and older adults [49]. Furthermore, both small and large amounts of LTPA are associated with a lower prevalence of depression, with comparable effects [19]. These discrepancies may arise from differences in how PA intensity is categorized, the participant selection criteria, or regional characteristics across the studies.

This study also clearly observed that after controlling for socioeconomic factors such as income levels, higher moderate-to-vigorous-intensity OPA was associated with higher depressive symptoms. This negative predictive effect remained significant and consistent across all waves of data (Table 4). This result aligns with previous studies. Research from Brazil and South Korea reported that participants with higher levels of OPA were more likely to experience depressive symptoms [20], and that the higher the level of work-related PA, the greater the likelihood of depressive symptoms [50]. Similarly, OPA appears to be associated with an increased risk of depression [51]. However, these results contradict those of other studies. For instance, research from the United States suggested that OPA does not significantly predict depression regardless of gender [52], while a study from Ghana found that depression decreased as work-related PA increased [53]. As our study controlled for socioeconomic characteristics, these differences suggest that the effect of OPA on depressive symptoms may vary depending on the level of economic development or overall social progress in a given region.

Collectively, these findings support the important perspective that the effects of PA on depressive symptoms vary depending on the domain and intensity of the activity. This study adds to the existing research on the PA paradox and PA parameters [54]. Overall, our findings validate and expand upon the PA paradox in the mental health domain, showing that LTPA, particularly low-intensity exercise in LTPA, is associated with lower depressive symptoms, whereas moderate-to-vigorous-intensity OPA is linked to higher depressive symptoms. These 2 distinct forms of PA exert opposite effects on depressive symptoms in middle-aged and older adults [51]. Leisure exercise and occupational labor, as fundamentally different drivers of PA, likely result in varying degrees of subjective willingness and well-being, which may have divergent long-term effects on mental health [55]. Particularly in many developing countries, moderate-to-vigorous-intensity OPA is often linked to limited individual job skills and is usually accompanied by poorer working conditions and lower levels of welfare protection.

When examining the dynamic effects of PA on depressive symptoms, this study further revealed the heterogeneous characteristics of different domains of PA. Using parallel-processed LGCM, we found that the initial level of total LTPA in middle-aged and older adults negatively predicted the initial level of depressive symptoms. This indicated that individuals with higher initial LTPA levels tended to have lower initial levels of depressive symptoms (Figure 2). This finding is consistent with the results of Heesch et al [56], who reported that low LTPA and walking levels were associated with reduced anxiety and depression scores. One possible explanation is that individuals with depressive symptoms are less likely to engage in PA. Additionally, confounding factors may have influenced this association.

This study also identified, for the first time, that OPA is not only significantly positively associated with the initial level of depressive symptoms, but also significantly predicts the trajectory of change in depressive symptoms. Specifically, middle-aged and older adults with higher initial OPA levels tended to exhibit higher initial levels of depressive symptoms. However, higher OPA levels appeared to suppress the upward trajectory of depressive symptoms over time (Figure 2). This finding highlights the complexity and duality of OPA's influence on the depressive symptom trajectory. On the one hand, high-intensity or repetitive OPA may increase physical burdens, contributing to higher initial depressive symptoms. On the other hand, the "steeling effect" resulting from prolonged OPA may enhance individuals' resilience to negative experiences and improve physiological adaptability, thereby mitigating the increase in depressive symptoms over time [57,58]. Moreover, OPA may exert long-term positive effects on mental health through mechanisms such as improving physical metabolism,

XSL•FO
RenderX

maintaining a regular daily routine, and reducing sedentary behavior. These benefits may partially offset the negative effects.

Effects of Community-Built Environment on Trajectories of Depressive Symptoms and Physical Activity

To the best of our knowledge, few studies have attempted to develop indicator systems or variable sets for international microsurvey databases to assess a community's physical environment. Jones-Smith and Popkin [59] proposed a scale for assessing community contextual characteristics but did not pay enough attention to physical built environments. Taking the CHARLS community questionnaire as an example, this study developed CBE indicators for international microsurvey databases, which can provide references for other studies. Specifically, incorporating the variables of the diversity of senior care facilities and sports venues directly addresses the unique needs of adults aged 45 years or older. Assessing the level of access to senior care and exercise facilities within the community is particularly important for this age group. The density of public facilities and accessibility of public facilities reflect the richness of community services and the convenience of facility distribution, providing valuable insights into middle-aged and older adults' ease of access to essential daily services. These factors are closely linked to the overall livability and quality of life within the community. Additionally, the infrastructure conditions variable covered several fundamental aspects critical to the community environment, such as road quality, waste disposal systems, sewer availability, and waste management practices. By comprehensively accounting for these infrastructure elements, this system effectively represents the community environmental realities in China.

Our study identified infrastructure conditions and accessibility to public facilities as the 2 most critical CBE factors influencing the trajectory of depressive symptoms among middle-aged and older adults (Figure 2). First, these factors significantly predicted the initial level of depressive symptoms; middle-aged and older adults residing in communities with better infrastructure conditions and higher accessibility to public facilities exhibited significantly lower initial levels of depressive symptoms. This finding aligns with those reported in the existing literature. Fan et al [60] highlighted the crucial role of community factors such as infrastructure and senior centers in mitigating depressive symptoms among middle-aged and older adults. Similarly, Li et al [61] found that a lack of infrastructure in villages was positively associated with the prevalence of depression in older adults in rural China. Moreover, the availability of recreational facilities in urban communities was associated with a lower incidence of depressive symptoms [62]. Perceived proximity to community facilities is an important factor influencing depressive symptoms among low-income older adults. Improving accessibility to such facilities may help alleviate depressive symptoms [63]. From a mechanistic perspective, high-quality infrastructure provides a safer and more comfortable living environment and reduces the sources of psychological stress. Concurrently, convenient public facilities promote social participation and PA, offering environmental support for mental well-being.

Through a long-term analysis of depressive symptom trajectories, our study not only confirmed the effect of accessibility to public facilities on the initial level of depressive symptoms but also revealed its predictive role in the upward trajectory of depressive symptoms. Contrary to expectations, greater accessibility to public facilities was found to significantly accelerate the upward trajectory of depressive symptoms among middle-aged and older adults in China (Figure 2). This can be attributed to 2 reasons. First, higher accessibility may be associated with greater community activity and more complex social interactions, which can introduce additional environmental stressors, such as noise, social conflicts, or other pressures that negatively affect mental health [64]. Second, the inadequate service quality of public facilities and insufficient consideration of the needs of vulnerable populations could also play a key role. Middle-aged and older adults may have higher expectations of accessible public facilities; however, if these facilities fail to meet their needs—due to issues such as overcrowding, usage restrictions, or poor design—it may lead to disappointment or frustration [65]. In developing countries, public facilities are often designed with a focus on quantity and coverage, whereas service capacity and the needs of disadvantaged groups are frequently overlooked. This limitation may exacerbate mental health challenges in middle-aged and older adults by introducing potential risk factors.

Our study further demonstrates the significant effect of CBE on the initial level of total LTPA, emphasizing the importance of infrastructure conditions and accessibility to public transport. The results indicated that middle-aged and older adults living in communities with better infrastructure or higher public transport accessibility had significantly higher initial LTPA levels. These findings provide new insights into how the built environment influences health behaviors among middle-aged and older adults. Additionally, middle-aged and older adults in communities with better infrastructure and higher public facility accessibility engaged in significantly lower initial OPA. Furthermore, infrastructure conditions positively predicted a declining trajectory in OPA levels over time (Figure 2). As residential communities are not direct venues for occupational activity, a plausible explanation is that infrastructure conditions and public facility accessibility reflect the overall quality, location advantages, and amenities provided within the community. In China, residents of higher-tier communities are typically part of the nonlabor force population, while manual laborers tend to reside in communities with poorer infrastructure and fewer amenities [66]. This community-level differentiation significantly impacts the intensity and type of occupational activity, reflecting the observed community segregation and spatial stratification within Chinese society [67]. However, due to the lack of data on community-level economic variables, this study could not fully account for the potential influence of these factors on the results. Further research is needed to validate these associations and explore the underlying mechanisms.

Implications

Our findings could offer valuable insights for public health management practices and community environmental planning, with relevance to other developing countries or regions. When formulating community PA guidelines, it is crucial to consider the distinct effects of different types of PA. LTPA should be integrated into community mental health intervention programs, with a focus on encouraging middle-aged and older adults to engage in activities such as walking. However, relevant authorities should also guide middle-aged and older adults in reducing the intensity of OPA, optimizing workplace conditions and workflows, and providing mental health support. This recommendation is particularly critical for developing countries, where physical labor constitutes a significant portion of the workforce.

From the perspective of CBE, improving community infrastructure and enhancing the accessibility of public facilities are key strategies for preventing and addressing mental health issues in middle-aged and older adults, while also promoting PA. This includes, but is not limited to, upgrading road quality, improving water and sewage systems, and enhancing electricity services. These measures can lead to better depressive symptom outcomes and encourage LTPA in middle-aged and older populations. Furthermore, improving public transportation accessibility has the potential to promote LTPA in this demographic. However, we recommend that governments carefully consider the potential environmental stressors associated with enhanced public facilities and focus on improving their service capacity and quality. Special attention should be given to addressing the needs of vulnerable populations to mitigate negative effects and more effectively promote community mental health.

Limitations and Future Research

First, we excluded participants with missing PA or depressive symptom scores. While this approach is common, it may introduce bias, as it is challenging to determine whether the missing values are associated with participants who have lower PA levels or higher depressive symptom scores. Second, although the findings offer critical empirical support for the PA paradox, the study is constrained by its design and data availability, with limited consideration of factors such as workplace environment, working conditions, and job autonomy. These factors may mediate or confound the relationship between PA and mental health. Future research should incorporate these variables to comprehensively elucidate the complex mechanisms linking OPA and mental health. Third, the wave 2020 data used in this study were collected during the COVID-19 pandemic, which may have influenced the results. Fourth, due to space constraints and the study's objectives, insufficient attention was given to subgroup analyses or population heterogeneity, which future research could explore in greater detail. Finally, the CBE data in the CHARLS were published for only 1 wave without subsequent follow-up, limiting this study's ability to examine changes in the role of CBE in the relationship between PA and depressive symptom trajectories. Future research should incorporate dynamic geographical information to capture the effects of CBE changes on mental health or PA trajectories.

Conclusions

Communities play an integral role in the daily lives of residents. This study offers valuable insights from developing countries by highlighting the effects of PA on depressive symptom trajectories and the role of CBE factors as physical determinants. The findings reveal that the impact of PA on depressive symptoms varies by domain and intensity. Overall, higher levels of LTPA were associated with lower depressive symptom levels among middle-aged and older adults, whereas OPA, particularly at moderate-to-vigorous intensities, had negative effects on depressive symptoms. Additionally, OPA exhibits a dual effect: while a higher initial level of total OPA was associated with a higher initial level of depressive symptoms, it also contributed to slowing the upward trajectory of depressive symptoms over time. Among the CBE factors, infrastructure conditions and accessibility to public facilities emerged as the most critical determinants influencing depressive symptom trajectories. Better infrastructure and greater accessibility to public facilities were linked to lower initial levels of depressive symptoms; however, greater accessibility to public facilities might exacerbate the upward trajectory of depressive symptoms. Furthermore, infrastructure conditions and accessibility to public transport played positive roles in promoting LTPA.

These findings provide novel perspectives on the PA paradox in mental health research, offering valuable guidance for developing more precise public health strategies. Such strategies should aim to promote PA types that effectively reduce depressive symptoms while minimizing potential adverse effects. By identifying the specific impacts of CBE factors, this study underscores that optimizing the built environment is not merely a physical enhancement but also a vital public health approach to improving residents' mental health. We advocate for enhancing community environments to encourage beneficial PA and alleviate depressive symptoms among middle-aged and older adults.

Abstract

Background: The major drawback of a cohort study design is the loss to follow-up, which increases selection bias and threatens external validity, particularly in online surveys. It is important to identify factors beyond population or demographics that influence nonresponse rates in cohort studies.

Objective: This study aimed to examine the nonresponse rate and associated factors over a 10-year follow-up period among female participants in the Korea Nurses' Health Study using data from the initial and subsequent surveys.

Methods: The Korea Nurses' Health Study recruited 20,613 female nurses in 2013 using simple random sampling. The participants were followed up 10 times through 2022. We identified the demographic, work-related, survey-related, and psychological characteristics of nonresponding nurses during the 10-year follow-up and compared them with those who continued to participate. Descriptive statistics, chi-square tests, and multivariate logistic regression models were used for the analysis.

Results: The nonresponse rate of the follow-up surveys from the 2nd to the 11th survey varied between 25.5% (5258/20,613; second survey) and 61.2% (12,620/20,613; sixth survey). The influence of age, education, and the usability of survey websites on nonresponse lasted up to the 11th survey. Nurses in their 20s were less likely to respond to the follow-up surveys than those in their 30s. Those who had an associate degree and neutral feelings about the usability of the survey websites were less likely to respond to the follow-up surveys than those who were satisfied with the initial survey. The influence of geographical region, hospital size, and psychological factors—including stress, fatigue, and sleep disturbance—was evident from the second to the sixth survey.

Conclusions: When designing and recruiting female nurse participants for community-based cohort studies, researchers should consider the factors that influence nonresponse and adopt tailored strategies based on demographic characteristics. In addition, improving the usability of survey websites is recommended to reduce nonresponses at follow-up in cohort studies involving female participants.

Introduction

Background

A cohort study was conducted in 1935 in the United States to determine the incidence of tuberculosis [1]. Despite their costly and time-consuming nature, cohort studies have been recognized as valuable longitudinal research methods. Cohort studies have been widely conducted to identify associations between known and unknown risk factors for specific diseases [2]. One of the major drawbacks of the cohort study design is the loss of participants at follow-up. With awareness of the differences in health disparities and determinants of health between men and women, cohort studies have been conducted to identify salient factors related to health and illness among women across several countries [3-5]. In 2013, the Korea Nurses' Health Study, a national cohort study of 20,613 female nurses aged between 20 and 45 years, was initiated to determine the sociodemographic, occupational, and lifestyle factors affecting the health and disease status of Korean women [6]. Follow-up surveys were conducted annually for more than 10 years, allowing the recognition of long-term patterns formed from early to middle adulthood. Participants accessed the Korea Nurses' Health Study through an online platform, with invitations delivered via phone, SMS text messages, or email.

Nonresponse is a significant issue in longitudinal studies, with response rates varying widely across different populations. In general, a response rate of 50% is considered acceptable [7]. Studies of nurses in Western countries have often reported response rates below 30% [3,8-10]. Similarly, health surveys in the Netherlands reported nonresponse rates of 53% [11], while the Thai Nurse Cohort Study reported nonresponse rates of 39.8% [12]. In Korea, the Nurses' Health Study, a prospective cohort study of women's health that has been ongoing for more than 10 years, has a nonresponse rate of 50% [13]. In this study, we examined the nonresponse rate and its associated factors in up to 10 years of follow-up surveys.

Literature Review

Nonresponse generally describes cases in which individuals do not participate in follow-up data collection [14] and the loss of participants over time, particularly in later data collection surveys, owing to factors such as loss of contact, incapacity, or refusal to continue participating [15]. Nonresponse can also occur when participants are lost to follow-up, choose to withdraw from the study, do not respond to follow-up surveys, or die during the study period [16]. This issue is particularly pronounced in online surveys, where a high rate of nonresponse increases the likelihood of nonrandom missing data [17]. Factors such as indifference to the study, rapidly changing health care environments, and illness might also contribute to nonresponse [3,17]. Previous cohort studies have examined factors related to nonresponse, with a focus on demographic factors, such as age [18], gender [19], education level [19-21], socioeconomic status [19], and health status [22]. However, participation in a survey can also be influenced by psychological factors, including the presence of stressful life events [23], depression, and anxiety disorders [21], along with participants' perceptions of the survey, which have rarely been studied. This is particularly significant, as most previous cohort studies identifying factors associated with nonresponse have focused on individuals with health issues [21,24] or older adult populations [25,26]. Moreover, survey satisfaction and the time required to complete the surveys are factors that can influence future participation in cohort studies. Participants who were satisfied with the survey process were more likely to participate in a follow-up survey [23]. Conversely, long or burdensome surveys may increase nonresponse in subsequent surveys [8]. Thus, a comprehensive understanding of psychological and survey-related factors is crucial to address nonresponse rates in cohort studies.

Methods

Design and Participants

The Korea Nurses' Health Study, initiated in 2013 with 20,613 participants, was originally developed based on the Nurses' Health Study 3 conducted in the United States [10], which is the oldest cohort study on women's health involving nurses as participants. For the Korea Nurses' Health Study, registered nurses aged 20 to 45 years working at hospitals across Korea at the time of data collection were recruited through simple random sampling. According to the Korean Nursing Association, 157,569 women of childbearing age were identified as nurses. The target sample size was determined based on population parameters and was calculated to be 20,000 female nurses, considering a 95% CI with a 1% permissible error [6]. After recruiting 20,613 registered nurses in the first survey in 2013, follow-up surveys were subsequently conducted: second survey (March 2014 to April 2019), third survey (November 2014 to April 2019), fourth survey (September 2015 to April 2019), fifth survey (June 2016 to April 2019), sixth survey (September 2017 to April 2019), seventh survey (December 2018 to April 2019), eighth survey (October 2019 to April 2020), ninth survey (October 2020 to April 2021), 10th survey (October 2021 to August 2022), and 11th survey (March 2022 to April 2023).

Participants in the initial survey were invited to participate in the follow-up surveys. This approach ensured high response rates without affecting the consistency of response and nonresponse rate calculations because the timing of survey availability did not influence participant responses [13]. While deaths during the study period were not specifically investigated, the number of nurses eligible to respond changed over time due to refusals to continue follow-up contact. Participants who left the nursing field during the study period were included in follow-up surveys to capture changes in health outcomes and ensure that the study reflected the broader scope of women's health. In addition, the participants were notified through SMS text messages and email reminders to encourage their participation. Surveys were accessible via both web and mobile platforms, ensuring convenience for participants.

Measures

On the basis of the literature, we included demographic and work-related characteristics, psychological variables, and survey-related characteristics from the initial survey to examine the factors associated with nonresponse in the follow-up surveys. The participants self-reported these characteristics throughout the survey.

Demographic and Work-Related Characteristics
