After determining the best-fitting model, R3STEP (auxiliary procedure that implements the 3-step method for adding predictors of latent class membership specified by Mplus) was applied to examine associations between class membership and time-invariant covariates (ie, age, biological sex, race/ethnicity, parental education, recreational cannabis legal status, and total family income). This procedure accounts for the uncertainty in class assignments by incorporating posterior probabilities into auxiliary multinomial logistic regressions. This approach improves estimation accuracy and protects against biased parameter estimates [92,93]. Race/ethnicity was specified as a nominal variable in Mplus, which dummy-coded the variable using non-Hispanic White as the reference category. Mplus then reported the overall omnibus effect of the race/ethnicity block rather than separate coefficients for each category unless individual dummy-coded contrasts produced statistically separable estimates across class comparisons. The full set of dummy contrasts nevertheless contributed internally to the estimation of the classification error–adjusted multinomial logistic model.

To further explore predictive associations with time-varying variables (ie, family cannabis rules, parental monitoring, family conflict, and psychopathology), 2 complementary models were estimated. A class-specific effects model was used to assess the different effects of time-varying predictors across latent classes without interfering with the predefined trajectory classes. This approach revealed heterogeneity in the associations between time-varying predictors and outcome variables across developmental trajectories. As a sensitivity analysis, a common effects model was used to estimate population-average associations between the time-varying predictors and outcome variables under the assumption that the effects of the time-varying predictors on the outcome variables are homogeneous across all latent classes. This model provides insights to understand the general exposure effects that are consistent across subpopulations.

All LCGA models were estimated using Mplus 8.11 [94]. To ensure model stability and reduce the risk of convergence on the local maxima, a multistage estimation procedure was used. Each model was initialized with 1000 random sets of starting values, from which the 250 best-fitting solutions were retained for final optimization. To further verify solution stability, log-likelihood values were required to replicate across 20 iterations. Likelihood ratio tests (eg, LMR-aLRT) were conducted with an additional set of 1000 random start replications, with 200 used for preliminary evaluation and 500 selected for final optimization, repeated 100 times, to ensure the reliability of model comparison results. Missing data of predictors were imputed using the nonparametric random forest–based approach, which has been shown to perform well in retaining nonlinear relationships and interactions among variables in mixed-type datasets [95]. Descriptive statistics were conducted with R 4.5.0 (via RStudio, Posit). The reporting of this study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1) [96].

## Results

### Descriptive Statistics

Table 1 presents the descriptive statistics of the study sample across the 3 time points. The positive expectancies of cannabis use effects score measured among the participants demonstrated an increasing trend (T1: mean 6.41, SD 2.85; T2: mean 7.20, SD 2.93; T3: mean 7.96, SD 2.99; $P$<.001). Similarly, the proportion of strict family cannabis use rules increased over time from 97.9% (T1) to 98.9% (T3) ($P$<.001). Moreover, family conflict scores increased from 1.90 (SD 1.88) to 2.09 (SD 1.96) ($P$<.001). Parental monitoring scores showed a slight decrease across waves (T1: mean 4.51, SD 0.45; T3: mean 4.38, SD 0.50; $P$<.001).

| Lenient/no rules | 1685 (2.3) | 1331 (1.8) | 1010 (1.1) | |
| Strict rules | 5712 (97.9) | 6033 (98.2) | 6207 (98.9) | |

[a]Except for the baseline sociodemographic characteristics (biological sex, race/ethnicity, parental education, and recreational cannabis legal status), all other variables were measured repeatedly from time 1 (T1) to time 3 (T3).

[b]Values represent unweighted frequencies and weighted proportions for categorical variables, and weighted means with SDs for continuous variables. Frequencies may not sum to the total sample size due to missing data.

[c]*P* values were generated using weighted ANOVA for continuous variables and weighted chi-square tests for categorical variables to test differences across waves.

[d]Not applicable.

[e]NH: non-Hispanic.

[f]The cannabis recreational legal status was determined based on the participant's state of residence at the time of their baseline interview in the ABCD Study, which is approximately 1 year prior to T1 in this study.

### Unconditional LCGA Model Statistics Regarding Positive Expectancies of Cannabis Use Effects

Table 2 presents the latent class model fit comparisons of the optimal class solutions, ranging from 1 class to 7 classes. Table 3 presents the sizes of the individual classes. While models with a greater number of classes (5-class to 7-class trajectory solutions) were explored, they yielded subgroups with minimal representation (ie, group size <5% of the total sample), raising concerns about model overfitting and limited interpretability.

**Table .** Latent class model fit comparisons for unconditional latent class growth analysis models regarding positive expectancies of cannabis use effects.

| Trajectory (model) | Log likelihood | BIC[a] | aBIC[b] | AIC[c] | LMR-aLRT[d] *P* value | BLRT[e] *P* value | Entropy[f] | Minimal class membership[g] (%) |
|---|---|---|---|---|---|---|---|---|
| 1 class | −55350.179 | 110744.910 | 110729.021 | 110710.358 | —[h] | — | — | — |
| 2 classes | −53156.244 | 106383.722 | 106358.349 | 106328.488 | <.001 | <.001 | 0.734 | 38.9 |

| 7 classes | −51396.675 | 102998.291 | 102925.202 | 102839.351 | <.001 | <.001 | 0.866 | 0.4 |

[a]BIC: Bayesian information criterion.

[b]aBIC: sample size–adjusted Bayesian information criterion.

[c]AIC: Akaike information criterion.

[d]LMR-aLRT: Lo-Mendell-Rubin adjusted likelihood ratio test; *P* value for k-1 refers to a significant improvement in model fit between the class (k) and the preceding class (k-1), which compares whether a profile solution with k profiles fits significantly better than a profile.

[e]BLRT: parametric bootstrapped likelihood ratio test, which is similar to the LMR-aLRT; *P* value refers to a significant improvement in model fit between the class (k) and the preceding class (k-1).

[f]Entropy indicates classification accuracy, with a higher value indicating better classification (range 0-1).

[g]Minimal class membership represents the proportion of participants in the latent class with the smallest membership.

[h]Not applicable.

[i]Selected model.

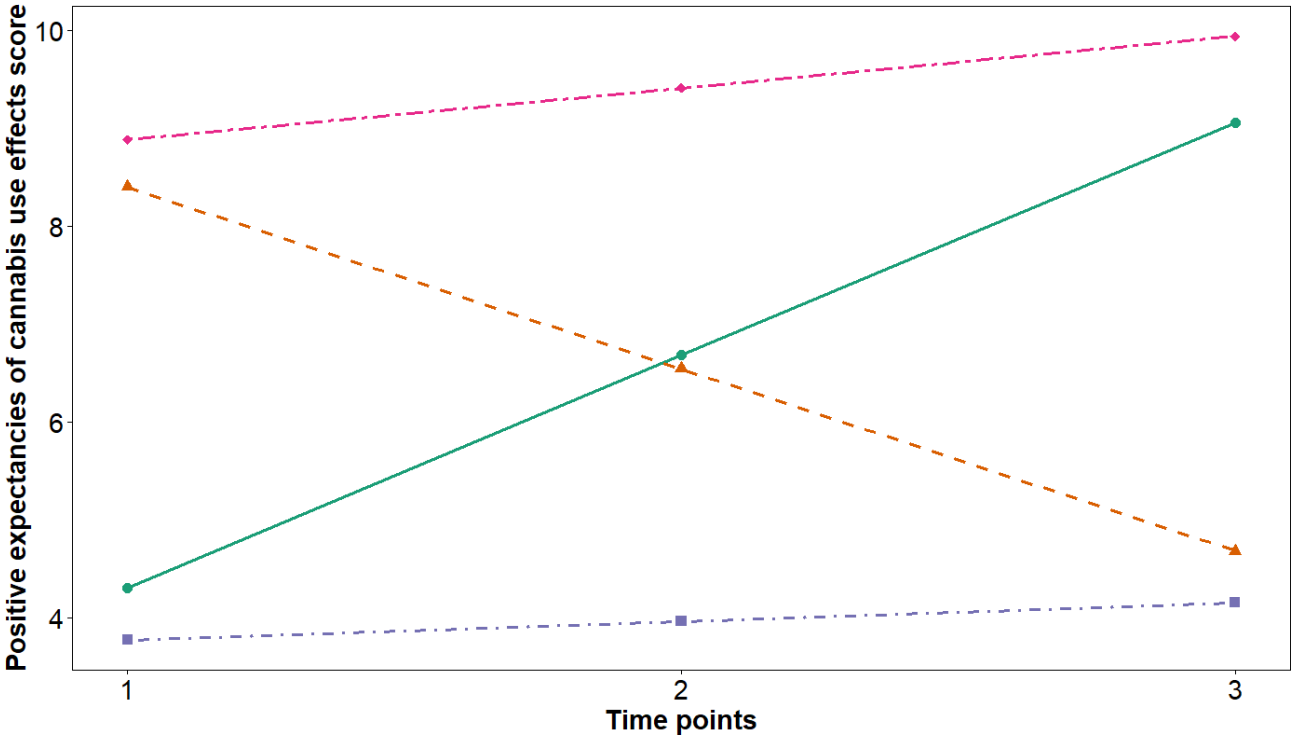
**Table .** Sizes of the classes (N=7409).

| Trajectory (model) | Class[a] | | | | | | |
|---|---|---|---|---|---|---|---|
| | Class 1, n (%) | Class 2, n (%) | Class 3, n (%) | Class 4, n (%) | Class 5, n (%) | Class 6, n (%) | Class 7, n (%) |
| 1 class | 7409 (100.0) | —[b] | — | — | — | — | — |
| 2 classes | 4530 (61.1) | 2879 (38.9) | — | — | — | — | — |
| 3 classes | 4125 (55.7) | 2035 (27.5) | 1249 (16.9) | — | — | — | — |
| 4 classes[c] | 2111 (28.5) | 684 (9.2) | 1496 (20.2) | 3118 (42.1) | — | — | — |
| 5 classes | 1897 (25.6) | 328 (4.4) | 3054 (41.2) | 1470 (19.8) | 660 (8.9) | — | — |
| 6 classes | 1864 (25.2) | 674 (9.1) | 502 (6.8) | 1375 (18.6) | 2774 (37.4) | 220 (2.9) | — |
| 7 classes | 1247 (16.8) | 31 (0.4) | 1439 (19.4) | 219 (2.9) | 1433 (19.3) | 2398 (32.4) | 642 (8.7) |

[a]Each cell displays the frequency and corresponding proportion of individuals within each latent class. Frequencies represent the unweighted counts, while proportions are calculated relative to the total number within each class or group.

[b]Not applicable.

[c]Selected model.



The 4-class model was selected as the optimal solution based on both statistical fitness and conceptual interpretability. This model demonstrated comparatively lower values for the BIC, aBIC, and AIC and higher entropy compared with the 3-class model, indicating improved classification precision. Compared with the 5-class model, it maintained a balanced class distribution, with each subgroup exceeding the recommended 5% minimum threshold (the smallest group being class 2, with 684 cases or 9.2% of the total sample). Therefore, the 4-class solution balanced parsimony with meaningful subgroup differentiation, which avoided interpretive challenges posed by extremely small latent classes observed in higher-order models.

XSL•FO
RenderX

Figure 1 visualizes the 4-class trajectories. The largest subgroup followed a moderate-increasing trajectory that was characterized by a high baseline level but a moderate increasing trend over time (class 4: moderate-increasing class; n=3118, 42.1% of the sample). The second most prevalent trajectory followed a high-increasing trajectory that was characterized by a moderate baseline level and a steep increase across the study period (class 1: high-increasing class; n=2111, 28.5% of the sample). The third most prevalent trajectory followed a low-increasing trajectory that was characterized by a low baseline level with a slight increase (class 3: low-increasing class; n=1496, 20.2% of the sample). The smallest group followed a high-decreasing trajectory that was characterized by a high baseline level that declined sharply (class 2: high-decreasing class; n=684, 9.2% of the sample). Parameter estimates and detailed trajectory features are reported in Table S3 in Multimedia Appendix 1.

**Figure 1.** The 4-class developmental trajectories of positive expectancies of cannabis use effects at 3 time points. The y-axis represents the mean positive expectancies of cannabis use effects score, and the x-axis represents the 3 examined time points. The 4 trajectories represent latent classes identified through latent class growth modeling: class 1 is plotted with a solid green line and filled circle markers (2111/7409, 28.5%), class 2 is plotted with an orange dashed line and filled triangle markers (684/7409, 9.2%), class 3 is plotted with a purple dot-dash line and filled square markers (1496/7409, 20.2%), and class 4 is plotted with a pink 2-dash line and filled diamond markers (3118/7409, 42.1%).

## Associations Between Baseline Time Invariant Variables and Latent Class Membership

Table 4 presents the results of multinomial logistic regression with the low-increasing class (class 3) serving as the reference category. Compared with this group, youth in the high- and moderate-increasing classes were older (adjusted odds ratio [aOR] 1.13, 95% CI 1.01 - 1.25; *P*=.04 and aOR 1.45, 95% CI 1.31 - 1.60; *P*<.001, respectively). Those in the moderate-increasing class were also more likely to reside in states with legalized recreational cannabis use and be from higher-income families. Multinomial logistic regression findings with other groups as reference categories are reported in Tables S5 - S7 in Multimedia Appendix 1.

XSL•FO

**Table .** Multinomial logistic regression predicting latent class membership (reference class: class 3).

| Class[a] and variable[b] | aOR[c,d] (95% CI) | *P* value |
|---|---|---|
| Class 1 | | |
| Biological sex | 0.94 (0.82 - 1.08) | .39 |
| Race/ethnicity | 1.03 (0.98 - 1.08) | .27 |
| Parental education | 1.06 (0.88 - 1.28) | .53 |
| Recreational cannabis legal status | 1.13 (0.96 - 1.32) | .16 |
| Age | 1.13 (1.01 - 1.25) | .04[e] |
| Total family income | 1.00 (0.87 - 1.16) | .97 |
| Class 2 | | |
| Biological sex | 1.05 (0.88 - 1.27) | .59 |
| Race/ethnicity | 0.97 (0.90 - 1.04) | .40 |
| Parental education | 0.85 (0.67 - 1.09) | .17 |
| Recreational cannabis legal status | 1.06 (0.85 - 1.32) | .60 |
| Age | 0.99 (0.85 - 1.14) | .88 |
| Total family income | 1.09 (0.90 - 1.32) | .40 |
| Class 4 | | |
| Biological sex | 1.01 (0.89 - 1.15) | .84 |
| Race/ethnicity | 1.02 (0.97 - 1.07) | .38 |
| Parental education | 0.99 (0.83 - 1.17) | .88 |
| Recreational cannabis legal status | 1.28 (1.11 - 1.49) | .003[f] |
| Age | 1.45 (1.31 - 1.60) | <.001[g] |
| Total family income | 1.25 (1.09 - 1.42) | .004[f] |

[a]The reference category for this model is class 3 (low-increasing), which represents 1496 participants (20.2%).

[b]For covariates, the reference groups are as follows: female for biological sex, non-Hispanic White for race/ethnicity, high school education or less for parental education, non-legalized status for recreational cannabis legal status, and total family income below US $75,000 for family income. Race/ethnicity was specified as a 5-category nominal covariate and was dummy-coded internally by Mplus. Mplus reports a single omnibus effect representing the overall effect of this multicategory covariate.

[c]aOR: adjusted odds ratio.

[d]Reported odds ratios represent the relative odds of belonging to each latent class versus the reference class for each covariate category.

[e]*P*<.05.

[f]*P*<.01.

[g]*P*<.001.

## Dynamic Associations of Family Environment and Psychopathology With the Trajectories of Positive Expectancies of Cannabis Use Effects Within Each Latent Trajectory Class

Table 5 presents the results from the class-specific effects model estimating the time-varying associations of familial and psychopathological predictors with positive expectancies of cannabis use effects across the 4 identified latent trajectory classes. Each class was modeled independently to capture heterogeneity in relation to the predictors over time. Distinct time-varying familial and psychopathological predictors emerged, underscoring differential developmental processes. In the high-increasing class, lower parental monitoring predicted greater expectancy growth at both T1 (β=−0.152, SE=0.072; *P*=.04) and T2 (β=−0.477, SE=0.122; *P*<.001), while increased family conflict at T3 (β=0.071, SE=0.019; *P*<.001) predicted elevated positive expectancies of cannabis use effects. In the high-decreasing class, only family conflict at T2 (β=0.124, SE=0.063; *P*=.047) was a significant risk factor, possibly reflecting transient reinforcement of positive expectancies before decline. The low-increasing class exhibited no significant associations across time points, though family conflict at T3 approached significance (β=0.038, SE=0.021; *P*=.07). In contrast, the moderate-increasing class (the largest group) showed the most consistent effects: less strict family cannabis use rules were significantly associated with expectancy increases at T1 (β=−0.171, SE=0.063; *P*=.006) and T2 (β=−0.212, SE=0.091; *P*=.02), lower parental monitoring was significant at both T2 (β=−0.275, SE=0.088; *P*=.002) and T3 (β=−0.307, SE=0.066; *P*<.001), and family conflict was the most robust predictor from T1 to T3 (*P*<.005).

[a]The outcome variable is the individual's level of positive expectancies of cannabis use effects at each time point (time 1, time 2, and time 3) within each latent class. All covariates are repeated measures within respondents from time 1 to time 3. This model does not predict the growth trajectory, but instead, it estimates how time-varying predictors are associated with variation in the positive expectancies of cannabis use effects score over time within each trajectory class.

[b]*P*<.05.

[c]*P*<.001.

[d]*P*<.01.

### Shared Associations of Family Environment and Psychopathology With Positive Expectancies of Cannabis Use Effects Across Latent Trajectory Classes

Results from the common effects model are presented in Table S8 in Multimedia Appendix 1, where time-varying familial and psychopathological predictors were constrained to have equal influence across all latent trajectory classes. Strict family cannabis use rules were significantly associated with lower positive expectancies of cannabis use effects at T1 only (β=−0.130, SE=0.040; *P*=.001). However, parental monitoring remained a significant predictor for positive expectancies of cannabis use effects across all 3 time points (T1: β=−0.089, SE=0.040; *P*=.03; T2: β=−0.315, SE=0.061; *P*<.001; T3: β=−0.185, SE=0.040; *P*<.001). Family conflict was a consistent and robust risk factor, with its influence increasing from T2 to T3 (*P*<.001).

## Discussion

### Heterogeneous Trajectories of Positive Expectancies of Cannabis Use Effects in Early Adolescence

To the best of our knowledge, this is the first study to use a large-scale longitudinal dataset to examine the developmental trajectories of positive expectancies of cannabis use effects in early adolescents, using a person-centered analytic framework. By modeling the development of positive expectancies of cannabis use effects across early adolescence, this study offers novel insights into the dynamic, heterogeneous nature of the formation of positive expectancies of cannabis use effects during this sensitive developmental phase. It identified the following

XSL•FO
RenderX

4 distinct trajectories of positive expectancies of cannabis use effects: high-increasing, high-decreasing, low-increasing, and moderate-increasing trajectories. These trajectories highlight the substantial variability in both the baseline levels and patterns of change in positive expectancies of cannabis use effects, underscoring early adolescence as an important period for tailoring interventions to prevent cannabis use.

Although weighted descriptive statistics across the sample indicated relatively modest population-level changes over the 3 waves, this pattern is expected given the narrow but critical developmental window of early adolescence (approximately ages 11 - 13 years) represented in our sample from the ABCD Study cohort. During this period, many psychosocial and contextual characteristics exhibit relative stability at the population level [97], yet substantial *within-person* variability persists in cognitive-affective processes such as substance-related expectancies, social-emotional development, and dynamic familial factors [7,98-100]. LCGA, a person-centered approach, is uniquely suited to capturing individual-level heterogeneity because it identifies subgroups of youth who share similar developmental trajectories even when the overall mean trend appears relatively flat. Accordingly, the 4 trajectory classes identified in this study represent distinct and meaningful expectancy development over time rather than simple cross-sectional differences based on average levels [52,101]. In addition, although the trajectory classes are derived from repeated measures of positive expectancies of cannabis use effects, the LCGA analytic framework used in this study helps minimize potential bias arising from factors, such as parental monitoring and family conflict, which may influence both the development of positive expectancies of cannabis use effects and the predictors included in the R3STEP model. LCGA does not stratify individuals on a single observed positive expectancies of cannabis use effects score; instead, it forms subgroups based on model-estimated posterior probabilities that reflect the overall pattern of trajectories. Moreover, R3STEP estimates covariate associations only after class formation and incorporates adjustment for classification uncertainty, reducing the bias that can arise when treating uncertain class assignments as if they are certain [92]. Within this framework, associations between predictors and class membership represent correlational patterns among latent developmental pathways rather than artifacts of the analytic strategy. Thus, the heterogeneity observed across classes reflects meaningful differences in expectancy development over time, highlighting the advantage of mixture modeling for uncovering nuanced developmental processes that would remain obscure in traditional variable-centered analyses.

Using this approach, the largest trajectory class identified in this study was the moderate-increasing trajectory, which was characterized by relatively high initial levels of positive expectancies of cannabis use effects that increased steadily with time, suggesting an active expectancy formation phase. This pattern may reflect normative developmental processes in early adolescence, where adolescents increasingly seek self-identity and autonomy, and become increasingly susceptible to substance use opportunities [102]. Multivariable comparisons revealed that youth in this trajectory were more likely to be older, from high-income families, and living in states with recreational cannabis legalization. Notably, the consistently elevated and gradually intensifying positive expectancies of cannabis use effects observed in this group are concerning, as the findings point to a sustained expectancy formation process that may heighten the risk for future initiation and persistent use. Youth in this trajectory may be actively shaping their cognitive belief around cannabis use prior to engaging in cannabis use, which may be reinforced by their developmental maturity (older age) and the legal status of recreational cannabis use in their environment. These findings suggest that prevention efforts should extend beyond traditionally high-risk youth to include those on seemingly normative developmental pathways who may nonetheless be building pro-cannabis expectancies that increase long-term vulnerability. The other 3 trajectories provide further insights into heterogeneity in the development of positive expectancies of cannabis use effects, highlighting the substantial variability in both the onset and developmental course of positive expectancies of cannabis use effects and pointing to multiple pathways of risk and resilience in early cannabis-related cognitions.

### Familial Protective and Risk Factors

Findings from the common effects model showed that stricter family cannabis use rules and higher levels of parental monitoring were protective against positive expectancies of cannabis use effects during early adolescence. These effects were the strongest at earlier ages, particularly at 10 - 11 years (T1) and 11 - 12 years (T2). Parental monitoring demonstrated a consistent inverse association with positive expectancies of cannabis use effects across all 3 time points, with the strongest effect at ages 11 - 12 years. In contrast, cannabis-specific rules were significant only at T1, with diminished predictive value at later time points. These protective effects align with the findings of a large body of developmental research emphasizing the critical role of structured and engaged parenting in deterring adolescent substance-related cognitions and behaviors [43,103].

The early and pronounced influence of family cannabis use rules underscores their importance in shaping adolescents' cognitive attitudes regarding substance use when they are most embedded within the family context and are more receptive to parental expectations and boundaries [104]. These rules function as clear behavioral norms, potentially counterbalancing early exposure to peer influences and emerging social scripts around cannabis. Although the direct statistical effect weakened by ages 11 - 12 years, such rules may establish enduring internalized norms that persist even when external risks are present. Prior research suggests that early parental rule-setting exerts long-term influence on substance-related decision-making. For example, the authoritative parenting style is characterized by setting limits and is linked to lower substance use and less positive attitudes toward drugs throughout adolescence [105-107].

Parental monitoring demonstrated a more enduring and stable protective effect across the developmental period studied. Unlike rule-setting, monitoring reflects an ongoing dynamic engagement with the daily lives of adolescents, which provides not only behavioral oversight but also emotional attunement

XSL•FO
RenderX

and accountability [108]. This form of proactive parenting has been consistently shown to reduce adolescents' opportunities to engage in risk behaviors and to shape substance-related cognitions in a protective direction [65,108]. The heightened impact observed at ages 11-12 years may indicate a critical developmental "sweet spot," when adolescents begin to seek autonomy but remain highly responsive to external regulation and support. These findings emphasize the importance of initiating family-based prevention efforts during early adolescence, leveraging this window to reinforce cognitive resistance to substance use before peer norms and societal influences exert stronger effects.

Family conflict emerged as a robust risk factor for elevated positive expectancies of cannabis use effects at ages 12-13 years (T3). In addition, class-specific models showed that this effect was the strongest in the moderate- and high-increasing classes, suggesting that sustained family tensions may accelerate the formation of positive expectancies of cannabis use effects, particularly when not offset by protective parenting practices. This finding is consistent with the findings of a substantial body of literature linking family dysfunction to increased vulnerability to substance use [109,110]. Chronic conflict may erode emotional regulation capacities and model maladaptive coping strategies, thereby reinforcing cannabis as a perceived tool for managing stress [111]. These findings highlight the dual importance of reinforcing protective parenting practices and reducing family conflict during this critical developmental period.

### Class-Specific Nuances

Unlike the common effects model, which assumes that predictors operate uniformly across all trajectories, the class-specific model allows the effects of parental and familial factors to vary by trajectory and captures heterogeneity in developmental processes. The findings revealed notable differences in the influences of familial and psychopathological factors across the 4 trajectories of positive expectancies of cannabis use effects.

Parental monitoring was pronounced among adolescents who followed trajectories marked by moderate- and high-increasing risk, where higher monitoring during early and mid-adolescence (ages 10 - 12 years) was associated with significantly lower positive expectancies of cannabis use effects. Additionally, stricter family cannabis use rules were associated with lower positive expectancies of cannabis use effects in the moderate-increasing group at ages 10-11 and 11-12 years. These effects were most pronounced prior to the age of 13 years, underscoring a sensitive developmental window when parental guidance may shape substance-related cognitions before peer norms and autonomy-seeking dominate [112,113]. It is also possible that elevated parental monitoring reflects a reactive process, wherein parents increase oversight in response to perceiving their child's heightened risk or early signs of problematic behaviors. In this interpretation, monitoring may serve as a preventive and responsive strategy, suggesting that parents who recognize vulnerability may intensify supervision as a preemptive measure against further risk escalation.

However, these protective effects were less evident or absent in the high-decreasing and low-increasing trajectories. In the high-decreasing group, early high levels of positive expectancies of cannabis use effects declined over time, and neither parental monitoring nor rule-setting was significantly associated with these shifts. This may suggest that reductions in positive expectancies of cannabis use effects were driven by other factors, such as experiential disconfirmation or broader contextual influences, and further research is warranted for this group of youth. In the low-increasing group, neither monitoring nor rule-setting showed significant associations, though family conflict emerged as a marginal risk factor at later ages. The absence of early effects in this group could reflect other protective dispositional factors (eg, low sensation-seeking) or structural buffers (eg, strong school engagement) not captured in our analysis.

Family conflict emerged as the most robust and class-differentiating risk factor across trajectories, particularly for those at elevated or increasing risk. Adolescents in the moderate- and high-increasing groups exhibited significantly elevated positive expectancies of cannabis use effects in association with greater family conflict, especially by ages 12-13 years. This pattern suggests that interpersonal stress within the home may amplify the development of positive expectancies of cannabis use effects during a period of heightened social and emotional reactivity. In line with developmental cascade models [114], chronic exposure to family conflict may erode previously adaptive cognitive trajectories and accelerate the adoption of risk-promoting beliefs. Conflict was also a significant predictor in the high-decreasing group at mid-stage (ages 11-12 years), suggesting a contemporaneous, level-shifting effect of conflict rather than a change in growth rate. In contrast, conflict showed no impact among adolescents in the low-increasing class, potentially reflecting greater resilience or the presence of unmeasured compensatory mechanisms, such as school connectedness and temperamentally based self-regulation.

Psychopathological symptoms played a more nuanced, temporally specific role. Across most trajectories, they were not significant predictors in early adolescence but became increasingly relevant by ages 11-12 and 12-13 years in the moderate-increasing class. This shift may reflect the growing salience of emotional distress in early adolescence, when academic, social, and identity-related demands intensify, and cannabis may be perceived as a coping tool.

Collectively, several effects were close to statistical significance based on the *P* value. It is likely that we detected small effects because of our large sample size. Therefore, the findings warrant replication.

### Limitations

Several limitations should be considered when interpreting the findings of this study. First, the analysis was limited to 3 waves of data collected during early adolescence, which restricts the ability to capture the full developmental trajectory of positive expectancies of cannabis use effects into middle and late adolescence. Given that substance-related attitudes and behaviors often intensify during these later periods, future research with a longer follow-up is needed to determine whether the identified trajectories persist, shift, or predict distal actual cannabis use behavior. Second, the measure of recreational

XSL•FO
RenderX

cannabis legalization status was based on state-level policy 1 year prior to this study's baseline (T1) assessment. While useful as a contextual marker, this static measure may not fully reflect the evolving influence of recreational legalization over time, particularly as policy implementation and social norms continue to change. Third, this study used a 3-step LCGA in which covariates and predictors were deliberately excluded from the trajectory formation process and incorporated only in the R3STEP multinomial logistic regression and subsequent class-specific and common effects models. While this approach preserves the integrity of class estimation, unmeasured or imperfectly measured factors may still be associated with both the trajectory of positive expectancies of cannabis use effects and class membership, introducing the possibility of residual confounding. Fourth, the study was unable to account for a range of other social and contextual influences that are becoming increasingly relevant to adolescent development and substance-related behaviors. Given emerging evidence that cannabis-related content on social media can shape adolescents' attitudes, expectancies, and perceived norms, future studies should integrate time-matched assessments of digital media exposure to provide a more comprehensive understanding of expectancy formation.

### Public Health Implications

This study fills a critical gap in the literature by identifying 4 distinct developmental trajectories of positive expectancies of cannabis use effects among early adolescents, underscoring the need for prevention strategies that extend beyond universal, one-size-fits-all models. While universal prevention remains important, interventions must be tailored to the heterogeneous developmental pathways identified in this study.

In addition to these practical implications, the observed trajectory patterns and associated family predictors contribute to the development of the current theory. The identification of distinct developmental trajectories of positive expectancies of cannabis use effects suggests that expectancy formation during early adolescence may be heterogeneous rather than uniformly increasing. The findings that stricter household rules and higher parental monitoring were associated with membership in lower or declining classes of positive expectancies of cannabis use effects and that greater family conflict was associated with higher-risk classes of positive expectancies of cannabis use effects are consistent with the social learning theory that emphasizes the role of family environments in shaping evaluative beliefs and related motivational states. Together, these findings suggest that theoretical models of adolescent cannabis use may benefit from incorporating heterogeneity in the development of positive expectancies of cannabis use effects and accounting for the structuring influence of family dynamics during this critical developmental period.

Parental monitoring and clear cannabis use rules were most protective in early adolescence, particularly between the ages of 10 and 12 years, when parental influence remains salient. Intervening during this sensitive period may delay or suppress the rise in positive expectancies of cannabis use effects before peer norms and autonomy-seeking behaviors exert greater influences. These practices are especially critical for adolescents in moderate- and high-increasing trajectories, where sustained parental engagement may disrupt escalation in expectancies. In contrast, family conflict emerged as a robust risk factor, particularly in the later stages of early adolescence. Chronic conflict may amplify cognitive vulnerability, destabilize otherwise adaptive trajectories, and accelerate the internalization of risk-promoting beliefs. Prevention programs that educate parents about conflict management and communication skills could therefore provide meaningful protection. Psychopathology also became increasingly salient by ages 11‐13 years, reinforcing the importance of integrated prevention that includes mental health screening and timely intervention. Addressing emotional distress and teaching adaptive coping strategies may reduce the perceived utility of cannabis for managing stress.

Collectively, these findings highlight the value of early, sustained, and nuanced family involvement across developmental stages. Cannabis use prevention programs should also focus on enhancing parental self-efficacy by providing practical tools for effective communication, conflict resolution, and the implementation of developmentally appropriate cannabis use rules [115]. Early adolescence is a critical period during which parental authority still has a dominant influence, particularly for adolescents not yet embedded in high-risk trajectories. For these adolescents, clear and consistent rule-setting within a supportive context may help prevent escalation in expectancies and delay susceptibility.

## Acknowledgments

Data used in the preparation of this article were obtained from the Adolescent Brain Cognitive Development Study (ABCD Study) [58], held in the National Institute of Mental Health Data Archive (NDA). This is a multisite, longitudinal study designed to recruit more than 10,000 children aged 9-10 years and follow them over 10 years into early adulthood. The ABCD Study is supported by the National Institutes of Health (NIH) and additional federal partners under award numbers U01DA041048, U01DA050989, U01DA051016, U01DA041022, U01DA051018, U01DA051037, U01DA050987, U01DA041174, U01DA041106, U01DA041117, U01DA041028, U01DA041134, U01DA050988, U01DA051039, U01DA041156, U01DA041025, U01DA041120, U01DA051038, U01DA041148, U01DA041093, U01DA041089, U24DA041123, and U24DA041147. A full list of supporters is available on the ABCD Study website [116]. A list of participating sites and a complete list of the study investigators can be found on the ABCD Study website [117]. ABCD consortium investigators designed and implemented the study and/or provided data but did not necessarily participate in the analysis or writing of this report. This manuscript reflects the views of the authors and may not reflect the opinions or views of the NIH or ABCD consortium investigators. The ABCD data repository grows and changes over time. The ABCD data used in this report came from the ABCD 5.1 release [118].

## Abstract

**Background:** Public health restrictive measures adopted during the COVID-19 pandemic led to significant changes in lifestyles. Global declines in physical activity (PA) and increases in sedentary behavior were noted. These trends were observed within different regions of the world, pointing toward potential long-term implications for PA behaviors.

**Objective:** This mixed methods study aims to assess variations in daily step counts in Qatar using device-driven data throughout all 3 COVID-19 waves (February 2020 to February 2023) compared with a full pre–COVID-19 year. In-depth interviews were further conducted with randomly selected participants to gain insights into determinants, perceptions, and barriers of PA during the pandemic.

**Methods:** A total of 362 participants (60/362, 16.6% female) from the Step Into Health community-based program reported daily step counts using pedometers (170/362, 47%) or a mobile phone app (192/362, 53%). Linear mixed models examined changes in daily step counts across 19 phases of implementation and lifting of restrictions. Overall, 9 participants also completed semistructured interviews that were analyzed thematically and phenomenologically. Triangulation of quantitative and qualitative data was applied to interpret convergences and divergences between device-measured activity patterns and lived experiences.

**Results:** Significant declines in daily step counts (ie, from 689 to 1013 steps) were observed at the onset of each wave ($P$<.001), were especially marked at wave 2, and were followed by a recovery of step count following the lifting of restrictions at each wave (ie, increase of 609 to 1147 steps). Different patterns of change in step count emerged within sex ($P$=.03), age ($P$=.03), and BMI ($P$=.01) groups, where larger variations were seen among male individuals, pedometer users, and normal-weight participants. Qualitative themes (ie, disrupted routines, reliance on home-based exercise, and media influence) contextualized these patterns and explained subgroup differences.

**Conclusions:** The largest drops in daily step count coincided with increased case severity and Ramadan. Integration of quantitative and qualitative findings showed that declines in activity were shaped not only by restrictions but also by fear, motivation, and

XSL•FO
RenderX

contextual factors. These results underscore the importance of designing interventions that encourage outdoor activity and provide reliable social media–based guidance during public health crises.

## Introduction

COVID-19 was initially detected in December 2019 in Wuhan, China. This disease is caused by SARS-CoV-2 [1]. On March 11, 2020, the World Health Organization declared COVID-19 a global pandemic [2]. The first confirmed case of COVID-19 in Qatar was reported on February 27, 2020 [3]. Since then, progressive restrictions have been implemented in Qatar and worldwide as preventive measures to reduce the spread of the virus. These measures targeted various sectors, including business and leisure, transportation, outdoor and professional sports, education, health services, and social gatherings.

Physical activity (PA) is a critical determinant of health, contributing to the prevention of chronic diseases and the promotion of overall well-being [4]. According to the World Health Organization, adults aged 18-64 years are recommended to engage in at least 150-300 minutes per week of moderate-intensity PA, or a minimum of 75-150 minutes per week of vigorous-intensity PA, or a combination of both for substantial health benefits [5]. However, fulfilling these recommendations became particularly challenging during COVID-19 restrictions, although many countries have published targeted PA guidelines for times of pandemics, outbreaks, and home quarantine (eg, Qatar National PA Guidelines [6]). A global decline in total PA levels was observed [7-11] including vigorous-, moderate-, and light-intensity PA [8,9,12-14]. This was accompanied by a significant increase in total sedentary time [15,16].

Adequate and consistent PA has been suggested to enhance immune responses against respiratory viral infections, emphasizing its relevance during the pandemic [17]. Reductions in PA, along with increased sedentary behavior, can lead to adverse health outcomes such as diminished physical fitness and an impaired immune system response, negatively affecting quality of life [4].

In Qatar, a study examining PA levels before and during the first lockdown phase in 2020 revealed significant reductions in walking and both vigorous and moderate PA levels and increases in sedentary behavior [18]. A general decline in life satisfaction was also noted and reflected the profound physical and mental impact of the imposed restrictions [18]. Another survey-based study on Qatar's adult population confirmed increases in sedentary time and decreases in exercise time, which were associated with gains in body weight [19]. Both studies presented a few limitations, such as the reliance on subjective self-reported data and the lack of comparison with other periods of reduced PA in Qatar (eg, summer months or Ramadan). To address the latter, a recent study explored daily variations in step count before, during, and after the first COVID-19 wave in Qatar, covering a period of approximately 1 year [20]. Authors showed that the significant declines in daily step count following restrictions persisted after the lifting of restrictive measures, affecting mostly those who were physically active at baseline (ie, men, normal weight, and older individuals) [20]. The COVID-19 restrictions, which aimed to curb the spread of the virus, have continued disrupting normal life patterns in Qatar until November 2022. However, none of the studies from Qatar accounted for the second and third COVID-19 waves that resulted in potential long-term implications to PA. Such longitudinal data could provide better insights into the dynamics of PA behaviors in times of extended public health safety measures, particularly in regions where there is a paucity of data on PA changes during pandemics.

Lockdowns in the Arabian Gulf Peninsula and the Middle East and North Africa regions inadvertently decreased opportunities for regular PA and exacerbated sedentary lifestyles [21,22]. Although restrictions have been lifted, the long-term effects of the COVID-19 pandemic on physical and mental health are still emerging [23,24]. While much has been done on the immediate impacts, long-term behavioral shifts present a critical gap, particularly in regions like the Gulf Peninsula region, with its unique environmental and cultural characteristics [25].

Given the challenges and potential biases present in assessing PA through self-reported data and the rather short-term nature of most studies in the region, this study seeks to explore the impact of all 3 waves of COVID-19–related restrictions on device-measured daily step counts in Qatar. Understanding these disruptions over a period of 3 years is vital for shaping public health strategies that promote active lifestyles and address the ongoing post–COVID-19 challenges [26]. Using a mixed method approach, this study further aims to assess associated barriers, behavior changes, attitudes, and perceptions during the pandemic, providing valuable insights into how restrictions have influenced PA patterns in Qatar and potentially the region.

## Methods

### Ethical Considerations

All participants in the "Step Into Health" program (SIH) provided a disclaimer at enrollment permitting the use of their step count data for research and program evaluation. Only limited, deidentified data were extracted from the SIH database for this study. For the qualitative part, interview participants provided separate written informed consent, including permission to audio-record the interview and to use anonymized quotations in publications. No compensation or incentives were provided to participants for their involvement in this research.

XSL•FO
RenderX

Privacy and confidentiality were strictly maintained in accordance with institutional review board approval (E202104021).

## Study Design and Population

This is a retrospective longitudinal cohort study, which aimed to explore the impact of all waves of COVID-19–related restrictions in Qatar on PA levels using mixed methods. Participants included in this research were members of the SIH, a pedometer-based community intervention designed to encourage residents of Qatar to walk 10,000 steps per day [20,27-30]. SIH is the largest PA community-based intervention in Qatar and is still ongoing since 2012. The program was initially publicized nationally through outreach advertisement campaigns targeting different settings (workplaces, campuses, and malls). Registration to the SIH was done on a voluntary basis through a dedicated online platform [20,27-30]. Upon registration, participants received a free pocket-sized pedometer (Omron HJ-324U, Omron Healthcare Co, Ltd) or a mobile phone app (Android and iOS operating systems; SIH; version 3.0.3; Aspire Zone), both of which were linked to a web database that recorded step counts [20,27-30].

Male and female participants of all nationalities (as registered in the SIH database) were included in the analysis. From the initial pool of participants that were actively recording their step count during the studied time frame (January 2019 to November 2022), a total of 3562 participants were retained after excluding those aged 18 years or younger or those presenting invalid step counts (ie, missing data or less than 500 or more than 60,000 steps per day). A further filtering step excluded participants presenting less than 3 activity days per week [31] or 5 days per month [32] over the entire studied period. After applying the last step, 362 participants were retained for the quantitative analysis.

## Qualitative Research

From the retained sample, 9 participants were invited to participate in in-depth interviews. A random selection process was applied (ie, every 40th individual in the SIH database) to reduce researcher selection bias and give all participants an equal chance of recruitment. Although not purposive, this process resulted in a sample with diversity in sex, age, and activity behaviors, which allowed a range of perspectives to be captured. Data collection continued until thematic saturation was observed, with no new themes and codes emerging after the ninth interview. At that point, the information became repetitive across participants, indicating that the sample size was sufficient to capture the diversity of perspectives. Participants were contacted individually by phone to confirm their participation. Interviews occurred between September 2021 and November 2021.

## Study Measures

### *Quantitative: Daily Step Count*

The mobile phone app reads steps counted by the phone's built-in sensors and transfers the data to the cloud. Pedometer users were asked to upload their data daily or as frequently as possible. More information on the program is cited elsewhere [20,27-30].

Data extracted from the SIH web database included the available active members who had uploaded their steps before, during, and after the COVID-19–related restrictions phases. Demographic data, self-reported upon registration, were extracted from participants' SIH profiles, which included age, sex, and nationality, as well as body height and mass. BMI was calculated as the ratio between mass (kg) and height squared ($m^2$). Participants were then grouped according to their sex (ie, male and female), age (ie, <50 years and ≥50 years), nationality (ie, Qatari and non-Qatari), BMI classification (ie, normal weight with values <25, overweight with values between 25 and <30, and obesity with values of ≥30) and the type of device used (ie, pedometer or mobile phone app).

### *Qualitative: In-Depth Interviews*

This study used qualitative methods to explore participants' experiences, attitudes, and perceptions regarding PA during the COVID-19 pandemic in Qatar. A total of 9 in-depth interviews were conducted remotely via online platforms or phone calls with participants of the SIH program to examine behavioral changes, barriers, and motivators related to PA during all restrictive waves of the COVID-19 pandemic. The sample included 5 male and 4 female individuals, selected to ensure diverse perspectives.

All interviews were conducted in English or Arabic, based on the participant's preference. Interviewers were fluent in both languages, and interview questions were translated into Arabic for Arabic-speaking participants. Prior to the interviews, interviewers received comprehensive training on the interview protocol to ensure consistency and clarity in question delivery.

The interviews were semistructured, focusing on key themes such as the importance of PA, changes in exercise habits prepandemic and postpandemic, the impact of COVID-19 restrictions on PA, barriers to staying active, and motivators for exercise. Participants were also asked about their experiences with home-based exercise routines, the role of the media in shaping their activity choices, and their intentions regarding future PA post restrictions.

Each interview lasted between 30 and 60 minutes. Interviews were conducted virtually or in-person, adhering to the appropriate COVID-19 safety protocols for in-person sessions. All interviews were audio-recorded for quality assurance, and transcripts were created from the recordings. Deidentified transcripts were stored for record-keeping and coding purposes.

## Timeline of the 3 COVID-19 Waves in Qatar

Table 1 details the main COVID-19 phases considered during the 3 waves relating mainly to the restrictions that were imposed and lifted by the Qatar's Ministry of Public Health. A pre–COVID-19 period of over a full year (T0) is used as a reference to annual changes in daily step count. The data presented in Table 1 were compiled from the Ministry of Public Health website and other reliable news sources from the written press.

XSL•FO
RenderX

**Table 1.** Timeline of implementation and lifting of COVID-19 restrictions during the 3 COVID-19 waves in Qatar. T0 represents a pre–COVID-19 reference phase of more than 1 year.

| Phase | Start date | End date | Description |
|---|---|---|---|
| T0 | January 1, 2019 | February 28, 2020 | Pre–COVID-19 |
| T1 | February 29, 2020 | March 11, 2020 | First confirmed case in Qatar until the start of lockdown |
| T2 | March 12, 2020 | June 14, 2020 | Wave 1: Qatar begins to implement lockdowns |
| T3 | June 15, 2020 | June 30, 2020 | Wave 1: Phase 1 gradual lifting of restrictions |
| T4 | July 1, 2020 | July 31, 2020 | Wave 1: Phase 2 gradual lifting of restrictions |
| T5 | August 1, 2020 | August 31, 2020 | Wave 1: Phase 3 gradual lifting of restrictions |
| T6 | September 1, 2020 | February 3, 2021 | Wave 1: Phase 4 gradual lifting of restrictions |
| T7 | February 4, 2021 | May 27, 2021 | Wave 2: Qatar to reimpose COVID-19 restrictions |
| T8 | May 28, 2021 | June 17, 2021 | Wave 2: Phase 1 gradual lifting of restrictions |
| T9 | June 18, 2021 | July 8, 2021 | Wave 2: Phase 2 gradual lifting of restrictions |
| T10 | July 9, 2021 | August 5, 2021 | Wave 2: Phase 3 gradual lifting of restrictions |
| T11 | August 6, 2021 | October 2, 2021 | Wave 2: Phase 3.2 gradual lifting of restrictions |
| T12 | October 3, 2021 | February 1, 2022 | Wave 2: Phase 4 gradual lifting of restrictions |
| T13 | February 2, 2022 | April 1, 2022 | Wave 3: Qatar reimposes COVID-19 restrictions |
| T14 | April 2, 2022 | May 20, 2022 | Wave 3: gradual lifting of restrictions: 100% employees back to work |
| T15 | May 21, 2022 | July 6, 2022 | Wave 3: gradual lifting of restrictions: mask required in health care |
| T16 | July 7, 2022 | August 31, 2022 | Wave 3: reimpose mask in all settings |
| T17 | September 1, 2022 | October 31, 2022 | Wave 3: gradual lifting of restrictions: mask required in health care |
| T18 | November 1, 2022 | February 28, 2023 | Wave 3: gradual lifting of restrictions: Ehteraz[a] no longer required |

[a]Ehteraz is the mandatory mobile app used in Qatar to track the population's health status during COVID-19.

## Statistical Analysis

### *Quantitative Analysis*

Data were analyzed using the SPSS software (version 21.0; IBM Corp). A descriptive analysis presented continuous variables (eg, age and BMI) and daily step count as mean, SD, and 95% upper and lower CIs. Distribution (count and frequencies) was used to present participants' characteristics on categorical variables like nationality and sex. Time series 7-day moving average on daily step count was computed to plot the trend of PA across the study period stratified by age, sex, BMI status, and nationality. Linear mixed models were used to examine changes in daily step counts over all the 19 studied time phases (Table 1), based on independent factors such as sex, age, BMI classification, nationality, and device. All factors and their interaction with factor time were included in the linear mixed models. Pairwise comparisons were used to examine significant changes in step count between the time phases studied. By adding subject ID as a random effect with a random intercept, we accounted for individual-level variation and within-subject correlation. An unstructured covariance structure was found to be the best fit.

### *Qualitative Analysis*

The qualitative data from the in-depth interviews were analyzed thematically to identify key patterns and insights related to participants' experiences, attitudes, and perceptions of PA during the COVID-19 pandemic. Transcripts of the interviews were reviewed and coded inductively, allowing for the emergence of recurring themes associated with changes in PA behaviors, perceived barriers, and motivators, and the broader psychological and emotional impacts of the pandemic.

The qualitative analysis was conducted by 1 researcher (SS), who has training and experience in qualitative research. A thematic analysis was carried out following Braun and Clarke's [33] 6-step framework (ie, familiarization with data, coding, generating themes, reviewing themes, defining/naming themes, and reporting). This inductive process enabled the identification of recurring patterns. A phenomenological approach was then used to interpret the lived experiences of participants, focusing on the subjective meaning they attributed to disruptions and adaptations in their PA routines during the pandemic. Although a single researcher conducted the coding, credibility was strengthened through repeated immersion in the transcripts, detailed documentation of coding decisions, and reflective discussions with the wider research team to ensure interpretations were consistent and trustworthy.

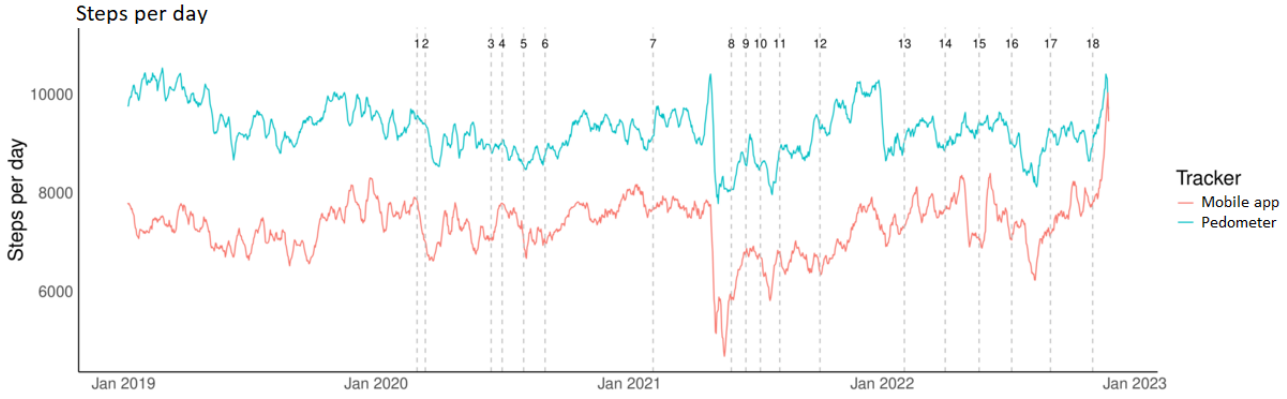
To integrate the qualitative and quantitative findings, methodological triangulation was used. Quantitative step count data and qualitative interview data were first analyzed independently, then compared to identify areas of convergence and divergence. Data triangulation was also incorporated by drawing on step count measurements from 2 different devices (pedometers and mobile apps) alongside qualitative accounts.

XSL•FO
RenderX

This approach enhanced the depth and validity of the findings by linking device-measured activity with participants' lived experiences and contextual factors.

# Results

## Quantitative Results



### Population's Characteristics

A total of 362 participants, including 60 (16.6%) female and 302 (83.4%) male individuals, met the inclusion criteria, demonstrating consistent tracking of their daily steps throughout the entire pandemic period. On average, participants were aged 47.4 (SD 9.0) years and presented a BMI of 27.9 (SD 4.4) kg/m$^2$. About a third of the studied population (n=137, 37.8%) was aged 50 years or older, while 75.1% (272/362) were classified either with overweight (n=184, 50.8%) or obesity (n=88, 24.3%). Qatari nationals represented 30.7% (n=111) of the studied population, which reflects a relatively good representation compared to the overall population of Qatar. From the entire sample, 170 (47%) participants were pedometer users and 192 (53%) used the mobile app (ie, n=58, 16% Android and n=134, 37% Apple iPhone) to track their activity level.

### Effect of COVID-19 Phases on Step Count

The analyses revealed a significant effect of time ($F_{18, 5027.03}$=5.901; $P$<.001), device ($F_{1, 1598.03}$=6.275; $P$=.01), and an interaction between device and time ($F_{18, 5157.67}$=1.70; $P$=.03) on step count (Figure 1). In comparison to the pre–COVID-19 period, significant decreases in step count ranging from 689 to 1013 steps were observed following implementation of restrictive measures for each of the 3 COVID-19 waves (Figure 1). Specifically, restrictions reimposed at the start of wave 2 brought about the largest decreases in daily step count. With the lifting of restrictions, significant increases in step count were found at the end of each wave (ie, between 609 and 1147 steps; Figure 1). On average, pedometer users presented 690 additional daily steps as compared to those using the mobile app ($P$=.01; Figure 1). Main patterns of change in step count with time were comparable between pedometer and mobile users, with some interactions noted. For instance, after September 2022 (ie, T17 and T18, end of wave 3) the increase in step count among mobile users was larger than that observed in pedometer users with the final lifting of restrictions (Figure 1). In the following sections, data from pedometer and mobile users are presented separately.

**Figure 1.** The 7-day moving average of daily step count for pedometer and mobile app users within the studied period covering 1 year before COVID-19 (T0: January 1, 2019, to February 28, 2020) and the 3 COVID-19 waves (T1-T18: February 29, 2020, to February 28, 2023). Details on the 19 time points reflecting the implementation and lifting of restrictions are found in Table 1.

### Effect of COVID-19 Phases on Step Count by Sex and Nationality Groups

Although the main effect of sex ($F_{1, 360.74}$=0.125; $P$=.72) and its interaction with device ($F_{1, 2384.61}$=0.888; $P$=.35) or time ($F_{18, 5167.25}$=1.39; $P$=.12) were not statistically significant, post hoc comparisons revealed noticeable significant sex differences, mostly evident for mobile users (Figure 2). For mobile users (Figure 2), female individuals recorded an average of 1764 fewer daily steps as compared to male individuals at the pre–COVID-19 period ($P$=.03). The only other large difference between male and female groups was detected at the lifting of restrictions in wave 3, which corresponded to the return to work of 100% of the employees in Qatar (T14, 2227 less steps in female compared to male individuals; $P$=.01; Figure 2). However, step count for female mobile users was not significantly affected by the first or second waves of COVID-19, where even significant increases in values were recorded at the end of wave 1 (+1059 steps; $P$=.046) and at the last studied phase (+2219 steps; $P$=.01) compared to pre–COVID-19 (Figure 2). Male mobile users recorded significant decreases in steps at each of the first 2 waves as compared to the pre–COVID-19 period (–932 steps; $P$<.001; –954 steps; $P$<.001; respectively); however, they were less affected by the third wave, where a significant increase in values was observed at the last studied phase compared to pre–COVID-19 (+871 steps; $P$=.008; Figure 2). For pedometer users, sex differences were less evident at the pre–COVID-19 period; however, female individuals recorded 1736 more steps at the time when 100% of employees returned to work during wave 3 (T14; $P$=.05; Figure 2). The only significant change in step count of female pedometer users was seen in wave 2 with a decrease of –1443 steps compared to pre–COVID-19 ($P$=.03), after which step count went back to pre–COVID-19 values (Figure 2). Step count of male pedometer users was more significantly affected by the restrictions imposed during all COVID-19 waves, where significant declines compared to pre–COVID-19 of 993 steps (wave 1; $P$<.001), 1099 steps (wave 2; $P$<.001) and 1499 steps

XSL•FO
RenderX

(wave 3; *P*<.001) were observed (Figure 2). Values remained significantly lower throughout wave 3 and were still 708 steps lower than pre–COVID-19 at the last studied phase (*P*=.06).

**Figure 2.** The 7-day moving average of daily step count for male and female groups within the studied period covering 1 year before COVID-19 (T0: January 1, 2019, to February 28, 2020) and the 3 COVID-19 waves (T1-T18: February 29, 2020, to February 28, 2023). Details on the 19 time points reflecting the implementation and lifting of restrictions are found in Table 1. Data from pedometer and mobile app users are presented separately.

No significant differences in daily step count were observed between the nationality groups (*P*>.05). Please refer to Tables S2 and S3 in Multimedia Appendix 1 for the average daily step count of each of the 19 studied periods for pedometer and mobile users, respectively, among all subgroups.

### *Effect of COVID-19 Phases on Step Count by Age Group*

A significant effect of age ($F_{1, 9233.62}$=4.919; *P*=.03) was evident on daily step count (Figure 3) in the studied period. Generally, the older group (ie, >50 years) moved less, with an average of 301 fewer steps than the younger group (ie, ≤ 50 years; Figure 3). A significant interaction effect between age and device type ($F_{1, 9031.59}$=24.764; *P*<.001) and a more detailed post hoc comparison showed a different pattern of change in step count between age groups according to the device used (Figure 3). In mobile users, the older group had initially higher step counts at the pre–COVID-19 period compared to the younger group (1344 steps) and were less affected by the first wave of COVID-19 (Figure 3). Step count of the older group, however, was significantly decreased at the second wave (–1545 steps at T11 as compared to pre–COVID-19; *P*<.001), which persisted through the entire second wave and most of the third wave. At the end of the studied period (T18), both groups regained pre–COVID-19 values, with the younger even presenting 1562 additional daily steps as compared to pre–COVID-19 (Figure 3). For pedometer users, a significant decrease in step count was recorded at the start of wave 1 for younger (–838 steps; *P*=.003) and older groups (–756 steps; *P*=.005). While the younger group's step count regained pre–COVID-19 values at the end of waves 2 and 3 with gradual increases recorded until the last phase (+699 steps compared to T0), the older group did not regain initial pre–COVID-19 values following restrictions of waves 2 and 3, with further decreases recorded at wave 3 (–1585 steps as compared to pre–COVID-19; *P*<.001) and significantly lower values at the last period (–768 steps) as compared to the pre–COVID-19 period (*P*=.48; Figure 3). Please refer to Tables S2 and S3 in Multimedia Appendix 1 for the average daily step count of each of the 19 studied periods for pedometer and mobile users, respectively, in all subgroups.

XSL•FO
RenderX

**Figure 3.** The 7-day moving average of daily step count for the younger (ie, ≤ 50 years) and older (ie, >50 years) groups within the studied period covering 1 year before COVID-19 (T0: January 1, 2019, to February 28, 2020) and the 3 COVID-19 waves (T1-T18: February 29, 2020, to February 28, 2023). Details on the 19 time points reflecting the implementation and lifting of restrictions are found in Table 1. Data from pedometer and mobile app users are presented separately.

### *Effect of COVID-19 Phases on Step Count by BMI Groups*

A significant effect of BMI ($F_{2, 362.63}$=4.210; *P*=.02) was shown on average daily step count in the studied time period (Figure 4). Findings indicated that the normal weight group had an average of 1191 and 1557 daily steps more than the overweight (*P*=.04) and obesity (*P*=.02) groups, respectively. No significant overall differences in daily step count were revealed between the overweight and obesity groups (*P*=.85). Although no significant interaction effect was found between BMI and device type ($F_{2, 507.93}$=1.459; *P*=.23), post hoc comparisons showed noteworthy differences between BMI groups using different devices (Figure 4). For instance, among mobile users, the normal weight group showed the highest fluctuations, with the different phases revealing significant decreases in step count following implementation of restrictions for wave 1 (–1276 steps compared to pre–COVID-19; *P*=.02) and a trend for wave 2 (–1070 steps compared to pre–COVID-19; *P*=.07), while no significant changes were recorded at wave 3 compared to the pre–COVID-19 period. At the end of each wave, the normal weight group recovered similar (slightly but not significantly higher) pre–COVID-19 values (Figure 4). For mobile users with overweight and obesity, less variations in step count were recorded with time. Specifically, the overweight group recorded an initial significant decrease in step count at the start of wave 1 (–691 steps compared to pre–COVID-19; *P*=.02) with no further changes until values significantly increased at the last phase of wave 3 when all restrictions were waived (+1744 step compared to pre–COVID-19; *P*<.001). The group with obesity only recorded a slight decrease of 769 steps at the start of wave 1 (compared to pre–COVID-19; *P*=.06) that persisted and became significant during wave 2 (–1259 steps compared to pre–COVID-19; *P*=.005). Slight increases in step count were seen for the group with obesity toward the end of the studied period, where daily step count regained their pre–COVID-19 values (*P*=.99; Figure 4). For pedometer users, the normal weight group recorded an initial significant decrease in values at the start of wave 1 (–1398 steps compared to pre–COVID-19; *P*=.001) and another larger significant decrease at the start of wave 2 (–1858 steps compared to pre–COVID-19; *P*<.001; Figure 4). After wave 2, values remained significantly lower until T17 (–1157 steps compared to pre–COVID-19; *P*=.02), and at the last studied period (T18), 1124 less steps were still noted compared to pre–COVID-19 (*P*=.08). The overweight group presented a similar pattern of change when compared to the pre–COVID-19 period. At the start of waves 1, 2, and 3, decreases of 995 steps (*P*=.002), 1145 steps (*P*=.002) and 1088 steps (*P*=.009) were respectively noted for the overweight group; however, an increase in values was also observed at the end of each wave with similar values noted at the end of the studied period as compared to pre–COVID-19 (Figure 4). Finally, no significant variations in step count were revealed throughout all waves for the group with obesity using the pedometer. Please

refer to Tables S2 and S3 in Multimedia Appendix 1 for the average daily step count of each of the 19 periods studied for pedometer and mobile users, respectively, in all subgroups.

**Figure 4.** The 7-day moving average of daily step count for groups of normal weight, overweight, and obesity within the studied period covering 1 year before COVID-19 (T0: January 1, 2019, to February 28, 2020) and the 3 COVID-19 waves (T1-T18: February 29, 2020, to February 28, 2023). Details on the 19 time points reflecting the implementation and lifting of restrictions are found in Table 1. Data from pedometer and mobile app users are presented separately.

## Qualitative Results

### *Overview*

This study explored the experiences of 9 participants regarding their PA habits during the COVID-19 pandemic. Participants provided insights into the impact of the pandemic on their PA routines, health behaviors, and motivations. The thematic analysis identified several key themes that were consistent across the transcripts. The pandemic had a significant impact on participants' PA behaviors, perceptions, and preferences.

### *The Importance and Awareness of PA*

All participants acknowledged the importance of PA for both physical and mental health. Many participants emphasized that exercise is vital for managing stress and maintaining overall well-being, especially during stressful times like the COVID-19 pandemic.

> *It's very important to me, especially, you know, for stress relief. PA makes me feel better.* [Participant 1, Male, 30-39 years old]
>
> *It's vital for keeping your body and mind in good shape ... in these times, it's even more important for me.* [Participant 4, Female, 30-39 years old]
>
> *PA helps to reduce stress.* [Participant 5, Male, 40-49 years old]
>
> *Very important to me and to everybody. The benefits, for example, nowadays, with everybody being full of stress, walking helps relief that.* [Participant 8, Female, 40-49 years old]

While all participants acknowledged the importance of PA, there were differences in how they prioritized exercise. Several participants, particularly those who had prepandemic gym routines, viewed PA as a key part of their lifestyle. Others, however, indicated that their exercise habits were less structured during the pandemic due to limited time or motivation.

### *Disruptions to Routine and Shifting to Alternatives*

The pandemic led to significant disruptions in participants' usual exercise routines. A total of 8 (89%) participants reported difficulty maintaining regular PA due to gyms closures, restricted access to outdoor spaces, and limited group fitness classes. Many of those participants transitioned to home-based exercises, including using fitness apps, virtual classes, and simple home exercises such as walking and rope jumping. However, limitations like space, lack of equipment, and safety concerns impacted the intensity and variety of exercises. The most notable difference was that participants who had relied heavily on gyms and group fitness classes before the pandemic, such as cycling and CrossFit, experienced a more significant disruption in their PA habits. In contrast, participants who engaged in outdoor activities, such as walking or running, were somewhat less affected.

XSL•FO
RenderX

*Before COVID, I used to go to the gym almost every day. After restrictions started, it became difficult to continue my routine.* [Participant 2, Female, 40-49 years old]

*I couldn't go to the gym during the lockdown, and gyms were closed, so I had to stop everything.* [Participant 3, Male, >50 years old]

*My usual routine was walking and cycling, but with the restrictions, I had to adjust to home-based workouts.* [Participant 6, Female, >50 years old]

*COVID impacted my PA a lot. All gyms closed, and I was stuck at home.* [Participant 9, Male, >50 years old]

*I started doing home workouts with an app. It helped me stay active, even if it was hard sometimes.* [Participant 1, Male, 30-39 years old]

*I found some virtual classes and YouTube tutorials. I joined a few online workouts but did mostly walking.* [Participant 4, Female, 30-39 years old]

*During the pandemic, I worked out at home mostly, with some virtual classes. It was a bit hard to stay motivated at times.* [Participant 5, Male, 40-49 years old]

*I was doing indoor exercises with an app. It was quite easy since I had enough time at home.* [Participant 9, Male, >50 years old]

### *Impact of COVID-19 on Lifestyle and Sedentary Behavior*

A total of 7 (79%) participants reported an increase in their sedentary behavior during the pandemic. Working from home, limited outdoor activities, and lockdowns led to an overall reduction in physical movement, contributing to a more sedentary lifestyle for some. Participants noted spending longer hours in front of screens, either working or watching TV, which led to a more sedentary lifestyle. Participants who had previously been more active reported a noticeable decrease in PA, with some struggling to maintain their prepandemic routines. On the other hand, 2 (22%) participants who were less active before the pandemic reported that the lockdowns did not significantly alter their sedentary behaviors.

*I didn't move much during COVID. Most of my time was spent on my bed, working and watching TV.* [Participant 5, Male, 40-49 years old]

*I found myself sitting for long periods while working from home. I wasn't as active as before.* [Participant 7, Male, 30-39 years old]

*During the lockdown, I stayed at home most of the time, and there were no real opportunities for exercise.* [Participant 9, Male, >50 years old]

*Sedentary behavior increased during the pandemic ... I was mostly indoors, working, and didn't get as much exercise as I wanted.* [Participant 2, Female, 40-49 years old]

### *Motivation and Support System*

Motivation was a key factor in maintaining regular PA during the pandemic. A total of 6 (67%) participants reported relying on external sources for motivation, such as family members, social media, or online fitness communities to continue exercising. However, 3 (33%) participants struggled with maintaining consistency due to isolation, lack of support, or insufficient motivation. Participants who had a structured workout routine before COVID-19 were often able to maintain higher levels of activity during the lockdown.

*Social media really helped me stay motivated. I followed a few trainers and exercise groups that kept me going.* [Participant 3, Male, >50 years old]

*My family was supportive. They helped me stick to my routine. My wife did exercises with me at times.* [Participant 8, Female, 40-49 years old]

*I tried to stay motivated, but it was hard at times. I had to find ways like using apps and following trainers online.* [Participant 4, Female, 30-39 years old]

*Sometimes I felt bored, and that's when I used YouTube videos or watched football to keep me motivated.* [Participant 8, Female, 40-49 years old]

### *Perceptions of Media and Communication During COVID-19*

The media played an important role in shaping participants' perceptions of COVID-19 restrictions and the importance of PA. A total of 8 (89%) participants mentioned that the media played an important role in shaping their perceptions of COVID-19 restrictions and the importance of PA. Social media influenced many participants by providing inspiration for home workouts, although some expressed feeling overwhelmed by conflicting advice on exercise and health.

*The media kept reminding us how important it is to stay active even at home. That kept me going.* [Participant 3, Male, >50 years old]

*Social media was very influential. I saw many people post about their home workouts and how to stay healthy. That motivated me to try new things.* [Participant 9, Male, >50 years old]

*The media coverage was helpful in showing us what exercises we could do at home to stay active during the pandemic.* [Participant 2, Female, 40-49 years old]

*Media has helped to remind us about the importance of being active during COVID. But sometimes it was overwhelming and confusing.* [Participant 8, Female, 40-49 years old]

### *Barriers to PA During the Pandemic*

Barriers such as lack of space, absence of equipment, and restrictions on outdoor activities were significant obstacles for participants trying to maintain regular exercise during the pandemic. A total of 7 (78%) participants reported facing significant barriers to maintaining PA during the pandemic.

XSL•FO
RenderX

These barriers included lack of space, absence of equipment, restrictions on outdoor activities, and psychological factors like reduced motivation or feeling overwhelmed by the stress of the pandemic. Those with access to outdoor spaces or home gyms had fewer barriers compared to those living in smaller apartments or with limited space. Additionally, participants who faced health issues or stress had more difficulty maintaining an active lifestyle during the pandemic.

> *I was missing my usual gym routine ... at home, I didn't have the right equipment, and the space was limited.* [Participant 5, Male, 40-49 years old]
>
> *The biggest barrier for me was not being able to go outside or go to the gym ... I didn't have enough space or equipment at home.* [Participant 7, Male, 30-39 years old]
>
> *It was hard to get motivated at home. And with all the stress of the pandemic, sometimes I just didn't feel like working out.* [Participant 4, Female, 30-39 years old]
>
> *The restrictions on outdoor activities were a big problem. It really affected my PA levels.* [Participant 8, Female, 40-49 years old]

### *Changes in PA Behavior After Lifting of Restrictions*

As COVID-19 restrictions were eased, 6 (67%) participants expressed a desire to return to their previous exercise routines, such as going back to the gym or engaging in group activities. However, 3 (33%) participants were still hesitant, preferring home-based workouts or smaller, less crowded exercise options due to lingering safety concerns.

> *Now that restrictions are lifted, I prefer going back to the gym. I missed the group classes.* [Participant 6, Female, >50 years]
>
> *I am still not comfortable going back to gyms. I prefer to continue exercising at home for now.* [Participant 4, Female, 30-39 years old]
>
> *I would like to use the gym, but you know, I have a gym at home. And the gym facilities outside are too expensive.* [Participant 8, Female, 40-49 years old]
>
> *I've started going back to the gym, but I am more cautious about the crowds. I prefer small group classes now.* [Participant 9, Male, >50 years old]

### *Reluctance to Return to Prepandemic Routines*

The long-term impact of COVID-19 on participants' PA habits was mixed. A total of 5 (56%) participants planned to continue with home-based exercises and more flexible routines post pandemic. Conversely, 4 (44%) participants were uncertain about how to reintegrate into their prepandemic activities. The pandemic also led some to reassess their health and fitness priorities. Mainly, those who had struggled to stay active during the pandemic showed uncertainty about returning to high-intensity or group activities.

> *I think after COVID, I will stick to some home exercises. It's more convenient for me.* [Participant 3, Male, >50 years old]
>
> *I don't think I will return to the same routine ... maybe I will walk more, but I don't see myself going back to the gym regularly.* [Participant 5, Male, 40-49 years old]
>
> *After all of this, I plan to keep working out at home. It fits my lifestyle better.* [Participant 6, Female, >50 years old]
>
> *I've been working out more at home during COVID, and I'll probably continue that for now.* [Participant 9, Male, >50 years old]

## Triangulation of Results

The use of methodological triangulation allowed for the integration of quantitative and qualitative strands, strengthening the interpretation of results. Patterns observed in step count data (such as declines during restriction phases, subgroup differences, and device-related discrepancies) were consistent with themes identified in interviews regarding disruptions to PA routines, motivational challenges, and adaptations to home-based exercise. Data triangulation further enriched the analysis by contrasting findings across devices (pedometer vs mobile phone) with participants' perceptions. This combined approach provided a more comprehensive understanding of PA behaviors during the COVID-19 pandemic and increased the rigor of the conclusions.

Increased sedentary behavior was noted in our analyses, linked to lockdown restrictions, working from home, and limited outdoor activity. Motivation emerged as a key factor in maintaining activity, with external support from social media and family playing a significant role. These qualitative insights were reflected in the quantitative data, which indicated that engagement with online communities helped sustain exercise habits.

Barriers such as limited space, lack of equipment, and psychological factors were consistent across both data sources. Qualitative findings further highlighted how these barriers were exacerbated by stress and mental health challenges, offering a deeper context to the quantitative results. Post pandemic, participants expressed mixed intentions about returning to prepandemic routines, with some preferring home-based workouts, which was also reflected in the quantitative data.

The quantitative finding that wave 2 produced the largest declines in step count, especially among older adults, was echoed in interview data: participants described heightened fear and caution, reporting that "with all the stress of the pandemic, sometimes I just didn't feel like working out" (Female, 30-39 years old). Similarly, discrepancies between pedometer and mobile users were contextualized by participants' reports of not always carrying phones during exercise or preferring home-based workouts, which may have reduced recorded steps ("I was doing indoor exercises with an app. It was quite easy since I had enough time at home" [Male, >50 years old]). On the other hand, while female mobile users recorded fewer steps than male users in the pre–COVID-19 phase, some women reported higher motivation after returning to work, which corresponded with the observed increase in their step counts in wave 3 ("My family was supportive. They helped me stick to

XSL•FO
RenderX

my routine" [Female, 40-49 years old]). These examples show where the qualitative themes supported or nuanced the quantitative results, highlighting both convergences and divergences.

The integration of findings through triangulation enhanced interpretive validity and underscored the value of mixed methods approaches in capturing both behavioral trends and contextual complexities. This convergence of evidence supports a more holistic understanding of PA adaptation during public health crises and informs future interventions that address both structural and psychosocial determinants.

## Discussion

### Main Findings

This study examined the impact of COVID-19 phases of restrictions on PA levels as measured by daily step count during the entire pandemic period spanning over the 3 waves. Results offer valuable insights into behavioral adaptations to restrictive measures while considering the influence of sex, age, nationality, and BMI, as well as the impact of the device used to track step count. Generally, the findings confirm significant declines in daily step count at the implementation of restrictions within each COVID-19 wave followed by a recovery of values toward the end of each wave. The latter is consistent with previous reports focusing on the first COVID-19 wave in Qatar [20] and elsewhere using community-based longitudinal interventions [34,35]. Barriers reported by participants included lack of space, absence of equipment, restrictions on outdoor activities, and psychological factors, such as reduced motivation, stress, or feeling overwhelmed.

The most pronounced decreases in PA were observed at the second wave, coinciding with the arrival of the Omicron variant in Qatar [36]. This aligns with reports of peak severity, criticality, and fatality in locally confirmed cases between March and May 2021 [37]. Heightened public fear and/or perceived risk, potentially leading to stricter adherence to restrictions, seemed to act as important barriers to PA behavior in the given context. Indeed, in addition to several barriers reported by interviewed participants, the stress of the pandemic and relative caution came up as limiting factors ("... and with all the stress of the pandemic, sometimes I just didn't feel like working out"; "... but I am more cautious about the crowds. I prefer small group classes now"). This interpretation might indicate that severity, criticality, and fatality of cases strongly advertised on social media platforms and news outlets might have played a critical role in PA level, rather than the reported number of daily confirmed cases that peaked at a different time. Additionally, the period between April 12 and May 12, 2021, characterized with the most severe drops in daily step counts, also coincided with the month of Ramadan, where Muslims fast from dawn to sunset and naturally decrease their daily steps [38]. Large vaccination campaigns and advances in case management were among the factors that favored a 95% drop in the rates of severe, critical, and fatal cases with a turning point recorded in March 2022 [37] where increases in daily step counts were noted.

A primary factor to consider in the interpretation is the discrepancy found in the patterns of change in recorded steps between pedometer and mobile phone users. Pedometer users recorded an average of 690 daily steps more than mobile users, consistent with previous literature. A previous study showed that step count was 12% lower in iPhone users as compared to pedometer users [39]. Although underestimations seen in mobile devices are mainly attributed to noncarrying time that is influenced by the setting or context (eg, being at home or outside), other factors are worth considering. Mobile carrying habits could explain sex differences found between device groups, as women might tend to favor carrying their phones in their bags and men in their pockets [39]. Additionally, pedometers are dedicated to activity tracking unlike mobile phones, and the simple fact of carrying one can alter behaviors. Findings from a previous study on the SIH population indicated that pedometer users were significantly more committed to uploading their data and presented higher retention to the program as compared to mobile users [30]. Authors suggested that offering a free pedometer might have enhanced feelings of responsibility and motivation toward the program [40]. Finally, mobile phones fail to account for steps during activities where it is impractical to carry a phone (eg, gym training or playing team or racket ball sports) [41] which could be favored by younger groups. A recurrent observation from the qualitative analysis is that most PA routines were shifted to home-based exercises (ie, "My usual routine was walking and cycling, but with the restrictions, I had to adjust to home-based workouts"; "I started doing home workouts with an app"; "I found some virtual classes and YouTube tutorials"; "During the pandemic, I worked out at home mostly, with some virtual classes"; "I was doing indoor exercises with an app"). It is reasonable to assume that tracking activity within a limited space at home is less practical with a mobile phone as compared to a dedicated activity tracker.

In this study, differences in step count between pedometer and mobile users varied from 609 to 1264 steps according to the studied phase, with the largest differences noted toward the end of all restrictions (ie, wave 3) where 100% of employees were back to work. These observations further confirm that steps recorded by mobile phones can easily underestimate actual daily step counts in certain contexts. Moreover, pedometer users might also represent the most motivated and health-conscious portion of the population. Regardless of the device used to track steps, results should be interpreted with caution, as findings could be conflicting when trying to compare data from pedometer and mobile over an extended period of time among different subgroups, each presenting specific characteristics that might either enhance or hinder step count. These findings show that while device-driven data present an increased objectivity as compared to self-reported measures, bias in activity tracking still exists based on the presented limitations.

Overall, the qualitative analysis points toward a reluctance to go back to pre–COVID-19 PA routines and shifting to exercise within the home context (ie, "I think after COVID, I will stick to some home exercises. It's more convenient for me"; "I don't think I will return to the same routine ... maybe I will walk more, but I don't see myself going back to the gym regularly"; "After

XSL•FO
RenderX

all of this, I plan to keep working out at home. It fits my lifestyle better"; "I've been working out more at home during COVID, and I'll probably continue that for now"). While this study examines perceptions of a population that is considered health-conscious, it reveals long-term or lasting implications of the pandemic on behaviors and perceptions, where leaving the house or being active in outdoor settings are less favored. This shift in behavior, pointing to a tendency to remain within a confinement "state of mind," could have significant implications for physical and mental health, especially with the emergence of the greater role of outdoor compared to indoor PA [42]. It is important to note, however, that while interpretations of potential long-term effects are limited to November 2022, this study is not able to report and/or speculate on any longer-term impacts on behavior beyond the studied time range. Findings do not represent current or ongoing trends and future research using more recent data is needed to determine whether observed changes persist over time.

While the literature is well supported by evidence on the effects of sex, age, and BMI on step count, or more recently on the impact of COVID-19 restrictions on step count, potential interactions between both categories of factors remain limited. In addition, discrepancies between data obtained from mobiles and pedometers add a layer of complexity to the interpretation that was not previously addressed in this context. Understanding these interactions is important to develop appropriate interventions and policies targeting the most vulnerable subgroups. Our findings point toward larger significant variations/fluctuations in step counts through restriction phases among male (compared to female) individuals, pedometer users (compared to mobile users), and normal weight participants (compared to individuals with overweight and obesity). At the pre–COVID-19 phase, these subgroups presented higher step count and were more affected by (or sensitive to) restrictive measures, which is in line with previous findings on Qatar's first COVID-19 wave [20]. Interestingly, male individuals, older individuals, and normal weight groups using pedometers did not recover their initial pre–COVID-19 step count (ie, –708, –768, and –1124 steps, respectively), while female individuals, younger individuals, and those living with overweight and obesity recovered their values recorded using pedometers. In contrast, all subgroups using their mobile regained their initial step count, and most presented significantly higher values at the end of wave 3 compared to pre–COVID-19, which is a novel result emerging from the inclusion of 2 assessment devices in this study.

In sum, the use of mobile apps to track daily steps warrants a deeper interpretation of the exact use of mobile during home confinement and possible PA opportunities. The perceptions of younger vs older individuals, and female vs male, are crucial in explaining discrepancies. Different patterns of home and outdoor activities and varying preferences for gym, walking, and other sports/exercises might explain differences between device users during this phase. Notably, women were possibly more occupied at home with childcare and household responsibilities and may have been more positively affected by the "return to work" at the end of the third wave, which is reflected in a substantial increase in their step counts at this time.

The triangulation of both qualitative and quantitative results reinforces these insights, with qualitative data providing deeper context on how different factors (eg, motivation, support systems, or media influences) shaped participants' PA behaviors during the pandemic. Ultimately, qualitative findings point at an important role of media and social media in favoring active lifestyles during periods of pandemic ("The media kept reminding us how important it is to stay active even at home"; "Social media was very influential. I saw many people post about their home workouts and how to stay healthy. That motivated me to try new things"; "The media coverage was helpful in showing us what exercises we could do at home to stay active during the pandemic"). It seems that remaining active was a common concern on social media that played an important motivating role; however, it was also perceived as overwhelming and confusing ("Media has helped to remind us about the importance of being active during COVID. But sometimes it was overwhelming and confusing"). Clear instructions and content on PA and exercise are essential during such periods and should be made available from reliable sources.

Finally, findings could be interpreted from the perspective of the social cognitive theory (SCT), which focuses on the reciprocal interaction between personal, behavior, and environmental factors [43,44]. According to this theoretical framework, the reduction in daily step count seen during restrictive phases or even during Ramadan supports the impact of environmental barriers on individual and collective behavior. Conversely, the gradual recovery of PA after the lifting of restrictions demonstrates the adaptive ability of motivated individuals to revert to usual PA as environments became more supportive. This goes in line with the SCT concept that environmental facilitators favor self-regulatory behavior. The characteristics of the studied population (eg, consistent engagement in tracking and uploading step count during the COVID-19 period and knowledge on the benefits of PA for health), which is likely to possess higher levels of self-efficacy as compared to the general population of Qatar, reflect an important determinant of PA behavior. Return to normal PA behavior with efforts to exercise from home show behavioral resilience throughout the pandemic in the sample studied. The reliance on social media for motivation and guidance, highlighted in the qualitative findings, aligns with SCT's concept of observational learning, where individuals learn behaviors through exposure to peer or media models. The availability of peer activity, health promotion campaigns, and online guidance for exercise during the COVID-19 have likely reinforced participants' motivation, therefore providing behavioral models at a time when usual opportunities were limited [45]. Overall, this interpretation is consistent with previous studies showing that access to supportive environments and modeled behaviors play an important role in sustaining PA during disruptive events [46]. Future research should explicitly measure SCT constructs such as self-efficacy, outcome expectations, social support, and observational learning to identify correlates and predictors of resilience or vulnerability in PA behavior [47], and to provide

XSL•FO
RenderX

stronger public health interventions based on theoretical foundations.

### Limitations

In addition to the main limitation noted earlier in the step count bias associated with the use of pedometers and mobile phones (eg, noncarrying time, carrying habits, type of activities, and settings), several other limitations should be acknowledged. While the exclusion criteria applied for this study are necessary for the analysis, the retained sample comprised health-conscious individuals who continued tracking their step count through the entire COVID-19 period and regularly uploaded their activity data. Therefore, the studied sample differs from the general population of Qatar and potentially from the initial SIH cohort. A previous SIH study on 16,711 participants reported a 50% retention rate from 2012 to 2019 and a 16% adherence rate to daily data uploading [30]. The SIH is a self-managed and voluntary program designed to increase PA among the adult population of Qatar. The program has already proved its effectiveness in increasing average daily step count at the 12th month of enrollment compared to baseline data [28], that may represent more closely PA levels of the general population of Qatar. Together, this information suggests that the requirement for continuous valid step data across the 3 COVID-19 waves likely produced a subgroup of the most active participants characterized by the highest retention and adherence to the program. These factors limit the generalizability of our findings to the wider population of Qatar and should only represent the most active portion of the population. Moreover, it is important to consider the unique environmental and cultural context of Qatar, which may further limit the generalizability of the results to other countries outside of the Gulf Peninsula region. Extreme summer temperatures, often exceeding 40 °C, can substantially restrict outdoor PA and may have influenced step count at both baseline and periods of COVID-19 restrictions. Cultural norms, including gender-specific expectations for outdoor activity and preferences for indoor vs outdoor exercise, further shape patterns of PA in the studied population of Qatar.

A further limitation is that participants were recruited for the interviews through random selection rather than purposive sampling informed by device type, activity level, or BMI. While this strategy minimized researcher bias and still yielded diversity in age and sex, it may have missed key perspectives. The interviews' small sample size (n=9) reached thematic saturation for the main themes identified, but limits the depth of subgroup-specific insights. Future studies could purposively recruit participants based on characteristics identified in the quantitative strand to strengthen the integration of mixed methods findings. Although participants' narratives sometimes referred to their use of social media for exercise motivation, no social media tracking or collection of identifiable data occurred. This reliance on self-reported perceptions avoids privacy risks but also limits the depth of analysis on media use.

### Conclusions

The findings from this study emphasize the need for caution when interpreting step count data from mobile devices for research purposes, as measurement accuracy may vary by context, individual factors (eg, age, sex, and BMI), user behavior, and preference of certain types of activities. With the advancements of wearable multisensor devices, future studies should account for potential bias and limitations associated with the use of mobile phones and pedometers as PA data collection tool. The COVID-19 pandemic has taught us a lesson supported by the data of this study: developing tailored interventions should aim to encourage outdoor activities after confinement periods and provide reliable social media sources for PA and exercise across diverse populations. It is crucial to consider the contextual (eg, severity, criticality, and fatality of cases) and personal factors (eg, psychological, age, and sex) that influence PA behavior during public health crises such as the COVID-19 pandemic, where long-term consequences are observed in PA behaviors.

## Data Availability

All data generated or analyzed during this study are included in this published article and its supplementary information file.

## Funding

Funding for the thematic analysis and interviews' recording was obtained through a Qatar University High Impact Grant led by Eirini Theodoropoulou and co-led by LM. The funder had no involvement in the study design, data collection, analysis, interpretation, or the writing of the manuscript.

## Authors' Contributions

Conceptualization: MC, ASA-M
Methodology: MC, SS, AF, LM, ASA-M
Formal analysis: AF, LM, SS
Interview administration and curation: FD
Writing of the original draft preparation: LM, SS
Project administration: AF, ASA-M, SS, LM
All authors have contributed to the review and editing and have read and agreed to the published version of the manuscript.

## Abstract

**Background:** Long-term surveillance of out-of-hospital cardiac arrest (OHCA) survivors is increasingly important, but patients who survive a second OHCA are rarely characterized because of the scarcity of such cases. The nationwide claims-based health data provide an opportunity to identify this uncommon survivor population and evaluate postdischarge outcomes at the population level. Understanding the prognosis and care needs of second-time OHCA survivors may help inform postarrest surveillance, risk stratification, and long-term care planning.

**Objective:** This study aimed to compare the clinical characteristics of adult patients who survived a single OHCA versus those who survived a second OHCA during a 5-year follow-up and assess and contrast their 5-year survival outcomes.

**Methods:** We conducted a nationwide retrospective cohort study using data from the National Health Insurance Research Database (2010-2020) in Taiwan. Survivors at discharge were classified as 1-OHCA survivors, defined as patients who survived exactly 1 OHCA episode and had no documented recurrent OHCA during follow-up, or 2-OHCA survivors, defined as patients who experienced exactly 2 documented OHCA episodes and survived to discharge after both events. Patients with more than 2 OHCA episodes were excluded. Postdischarge survival was measured from the qualifying discharge date: discharge after the first OHCA for 1-OHCA survivors and discharge after the second OHCA for 2-OHCA survivors. Variables included demographics, comorbidities, health care use, and life-sustaining device status. Five-year mortality was analyzed using the Kaplan-Meier and log-rank tests. Adjusted hazard ratios were derived from multivariable Cox models. Device use patterns were compared using Cochran-Armitage trend tests.

**Results:** Among 239,929 OHCA cases, 229,047 were eligible; 15,617 survived to hospital discharge. Five-year mortality was substantially higher among 2-OHCA survivors than among 1-OHCA survivors (191/201, 95% vs 6850/14,494, 47.3%; log-rank $P$<.001). In patients with 1 OHCA, mortality increased with age, male sex, and nasogastric tube use, whereas >3 outpatient visits, Foley catheter use, and tracheostomy or ventilation were associated with lower observed postdischarge mortality. In the 2-OHCA group, the rate of device-free status was lower, while the triple-device use rate was higher.

**Conclusions:** In this nationwide claims-based surveillance study, patients who survived discharge after a second OHCA represented a rare and clinically vulnerable postarrest population with poor subsequent 5-year survival and greater life-sustaining device dependence. Device-related variables should be interpreted as claims-based markers of postdischarge dependency, care setting, survivorship, and care intensity rather than evidence that device placement itself improves survival. As 2-OHCA survivor status is conditional on survival to a second OHCA and discharge after that event, these findings should be interpreted as descriptive and hypothesis-generating rather than causal. Population-level health data may support long-term postarrest surveillance and care planning for rare OHCA survivor populations.

## Introduction

Out-of-hospital cardiac arrest (OHCA) remains a global health burden with persistently low survival rates, despite advancements in emergency care. For example, in the United States, survival to hospital discharge following emergency medical service–treated OHCA is approximately 9% to 10% [1,2], while in Asia, the survival rate ranges between 3% and 8% [3,4]. With the increasing implementation of guideline-based resuscitation, a rising number of OHCA patients survive until hospital discharge. These patients require long-term follow-up [5].

Recognizing this clinical shift, the 2020 American Heart Association Guidelines introduced "recovery" as the sixth link in the chain of survival, emphasizing the importance of long-term surveillance and care for OHCA survivors [6]. However, there has been limited attention to the long-term trajectories of these survivors, particularly those who experience second OHCA events postdischarge [7,8]. Of the OHCA survivors, 6% to 10% experience a second cardiac arrest, often within the first year of discharge [7,9]. While a second OHCA is associated with exceedingly high mortality, data regarding patients who suffer a second OHCA and survive remain scarce. No study has systematically compared the survival patterns and baseline characteristics of patients who survive 1 OHCA with those who survive 2.

Survivors of 1-OHCA face increased risks of neurological injury, cardiovascular events, and long-term mortality [10,11]. Surviving 2 OHCA episodes may lead to greater physiological compromise, including cumulative hypoxic brain injury and myocardial dysfunction, which could profoundly influence long-term survival. Understanding whether the trajectories of these 2 groups diverge in terms of both survival curves and comorbidity profiles is crucial for planning postresuscitation care, developing rehabilitation strategies, and allocating resources.

Identifying patients who survive 2 OHCA events poses a substantial methodological challenge owing to the rarity of such events. Indeed, most single-center or regional databases lack sufficient sample sizes to permit meaningful analyses. To overcome this limitation, we leveraged Taiwan's National Health Insurance Research Database (NHIRD), a comprehensive nationwide claims-based database that captures nearly all medical events among 23 million residents [12].

From a public health surveillance perspective, 2-OHCA survivors represent a rare but high-risk population that is difficult to characterize using single-center registries or conventional clinical cohorts. Nationwide administrative claims databases can function as longitudinal health surveillance infrastructure by enabling identification of uncommon survivor populations, monitoring of long-term mortality, and assessment of postdischarge care dependency at the population level. Using a nationwide claims-based surveillance database, this study aimed to compare clinical characteristics, health care use, life-sustaining device dependence, and subsequent postdischarge survival between adult 1-OHCA and 2-OHCA survivors.

## Methods

### Study Design and Setting

This retrospective study used data from the Taiwan NHIRD. Established in 1995 under the nation's single-payer National Health Insurance program, the NHIRD contains comprehensive claims information for more than 23 million citizens, covering >99% of Taiwan's population [13]. These data include registries of insured individuals, diagnostic codes, outpatient and inpatient visits, prescriptions, and other relevant health care variables, forming a powerful resource for population-based and epidemiological research [13,14]. Additionally, the NHIRD can be linked to disease-specific registries and other government datasets, substantially augmenting real-world evidence generation [15]. To protect patient privacy, rigorous deidentification procedures and ethical oversight protocols are in place, ensuring that individual identities remain anonymous while allowing researchers to conduct robust retrospective analyses.

### Ethical Considerations

This study was approved by the institutional review board of the National Taiwan University Hospital (approval number 202502001RINC). The requirement for informed consent was waived by the institutional review board because this was a retrospective analysis using anonymized data. To protect patient privacy and confidentiality, all data used in the analysis were anonymized before access by the study investigators, and no directly identifiable personal information, such as names, medical record numbers, or other individual identifiers, was included in the analytic dataset or reported in the manuscript. The data were used solely for the purposes approved by the institutional review board. Because this study involved secondary analysis of existing anonymized data and did not involve direct contact with patients or prospective participant enrollment, no compensation was provided to participants. All study procedures adhered to relevant ethical standards and regulations, including the principles outlined in the Declaration of Helsinki [16].

### Study Population and Eligibility Criteria

We identified patients who experienced OHCA between 2010 and 2020 by querying the NHIRD. To be included, individuals had to present to the emergency department (ED) with a triage level of 1 and documented *International Classification of Diseases* (*ICD*) codes reflecting cardiac arrest (*ICD-9*: 427.4, 427.5, 798, 798.1, 798.2, 798.9, and 799.9; *ICD-10*: I46, I46.2,

XSL•FO
RenderX

I46.8, I46.9, and I49.0). Both *ICD-9* and *ICD-10* were used owing to the nationwide transition from the former coding system to the latter, which occurred after 2016. We excluded cases in which OHCA was attributed to traumatic events, individuals aged <18 years, and instances in which the recorded date of death preceded the OHCA. These criteria were designed to focus on the analysis of nontraumatic OHCA and ensure proper assessment of the risk factors for subsequent OHCA among survivors.

### Cohort Definition: 1-OHCA and 2-OHCA Survivors

First-event OHCA survivors (1-OHCA survivors) were defined as patients who had exactly 1 documented nontraumatic OHCA episode during the study period, survived to hospital discharge after that episode, and had no subsequent documented OHCA during follow-up. Second event OHCA survivors (2-OHCA survivors) were defined as patients who had exactly 2 distinct documented nontraumatic OHCA episodes during the study period and survived to hospital discharge after both events. In this study, survival to hospital discharge was operationalized as the absence of a death record in the NHIRD at the time of discharge. These definitions ensured that the 2 analytic groups were mutually exclusive: patients classified as 2-OHCA survivors were not counted as 1-OHCA survivors. Patients with 3 or more documented OHCA episodes were not included in the analytic cohort because such cases were exceedingly rare, typically limited to single-digit counts, and were subject to NHIRD privacy protection restrictions for rare and potentially identifiable cases. Accordingly, we used the term 2-OHCA survivors, rather than ≥2-OHCA survivors, throughout the revised manuscript to accurately reflect the analytic cohort.

### Covariates and Operational Definitions

For all covariates used in the mortality models, the anchor time was defined as the discharge date after the qualifying OHCA event: discharge after the first OHCA for 1-OHCA survivors and discharge after the second OHCA for 2-OHCA survivors. All covariates were entered into the Cox models as fixed baseline variables and were not updated during follow-up.

The variables were grouped into 4 main categories—demographic characteristics, comorbidities, health care use, and daily functional status—to characterize differences between 1-OHCA and 2-OHCA survivors and to evaluate factors associated with postdischarge mortality within each survivor group. Demographic characteristics included age and sex. Comorbidities included diabetes mellitus, hypertension, hepatitis, chronic kidney disease, asthma, peptic ulcer disease, heart disease, cancer, cerebrovascular disease, hyperlipidemia, chronic obstructive pulmonary disease, and liver cirrhosis, each identified using insurance claims and prescription histories before the anchor date. Health care use variables were assessed using prespecified look-back windows before the anchor date, including intensive care unit (ICU) admission within the previous 365 days, renal dialysis for more than 3 consecutive months, more than 3 outpatient visits within the previous 30 days, and more than 2 ED or inpatient visits within the previous 30 days. Daily functional status was approximated using claims-based indicators of nasogastric tube placement, Foley catheter use, and tracheostomy with long-term mechanical ventilation before or at the qualifying discharge, which served as surrogate markers of functional dependency and ongoing care needs at the start of mortality follow-up.

### Statistical Analysis

Descriptive statistics were used to summarize baseline characteristics, health care use, comorbidities, and life-sustaining device use. Continuous variables were compared using Student's *t* test, and categorical variables were compared using the chi-square test or Fisher exact test, as appropriate. We performed Kaplan-Meier analyses to describe postdischarge survival trajectories among 1-OHCA and 2-OHCA survivors, and differences in survival distributions were assessed using the log-rank test [17]. For 1-OHCA survivors, follow-up began at discharge after the first OHCA; for 2-OHCA survivors, follow-up began at discharge after the second OHCA. As the 2-OHCA survivor status is conditional on surviving the recurrent event and discharge, the survival curves were interpreted as descriptive postdischarge prognostic comparisons rather than causal estimates of the effect of recurrent OHCA.

To identify factors associated with postdischarge mortality within each survivor group, we first performed univariate Cox proportional hazards regression analyses for candidate variables. Variables with a univariate *P* value <.10 were considered for inclusion in the multivariable Cox proportional hazards models. Clinically important covariates, including age and sex, were also considered for inclusion when appropriate. The 1-OHCA and 2-OHCA groups were modeled separately, and adjusted hazard ratios (aHRs) with 95% CIs were reported. As the 2-OHCA survivor subgroup was relatively small, we used a parsimonious modeling strategy to reduce overfitting and model instability. Variables with sparse distributions, complete or near-complete separation, or unstable estimates were not forced into the final 2-OHCA model. The proportional hazards assumption was assessed for retained covariates using Schoenfeld residuals and graphical inspection of log-minus-log survival plots. No major violation of the proportional hazard assumption was identified [18].

On the basis of clinical considerations, ICU admission and more than 2 ED or ward hospitalizations were not included in the multivariable models because these variables were closely related to disease severity, ventilator use, and subsequent care intensity, and therefore could introduce collinearity or overadjustment. Device use patterns were compared between groups using Cochran-Armitage trend tests. All statistical analyses were performed using SAS software (version 9.4; SAS Institute). Statistical significance was defined as a 2-sided *P* value of <.05.

## Results

### Overview

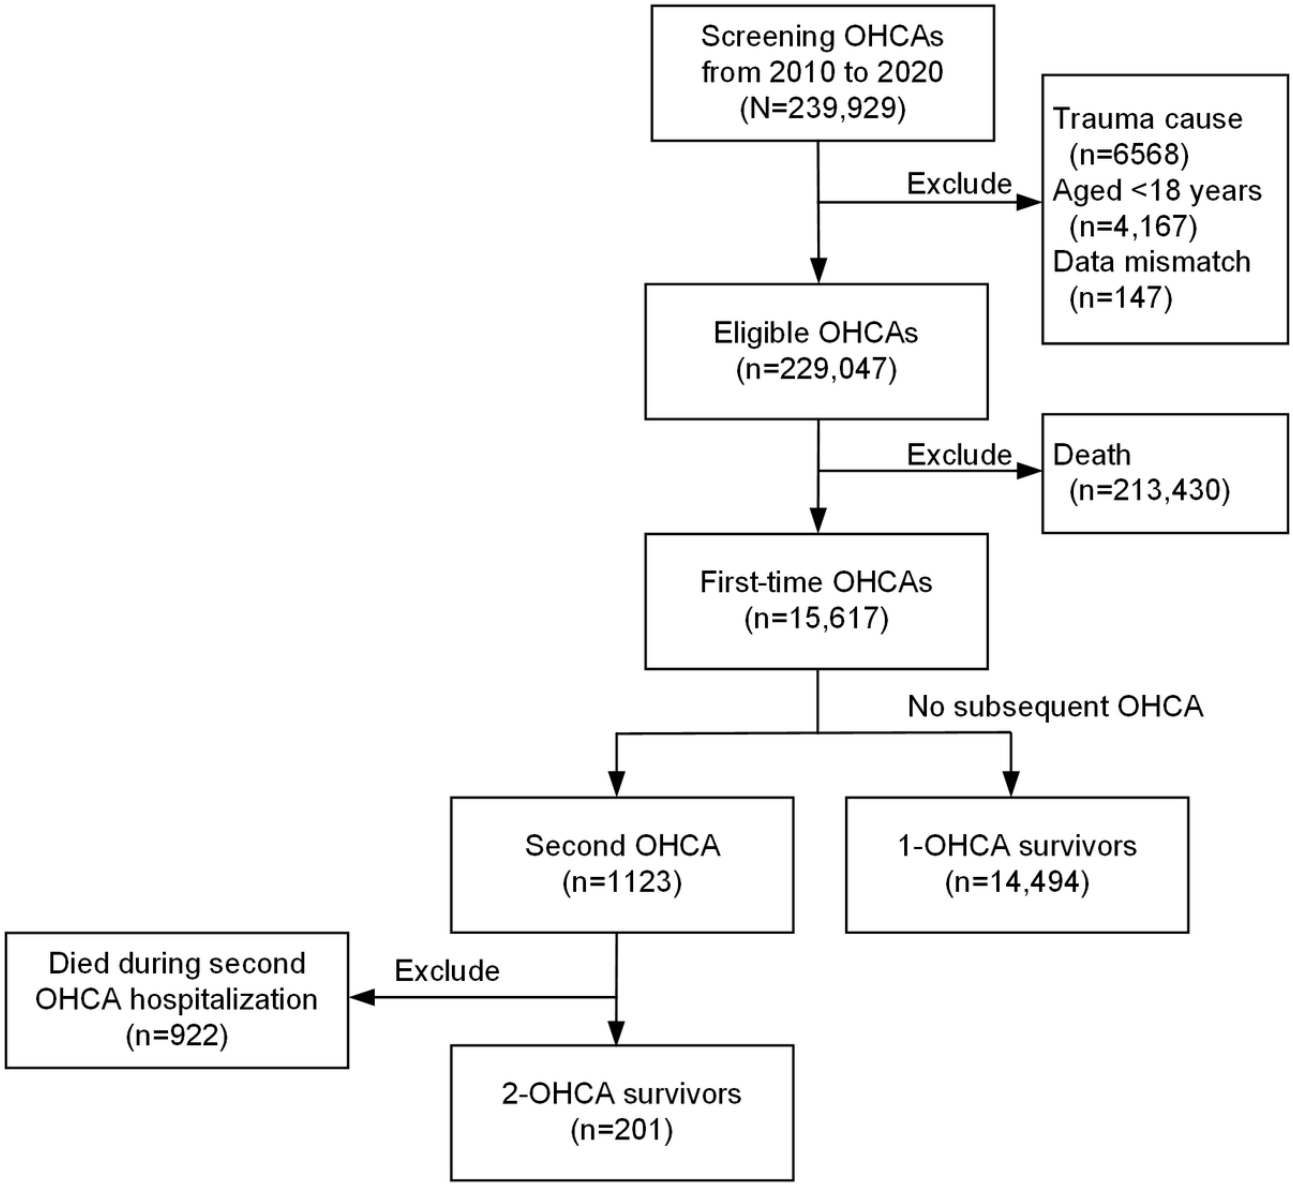

Figure 1 illustrates the patient selection process for the study cohort from 2010 to 2020. Among the 15,617 patients who survived to discharge after a first OHCA, 14,494 had no documented recurrent OHCA during follow-up and were classified as 1-OHCA survivors. A total of 1123 patients experienced a second OHCA. After excluding patients who died

XSL•FO
RenderX

during the hospitalization for the second OHCA event (n=922), 201 patients who survived to discharge after both OHCA events were classified as 2-OHCA survivors.

**Figure 1.** Flow diagram of cohort selection and group classification.

## Baseline Characteristics of the Groups

Table 1 presents the demographics, health care use, life-sustaining interventions, and comorbidities between 1-OHCA and 2-OHCA survivors. Patients in the 2-OHCA group were older (mean 63.13, SD 13.64 years vs mean 60.95, SD 17.42 years; *P*=.02), but sex distribution was similar between groups (127/201, 63.18% vs 8563/14,494, 59.08%; *P*=.24). Use of health care facilities was consistently higher in the 2-OHCA group, including ICU admission (103/201, 51.24% vs 4897/14,494, 33.79%; *P*<.001) and ED visits and/or ward hospitalizations >2 times (117/201, 58.21% vs 7351/14,494, 50.72%; *P*=.03). The rate of life-sustaining device use was significantly higher in the 2-OHCA cohort: nasogastric tube (148/201, 73.63% vs 6752/14,494, 46.58%; *P*<.001), Foley catheter (138/201, 68.66% vs 6339/14,494, 43.74%; *P*<.001), and tracheostomy with ventilator support (92/201, 45.77% vs 3185/14,494, 21.97%; *P*<.001). However, no significant differences between the groups were found in preexisting comorbidities such as diabetes mellitus, hypertension, chronic kidney disease, and liver cirrhosis.

[a]The qualifying discharge date was discharge after the first OHCA for 1-OHCA survivors and discharge after the second OHCA for 2-OHCA survivors. 1-OHCA survivors: survivors with only one OHCA event. 2-OHCA survivors: survivors with exact 2 OHCA events.

[b]ICU: intensive care unit.

[c]Assessed within the 365 days before the qualifying discharge date.

[d]Assessed within the 30 days before the qualifying discharge date.

[e]ED: emergency department.

## Multivariable Cox Regression Models for Postdischarge Mortality

Table 2 summarizes the multivariable Cox regression analyses evaluating factors associated with postdischarge mortality separately among 1-OHCA and 2-OHCA survivors. In the 1-OHCA group, mortality risk increased with older age (aHR 1.033 per year, 95% CI 1.031-1.035; *P*<.001), male sex (aHR 1.332, 1.268-1.399; *P*<.001), nasogastric tube placement (aHR 2.839, 95% CI 2.622-3.074; *P*<.001), diabetes mellitus (aHR 1.248, 95% CI 1.172-1.328; *P*<.001), chronic kidney disease (aHR 1.358, 95% CI 1.254-1.471; *P*<.001), and cancer (aHR 1.268, 95% CI 1.136-1.414; *P*<.001). Conversely, >3 outpatient visits within 30 days (aHR 0.236, 95% CI 0.224-0.249; *P*<.001), Foley catheter use (aHR 0.905, 95% CI 0.842-0.972; *P*=.006), and tracheostomy or ventilator support (aHR 0.786, 95% CI 0.742-0.832; *P*<.001) were associated with lower observed postdischarge mortality in the multivariable model. These associations should be interpreted as statistical associations rather than evidence of causal protection.

[a]The qualifying discharge date was discharge after the first OHCA for 1-OHCA survivors and discharge after the second OHCA for 2-OHCA survivors. 1-OHCA survivors: survivors with only 1 OHCA event. 2-OHCA survivors: survivors with exact 2 OHCA events. Variables were retained in each multivariable Cox model based on univariate screening, clinical relevance, and model stability. Sparse variables with unstable estimates were not included in the final 2-OHCA model.

[b]aHR: adjusted hazard ratio.

[c]Indicates variables not retained in the final multivariable Cox model.

[d]ICU: intensive care unit.

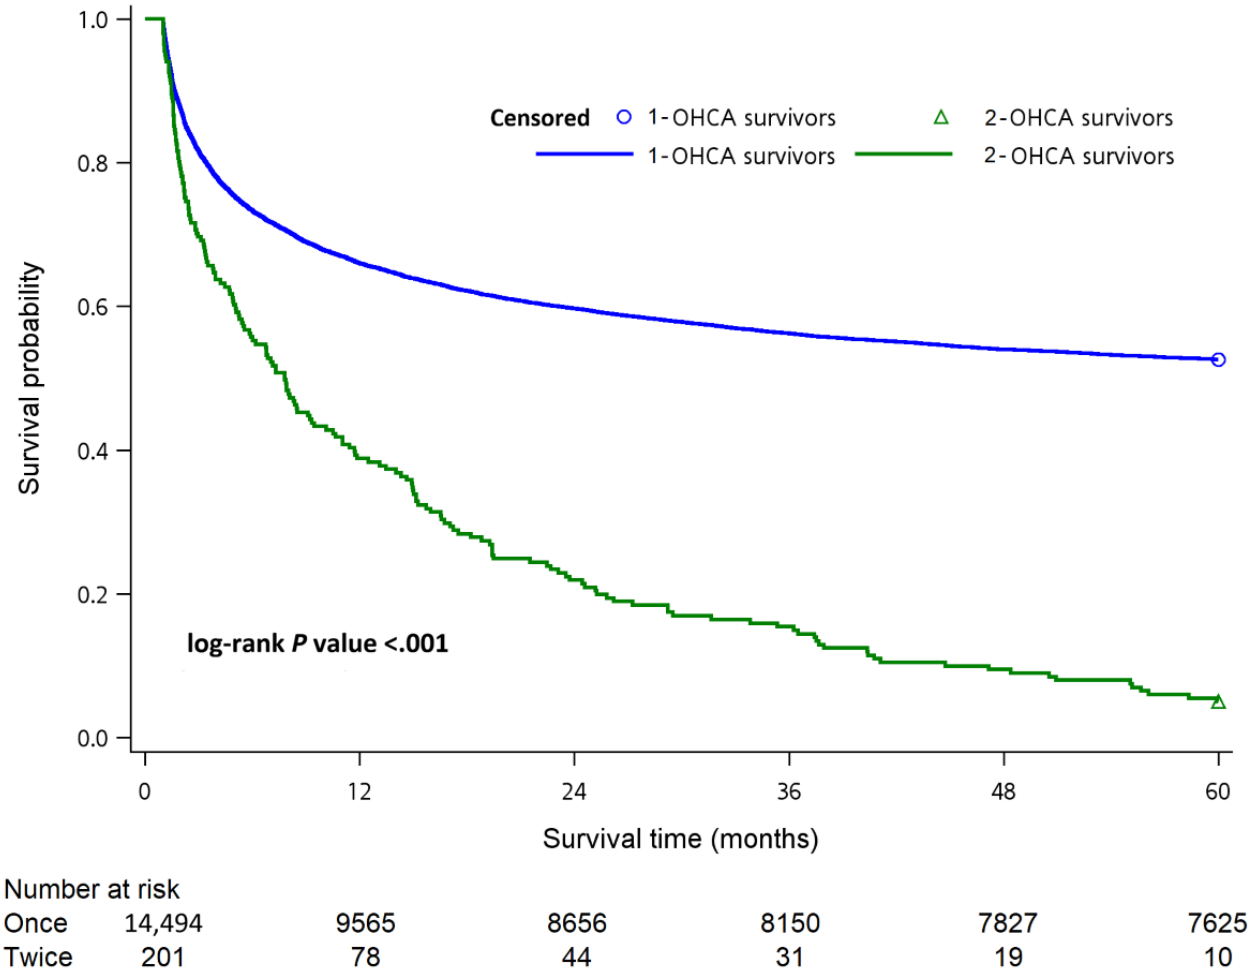
[e]Assessed within the 365 days before the qualifying discharge date.

[f]Assessed within the 30 days before the qualifying discharge date.

[g]ED: emergency department.

In the 2-OHCA group, although age and sex were clinically important covariates, they were not significantly associated with postdischarge mortality in the univariate Cox regression analysis among 2-OHCA survivors. Given the limited sample size of this subgroup, we did not force these variables into the final model to avoid overfitting and unstable estimates. Lower observed postdischarge mortality was associated with >3 outpatient visits (aHR 0.356, 95% CI 0.259-0.488; *P*<.001), Foley catheter use (aHR 0.469, 95% CI 0.277-0.795; *P*=.005), and tracheostomy or ventilator support (aHR 0.563, 95% CI 0.392-0.809; *P*=.002). No comorbidity was significantly associated with mortality in this subgroup.

The final Cox model for 1-OHCA survivors included 6850 mortality events among 14,494 patients (47.3%). The final Cox model for 2-OHCA survivors included 191 mortality events among 201 patients (95.0%). As the 2-OHCA survivor subgroup had a small overall sample size despite a high number of mortality events, we used a parsimonious modeling strategy to reduce overfitting and model instability. Variables with sparse



XSL•FO
RenderX

distributions, complete or near-complete separation, or unstable estimates were not forced into the final 2-OHCA model.

### Survivors of 2-OHCA Had Significantly Worse Long-Term Survival

Figure 2 shows the Kaplan-Meier curves describing survival after discharge from the qualifying OHCA event. For 1-OHCA survivors, follow-up began at discharge after the first OHCA; for 2-OHCA survivors, follow-up began at discharge after the second OHCA. The 1-OHCA survivor cohort demonstrated a consistently higher postdischarge survival probability than the 2-OHCA survivor cohort. The survival curve of the 2-OHCA group declined steeply during the first year after discharge from the second OHCA. By 60 months, survival remained substantially lower in the 2-OHCA group than in the 1-OHCA group. The log-rank test showed a statistically significant difference between the survivor-defined groups (*P*<.001). As 2-OHCA group membership is conditional on surviving the second OHCA hospitalization, this comparison should be interpreted as a descriptive prognostic comparison rather than a causal estimate of the effect of recurrent OHCA.

**Figure 2.** Kaplan-Meier survival curves for 1 out-of-hospital cardiac arrest (OHCA) and 2-OHCA survivors.

### The Distribution of Life-Sustaining Indwelling Device Patterns Among Survivors

Table 3 compares patterns of life-sustaining indwelling device use between 1-OHCA and 2-OHCA survivors. The rate of only Foley catheter use was lower in the 2-OHCA survivors compared with 1-OHCA survivors (5/201, 2.49% vs 704/14,494, 4.86%; *P*=.02). The rate of combined nasogastric tube and Foley catheter use was higher in 2-OHCA survivors (50/201, 24.88% vs 2938/14,494, 20.27%; *P*=.02). Most notably, the rate of using all 3 indwelling devices was significantly higher in 2-OHCA survivors (81/201, 40.30% vs 2642/14,494, 18.23%; *P*<.001), while the rate of patients requiring none of the catheters was markedly lower (45/201, 22.39% vs 6922/14,494, 47.76%; *P*<.001). Other patterns, including nasogastric tube-only, ventilator-only, and 2-device combinations, did not significantly differ between the groups.

XSL•FO
RenderX

**Table 3.** Patterns of life-sustaining indwelling catheter in 1 out-of-hospital cardiac arrest (OHCA) versus 2-OHCA survivors.

| | 1-OHCA survivors, n (%) | 2-OHCA survivors, n (%) | *P* value |
|---|---|---|---|
| Only nasogastric tube | 745 (5.14) | 9 (4.48) | .55 |
| Only Foley catheter | 704 (4.86) | 5 (2.49) | .02 |
| Only ventilator | 61 (0.42) | 1 (0.50) | .81 |
| Nasogastric tube combined with Foley catheter | 2938 (20.27) | 50 (24.88) | .02 |
| Foley catheter combined with ventilator | 55 (0.38) | 2 (1.00) | .05 |
| Nasogastric tube combined with ventilator | 427 (2.95) | 8 (3.98) | .22 |
| Combination of all 3 life-sustaining indwelling catheters | 2642 (18.23) | 81 (40.30) | <.001 |
| None of the above | 6922 (47.76) | 45 (22.39) | <.001 |

# Discussion

## Principal Findings

In this nationwide cohort, patients who survived discharge after a second OHCA had substantially poorer subsequent postdischarge survival than patients who survived a single OHCA and had no documented recurrence. As 2-OHCA survivor status was conditional on survival after the first OHCA, occurrence of a second OHCA, and survival to discharge after the second event, this comparison should be interpreted as a descriptive postdischarge prognostic comparison between survivor-defined groups rather than as evidence that the second OHCA itself caused poorer long-term survival. Moreover, the factors statistically associated with mortality in this group differed from those observed in 1-OHCA survivors and included claims-based indicators of life-sustaining device use. These device-related variables should be interpreted as markers of postdischarge dependency, care setting, and survivorship rather than as causal determinants of survival. Marked disparities in device dependence were also observed, whereas a substantial proportion of 1-OHCA survivors lived without supportive devices, and fewer than one-fourth of 2-OHCA survivors achieved device-free survival.

## Clinical Registry Versus Population-Level Registry

The study by Awad et al [19] examined 1-year survival among hospital discharge OHCA survivors using linked clinical registry and administrative data in British Columbia and were able to adjust for key OHCA characteristics and prehospital variables, including arrest location, witnessed status, bystander cardiopulmonary resuscitation, initial rhythm, and in-hospital interventions. In contrast, the NHIRD provides nationwide longitudinal coverage that allowed us to identify the extremely rare 2-OHCA survivor population, but it lacks granular resuscitation variables and direct neurological outcomes. This contrast highlights the trade-off between clinical granularity and population-level scale. Additionally, these findings highlight the value of population-level claims data for postarrest surveillance, particularly for rare survivor-defined groups that are difficult to evaluate in traditional clinical datasets.

## Explaining the Divergent Regression Models

The 2-OHCA survivors in our cohort constitute an even rarer, doubly selected population: those who survived the initial OHCA experienced a subsequent event and remained observable during the 5-year follow-up. This conditioning introduces a "depletion of susceptibles" effect [20] and attenuates the prognostic value of baseline comorbidities. Accordingly, traditional covariates (eg, age, male sex, diabetes, chronic kidney disease, and cancer) maintain strong associations with mortality in 1-OHCA survivors, whereas in 2-OHCA survivors, these associations are largely diminished or no longer significant. Instead, the current physiological status and context of care have become dominant determinants.

The pattern of device-related variables illustrates this shift. Among 1-OHCA survivors, nasogastric tube use is independently associated with higher mortality, likely reflecting dysphagia, frailty, and aspiration risk. In contrast, among 2-OHCA survivors, the prognostic impact of nasogastric tube use disappears, and survival is more closely associated with stable, organized support systems. Notably, the inverse associations observed for Foley catheter use and tracheostomy with ventilator support should not be interpreted as evidence that device use causally reduces mortality. More plausibly, these device-related variables reflect survivorship conditioning and postdischarge care context. Patients who were stable enough to receive long-term device support and survive to hospital discharge had already passed through the highest-risk phase after OHCA, whereas patients who died early would not have been observed as chronic device users in the postdischarge setting. Therefore, Foley catheter use and tracheostomy with ventilator support may serve as claims-based markers of survivorship rather than protective interventions.

## Increased Device Dependence After a Second OHCA

We also observed a significant shift toward increased dependence on life-sustaining indwelling devices in the 2-OHCA group. Single device use has been increasingly replaced by the concurrent use of multiple devices. Among the few individuals who remained device-free after recurrence, the absence of life-sustaining indwelling devices may indicate lower postdischarge dependency. However, because neurological outcomes were not available in the NHIRD, favorable neurological recovery cannot be directly inferred from these claims-based indicators. These observations are consistent with the regression results: in 2-OHCA survivors, mortality risk was more closely associated with current support status rather than with baseline comorbidities.

XSL•FO
RenderX

The distribution of device use patterns significantly differed between 1-OHCA and 2-OHCA survivors. Device dependence is an informative claims-based marker of ongoing vulnerability among 2-OHCA survivors. However, causality cannot be inferred. The prominence of device-related variables in the regression models may reflect disability severity, survivorship, care setting, care intensity, or unmeasured confounding rather than a direct effect of the devices themselves. These findings suggest that postdischarge dependency and care needs should be incorporated into risk stratification and follow-up planning, but they should not be interpreted as evidence that device placement is beneficial. Our findings highlight the importance of incorporating the device status into post-OHCA risk stratification and follow-up planning. The underlying mechanisms linking device dependence, care setting, and long-term survival require further investigation.

### Limitations

In this nationwide, population-based dataset, the scale and completeness enabled survival analyses that are rarely feasible even in large multicenter cohorts and clarified how risk structures differ between 1-OHCA and 2-OHCA cohorts. However, several methodological limitations should be emphasized. First, classification as a 2-OHCA survivor was conditional on surviving long enough after the first OHCA to experience a second OHCA and subsequently survive to discharge after the second event. Therefore, 2-OHCA status is inherently time-dependent, and comparison with 1-OHCA survivors may be affected by selection bias, survivorship conditioning, and guarantee-time or immortal-time-like bias. Accordingly, the Kaplan-Meier curves were interpreted as descriptive postdischarge survival trajectories after the qualifying OHCA event, rather than as causal estimates of the effect of a second OHCA. Second, device-related variables were derived from administrative claims and should be interpreted as surrogate indicators of functional dependency, care setting, care intensity, or unmeasured clinical status, rather than as direct measures of physiological benefit or care quality. Therefore, the inverse associations observed for Foley catheter use and tracheostomy or ventilator support should not be interpreted as causal or protective effects of device use. Third, the 2-OHCA survivor group was small, which limited statistical precision and increased the risk of sparse data bias, model instability, and overfitting. The absence of statistically significant associations for baseline comorbidities should not be interpreted as evidence that these conditions are clinically irrelevant, and the subgroup-specific Cox model should be viewed as exploratory and hypothesis-generating. Future studies using larger datasets, time-dependent Cox models, landmark analyses, or multistate models are needed to validate these findings and better estimate the dynamic effect of recurrent OHCA. Finally, confounding by indication is also possible, particularly for device-related variables. For example, tracheostomy with ventilator support may represent necessary ongoing life-sustaining care among chronically dependent patients rather than a directly protective intervention. Additionally, we did not have the granular OHCA clinical variables in the NHIRD, including initial rhythm, witnessed status, bystander cardiopulmonary resuscitation, prehospital resuscitation details, no-flow or low-flow time, and neurological outcome at discharge. These variables are among the strongest predictors of survival after cardiac arrest and could confound the observed associations between comorbidities, device-related variables, and mortality. It is a trade-off because the strength of the NHIRD is its nationwide coverage over a 10-year period, which enabled the identification of the extremely rare group of patients who survived exactly 2 OHCA episodes; however, this population-level scale comes at the cost of limited clinical granularity.

### Conclusions

In this nationwide cohort, patients who survived discharge after a second OHCA represented a rare, highly selected, and clinically vulnerable survivor population with poor subsequent 5-year survival. In exploratory subgroup analyses, mortality among 2-OHCA survivors appeared to be more closely associated with life-sustaining device status than with baseline comorbidities; however, this finding should be interpreted cautiously given the small subgroup size, model-selection constraints, and potential sparse data bias.

## Abstract

**Background:** Multiple primary carcinomas (MPC) represent a clinically significant yet underexplored phenomenon, where patients develop more than one distinct primary malignancy. While prior studies have examined MPC within specific cancer types, comprehensive real-world patterns of primary malignancies and their subsequent primary malignancies remain limited. Moreover, the survival outcomes associated with these MPC patterns, particularly in relation to demographic and clinical characteristics, are not well characterized.

**Objective:** This study aimed to establish the patterns and combinations of MPC across a wide range of cancers and to assess whether the mortality status of patients with MPCs varies according to their demographic characteristics and disease status.

**Methods:** We conducted a retrospective analysis of 1560 patients with MPC in Shanghai, China, from 2002 to 2015. Data were extracted from the Shanghai Cancer Registry, with follow-up until December 2017. Cause of death was ascertained through linkage with the Shanghai Vital Registration System. The distribution of the frequency and proportion of primary carcinoma (PC) combinations were depicted, and a life table was used to calculate the 1- to 5-year survival rates. Cox regression analysis was performed to analyze the survival risk factors of the first and second PCs.

**Results:** Among the 1560 patients (809/1560, 51.86% male and 751/1560, 48.14% female), the most frequent first PCs were colorectal, breast, and stomach cancers, while the most frequent second PCs were lung, colorectal, and stomach cancers. The most common combinations included colorectal and lung, colorectal and stomach, and colorectal and prostate. Survival rates were lowest for first PCs of skin (5 years=46.95%) and lung (5 years=41.54%) cancers, and for second PCs of pancreatic (5 year=9.13%) and liver (5 years=14.19%) cancers. A latency period of 12 months between PC diagnoses was associated with significantly higher cancer-specific mortality for both the first primary cancer (hazard ratio [HR] 3.539, 95% CI 2.822-4.438; *P*<.001) and the second primary cancer (HR 1.369, 95% CI 1.103-1.699; *P*=.004). Older age (>65 years) and advanced tumor stage (III+IV) were also significant independent risk factors for poor survival in both first PC (age: HR 2.049, 95% CI 1.689-2.485; *P*<.001; stage: HR 1.496, 95% CI 1.315-1.703; *P*<.001) and second PC (age: HR 1.575, 95% CI 1.242-1.996; *P*<.001; stage: HR 3.933, 95% CI 3.182-4.861; *P*<.001) analyses.

**Conclusions:** This study provides a comprehensive, real-world map of MPC patterns and highlights important findings: high-risk cancer combinations and key factors associated with poorer survival, including a short interdiagnosis interval (12 months),

XSL•FO
RenderX

advanced age, and advanced tumor stage. Comprehensive prevention and control strategies for MPC should be developed, and clinicians should be aware of the risks of MPC in vulnerable populations during the early diagnosis stage.

multiple primary carcinoma; site; survival rate; risk; real-world maps

## Introduction

In recent years, studies have repeatedly corroborated the fact that patients with cancer frequently have comorbid conditions, including cardiovascular disease, obesity, metabolic disease, mental health problems, and musculoskeletal disease [1,2]. Beyond these, the development of a second primary malignant neoplasm has been increasingly recognized as a distinct challenge for survivors with cancer [3,4]. A second primary carcinoma is a new primary cancer that is histologically or clonally unrelated to the first primary carcinoma, and is associated with a poorer prognosis that can substantially compromise long-term survival [5]. There has been significant progress in the prevention, diagnosis, and treatment of various metastatic malignant tumors [6]. However, the existence of primary malignancies and subsequent primary malignancies (multiple primary carcinomas [MPCs]), which differ clinically from metastatic malignancies, is a specific comorbid condition and a current hot topic in research. According to existing studies, patients with MPC are not a recent occurrence; indeed, in 1921, a report found that 4.7% of 3000 cases of malignancy showed “multiple growth” [4,7]. In some epidemiological studies, the frequency of certain MPC was reported to be in the range of 2% to 17% [8,9]. According to the study by Buikhuisen et al [10], which was based on the nationwide Netherlands Cancer Registry from 1989 to 2018, among 2933 patients with primary carcinoma (PC), 425 consecutive primary malignancies were observed in 376 patients [10]. Clinically, MPCs are considered to be of increasing relevance and importance. However, most existing studies in Asian and Western countries analyzed the occurrence of primary cancer of a specific type of cancer, such as lung, renal cell carcinoma, and squamous cell carcinoma of the esophagus [11]. Despite the reports on the frequency of MPC for certain types of cancer, the overall pattern of MPC based on the real-world data is not well established, which may result from the relatively small survey data and sometimes includes inadequate information on diagnosis and treatment [12].

While concerns about recurrence and metastatic disease are prevalent among survivors of common cancers such as lung, colorectal, gastric, and breast cancer [13], emerging research has focused on the investigation of survival outcomes and risk factors specifically associated with second primary cancers. Using the National Cancer Institute’s Surveillance, Epidemiology, and End Results (SEER) database from 1973 to 2002, Das et al. [14] found that 216,751 patients developed primary colorectal cancer (CRC), and over a follow-up period of 1,250,687 person-years, 5,595 developed a second primary CRC, with a standardized incidence ratio of 1.36 (95% CI 1.32-1.39). Similarly, based on the SEER data, Donin et al [15] revealed that among the 1,450,837 survivors of nonpulmonary cancers, 25,472 developed second primary lung cancers at a mean follow-up of 5.7 (SD 3.6) years, and increasing age and being divorced, widowed, or separated were independent risk factors for second primary lung cancer in most primary cancer types [15]. Moreover, the period of diagnosis of the first primary CRC was also found to be an independent risk factor for a subsequent primary CRC, with a relative hazard ratio (HR) of 1.18 (95% CI 1.06-1.31) [14]. However, by reviewing the existing studies, information related to the risks of mortality for the first PC and the second PC is seldom communicated, which may reveal more opportunities in the prevention or detection of subsequent primary cancers in their early stages [16]. In China, despite some efforts to study MPC, existing research is mostly limited to high-incidence tumors such as primary lung cancer and liver cancer [17]. Comprehensive, population-based analyses delineating the spectrum of MPC across all cancer sites are scarce, with few studies leveraging long-term data from cancer registries. Similarly, there is a lack of information on the comprehensive patterns and common combinations of MPC, as well as their specific survival rates and risk factors [18].

Therefore, it is important to provide comprehensive information on the prevalence of MPC patterns, their corresponding survival rates of various cancer sites, and the risk factors for the first and second site MPC. This study aimed to (1) establish the patterns and combinations of MPC across a wide range of cancers using data from the Cancer Registry in Shanghai, China; (2) analyze the survival rates across common MPC categories in the first and second PC sites; and (3) assess whether the mortality status of patients with MPC varied according to the individuals’ characteristics and disease situation.

## Methods

### Data Source

In our study, data on the diagnosis and survival rates of MPC were collected from the Cancer Registration System of Shanghai, which collects data from 86 public health institutions in Shanghai, China. In China, the uniform standard of diagnosis and survival information of patients with cancer has been collected since the 1970s. The Cancer Registration System was gradually established and achieved complete population coverage for Shanghai residents starting in 2002 [19].

The inclusion of patient data into the registry followed a systematic procedure. According to the registry’s operational protocol, cancer cases were reported by participating institutions. Patients or their families provided informed consent for their data to be included in the population-based cancer registry and for participation in routine follow-up surveys. The survey was conducted annually to check the survival status of patients via

XSL•FO
RenderX

telephone or home visit in accordance with standardized epidemiologic protocols [20]. Additionally, the survival information of patients was obtained from the coroner's registrar and was restricted to Shanghai residents. Cause of death was ascertained through routine linkage with the Shanghai Vital Registration System, and cancer-specific mortality was defined accordingly. The quality of data was checked and evaluated based on the Guidelines for the Chinese Cancer Registration [21] and International Agency for Research on Cancer and International Association of Cancer Registries' data quality criteria [22]. The research team had full access to the deidentified data from the Shanghai Cancer Registry for the purpose of this study.

## Data Collection

In this study, the data of patients with MPC were extracted through a systematic, multistep process according to the *ICD-10* (*International Statistical Classification of Diseases and Related Health Problems 10th Revision*) from the Cancer Registration System of Shanghai. The data included patients who were diagnosed with primary cancer (*ICD-10*: C97) in whom the second primary cancer occurred during 2002-2015.

The start year of the first primary cancer was retrospectively established as 1988, considering the data quality of the information of patients with cancer. In detail, the Shanghai Cancer Registration System began collecting complete mortality data in 1988. However, the data from 1988 to 2001 do not include full population registration data. In 2002, the Shanghai Cancer Registration System collected data from all reports of hospitals with tumor diagnostic qualifications and medical records obtained from autopsies and community follow-ups, and the data were further verified by the local Center for Disease Control and Prevention. Given that the supplementary data from 1988 to 2001 were conducive to the analysis of the first primary cancer in this article, these data were incorporated. Data cleaning also confirmed that the quality for this earlier period was acceptable, with minimal missing critical information, justifying its inclusion for a more complete analysis of the first primary cancer.

The starting year was 2002 for the second PC because the system was deemed complete at that point, and the end year was 2015. Due to the time lag in information collection and data quality control, follow-up of deaths ended on December 31, 2017. The Shanghai Cancer Registry has achieved full population coverage, and death registration is a legal requirement related to the cancellation of a resident's household registration and property inheritance. Therefore, the survival status of patients with cancer can be accurately traced to a specific date. Consequently, in our current analysis of patients with cancer from 2002 to 2015, with the endpoint of survival outcome set as December 31, 2017, we effectively avoided underreporting cases and had no cases of survival or loss to follow-up.

Electronic data were used to compare the incidence, mortality, and survival of cancers. Detailed variables, including age, sex, cancer type, date of diagnosis, pathology, treatment, date and cause of death, tumor, node, and metastases stage (TNM stage), and registered residence, were collected. All cancers from the registration system were combined, and 26 cancer types were identified according to the *ICD-10*.

## Variables

### *MPC*

MPC refers to the occurrence of two or more independent primary malignant tumors in the same individual, either simultaneously or sequentially. MPCs were identified according to established Warren and Gates criteria, which require that (1) each tumor is histologically confirmed as malignant, (2) each tumor is distinct in its pathological morphology (or, if morphologies are similar, the tumors are anatomically separate), and (3) each tumor is neither a metastasis nor a recurrence of any prior tumor. According to the temporal sequence, MPCs were categorized based on the interval between diagnoses [23].

In this study, we observed two types of MPCs: patients with 2 PCs (first PC [site A] + second PC [site B]), and those with 3 PCs (first PC [site A] + second PC [site B] + third PC [site C]). Due to the low number of PCs (3), we focused on sites A and B when analyzing the pattern, combination, and survival rate using Cox regression.

### *Demographic Variables of Patients With MPC*

We collected data on the following demographics: sex (male and female), age (65 years and 65 years, indicating the older adult group and non–older adult group, respectively), TNM (tumor, node, metastases) stage of cancer (in stage of III and IV, I, and II), diagnosis time (2002-2008, 2009-2015; 2008 was chosen because it was the median of this period), the level of the therapeutic hospital where the treatment was received (secondary hospital vs tertiary hospital in China, all patients with cancer are treated at secondary or tertiary hospitals when they were first diagnosed, since the large hospitals have sufficient expertise in diagnosing tumors), latency between the first and second PC (12 months or 12 months), and number of PCs (2 or 3).

## Statistical Analysis

The distribution of the frequency and proportion of first and second PCs was depicted using Adobe Illustrator CS5. A life table method was used to calculate the 1- to 5-year survival rates. Kaplan-Meier analysis was used to estimate the patients' survival status, and Cox regression was performed to identify the risk factors associated with survival, for both first and second PCs. These conventional methods were selected as the primary analytical tools given the descriptive nature of this real-world mapping study. Competing risk regression was not applied, as our primary aim was to describe MPC combination patterns and identify associated survival risk factors in this real-world cohort, rather than to estimate the cumulative incidence function. Cases with missing data for the TNM stage variable were excluded from the Cox regression analyses.

All statistical analyses were 2-sided and performed using the Statistical Package for the Social Sciences software (version 20.0; SPSS, Inc). Statistical significance was set at $P<.05$ (2-sided).

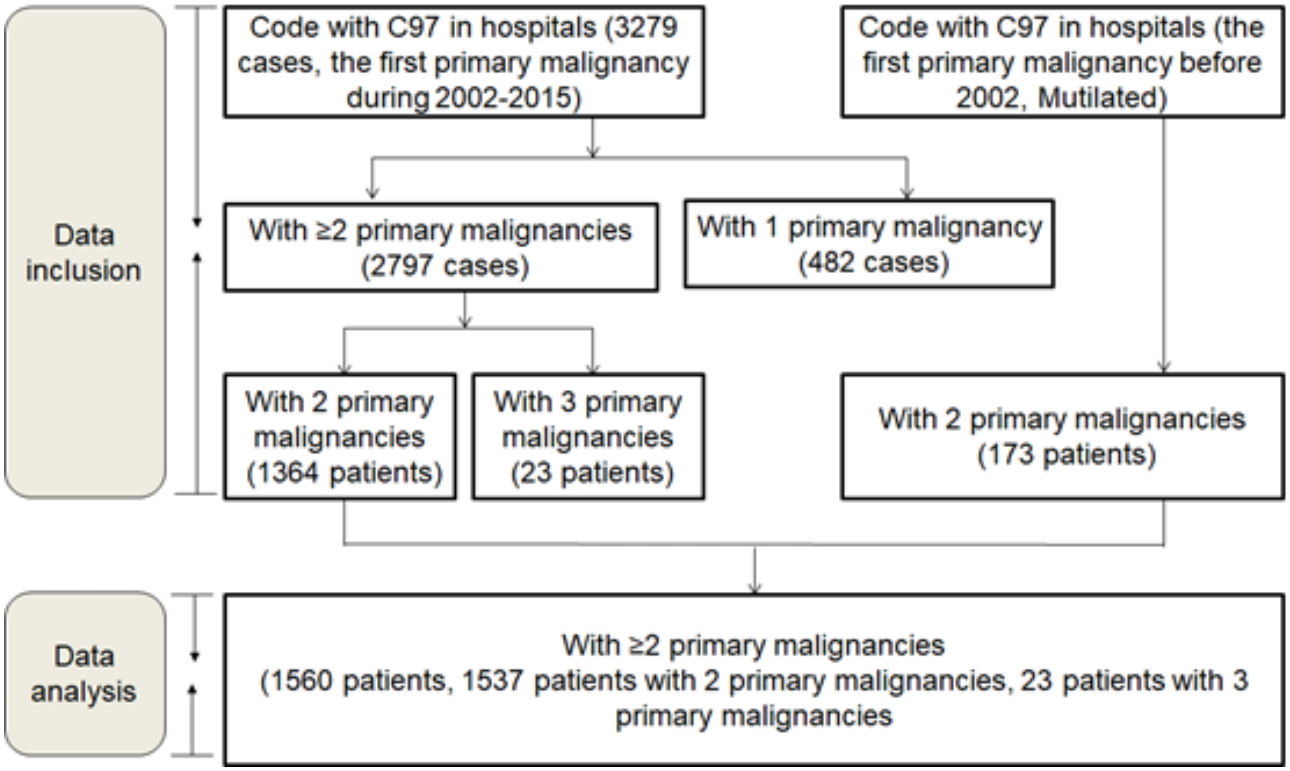
XSL•FO
RenderX

### Reporting Guidelines

Results are presented in accordance with the TRIPOD (Transparent Reporting of a multivariable Prediction model for individual Prognosis or Diagnosis) guidelines. STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) and RECORD (Reporting of studies Conducted using Observational Routinely collected health Data) guidelines for observational studies and studies using routinely collected health data were also considered. The study was conducted in accordance with relevant institutional guidelines. The completed RECORD checklist is provided in Multimedia Appendix 1.

### Ethical Considerations

This retrospective registry-based study used existing, deidentified data from the Shanghai Cancer Registry. The original data collection for the registry was conducted after the approval of the Institutional Review Board of Shanghai Municipal Center for Disease Control and Prevention, as part of the legally mandated population-based cancer surveillance system authorized by Shanghai public health authorities. For the purpose of this specific research analysis, the study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki and was approved by the Ethics Committee of Fudan University, Shanghai, China (IRB00002408 and FWA00002399). The need for additional informed consent for this retrospective analysis was waived by the Ethics Committee, as the study involved the analysis of anonymized data collected for public health purposes. All data were handled confidentially, and no compensation was provided.



## Results

### Overview

In this study, data from 1387 patients (2797 cancer cases; cases describing the site of cancer) included the type of the first PC. In addition, 1364 patients (2728 cases) had 2 PCs, and 23 patients (69 cases) had 3 PCs. In total, 173 patients (all of whom had 2 PCs) had their first PC before 2002. Our dataset included a total of 1560 patients with ≥ 2 PCs ([1364 with 2 PCs from 2002 to 2015] + 23 [with 3 PCs from 2002 to 2015] + 173 [with 2 PCs, with the first occurring before 2002]) for the analysis of MPC patterns and survival rates. The median follow-up time for the first and second PC groups was 6.86 years (IQR 4.42-12.18) years and 2.23 (IQR 1.46-5.39) years, respectively (Figure 1).

As shown in Table 1, among the 1560 patients with MPC (1537 with 2 PCs and 23 with 3 PCs), the distribution of male (809/1560, 51.86%) and female (751/1560, 48.14%) patients were similar. The proportion of patients >65 years of age was greater in the 2 PCs group (≤65 years, 590/1560, 38.39%; >65 years, 947/1560, 61.61%; *P*<.001). There was a higher number of patients with I + II with 2 PCs (652/1537, 42.42%) and 3 PCs (11/23, 47.83%) compared to those with III + IV PCs (2 PCs, 249/1537, 16.20%, *P*=.004; 3 PCs, 4/23, 17.39%, *P*=.88). In both groups with 2 and 3 PCs, there were higher proportions of patients who were diagnosed in 2009-2015 (2 PCs, 944/1537, 61.42%, *P*=.40; 3 PCs, 15/23, 65.22%, *P*=.02) and in secondary hospitals (2 PCs, 1067/1537, 69.42%, *P*=.44; 3 PCs, 15/23, 65.22%, *P*=.88). In addition, our results showed that 74.50% (1145/1537) of patients had a 12-month interval between the first and second PC diagnosis in the 2 PCs group and 78.26% (18/23) of patients in the 3 PCs group.

## MPC Combination Patterns in the First and Second PC Sites

Figure 2 indicates the specific cancer distribution among the 1560 patients with MPC. The results show that the top three first PCs were accumulated in the colon (204/1560, 13.08%), breast (181/1560, 11.60%), and stomach (145/1560, 9.29%). With CRC as the first PC, the second PCs included the lung (49/1560, 24.02%), stomach (27/1560, 13.24%), prostate (14/1560, 6.86%), and breast (14/1560, 6.86%). For patients with breast cancer as the first PC, thyroid (34/1560, 18.78%), colorectal (31/1560, 17.13%), and lung (26/1560, 14.36%) cancers accounted for the highest proportions of second PCs. Stomach cancers as the first PC most commonly occurred with colorectal (41/1560, 28.28%), lung (27/1560, 18.62%), and skin (10/1560, 6.90%) cancer as second PCs. The patterns of all cancers are shown in Multimedia Appendix 2.

The top three secondary PCs were lung cancer (274/1560, 17.56%), colorectal cancer (254/1560, 16.28%), and stomach cancer (142/1560, 9.10%), which collectively accounted for 42.94% (670/1560) of all secondary PCs. The most frequently observed combinations with lung cancer as the secondary PC were colorectal and lung cancer (49/274, 17.88%), stomach and lung cancer (27/274, 9.85%), and breast and lung cancer (26/274, 9.49%). Overall, stomach and colorectal cancer (41/254, 16.14%) and breast and colorectal cancer (31/254, 12.20%) were the most frequently observed MPC combinations. With stomach cancers as the secondary PC, colorectal and stomach (27/142, 19.01%), lung and stomach (18/142, 12.68%), and bladder and stomach (12/142, 8.45%) cancers accounted for the highest percentage. The complete combination patterns of all cancers are shown in Multimedia Appendix 3.

As depicted in Figure 3, the colon, stomach, and lung were the most frequently observed first PC sites for both male and female patients. Cancers of the reproductive system were also frequently diagnosed, with prostate cancer ranked the third most frequently observed (86/809, 10.63%) in male patients, and breast cancer ranked first (178/751, 23.70%) in female patients. Moreover, thyroid (ranked third), brain and central nervous system (ranked sixth), corpus uteri (ranked seventh), and ovary (ranked eighth)

XSL•FO
RenderX

cancers were more common in female patients, while bladder (ranked fifth), kidney (ranked sixth), and liver cancers (ranked seventh) were more common in male patients. Lung cancer was the most frequently diagnosed secondary PC in men (166/809, 20.49%) and the second most frequent in women (108/751, 14.40%). Male patients also demonstrated a higher rate of esophageal cancer (ranked eighth) as a second PC than as a first PC. In women, liver (ranked sixth), pancreatic (ranked seventh), and gallbladder (ranked eighth) cancers were more commonly observed as second PCs than first PCs.

## Survival Rates According to the Type of Cancer in the First and Second PC Sites

The survival rates for the first and second PCs are displayed in Table 2. Focusing on the first PC site, patients with breast cancer had the highest 1-year survival rate (96.69%). Patients with thyroid cancer as the first PC had the longest 2-year (93.12%), 3-year (90.01%), 4-year (86.76%), and 5-year (83.09%) survival rates. Although ranked 10th most frequently observed, patients with brain and central nervous system cancer as the first PC had relatively high 1- and 2-year survival rates. Patients with kidney cancer as the first PC had high 3-, 4-, and 5-year survival rates. It is worth noting that skin and lung cancers were associated with the lowest survival rates in patients.

Similarly, patients with thyroid cancer as the second PC had the highest survival rates (1-year, 95.04%; 2-year, 95.04%; 3-year, 90.77%; 4-year, 84.61%; 5-year, 84.61%), followed by breast cancer. Comparatively, patients with pancreatic cancer as the second PC had the lowest survival rates (1-year, 16.90%; 2-year, 14.08%; 3-year, 14.08%; 4-year, 11.74%; 5-year, 9.13%), which were similar to those of liver cancer as the second PC (1-year, 32.81%; 2-year, 26.08%; 3-year, 17.74%; 4-year, 17.74%; 5-year, 14.19%).

**Table 2.** One- to five-year survival rates for first and second primary carcinoma sites among patients with multiple primary carcinomas in Shanghai, China (2002-2015).

| | First primary carcinoma site | | Survival rates (%) | | | | | Second primary carcinoma site | | Survival rates (%) | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Rank | Sites | N | 1-year | 2-year | 3-year | 4-year | 5-year | Sites | N | 1-year | 2-year | 3-year | 4-year | 5-year |

## Possible Risk Factors for Survival Status in the First and Second PC Sites

The Kaplan-Meier analyses show that there were significant differences in overall and cancer-specific survival rates with regard to the first PC between sex, age, TNM, and diagnosis time and latency ($P$<.001; Figure S1A in Multimedia Appendix 4). The survival disparity between latency >12 months and < 12 months was the most sizeable. When assessing the second PC (Figure S1B in Multimedia Appendix 4), there was no significant survival difference with diagnosis time as the variable ($P$>.05), but the survival rates differed significantly based on the level of hospital where treatment was sought ($P$<.001).

Table 3 demonstrates the results of Cox regression analysis, showing that for the first PC site, there was a significantly higher HR of cancer-specific mortality in the >65-year-old group (HR 2.049, 95% CI 1.689-2.485; $P$<.001) in the patients with stage III+IV (HR 1.496, 95% CI 1.315-1.703; $P$<.001), with diagnosis times between 2009 and 2015 (HR 2.377, 95% CI 1.874-3.015; $P$<.001). Similar results were observed when assessing all-cause mortality. For the second PC, patients with an age >65 years (HR 1.575, 95% CI 1.242-1.996; $P$<.001) and at stage III+IV (HR 3.933, 95% CI 3.182-4.861; $P$<.001) also showed a higher risk of cancer-specific mortality, as well as all-cause mortality. There were also fewer male patients with higher HR cancer-specific mortality (HR 0.691, 95% CI 0.568-0.840;

XSL•FO
RenderX

*P*<.001). Notably, patients with an interdiagnosis interval of ≤12 months had a significantly higher risk of both cancer-specific and all-cause mortality from the first primary cancer (cancer-specific: HR 3.539, 95% CI 2.822-4.438; all-cause: HR 3.533, 95% CI 2.824-4.420) and from the second primary cancer (cancer-specific: HR 1.369, 95% CI 1.103-1.699; all-cause: HR 1.339, 95% CI 1.081-1.659), compared to those with an interval of >12 months. Regarding the number of primary cancers, there was no significant difference between the mortality of patients with primary malignancies in the first site and second site (*P*>.05).

**Table 3.** Cox regression analysis of risk factors for cancer-specific and all-cause mortality in first and second primary carcinoma sites among patients with multiple primary carcinoma[a].

| Variables | Cancer-specific mortality | | All-cause mortality | |
|---|---|---|---|---|
| | HR (95% CI) | *P* value | HR (95% CI) | *P* value |
| **In the first primary carcinoma site ( n=916)** | | | | |
| Sex (male vs female) | 0.842 (0.705-1.005) | .06 | 0.849 (0.713-1.011) | .07 |
| Age (>65 vs ≤65 years) | 2.049 (1.689-2.485) | <.001 | 2.092 (1.728-2.532) | <.001 |
| TNM[b] stage (III + IV vs I + II) | 1.496 (1.315-1.703) | <.001 | 1.497 (1.318-1.700) | <.001 |
| Diagnosis time (2009-2015 vs 2002-2008) | 2.377 (1.874-3.015) | <.001 | 2.302 (1.820-2.913) | <.001 |
| Therapeutic hospital level (secondary vs tertiary) | 1.143 (0.937-1.395) | .19 | 1.149 (0.945-1.399) | .16 |
| Latency (≤12 months vs >12 months) | 3.539 (2.822-4.438) | <.001 | 3.533 (2.824-4.420) | <.001 |
| Number of PCs[c] (with 3 PCs vs with 2 PCs) | 1.253 (0.667-2.353) | .48 | 1.212 (0.645-2.275) | .55 |
| **In the second primary carcinoma site (n = 844)** | | | | |
| Sex (male vs female) | 0.691 (0.568-0.840) | <.001 | 0.705 (0.581-0.855) | <.001 |
| Age (>65 vs ≤65 years) | 1.575 (1.242-1.996) | <.001 | 1.562 (1.236-1.973) | <.001 |
| TNM stage (III + IV vs I + II) | 3.933 (3.182-4.861) | <.001 | 3.837 (3.114-4.729) | <.001 |
| Diagnosis time (2009-2015 vs 2002-2008) | 1.188 (0.918-1.536) | .19 | 1.130 (0.879-1.453) | .34 |
| Therapeutic hospital level (secondary vs tertiary) | 1.033 (0.848-1.258) | .75 | 1.035 (0.851-1.259) | .73 |
| Latency (≤12 months vs >12 months) | 1.369 (1.103-1.699) | .004 | 1.339 (1.081-1.659) | .007 |
| Number of PCs (with 3 PCs vs with 2 PCs) | 1.041 (0.565-1.917) | .90 | 1.024 (0.556-1.885) | .94 |

[a]Note: In the Cox regression for the first primary carcinoma site, 644 samples were missing values for the TNM stage variable (1560-916), so only 916 samples were included. For the second primary cancer, 716 samples (1560-844) were missing data; thus, 844 samples were analyzed.

[b]TNM: tumor, node, and metastases stage.

[c]PC: primary carcinoma.

# Discussion

## Principal Findings

This study provides the first comprehensive population-based mapping of MPC patterns in Shanghai, China, analyzing their occurrence, combinations, and survival using real-world registry data. By extending follow-up through 2017 and retrospectively including cases dating back to 1988, we obtained long-term observation that offers valuable insight into these relatively rare events. Moreover, the observed patterns and risk factors reflect fundamental biological and demographic influences, supporting their continued clinical relevance beyond the study period.

Our analysis of real-world data revealed that colorectal, stomach, and reproductive cancers (breast cancers in women and prostate cancers in men) were the most frequently diagnosed first PC. A previous study, which compared global cancer statistics data from China to other countries, found that among patients of both sexes, China had the largest proportion of lung, colorectal, and female breast cancer (38.9% of total cases; United Kingdom: 34.8%, United States: 29%), and also had a greater proportion of infection-attributable cancers (17.8% of liver and stomach cancers) [24]. Similarly, the results of our study indicate that the prevalence of digestive tract cancers, such as colorectal and stomach cancers, were higher [25]. Moreover, Feng et al [25] study on countrywide cancer prevalence found that 36.4% of Chinese cancer-related deaths were due to digestive tract cancers (stomach, liver, and esophageal cancer), compared to ≤5% of the total cancer-related deaths in the United States or the United Kingdom [25]. We concluded that primary lung cancer ranked first as the second PC site, but was the fourth most frequently observed PC in the first site, which does not agree with the findings of Feng et al [25] or with other previous studies, in which lung cancer has always ranked first. One reason for the difference in incidence rates between this study and prior studies may be the inadequate number of data sources and research on varying MPCs; thus, further study remains necessary. Additionally, sex-specific differences in MPC distribution were also observed. When organized by sex, the order of the top 10 PCs existed as the first and second PCs between male and female

XSL•FO
RenderX

patients were distinct. Men had higher rates of infection-attributable cancers (stomach and liver), but women had higher rates of thyroid cancer. These patterns reflect the underlying differences in cancer etiology between sexes and may inform site-specific surveillance strategies for survivors with cancer.

When analyzing the PC combinations, we found that PCs including colorectal and lung, colorectal and stomach, colorectal and prostate, and breast and thyroid, breast and colorectal, stomach and colorectal, and stomach and lung were the most frequently observed. Moreover, it was common to observe comorbidities of the same system; for instance, there was a higher probability of cooccurrences of multiple digestive tract cancers (stomach and liver) [26]. Our results revealed patterns among the MPC that cooccurred; for instance, breast cancer appeared frequently with thyroid cancer. However, it is important to note that these observed patterns represent clinical cooccurrences whose frequency may be influenced by the high background incidence or survival rate of the involved cancers. Therefore, future studies incorporating standardized incidence ratios are needed to determine whether these observed combinations represent an elevated risk beyond chance. According to the study by Buikhuisen et al [10], concomitant diagnoses in the first year mainly comprised lung and renal cancer. Metachronous malignancies beyond the first year were most frequently observed for patients with breast, colorectal, prostate, and lung cancer [10]. Furthermore, a study of patients hospitalized at the Department of Oncology from 2003 to 2009 found that the incidence of MPC was 2.4%, and of the 103 patients with MPC, 97 had two, and 6 had three primary tumors. Moreover, the most frequently observed tumor combinations in men were prostate cancer-digestive system malignancies (especially colorectal cancer) and vice versa, as well as hematological malignant tumor-digestive system malignancies. In women, the most frequently observed multiple tumor occurrences were breast cancer, cancer of the contralateral breast, and hematological malignant tumors (especially non-Hodgkin lymphoma)-breast cancer. The observed associations between certain cancers are likely multifactorial in origin. Potential contributing mechanisms include shared hormonal pathways, common genetic susceptibilities, and environmental exposures. Additionally, the potential long-term effects of treatments received for the first PC should also be considered as a possible risk factor for subsequent malignancies in particular organs. Therefore, clinicians should be aware of these frequently observed combinations. Future analytical studies using standardized incidence ratios are warranted to confirm whether these pairs represent an excess risk beyond that expected by chance. Moreover, in this study, the 1-, 2-, and 3-year survival rates of patients with first or second PCs were higher, but the 4-year and 5-year survival rates were lower, which underscores the critical importance of sustained, long-term surveillance beyond the initial treatment period. Moreover, the survival rates of patients with breast and thyroid MPC were relatively high, which is consistent with the findings of previous studies [27]. Building on the patterns of metachronous cancer identified, our findings advocate for a paradigm shift in survivorship care, from a model focused solely on the primary tumor to a comprehensive, lifelong strategy. This necessitates a multidisciplinary approach that moves beyond the initial organ site to implement coordinated surveillance for the most likely subsequent cancers, based on the primary site, shared risk factors, and treatment history, thereby enabling earlier detection and improving long-term prognosis for survivors. For instance, given the high frequency of lung cancer as a second primary, future research should evaluate the potential role of enhanced surveillance strategies, such as low-dose chest computed tomography, in high-risk survivor populations.

Our results showed that, among the first PCs, skin and lung cancers had the lowest survival rates, which is consistent with the findings of other studies. For example, in Barton et al [28] systematic review, they found that the survival rates of nonmelanoma skin cancer, across both squamous cell carcinoma and basal cell carcinoma, tended to be poorer when it existed as a second PC. However, further study is required to more precisely characterize these associations and elucidate the underlying mechanisms. Patients with lung cancer as the first primary cancer also had relatively low survival rates, possibly because lung cancer is often not detected until it has spread; this finding is consistent with previous countrywide studies [29]. However, it should be noted that these survival estimates may be influenced by the retrospective design of our study. The Shanghai Cancer Registry achieved full population coverage in 2002, and patients with a first PC diagnosed before 2002 were required to survive until at least 2002 to be included. This introduced immortal time bias, which may lead to overestimation of survival for first primary cancers, especially for those diagnosed in earlier periods. Therefore, the absolute survival rates for first PCs should be interpreted with this limitation in mind. And future studies should use prospective designs or more uniformly enrolled cohorts to provide more precise survival estimates.

We observed low incidences of pancreatic and liver cancers as second primary cancers (ninth and eighth rankings, respectively), and the lowest survival rates among the most commonly occurring cancers. Pancreatic cancer often presents at an advanced stage, which contributes to poor 5-year survival rates of approximately 2%-9%, ranking firmly last among all cancer sites in terms of prognostic outcomes for patients [30]. Regarding liver cancer mortality in China, the mortality rate (422.1/1000) was lower than that of lung (610.2/1000) and stomach (498/1000) cancer, but higher than that of colorectal cancer (191/1000). Previous studies have found that liver cancer mortality is especially high in parts of Eastern China, such as Shanghai [22].

Notably, our study found that when the latency between the first and second PC diagnosis was ≤12 months, patients had a higher risk of mortality than those with an interval of >12 months. This finding indicates that the faster the new primary cancer occurs, the higher the mortality risk. Several mechanisms may underlie this association. First, a short latency period may reflect aggressive tumor biology or shared genetic susceptibility predisposing to the rapid development of a second PC. Second, treatment-related effects, especially the radiotherapy and chemotherapy administered for the first PC, may contribute to the development of second PC, with shorter latency potentially

XSL•FO
RenderX

indicating greater genotoxic susceptibility or higher cumulative exposure. Third, surveillance bias and reverse causation may contribute, as patients with more frequent follow-up or more aggressive first PC are more likely to have a second PC detected earlier or incidentally. However, this seems to differ for nonprimary cancers, as patients must receive early diagnoses followed by chemotherapy and radiotherapy, which can help delay the occurrence of secondary cancer and mortality [31]. Further clinical analysis is needed to determine if there are differences in trends between different types of cancers.

This finding was different from those of other studies that researched nonprimary cancers, indicating that more attention should be given to the distribution of cancers by sex for the prevention of subsequent primary cancers. Moreover, female patients had higher mortality rates than male patients in the second PCs, but there was no significant difference between the first PCs. This finding appears to be different from previous studies on general Chinese cancer statistics, which have indicated that male patients have higher overall mortality rates [25]. In this study, patients >65 years old had higher mortality regardless of whether they existed in the first or second PCs than the younger. A prior study concluded that increased age correlated with higher rates of cancer diagnosis. Moreover, in recent years, the incidence of cancer in people >65 years old has been 10 times higher than that of people aged <65 years in the United States [32]. Furthermore, Ershler et al [33] found that cancer mortality rates were higher for older adults, with approximately 70% of all cancer-related deaths occurring in people aged >65 years. Consistent with other studies, our results showed that patients with stage III + IV cancer in both first and second sites had higher mortality. This is mainly due to the inability of these late-stage-diagnosed patients to receive early detection and treatment [34]. Also, it was found that patients diagnosed between 2009 and 2015 had a higher mortality. Correspondingly, there were more patients diagnosed between 2009 and 2015 in the III+IV stage, and more patients diagnosed between 2002 and 2008 in the I+II stage. However, due to the limited number of samples with multiple primary tumors, only 23 patients had third primary tumors. Therefore, we calculated the time based on the first diagnosis of each primary tumor. In addition, we found no significant differences between patients with 2 PCs and 3 PCs when comparing both cancer-specific and all-cause mortality. This finding is unique compared to previous non–primary cancer studies by Sarfati et al [31], which concluded that more cancer comorbidities led to higher mortality. However, further research is still needed to explore the effects of various kinds of cancer.

There are several limitations in this study. First, our sample was based only on data from the Shanghai Cancer Registry System, with a relatively small size [35-37], and stringent data governance policies after 2016 limited access to more recent cases. Therefore, future studies should include larger, updated samples as data sharing frameworks evolve. Second, the current registry data lack detailed information on lifestyle factors and genetic predisposition, which limits comprehensive risk factor analysis. Future studies integrating such data would help determine whether the observed cancer combinations share common hereditary or environmental causes. Third, a substantial amount of data, particularly on TNM staging, was missing from the registry, primarily due to delayed pathology reporting relative to cancer diagnosis. This led to the exclusion of cases from the Cox regression analyses, potentially introducing selection bias and reducing the statistical power of these models. Additionally, due to the insufficiency of the Cancer Registration System, patients with a first cancer before 2002 had to survive until at least 2002 to be included in the dataset, which may cause an overestimation of survival for first primary cancers and an overrepresentation of less aggressive cancer types in our observed MPC patterns. Fourth, our survival analyses employed standard Kaplan-Meier and Cox proportional hazards models. These methods may overestimate cancer-specific mortality in the presence of competing risks. Future studies with more granular cause-of-death data are encouraged to apply competing risk models to obtain more precise estimates. Additionally, in line with the descriptive aim of profiling cancer combinations, our models for the second primary cancer did not adjust for the site of the first PC, which did not isolate the independent effect of the second cancer itself. Future etiological studies may consider such adjustments.

## Conclusions

In this study, we provide comprehensive information synthesis from large, long-term datasets to improve the understanding of the prevalence of common MPC patterns and factors affecting survival status between various PC sites. Our results highlight specific cancer combinations with low survival rates, as well as risk factors, including a short interdiagnosis interval (≤12 months), advanced age (>65 years), and late tumor stage (III+IV). These results underscore the need for comprehensive prevention and control strategies toward the highly occurring MPC combinations in China and other countries, and also highlight the importance of clinical awareness directed toward the identified high-risk populations to enable earlier detection and intervention at an early stage of diagnosis.

## Acknowledgments

The authors are grateful to the health institutions for contributing to the data collection.

Authors XL and HJ are co-corresponding authors of this paper. XL can be reached at xiaopanli0224@126.com.

## Funding

This study was supported by the National Natural Science Foundation of China (grant numbers 71603182, 72104183), and the Project of the 2025 Open Fund of the Shanghai Key Laboratory of Meteorology and Health (No. QXJK202509 to XL). The funders had no involvement in the study design, data collection, analysis, interpretation of results, or the writing of the manuscript.

## Abstract

**Background:** With global aging, the burden of tuberculosis (TB) among older adults escalates, yet spatial studies on this group are scarce. In Chongqing, where 18.87% of the population are aged 65 years and older and TB burden is high, controlling older adult TB remains a major challenge.

**Objective:** This study analyzed the spatiotemporal patterns of TB among adults aged 65 years and older in Chongqing, China, to inform local prevention and control strategies.

**Methods:** The study data were obtained from the Tuberculosis Information Management System of China. Global and local spatial autocorrelation analyses were conducted using ArcGIS (version 10.7) to identify high-risk spatial clusters and visualize their distribution. Spatiotemporal scan statistics were performed using SaTScan (version 10.3.2) to detect clusters of TB cases among the older adult population. Statistical significance was set at $P<.05$.

**Results:** The average annual incidence of TB among older adults in Chongqing was 69.59 per 100,000 population, with peaks occurring in spring and summer. The global Moran *I* ranged from 0.618 to 0.756 ($P<.001$ in all cases), indicating significant clustering. Persistent high-risk areas were identified in the northeastern and southeastern parts of Chongqing. Spatiotemporal scan statistics detected 1 most likely cluster (relative risk=3.52, 95% CI 3.37 - 3.68; log-likelihood ratio=1017.43; $P<.001$) and 3 secondary clusters.

**Conclusions:** Significant seasonal patterns of TB among older adults were observed in Chongqing. High-risk areas were predominantly concentrated in the northeastern and southeastern parts of the municipality. More targeted public health interventions are imperative.

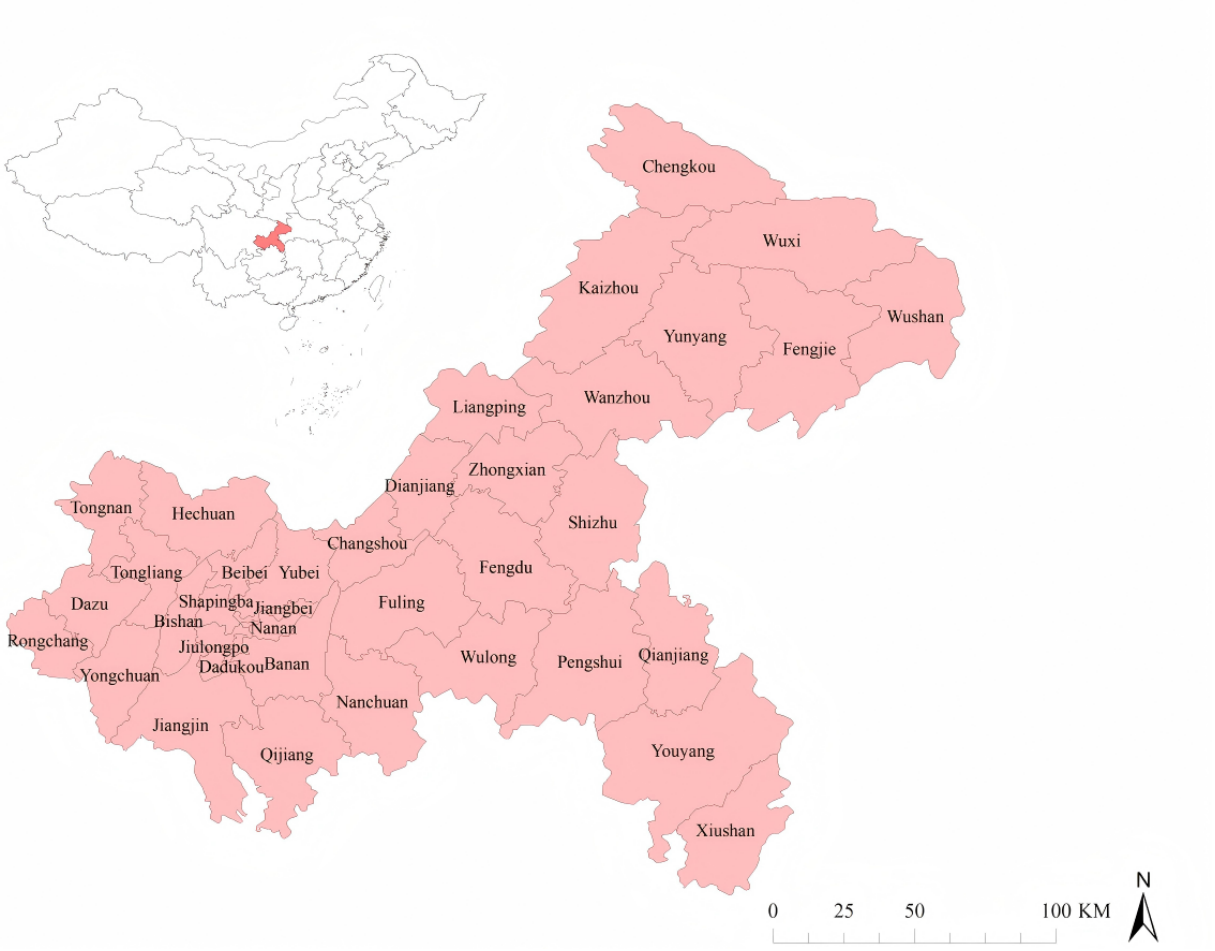
## Introduction

Tuberculosis (TB), a chronic infectious disease primarily affecting the lungs, is caused by *Mycobacterium tuberculosis*. It ranks among the top 10 causes of death worldwide and represents a significant public health and social challenge worldwide [1]. According to the World Health Organization's *Global Tuberculosis Report 2024* [1], an estimated 10.8 million individuals developed TB worldwide in 2023, resulting in approximately 1.25 million deaths. Among the 30 high–TB burden countries, China bears the third highest burden, with 741,000 new TB cases reported in 2023, accounting for 6.8% of the global incidence. Among these cases, 25,000 fatalities were attributed to TB. Although China has witnessed a declining trend in TB incidence over the years, the situation remains challenging due to its large population [2].

With increasing life expectancy and declining fertility rates, the pace of global population aging has accelerated markedly in the new century [3]. Older adults are more susceptible to TB due to immunosenescence, a higher prevalence of comorbid chronic diseases, and an increased risk of latent infection reactivation [4-6]. Consequently, the older adult population has become a critical challenge for TB control efforts. In the Western Pacific Region of the World Health Organization, the highest number of TB cases is observed in the age group of 65 years and older, largely driven by the demographic aging in China [1]. Located in southwestern China, Chongqing is a major populous municipality where the reported TB incidence has consistently ranked among the highest nationally. A study in Chongqing

XSL•FO
RenderX

indicated that the average annual reported TB incidence from 2018 to 2022 was 65.01 per 100,000, exceeding the national average of 52.00 per 100,000 during the same period, with the peak incidence observed among individuals aged 65 years and older [1,7]. Another study reported that the spatial distribution of TB cases in Chongqing is heterogeneous, predominantly clustered in the northeastern and southeastern areas [8]. According to statistical data [9], the population aged 65 years and older in Chongqing reached 6.02 million by 2024, accounting for 18.87% of the municipality's total population. Furthermore, TB management in older adults is compounded by challenges including delayed diagnosis, poor treatment adherence, and higher rates of adverse outcomes, presenting substantial obstacles to public health control efforts [10-12].



In recent years, spatiotemporal analysis has been widely used to characterize the distribution patterns and transmission dynamics of TB across space and time [13,14]. Studies conducted in China [15,16] and other countries [17-19] have demonstrated that TB exhibits highly complex dynamics with significant spatial heterogeneity at provincial, national, and international levels. The Chongqing municipality, characterized by its complex topography, significant urban-rural disparities, and frequent population mobility, demonstrates distinct spatial heterogeneity in its TB epidemic. However, few studies have investigated the spatiotemporal characteristics of TB distribution among the older adult population at the county level within Chongqing. Therefore, using reported TB data from 2020 to 2024 across Chongqing's 38 counties, this study aimed to examine the geographical distribution and spatiotemporal trends of TB among individuals aged 65 years and older. The findings are expected to provide a scientific basis for targeted TB control, resource allocation, and policy formulation.

## Methods

### Overview of the Study Area

Chongqing is located in the southwest of China in the upper reaches of the Yangtze River, between 28.10°N to 32.13°N and 105.11°E to 110.11°E, and is one of China's 4 direct-controlled municipalities. It spans approximately 470 km from east to west and 450 km from north to south, covering a total area of 82,400 $km^2$. The municipality comprises 38 counties, with a resident population of 31.90 million in 2024. Chongqing experiences a humid subtropical monsoon climate characterized by a mean annual temperature of 17.7 °C and an average relative humidity of 79.9% (Figure 1) [20].

**Figure 1.** Geographical location and county-level administrative divisions of the Chongqing municipality, China.

### Data Collection and Management

The data for this study were obtained from the Tuberculosis Information Management System (TBIMS) of China, which collects case reports for all patients with TB during a specified period. TB incidence statistics were compiled based on patients' current residential addresses. This study statistically analyzed the incidence of cases according to the patients' current residences, collecting data on newly diagnosed older adult patients with TB aged 65 years and older reported in the system by medical institutions in the 38 counties of Chongqing from January 1, 2020, to December 31, 2024. To protect patient privacy and prevent duplicate reporting, each reported TB case was assigned a unique identifier. Each patient record contained demographic and clinical information, including age, sex, current residential address, patient type, diagnosis date, and diagnostic results. The diagnosis of TB followed the standards outlined in the WS 288-2017 guidelines issued by the National Health Commission of the People's Republic of China [21] and the *Technical Guidelines for Tuberculosis Prevention and Control in China* [22]. From 2020 to 2024, population data for individuals aged 65 years and older in each county-level area of the Chongqing municipality were obtained from the records for the corresponding years in the 2024 Chongqing Statistical Yearbook [20] and the 2024 Chongqing Statistical Bulletin on National Economic and Social Development [9]. County-level administrative boundary vector maps for China and specifically for the Chongqing municipality were obtained from the National Platform for Common Geospatial Information Services. All spatial data were obtained in the WGS 84 geographic coordinate system.

### Spatial Trend Surface Analysis

Trend surface analysis uses a 3D coordinate system ($x$, $y$, $z$) to generate a 3D projection of the data, thereby graphically illustrating the spatial distribution trends of TB. In this coordinate system, the x- and y-axes correspond to the longitude and latitude of the geometric center of each study unit, respectively, whereas the z-axis represents the incidence rate. A higher $z$ value indicates a greater TB incidence in the corresponding area. Thus, any point ($x$, $y$, or $z$) within this 3D space corresponds to the TB incidence level within a specific study region. By projecting the longitude and latitude coordinates of each county in Chongqing and their corresponding TB incidence rates onto the $x$-$z$ and $y$-$z$ planes and subsequently performing curve fitting using a polynomial model [23], the characteristics of incidence rate trends in relation to geographical coordinates can be further analyzed in 2D.

### Spatial Autocorrelation Analysis

Spatial autocorrelation measures the correlation of a single variable across different spatial locations, quantifying the degree of clustering for an attribute value among spatial units. It is typically categorized into global and local spatial autocorrelation analyses. This study used the global Moran $I$ index to assess global spatial autocorrelation. The value of the Moran $I$ ranges from −1 to 1. A Moran $I$ value greater than 0 indicates positive spatial autocorrelation, with higher values signifying more pronounced spatial clustering. Conversely, a Moran $I$ value of less than 0 indicates negative spatial autocorrelation, suggesting a dispersed pattern; values closer to −1 denote greater spatial disparity. A Moran $I$ of 0 implies the absence of spatial clustering, consistent with a random distribution [24]. The statistical significance was evaluated using the standardized $z$ score.

Global spatial autocorrelation was used to determine whether TB incidence was correlated across the entire study area, but it cannot pinpoint the specific locations of clusters. In contrast, local spatial autocorrelation analysis, conducted by generating cluster maps based on local indicators of spatial association (LISA), measures the concentration of high or low values. This method detects spatial hot spots and cold spots of disease occurrence, thereby revealing spatial heterogeneity within the data. The LISA cluster patterns are categorized into 4 types: high-high, high-low, low-high, and low-low. Among these, high-high and low-low clusters represent positive spatial autocorrelation, whereas high-low and low-high clusters indicate negative spatial autocorrelation. The high-high clusters, identified as hot spots, are typically prioritized areas for infectious disease control and were the primary focus of the spatial analysis of TB in the older adult population [25]. To assess robustness, we excluded 8 counties with populations of less than 100,000 (Dadukou, Yuzhong, Jiangbei, Nan'an, Liangping, Jiulongpo, Tongnan, and Shapingba) and reran LISA for 2020 to 2024 using the remaining 30 counties.

In this study, the spatial weight matrix for spatial autocorrelation analysis was constructed using the inverse distance method, with weights calculated as the reciprocal of the Euclidean distance between the centroids of each district and county. No distance threshold was set, meaning that all districts and counties were considered neighbors, and the weight matrix was row standardized before analysis.

### Spatial-Temporal Scan Statistic

Spatiotemporal scan statistics were used to identify spatial clusters of TB incidence among older adults in Chongqing and analyze their temporal evolution. The analysis was performed using the spatiotemporal scan statistic by Kulldorff [26], with a Poisson probability model applied to the number of reported TB cases, resident population data, and geographical coordinates. In this method, the scanning window is a dynamic cylinder whose base represents a circular geographic area and whose height corresponds to a time interval. As the center, radius of the base, and height of the cylinder vary, a log-likelihood ratio (LLR) is computed for each possible window to compare the risk of TB inside the window against the risk outside. The relative risk (RR) was calculated to estimate the magnitude of risk within each identified cluster. The 95% CIs for the RR were derived using the exact Poisson method based on the observed and expected case counts. The statistical significance of the LLR statistic was assessed using the Monte Carlo randomization method, with 999 iterations performed to derive the $P$ value. A larger, statistically significant LLR value indicates a stronger clustering effect. The window with the maximum significant LLR was identified as the most likely cluster, whereas other windows with statistically significant LLRs were classified as secondary clusters. For this study, the scan period spanned January 1, 2020, to December 31, 2024,

XSL•FO
RenderX

with 1 year defined as the basic temporal unit. The maximum spatial and temporal scan window sizes were both set to the default values, with the maximum spatial cluster size set to 50% of the at-risk population and the maximum temporal cluster size set to 50% of the study period to ensure that persistent aggregation phenomena could be detected and that the reported time range reflected the actual duration of increased risk [27]. Clusters were ranked based on their LLR values. The geographic coordinates (longitude and latitude) used for spatiotemporal scanning were the centroid coordinates of each county-level administrative district in Chongqing obtained from the National Geographic Information Public Service Platform of China. These coordinates represent the spatial location of each district for aggregated case data analysis rather than individual patient addresses.

### Statistical Software

Data collection, collation, and descriptive analysis for TB cases among individuals aged 65 years and older were performed using Microsoft Excel 2019. Joinpoint regression analysis (version 6.0.0.0; National Cancer Institute) was used to assess temporal trends in TB notification rates. Global and local spatial autocorrelation analyses, including the calculation of the Moran *I* index, spatial trend surface analysis, and visualization of incidence rates, were conducted using the ArcGIS software (version 10.7; Esri). Spatiotemporal scanning and the calculation of LLR values were performed using the SaTScan software (version 10.3.2). A threshold of $P<.05$ was applied to determine statistical significance for all analyses.

### Ethical Considerations

The use of TB case data in this study was approved by the ethics committee of the Chongqing Tuberculosis Control and Prevention Institute (audit 2025008) on April 14, 2025. This was a retrospective approval for the use of deidentified data collected from January 1, 2020, to December 31, 2024, from the routine TBIMS. The ethics committee waived the requirement for individual informed consent because the data were anonymized prior to analysis. The authors have obtained formal permission to access and use the data for this research. All personal identifiers were removed from the dataset prior to data analysis and reporting.

## Results

### Descriptive Analysis of TB Cases

A total of 20,265 new TB cases in individuals aged 65 years and older were reported from 2020 to 2024, yielding an average of 4053 cases annually. Among these 20,265 patients, 15,098 (74.5%) were male, and 5167 (25.5%) were female, resulting in a male-to-female ratio of 2.92:1. The average annual incidence rate was 69.59 per 100,000 population. The specific annual rates were 74.48, 72.04, 65.19, 68.05, and 68.68 per 100,000 population in 2020, 2021, 2022, 2023, and 2024 (Figure 2). Joinpoint regression analysis identified a statistically significant change in trend occurring in 2022. From 2020 to 2022, the notification rate decreased sharply, with an annual percent change (APC) of −6.26% (95% CI −9.94% to −2.09%; $P<.001$). From 2023 to 2024, the rate increased slightly, with an APC of 2.11% (95% CI −2.31% to 6.43%; $P=.28$). The average APC over the entire 2020 to 2024 period was −2.17% (95% CI –5.05% to 0.72%; $P=.16$), indicating that the overall incidence did not change significantly over the 5 years. Regarding age distribution, 35.99% (7293/20,265) of the patients were aged 65 to 69 years, 30.22% (6125/20,265) were aged 70 to 74 years, and 33.79% (6847/20,265) were aged 75 years or older. Patients were mainly referred, accounting for 71.22% (14,432/20,265) of the total, followed by direct visits with 12.22% (2476/20,265) and tracking with 11.56% (2343/20,265; Table 1). From 2020 to 2024, the number of TB cases showed seasonal variation, with the peak of reported cases mainly concentrated in spring and summer and a small peak occurring every year in March (Figure 3).

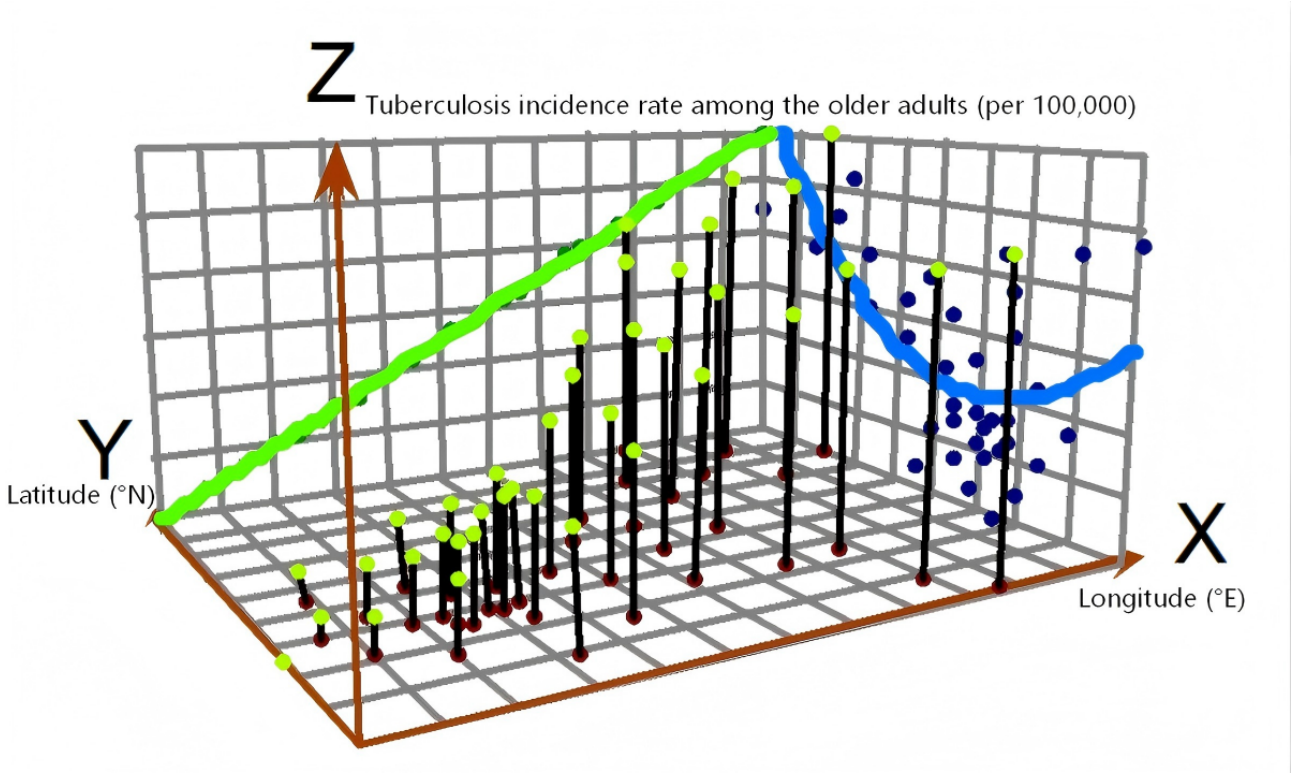
## Spatial Characteristics of TB Cases

Spatial distribution maps of reported TB incidence rates for the 38 counties in Chongqing (2020 - 2024) were generated using ArcGIS. From a spatial perspective, the incidence of TB was mainly distributed in the northeast and southeast of Chongqing. The top 5 regions with the highest reported TB incidence rates among individuals aged 65 years and older were Pengshui (255.38 per 100,000 population), Qianjiang (192.33 per 100,000 population), Wuxi (180.20 per 100,000 population), Wulong (175.44 per 100,000 population), and Xiushan (174.26 per 100,000 population; Figure 4).

**Figure 4.** Spatial distribution map of tuberculosis (TB) notification rates among the older adult population in the Chongqing municipality, 2020 to 2024.



XSL•FO
RenderX

## Spatial Trend Surface Analysis

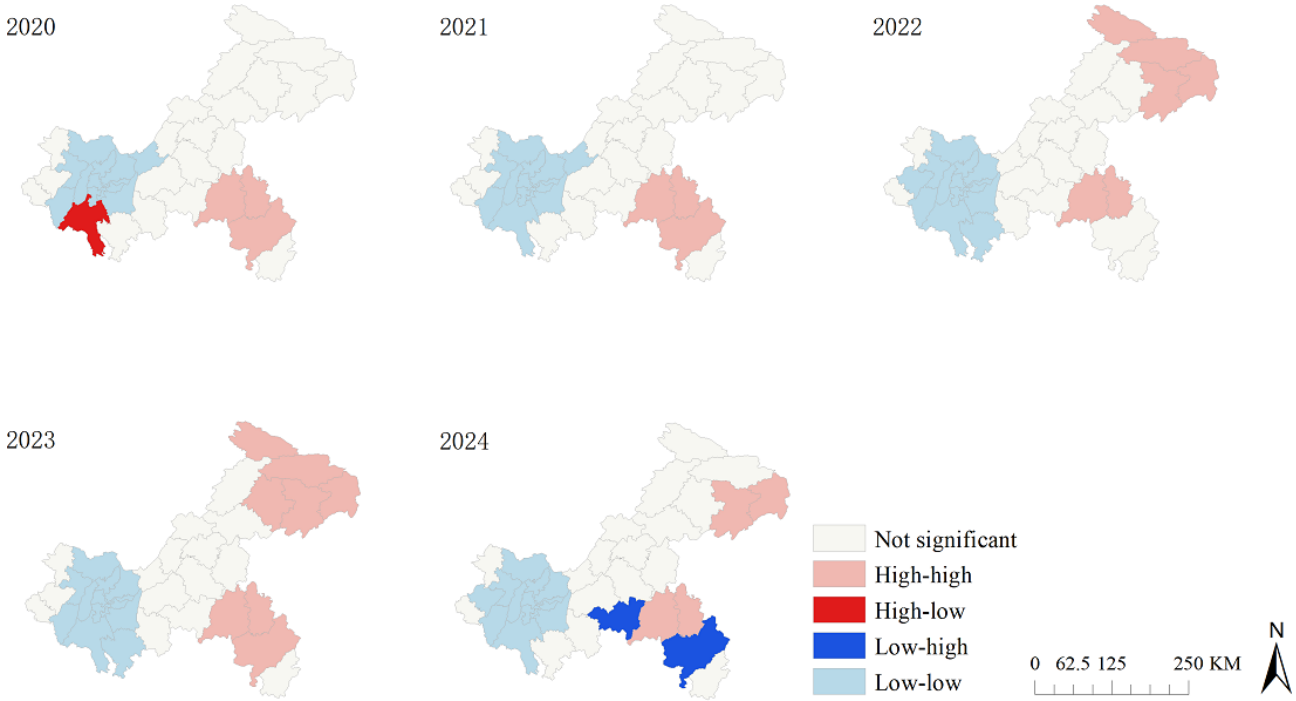
Using the reported incidence rate of TB among older adults in the 38 counties of Chongqing from 2020 to 2024 as the dependent variable (z-axis) and the latitude and longitude of the geometric center of the study area as the independent variables (x- and y-axes), the analysis revealed a clear east-west gradient, with incidence rates gradually increasing from west to east. In the north-south direction, the rates exhibited a U-shaped pattern, initially decreasing from north to south before rising rapidly further south. Overall, the trend surface indicated higher incidence rates in the eastern and northern regions than in the western and southern parts of the municipality (Figure 5).

**Figure 5.** Spatial 3D trend surface analysis of tuberculosis among older adults in the Chongqing municipality, 2020 to 2024.

## Spatial Autocorrelation Analysis

The results of the global spatial autocorrelation analysis of reported TB incidence among older adults in Chongqing from 2020 to 2024 showed that the global Moran *I* indexes were 0.636, 0.618, 0.756, 0.713, and 0.668, respectively, with all Moran *I* values greater than 0 and statistically significant (*P*<.001; Table 2). This indicates a positive global spatial autocorrelation in TB incidence from 2020 to 2024, meaning that there was spatial clustering. The spatial clustering of TB in older adults was highest in 2022.

**Table .** Global spatial autocorrelation analysis of tuberculosis notification rates among older adults in the Chongqing municipality, 2020 to 2024.



| Year | Moran *I* | *z* score | *P* value |
|---|---|---|---|
| 2020 | 0.636 | 6.613 | <.001 |
| 2021 | 0.618 | 6.560 | <.001 |
| 2022 | 0.756 | 7.476 | <.001 |
| 2023 | 0.713 | 7.086 | <.001 |
| 2024 | 0.668 | 6.844 | <.001 |

The LISA cluster maps from the local spatial autocorrelation analysis for the period from 2020 to 2024 revealed 4 types of spatial clustering patterns: high-high, high-low, low-high, and low-low clusters. Specifically, no low-high clusters were identified in 2020, neither high-low nor low-high clusters were observed from 2021 to 2023, and no high-low clusters were found in 2024. In 2020 and 2021, high-high clusters were located in the southeastern region, including Pengshui, Qianjiang, and Youyang. Starting in 2022, the high-high clusters expanded from the southeast to the northeast, encompassing Pengshui, Qianjiang, Youyang, Wushan, Fengjie, Wuxi, Chengkou, and Yunyang. Throughout the entire study period, Pengshui and Qianjiang in southeastern Chongqing consistently remained hot spots for TB among older adults. Cold spots were primarily distributed in the central urban districts and their surrounding counties (Figure 6).

XSL•FO
RenderX

**Figure 6.** Local spatial autocorrelation analysis of tuberculosis notification rates among older adults in the Chongqing municipality, 2020 to 2024.

The sensitivity analysis results show that the southeastern hot spots (Pengshui and Qianjiang) remained stable; northeastern hot spots began to appear in 2022, which is almost consistent with the LISA cluster patterns shown in Figure 6, in which high-high clusters were concentrated in southeastern Chongqing and expanded to the northeast after 2022. The counties that were excluded were all cold spots and had no impact on the core results (Multimedia Appendix 1).

## Spatial-Temporal Clustering Analysis Using SaTScan

The spatiotemporal scan analysis identified 1 most likely cluster and 3 secondary clusters of reported TB incidence among older adults in Chongqing from 2020 to 2024. The most likely cluster covered 5 counties (Xiushan, Youyang, Qianjiang, Pengshui, and Wulong) in the southeastern region, with a clustering period from January 2020 to December 2021. This cluster contained 1970 confirmed cases (RR=3.52, 95% CI 3.37-3.68; LLR=1017.43; *P*<.001), indicating the highest risk of TB among older adults in these areas. Secondary cluster 1 encompassed 17 counties (Wanzhou, Yunyang, Zhongxian, Kaizhou, Liangping, Shizhu, Fengjie, Dianjiang, Fengdu, Wuxi, Chengkou, Qianjiang, Changshou, Wushan, Pengshui, Fuling, and Wulong) primarily distributed across the northeastern and southeastern regions. Its clustering period was from January 2023 to December 2024, involving 4623 cases (RR=1.70, 95% CI 1.65-1.75; LLR=454.45; *P*<.001). Secondary cluster 2 included 3 counties (Yongchuan, Jiangjin, and Rongchang) and was observed from January 2020 to December 2021, with 924 cases identified (RR=1.21, 95% CI 1.13-1.29; LLR=14.55; *P*<.001). Secondary cluster 3 covered a single county, Qijiang, during the period from January 2020 to December 2021, with 312 cases (RR=1.27, 95% CI 1.14-1.42; LLR=8.31; *P*=.03; Table 3). It is worth noting that the detected clusters span multiyear periods (2020 - 2021 and 2023 - 2024) rather than single years. This is because the spatiotemporal scan analysis allowed for a maximum temporal cluster size of 50% of the study period (ie, 2.5 years), a standard setting that enables the identification of both short-term and persistent aggregations. Therefore, the 2-year duration of these clusters reflects sustained elevated risk in the affected regions rather than isolated annual events.

## Discussion

### Principal Findings

This study used spatial epidemiological methods to analyze the spatiotemporal characteristics of reported TB incidence among the population aged 65 years and older across 38 counties of Chongqing from 2020 to 2024, thereby delineating the epidemiological distribution of TB within this demographic.

This study found that, from 2020 to 2024, the average annual incidence rate among older people in Chongqing was 69.59 per 100,000 population, higher than the average TB incidence rate in China of 52.00 per 100,000 population [1] and the annual incidence rate of TB among people aged 65 years and older in Xuzhou of 51.27 per 100,000 population [28]. Furthermore, joinpoint regression analysis revealed a nonlinear trend in TB incidence among older adults in Chongqing, with a significant decline from 2020 to 2022 followed by a nonsignificant increase from 2023 to 2024. The average APC over the entire study period was −2.17% (95% CI −5.05% to 0.72%; *P*=.16). Although this decline did not reach statistical significance, the point estimate was substantially lower than the reported national average annual decline of −3.55% for older adult TB in China [29]. This finding may be attributable to Chongqing's high aging population, with 18.87% of people aged 65 years and older, which is higher than the national average of 15.40% [30]. Moreover, Chongqing is mostly mountainous, and the aging and empty nest phenomena are serious, resulting in lower health awareness among the local older adults left behind and a lack of knowledge about TB prevention and control [31]. Despite the nonlinear pattern identified by the joinpoint analysis, the overall incidence among older adults in Chongqing decreased from 74.48 per 100,000 population in 2020 to 68.68 per 100,000 population in 2024, a net decline consistent with observations from other Chinese provinces [32,33] and other countries [34,35]. The overall declining trend may be attributed to factors such as national socioeconomic development, improvements in health care infrastructure, and the implementation of effective public health interventions [36,37]. Concurrently, this trend aligns with a series of TB control policies enacted by the Chongqing municipal government and health administration. For instance, the Chongqing Action Plan for Tuberculosis Control (2019-2022) issued in 2019 [38] promoted initiatives including the Hundreds, Thousands, and Tens of Thousands of Volunteers campaign for TB knowledge dissemination, the integration of TB education into school health programs, and the comprehensive incorporation of TB control for migrant populations into localized management. These measures ensured seamless processes from screening and treatment to cross-regional coordination.

The turning point detected in 2022 by the joinpoint analysis closely mirrors the trajectory of the COVID-19 pandemic. It is important to acknowledge that the COVID-19 pandemic introduced significant disruptions to TB surveillance worldwide, which may have influenced case detection and reporting during our study period. A growing body of literature has documented the substantial impact of the pandemic on TB notifications worldwide. According to the World Health Organization, TB case notifications fell considerably below prepandemic levels from 2020 to 2021, with a global reduction of 18% in 2020 [39]. Studies from Brazil reported significant decreases in TB notifications in 2020 (13%) and 2021 (9%), with partial recovery in 2022 [40]. Similar disruptions were observed across multiple countries, attributed to health care system strain, reallocation of TB diagnostic resources and personnel to COVID-19 response, lockdown measures that limited health care access, and reduced health care–seeking behavior due to fear of infection [41,42]. The overlap of respiratory symptoms between TB and COVID-19 may also have contributed to diagnostic delays and underreporting [43].

XSL•FO
RenderX

In the context of these global disruptions, it is noteworthy that large-scale preventive measures implemented in China during the pandemic, such as disinfection and isolation protocols, may have helped limit TB transmission [44]. Simultaneously, reduced social activities and increased adherence to protective measures such as mask wearing among older adults likely diminished TB exposure risks [45]. These factors may have partially offset the surveillance disruptions observed elsewhere. However, the brief upward trend from 2022 to 2024 requires further consideration. This increase may be related to the relaxation of pandemic restrictions in China after 2022, which led to increased outdoor activities among older adults [46]. Additionally, some older adults who had been infected with COVID-19 may have experienced temporary immune impairment [47], potentially increasing their susceptibility to TB. This combination of behavioral and immunological factors likely contributed to the observed temporary increase against the backdrop of ongoing postpandemic recovery in health care use.

A marked male predominance was observed in TB cases among older adults, a finding consistent with those of numerous previous studies [48,49]. This disparity is primarily attributed to gender-specific differences in lifestyle behaviors and genetic susceptibility [50,51]. High-risk behaviors more prevalent in male individuals, such as smoking, alcohol consumption, and poorer adherence to medical care, can increase susceptibility to TB infection. Concurrently, male individuals may exhibit a higher probability of specific genetic variations that elevate the risk of contracting TB. The predominant patient source being referral was likely because older adults are a key population for TB control. When primary health care institutions detect suspected patients, they are typically transferred to designated TB facilities to mitigate the risk of clustered transmission [52]. Furthermore, our analysis revealed a distinct seasonal variation in TB incidence among older adults in Chongqing, with peaks predominantly occurring in spring and summer. This pattern aligns with observations from multiple regions, including the Hong Kong special administrative region, China [53], Guangxi [54], Turkey [55], and Japan [56]. This seasonality may be associated with care seeking delays among Chinese older adults. This may be related to delayed medical visits among older people in China. Winter in China is from December to February, during which people prepare to celebrate the Chinese New Year. Some patients with mild symptoms may choose to seek medical treatment after the New Year; therefore, medical visits are avoided or postponed during this period, leading to a decrease in the reported number of cases [57].

The spatial analysis confirmed that TB among older adults in Chongqing is not randomly distributed but exhibits significant clustering. The identification of persistent hot spots in both southeastern and northeastern regions aligns with areas previously characterized by mountainous terrain, ethnic minority populations, and limited health care access [58]. These geographic and socioeconomic factors likely contribute to delayed diagnosis and ongoing transmission, particularly among older adult residents with lower health literacy [8,20].

Sensitivity analysis revealed marked regional heterogeneity in the robustness of these spatial patterns. Southeastern hot spots (eg, Pengshui and Qianjiang) demonstrated exceptional stability, persisting even after excluding low-population counties, suggesting that risk in this region is driven by entrenched, population-independent factors. In contrast, northeastern hot spots exhibited greater temporal variability; although the expansion of risk to the northeast since 2022 was reproduced in the sensitivity analysis, the detection of individual counties was more sensitive to spatial weight structures. These findings have practical implications for TB control. The southeastern region is highly stable and requires continuous, population-wide interventions, including enhanced active case detection, routine screening, and health education campaigns [59,60]. However, the northeastern region experiences considerable fluctuations in the epidemic and requires localized strategies, such as conducting large-scale screenings regularly in newly identified high-incidence counties and detecting new cluster cases through real-time monitoring. To further investigate the spatiotemporal clustering of reported TB incidence among older adults in Chongqing and delineate the specific scope and size of the clusters, this study conducted a spatiotemporal scan analysis. The results identified the most likely cluster in 5 southeastern counties: Xiushan, Youyang, Qianjiang, Pengshui, and Wulong. Secondary clusters were distributed across 17 districts and counties in both the northeastern and southeastern regions. These findings are consistent with the results of the spatial analyses. No significant clusters were detected in 2022, which may reflect pandemic-related fluctuations in case detection or a more dispersed spatial distribution during that year. Therefore, for future prevention and control efforts, it is imperative to sustain and enhance surveillance and interventions in these key areas. TB control strategies should be adjusted and refined according to the specific clustering patterns observed in Chongqing to effectively reduce the risk of TB transmission and the overall disease burden.

## Limitations

Nevertheless, this study has several limitations. First, the data were derived from passively reported TB cases, which may not capture all incidents due to underreporting. In some remote areas, factors such as limited mobility among older adults and insufficient diagnostic capacity in primary health care institutions could lead to missed cases and incomplete registration. Second, the research period (2020 - 2024) largely overlapped with the COVID-19 pandemic, which may have affected TB case reporting through multiple pathways, such as health care system pressures, lockdown measures, and reduced health care–seeking behavior [3,4]. Although our data came from the mandatory national TB reporting system (TBIMS) with standardized procedures, we cannot rule out a certain degree of underreporting or diagnostic delays during the peak of the pandemic (2020-2022). At the same time, several pandemic-related factors may have introduced difficult-to-quantify confounding effects. The potential impact of these confounding effects on the spatiotemporal distribution characteristics also cannot be entirely ruled out. Despite these potential impacts, the spatiotemporal distribution patterns we identified—particularly the persistent clustering in the northeast and southeast regions of Chongqing—are consistent with prepandemic research results, indicating that the underlying epidemiological patterns remain valid. Future studies that

XSL•FO
RenderX

integrate multisource data, such as active surveillance data, postpandemic follow-up surveys, or health care use data, will help verify trends in true incidence and further clarify the confounding effects caused by the pandemic. Third, the absence of detailed geographical information at the township level for each county precluded a finer-scale spatiotemporal cluster analysis. Finally, as the older adult population is highly vulnerable to TB, its incidence is influenced by multiple factors, including socioeconomic status, health care accessibility, climatic conditions, and the intensity of policy support. The specific impacts of these factors on TB in older adults warrant further investigation.

## Conclusions

This study delineated the spatiotemporal distribution patterns and clustering characteristics of TB among individuals aged 65 years and older in Chongqing from 2020 to 2024. The incidence of TB among the older adult population showed a significant downward trend from 2020 to 2022 and no significant change from 2023 to 2024, with cases predominantly observed in older men and peaks occurring during spring and summer. Spatial analysis identified persistent high-cluster areas in both the northeastern and southeastern regions of Chongqing. Spatiotemporal scan analysis further indicated a higher TB burden and increased transmission risk in the southeastern part of the municipality. Therefore, it is crucial to sustain and strengthen TB control measures in these high-risk areas by adopting more targeted outbreak containment strategies, enhancing the diagnostic and treatment capabilities of health care professionals, and reducing underreporting of TB cases among older adults.

## Acknowledgments

The authors gratefully acknowledge the Chongqing Tuberculosis Control and Prevention Institute for providing the data used in this study. They also extend their appreciation to all health care workers and staff who have contributed to tuberculosis control and prevention efforts in Chongqing. This work was supported by the Chongqing Public Health Key Special Project (Discipline) Construction Fund, the Scientific Research Project of Chongqing Center for Disease Control and Prevention (2026JKXM037), and the Chongqing High-Level Young and Middle-Aged Medical Talents Project (YXGD202439).

## Funding

This research did not receive any specific grant from funding agencies.

## Data Availability

The datasets generated or analyzed during this study are not publicly available due to privacy and ethical restrictions (the patient-level data come from the Chinese Tuberculosis Information Management System) but are available from the corresponding author on reasonable request. Data can also be obtained from the Chongqing Tuberculosis Control and Prevention Institute upon reasonable request by contacting the author.

## Authors' Contributions

BG, YX, and CP conceptualized and designed the study. WL, LS, and CW assisted in obtaining data. BG, YX, JF, and QW conducted the statistical analysis. BG, YX, SH, XY, and YL assisted in interpreting the data and drafting the manuscript. WZ and CP carried out the literature search and manuscript review. All authors read and approved the final manuscript. CP served as the primary corresponding author responsible for editorial correspondence, whereas WZ served as the co-corresponding author.

## Abstract

**Background:** Stroke remains a leading cause of death and disability in China. Despite the nationwide poverty alleviation being achieved by 2020, residents of poverty-alleviated counties continue to experience poorer health outcomes. There is a critical knowledge gap regarding the evolving spatiotemporal patterns of stroke burden in this large postpoverty population.

**Objective:** This study aimed to quantify the longitudinal trends in stroke prevalence and incidence across all 832 poverty-alleviated counties in China from 2019 to 2024, stratified by age and sex; to characterize the spatiotemporal evolution and geographic clustering of the stroke burden; and to compare this burden in poverty-alleviated counties with that of the general Chinese population during the key transitional period from 2019 to 2021.

**Methods:** We conducted a nationwide retrospective analysis using data from China's National Health Poverty Alleviation Dynamic Management System (NHPADMS), covering 56.08 million residents. Temporal trends were analyzed using Joinpoint regression to calculate the annual percentage change and average annual percentage change (AAPC). Spatial clustering was assessed using Global and Local Moran *I*. Comparative analysis used age-standardized prevalence rates, referenced against the Global Burden of Disease standard population.

**Results:** Stroke prevalence surged markedly from 65.18 to 359.60 per 100,000 population (overall AAPC: +22.95%), with the steepest increase among adults aged 20 to 39 years (AAPC: +35.63%). Stroke incidence remained relatively stable from 2020 to 2023 but declined notably in 2024. While absolute prevalence remained lower, its growth rate in poverty-alleviated regions (+61.85%) far exceeded that in the nonpoverty-alleviated areas (+3.82%) during 2019 to 2021. Spatial analysis revealed persistent hyperendemic clusters in northern provinces (notably the Hebei-Heilongjiang-Jilin-Inner Mongolia corridor) and a significant north-south gradient.

**Conclusions:** The stroke burden in China's poverty-alleviated counties increased sharply in recorded prevalence, exhibited a worrying shift toward younger adults, and became geographically polarized. Economic advancement has not translated into proportionate health gains. These findings underscore the urgent need for precision public health interventions that are geographically targeted and demographically tailored to address this evolving epidemic.

## Introduction

Stroke ranks as the second leading cause of death globally, surpassed only by ischemic heart disease [1]. In China, it remains the leading cause of adult mortality and disability, exhibiting a persistently rising prevalence [2,3]. Notably, rural Chinese populations demonstrate significantly elevated stroke incidence and mortality rates among low-income groups compared to their higher-income counterparts [4].

Over the past decade, China has prioritized poverty eradication, achieving nationwide poverty alleviation across all 832 nationally designated impoverished counties by the end of 2020. Nevertheless, the health status of residents in these newly lifted-out-of-poverty counties continues to trail behind the national average [5]. Despite nationwide prevention initiatives and efforts to promote equitable health care access under the "Healthy China 2030" framework [6], effective burden reduction remains unachieved, particularly among vulnerable populations [7,8].

XSL•FO
RenderX

Prior epidemiological studies on stroke among China's poverty-alleviated populations have significant limitations: they often lack adequate population bases or are constrained by narrow scopes, such as restricting age ranges (eg, 35 - 64 y), exhibiting selection biases, relying on small and nonnationally representative samples, focusing solely on national or provincial scales, or being confined to periods during prealleviation poverty [9-13]. Critically, most foundational studies were conducted 10 to 30 years ago. Furthermore, China has undergone rapid health transitions and profound sociodemographic shifts during the poverty alleviation period [14]. Marked rises in the prevalence of hypertension, smoking, overweight or obesity, and diabetes represent contemporary shifts in key modifiable risk factors, potentially altering the stroke burden [15-17]. This creates a knowledge gap regarding how the burden of stroke has evolved among these populations following the elimination of absolute poverty, especially during the post-2020 transition studies [18,19].

To address this gap, our nationwide investigation conducts spatially explicit, age-stratified, and sex-stratified analyses of stroke incidence and prevalence trends across China's 832 poverty-alleviated counties from 2019 to 2024. This granular methodological approach distinctly identifies microscale geographic disparities typically obscured in aggregated data, thereby establishing a robust epidemiological foundation for designing precision interventions targeting high-risk clusters. This study aims to answer 3 core research questions: (1) How have the prevalence and incidence rates of stroke evolved longitudinally in poverty-alleviated counties, and do these trends exhibit variations by age, sex, or region? (2) What characterizes the spatiotemporal evolution of the stroke burden during the study period, including spatial clustering and regional diffusion patterns? (3) How does the stroke burden in poverty-alleviated counties during the transition period (2019 - 2021) compare with the concurrent burden across contemporary China?

# Methods

## Data Source

Incidence, prevalence, and population data (2019 - 2024) for the poverty-alleviated population were systematically extracted from China's National Health Poverty Alleviation Dynamic Management System (NHPADMS), maintained by the China Population and Development Research Center. The database encompasses 56.08 million officially registered poverty-alleviated residents across 832 county-level administrative divisions that completed national poverty eradication. Stratification followed NHPADMS age groups: 20 to 39, 40 to 64, and 65 years and older. The annual denominator population consists of these poverty-alleviated residents, which changes dynamically due to death, migration, or birth. The definition of "poverty-alleviated population" is provided by the National Administration for Rural Revitalization of China. The inclusion of "stroke" cases operates under the policy framework established by the National Health Commission of China, which lists stroke as a key disease for specialized treatment in poverty–alleviation health care initiatives. Consequently, all registered cases meet China's current clinical diagnostic criteria for cerebrovascular diseases. Stroke was diagnosed using National Clinical V.2.0 of the International Classification of Diseases, Tenth Revision, disease codes. Case ascertainment relied on passive registry linkage. As health-focused poverty-alleviation efforts have progressed, primary health care facilities in poverty-alleviated counties have carried out systematic screening and registration for key diseases, including stroke, which may have led to a significant increase in the detection rate of cases.

The county-level administrative boundaries used in this study were sourced from the National Geomatics Center of China (NGCC) [20]. All spatial analyses and the resulting distribution maps were generated using the unmodified standard basemaps provided by the NGCC (Map Audit number GS[2024]0650).

Comparative prevalence data for the general population of mainland China (2019 - 2021) were obtained from the Global Burden of Disease (GBD) 2021 study (Institute for Health Metrics and Evaluation) [3].

## Temporal Analysis

Temporal trends (2019 - 2024) in stroke prevalence and incidence were quantified using the Joinpoint regression model (Joinpoint Regression Program v5.2.0, National Cancer Institute). The optimal number of joinpoints (turning points) was selected using the Weighted Bayesian Information Criterion (WBIC), which is the default model selection method in Joinpoint version 5.0 and higher. WBIC combines the classical Bayesian Information Criterion (BIC) and the BIC3 (a modified BIC with a harsher penalty) using a data-driven weight based on the partial $R^2$, thereby adapting to the magnitude of slope changes in the data. This approach does not require manual specification of the maximum number of joinpoints. In Joinpoint regression, the maximum number of joinpoints is inherently constrained by the number of time points; for a 6-year series, the algorithm considers models with up to 3 joinpoints. The model identifies significant temporal turning points (joinpoints), representing years when the trend (eg, prevalence or incidence) slope undergoes a statistically significant change [21]. These turning points reflect shifts in disease dynamics, potentially linked to factors like public health measures or environmental exposures. The annual percentage change (APC) was calculated for each trend segment identified by the selected model, and the average annual percentage change (AAPC) was computed as a summary measure for the entire study period, with 95% CI estimated through the empirical quantile method.

The statistical analysis used the $\chi^2$ test to assess differences in rates (incidence or prevalence) across groups (age and sex strata), with pairwise comparisons adjusted using the Bonferroni correction ($\alpha$=.05).

## Spatial Analysis

Global and local spatial autocorrelation analysis was performed at the county level to identify the geographic clustering of incidence using ArcGIS 10.8 [22]. A spatial weights matrix was constructed based on the Inverse_Distance conceptualization, which defines the spatial relationship between counties as a function of the inverse distance between their geographic

XSL•FO
RenderX

centroids. To ensure the robustness of our findings, we conducted a sensitivity analysis by varying the distance threshold. Specifically, we compared results using 3 distance thresholds: (1) the default threshold automatically determined by ArcGIS, (2) a smaller threshold (50% of the default), and (3) a larger threshold (200% of the default). The statistical significance was determined using a permutation approach with 999 repetitions. For global analysis, we applied Global Moran *I* to assess the overall spatial pattern across the study area [23]. Values approximate −1 (dispersed) to 1 (clustered). A significantly positive Moran *I* (statistical significance was set at $P<.05$ for all analyses) indicates a clustered pattern where similar values are spatially aggregated, whereas a significantly negative value suggests a dispersed pattern. A value near zero implies a random spatial distribution. For local analysis, to pinpoint the specific locations and types of clusters, we conducted a Local Indicators of Spatial Association analysis using Anselin Local Moran *I* [24]. This method identifies statistically significant (statistical significance was set at $P<.05$ for all analyses) spatial units belonging to 4 categories: high-high clusters (a high-incidence county surrounded by other high-incidence counties, ie, a hotspot), low-low clusters (a coldspot), and spatial outliers (high-low or low-high units).

### Comparative Analysis With National Data

To control for the influence of differing population age structures on comparability, this study used the direct age standardization method to calculate the stroke prevalence rate. The GBD world population age standard was used as the reference population structure [25]. The key standardized metric, along with its definition and computational formula, is as follows:

Age-standardized prevalence rate (ASPR) represents the prevalence rate adjusted to a standard age distribution. It reflects the stroke prevalence that would be observed if the populations being compared shared an identical age structure, allowing for valid comparisons across groups with different age compositions.

$$(1)\ ASPR=\left(\sum \frac{\text{Age-Stratum prevalent cases}}{\text{Total population}}\right)\times\lambda[age]\times 100{,}000$$

λ is the standardized proportion according to the GBD world population age standard.

The comparative analysis focused on the years 2019 to 2021 because this period captured the most dramatic initial surge in age-standardized stroke prevalence within the poverty-alleviated population, increasing from 65.18 to 172.79 per 100,000 population. This steep rise established a new baseline for subsequent trends. To determine whether this rapid increase reflected a phenomenon specific to this recently poverty-alleviated group or was part of a broader national pattern, we compared the magnitude and pace of prevalence change with that of the nonpoverty-alleviated regions (defined as the population of China excluding those residing in poverty-alleviated regions) during the same 3-year window. This period also coincided with the conclusive phase of China's targeted poverty alleviation campaign (ending in 2020) and the onset of the pandemic, providing crucial context for interpreting shifts in health care engagement and data reporting.

### Ethical Considerations

This study involved a secondary analysis of deidentified national public health records. It was reviewed and confirmed to be exempt from full ethical review by the Naval Medical University Ethics Committee.

## Results

### Overall Trends in Prevalence and Incidence

From 2019 to 2024, the overall prevalence of stroke demonstrated a marked and sustained increase, rising from 65.18 to 359.60 per 100,000 population. The incidence rate remained relatively stable through 2023 before a notable decline in 2024. Joinpoint regression quantified a significant upward trend in prevalence for the overall population, with an AAPC of +22.95% ($P=.006$). This increasing trend was consistent across all subgroups but varied in magnitude: the most rapid rise was observed in the 20 to 39 years age group (AAPC=+35.63%, $P<.001$), followed by the 40 to 64 years (AAPC=+28.29%, $P<.001$), and the 65 years and older age groups (AAPC=+26.42%, $P<.001$). In the 20 to 39 years age group, prevalent stroke cases rose from 173 (1.07 per 100,000 population) in 2019 to 1728 (10.65 per 100,000 population) in 2024, with the absolute increase accounting for 0.90% of all new cases during the same period. Although the AAPC was highest in this group, the absolute burden remained modest. When stratified by sex, the AAPC was slightly higher for females (+24.31%, $P<.001$) than for males (+22.16%, $P<.001$; Table 1).

For overall stroke incidence, the WBIC selected a model with 2 joinpoints (2021 and 2023). Consequently, 3 trend segments were identified: 2020 to 2021 (APC=−7.99%, $P<.001$), 2021 to 2023 (APC=+2.92%, $P<.001$), and 2023 to 2024 (APC=−32.22%, $P<.001$). The steepest decrease occurred in the last year of the observation period. Cross-sectional analyses revealed consistent patterns within each individual year from 2019 to 2024. Specifically, in every year observed, both stroke prevalence and incidence increased with advancing age, from the 20 to 39 years to the 65 years and older age groups. Additionally, the rates for both metrics were consistently higher in males than in females within each annual cross-section. The most pronounced year-on-year increase in prevalence occurred between 2019 and 2020, whereas the largest annual decrease in incidence was observed between 2023 and 2024 (Figure 1).

To assess whether the observed 2024 incidence decline disproportionately influenced overall trend estimates, we repeated the Joinpoint regression analysis after excluding 2024 data (ie, using only 2020 - 2023 data). The overall incidence trend without 2024 remained stable and nonsignificant, confirming that the sharp decline in 2024 was not a statistical artifact that altered the long-term trend interpretation. In contrast, the prevalence trend without 2024 remained strongly positive (AAPC=+39.34%, 95% CI 16.47% - 65.40%, $P<.001$), consistent with the primary analysis. These results are presented in Multimedia Appendix 1.

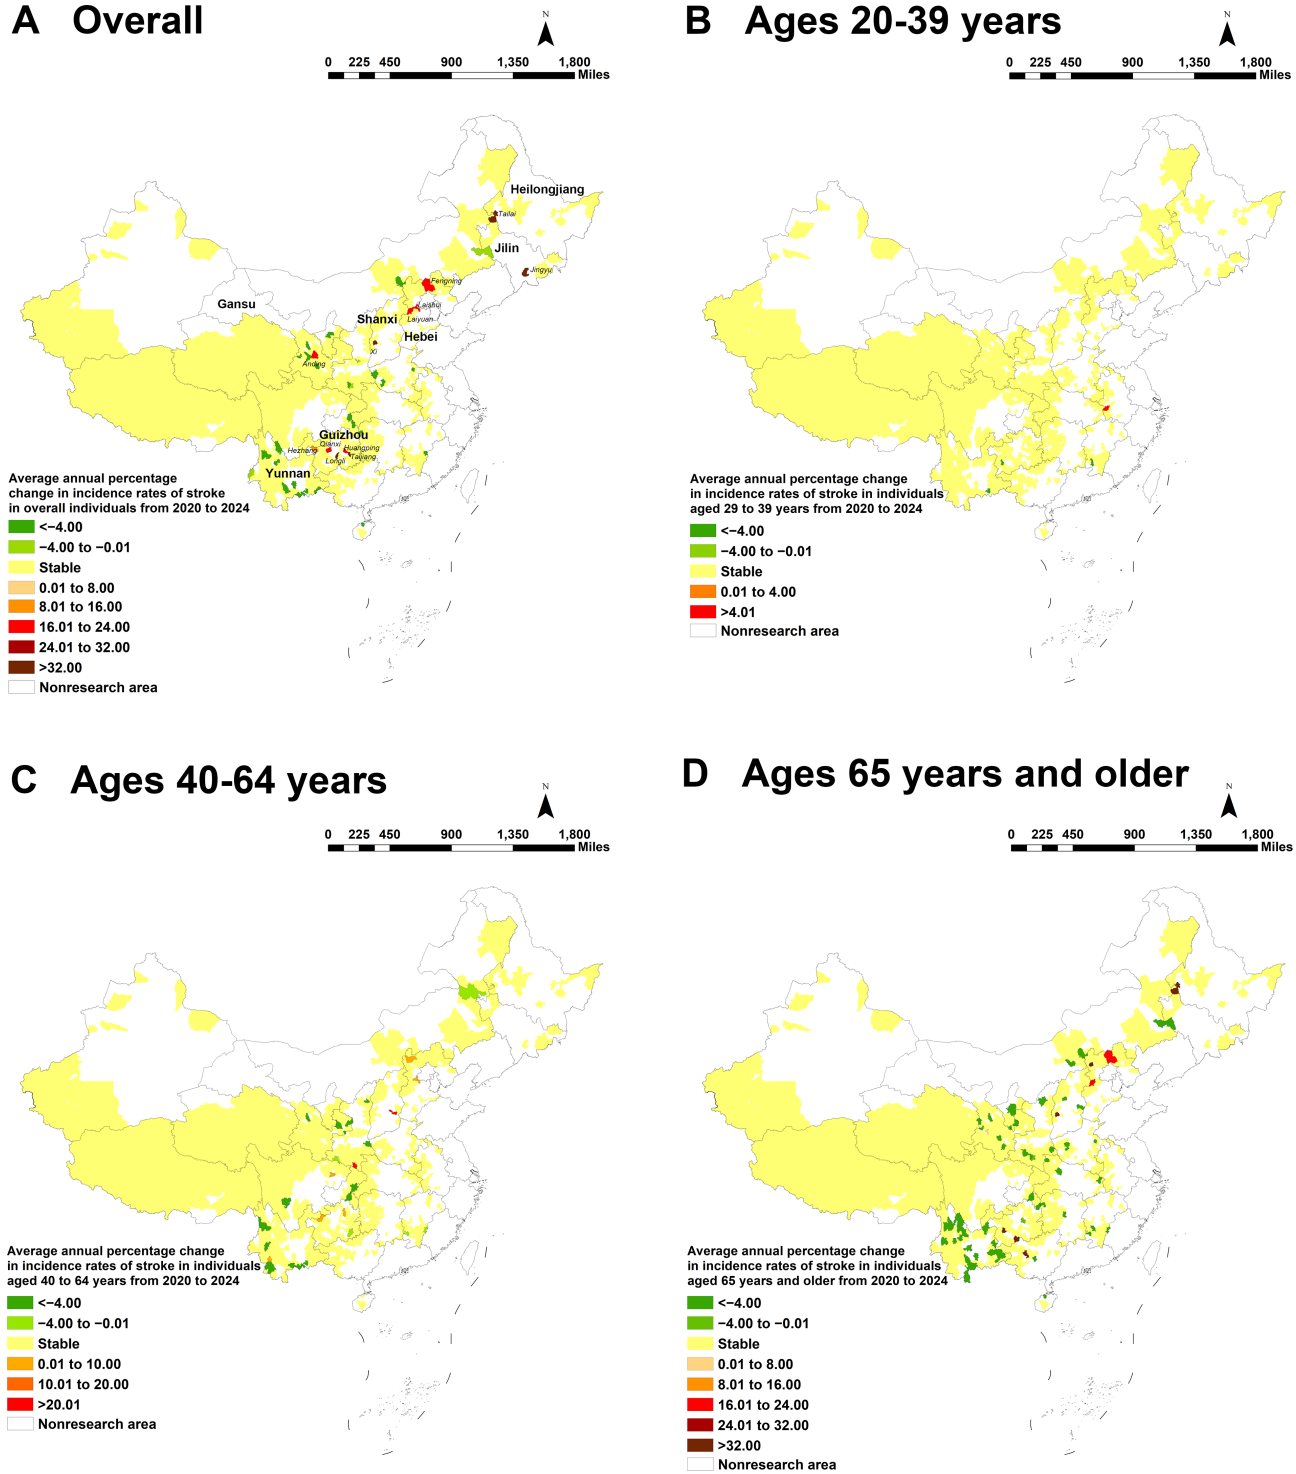
**Figure 1.** Trends in prevalence and incidence rates by age and sex groups among poverty-alleviated populations. (A) Trends in prevalence rates, 2019 - 2024. (B) Trends in incidence rates, 2020 - 2024. (C and D) Joinpoint regression analysis of stroke prevalence and incidence rates by sex and age groups among poverty-alleviated populations. Annual percentage change (APC) in prevalence rates (C) and incidence rates (D). In panels A and B, solid lines represent age groups (ages 20 - 39, 40 - 64, and 65 years and older) and dashed lines represent sex groups (male, female). Data are presented as rates per 100,000 population based on the registered poverty-alleviated population (n=56.08 million) across 832 counties. In panels C and D, * indicates that the APC value is statistically significant (*P*<.05).

## Temporal Distribution by County



Temporal trends in stroke incidence were analyzed in 832 poverty-alleviated counties between 2020 and 2024. Figure 2 presents the AAPC in incidence rates by county. Among these counties, 1.4% (n=12) showed a rising trend in stroke incidence, while 3.4% (n=28) exhibited a declining trend. No statistically significant upward or downward trends in incidence rates were observed in the remaining counties (AAPC=0, *P*>.05). The 12 counties demonstrating upward trends were distributed across 6 provinces: 5 in Guizhou (Qianxi, Hezhang, Huangping, Taijiang, and Longli), 3 in Hebei (Laishui, Laiyuan, and Fengning), and 1 each in Shanxi (Xi), Jilin (Jingyu), Heilongjiang (Tailai), and Gansu (Anding). In contrast, counties with declining trends showed a pronounced concentration in Yunnan Province in southern China, which accounted for 10 of the 28 counties.

Age-stratified analysis indicated that increasing trends were primarily observed in older age groups, with 8 and 9 counties showing rises in the 40 to 64 and 65 years and older age groups, respectively, compared to only one county in the 20 to 39 years age group. Notably, within the 65 years and older age group, Yunnan Province also had the highest number of counties (n=20), exhibiting a declining incidence trend (Figure 2).

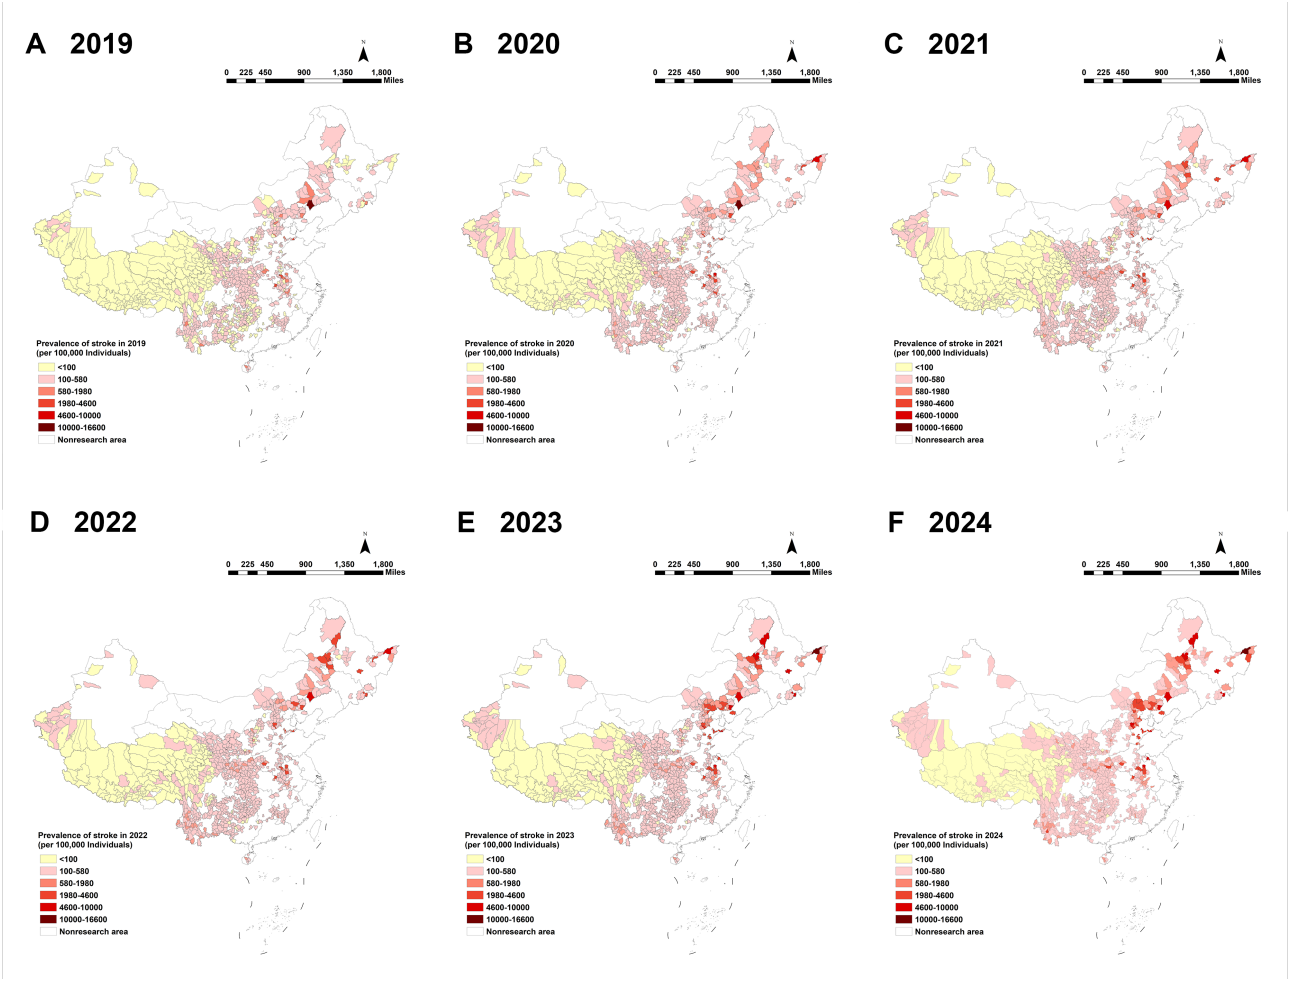
**Figure 2.** The average annual percentage change (AAPC) in stroke incidence among poverty-alleviated counties in China, 2020 - 2024. (A) AAPC of stroke incidence in the overall population at the county level. The 12 counties highlighted in red exhibited a statistically significant upward trend ($P$<.05) and are annotated with their respective county and province names. (B-D) AAPC of stroke incidence stratified by age group: 20 - 39 years (B), 40 - 64 years (C), and 65 years and older (D). White areas represent counties that were never designated as impoverished and thus are not poverty-alleviated counties; these counties are excluded from the analysis of this study.



The spatiotemporal analysis from 2019 to 2024 revealed a clear and persistent geographical hierarchy in stroke burden across China's poverty-alleviated counties: high in the north, low in the south, with the most severe concentrations localized in the northeast and north China regions. Counties with the highest prevalence clustered consistently within a northern corridor encompassing Hebei, Heilongjiang, Jilin, and Inner Mongolia, followed by Anhui Province in eastern China. This spatial pattern remained stable throughout the 6-year observation period, during which stroke prevalence rates showed a marked overall increase (Figure 3). The distribution of incidence from 2020 to 2024 mirrored this pattern, with high-incidence counties concentrated in the north (eg, Hebei, Heilongjiang, Inner Mongolia, and Jilin) and low-incidence clusters in the southwest (eg, Sichuan and Qinghai). In 2024, among approximately 54 million residents of poverty-alleviated counties, 25,458 incident

XSL•FO
RenderX

stroke cases and 194,911 prevalent cases were recorded. The highest incidence and prevalence rates nationwide were observed in Tongjiang City, Heilongjiang Province, underscoring the heightened burden in these high-burden northern regions (Figure 4).

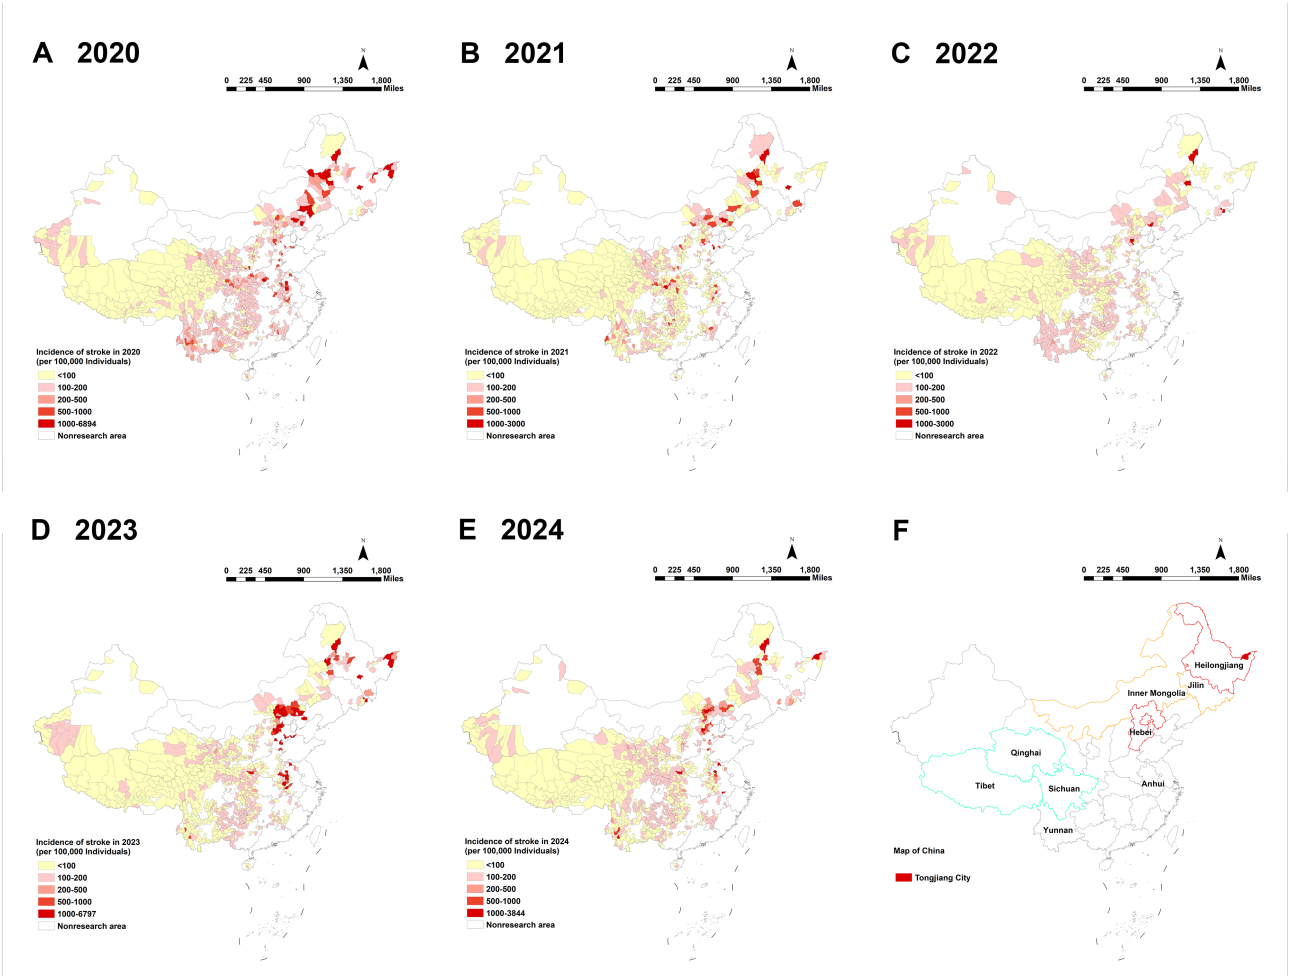


**Figure 3.** Spatiotemporal distribution of stroke prevalence among 832 poverty-alleviated counties in China, 2019 - 2024. (A-F) Spatial distribution of age-standardized stroke prevalence (per 100,000 population) across 832 counties for each year from 2019 (A) to 2024 (F). White areas represent counties that were never designated as impoverished and thus are not poverty-alleviated counties; these counties are excluded from the analysis of this study.

XSL•FO
RenderX

**Figure 4.** Spatiotemporal distribution of stroke incidence among 832 poverty-alleviated counties in China, 2020 - 2024. (A-E) County-level stroke incidence rates (per 100,000 individuals) for each year from 2020 (A) to 2024 (E). (F) A summary map synthesizing spatial patterns across the study period. Provinces are categorized based on the persistent clustering of incidence: high-incidence provinces (eg, Hebei, Heilongjiang, Jilin, Inner Mongolia, and Anhui) and low-incidence provinces (eg, Qinghai, Sichuan, Tibet, and Yunnan). Tongjiang City (highlighted in red), Heilongjiang Province, is highlighted for recording both the highest incidence and prevalence rates in 2024. A pronounced north-to-south decreasing gradient is evident, with hyperendemic clusters concentrated in the northern Hebei-Heilongjiang-Jilin-Inner Mongolia corridor. White areas represent counties that were never designated as impoverished and thus are not poverty-alleviated counties; these counties are excluded from the analysis of this study.

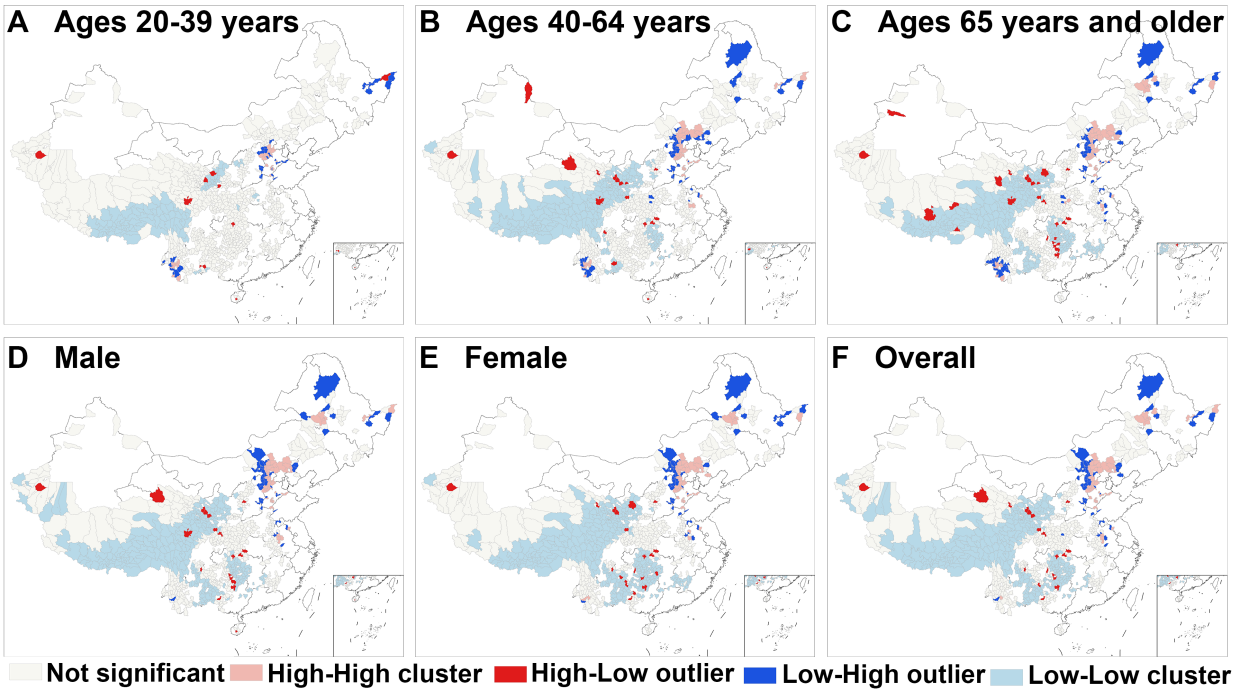
## Spatial Distribution by County

The results of the global spatial autocorrelation analysis are presented in Table 2. All annual Global Moran *I* indices demonstrated positive values (range: 0.09 - 0.30) with statistical significance (*P*<.001), indicating significant spatial clustering of stroke incidence in the general population. The Moran *I* exhibited progressive elevation from 2020 to 2023 (0.09→0.30), followed by a decline to 0.12 in 2024. Compared to the 20 to 39 years age group, both the 40 to 64 years and 65 years and older age cohorts exhibited higher and statistically significant Moran *I* values, revealing stronger spatial clustering of stroke incidence. An exceptional pattern emerged in the 2021 young-middle-aged cohort (20 - 39 y), demonstrating nonsignificant spatial autocorrelation (Moran *I*=0.003, *z*=0.64, *P*>.05). Both sex groups exhibited significant spatial clustering across all years (*P*<.001), though males displayed marginally higher Moran *I* values than females (eg, 2023: 0.32 vs 0.26). The sensitivity analysis using alternative distance thresholds (50% and 200% of the default) yielded Global Moran *I* values that were highly consistent with those obtained using the default threshold (Multimedia Appendix 2), confirming the robustness of our spatial clustering findings.

Statistical significance was achieved for all study years (*P*<.001) except in the 20 to 39 years subgroup. Spatial clustering intensity increased from 2020 to 2023 but declined in 2024. Positive Moran *I* values (*I*>0) indicate spatial clustering where high-incidence counties cluster with adjacent high-incidence counties and low-incidence counties cluster with adjacent low-incidence counties. Values represent Moran *I* with corresponding 95% CI (lower-upper). *P* values were computed using Monte Carlo permutation tests (999 repetitions; significance threshold α=.01). For details on spatial weight matrix construction and sensitivity analysis, see *Methods* (*Spatial Analysis* section).

We conducted a clustering and outlier analysis of stroke incidence rates across population subgroups in 832 counties that achieved poverty alleviation by 2024. The results revealed 4 distinct spatial clustering patterns in overall stroke incidence rates within these counties. High-high clusters predominantly emerged in northern Chinese cities, including Hebei, Inner Mongolia, and Heilongjiang, where stroke incidence

XSL•FO
RenderX



significantly exceeded that of neighboring areas and was consistent across all age-sex groups, except for those aged 20 to 39 years. This pattern may indicate high-risk disease zones. Identifying these high-cluster zones is essential for developing targeted disease prevention and control strategies; therefore, we compiled a list of county-level high-cluster zones with elevated stroke incidence across all subgroups for 2024 (see Multimedia Appendix 3 for details). Low-low clusters were concentrated in extensive contiguous areas of central and western China, such as Sichuan, Qinghai, Yunnan, and Guizhou, where stroke incidence was markedly lower than in neighboring regions. High-low clusters were scattered throughout central and western China, where counties exhibited higher stroke incidence while neighboring counties reported lower rates, potentially reflecting localized disease hotspots. Low-high clusters were sporadically distributed in northern China, where these areas demonstrated lower stroke incidence compared to neighboring regions with higher rates, possibly representing transitional zones for disease transmission (Figure 5).

**Table .** Global (Moran *I*) index for spatial association of stroke incidence (2020 - 2024).

RenderX

### Comparative Analysis

A comparative analysis between poverty-alleviated regions and nonpoverty-alleviated regions of China (2019 - 2021) revealed stark differences in the temporal trend of stroke prevalence. From 2019 to 2021, the age-standardized prevalence of stroke increased markedly in poverty-alleviated regions, with an APC of +61.85% (95% CI 14.99% - 129.60%, *P*<.001). This rate of increase was considerably steeper than the concurrent trend observed in nonpoverty-alleviated regions (APC=+3.82%, 95% CI 2.31% - 5.40%, *P*<.001). This accelerating trend was most pronounced in the 20 to 39 years age group, where the APC reached +88.96% (*P*<.001) in poverty-alleviated regions, compared to a much more modest increase of +1.94% (*P*<.001) in the same age group in nonpoverty-alleviated regions (Table 3).

It is important to note that the absolute prevalence estimates between the 2 datasets are not directly comparable due to fundamental differences in data sources and population coverage (see *Limitations* section). Therefore, only the direction and magnitude of temporal change (APC) are presented for comparative purposes. The underlying absolute values are provided in Multimedia Appendix 4 for transparency.

**Table .** Annual percentage change (APC, 95% CI) of stroke prevalence in poverty-alleviated regions and China (2019 - 2021).[a]

| Region | Overall, % (95% CI) | Ages 20 - 39 y, % (95% CI) | Ages 40 - 64 y,% (95% CI) | Ages ≥65 y, % (95% CI) |
|---|---|---|---|---|
| China (overall) | 1.64[b] (0.32 to 3.03) | 1.78[b] (1.09 to 2.47) | 1.57[b] (0.67 to 2.50) | 1.73[b] (0.04 to 3.62) |
| Poverty-alleviated regions | 61.85[b] (14.99 to 129.60) | 88.96[b] (26.77 to 184.81) | 73.62[b] (22.90 to 147.48) | 74.10[b] (26.97 to 136.55) |
| Nonpoverty-alleviated regions | 3.82[b] (2.31 to 5.40) | 1.94[b] (1.11 to 2.77) | 1.57[b] (0.52 to 2.65) | 0.96 (−0.72 to 2.83) |

[a]The group labeled "Nonpoverty-alleviated regions" refers to data for China excluding 832 designated poverty-alleviated regions. Prevalence rates were age-standardized using the Global Burden of Disease 2021 reference population structure (Institute for Health Metrics and Evaluation) to ensure comparability.

[b]Statistically significant annual trend, with a *P*<.001 for the APC. The APC and its 95% CI were calculated using Joinpoint regression (National Cancer Institute, V.5.2.0). *P*<.001 indicates a statistically significant annual trend in prevalence. As the model failed to detect the inflection point, the average annual percentage change and APC values are identical.

## Discussion

### Principal Results

This study presents the first retrospective analysis of data from all 832 poverty-alleviated counties in China, identifying the spatiotemporal trends of stroke epidemiology from 2019 to 2024 and revealing significant disparities in disease burden across different age groups, sexes, and geographical regions. This represents the largest spatiotemporal analysis of postpoverty transition epidemiology, overcoming prior fragmentation.

The increased stroke burden in China's poverty-alleviated population, with the heaviest burden observed in individuals aged 65 years and older, aligns with previously documented trends in rural areas [7,26]. Stroke prevalence surged significantly in poverty-alleviated counties, with the 20 to 39 years cohort exhibiting the steepest acceleration (AAPC=+35.63%)—a trend disproportionately exceeding concurrent national growth. The rising prevalence of stroke among young adults, particularly in the age group of 20 to 39 years, has become a notable concern, especially linked to rapid urbanization in low-income regions. Two interlinked mechanisms may explain this trend: (1) behavioral risks: these regions have been experiencing a surge in traditional vascular risk factors, including hypertension, diabetes, and dyslipidemia, which are commonly associated with urbanization, such as sedentary lifestyles [27] and changes in dietary habits due to increased access to processed foods and reduced physical activity levels. For instance, one study reported an alarming rise in traditional risk factors among young adults, emphasizing how lifestyle changes linked to urbanization contribute to this trend in stroke incidence [28-30]. (2) Health care access gaps. Socioeconomic factors, including decreased access to health care and health education, leave young adults vulnerable to undetected vascular risks. It has been observed that in low-income communities, awareness and response to stroke symptoms are often inadequate, which can lead to delayed treatment and worse outcomes [31,32]. Importantly, the outmigration of working-age populations may concentrate stroke-prone individuals (eg, those with disabilities or chronic illnesses) in impoverished counties [33,34]. These factors collectively signal a failure of current preventive strategies to adapt to postpoverty health challenges.

The decline in incidence in 2024 should be interpreted cautiously. This decline may reflect a combination of factors, including registration delays (cases from late 2024 not yet entered into the system), residual postpandemic changes in health care utilization, and possibly random variation. A sensitivity analysis excluding 2024 data (Table S4 in Multimedia Appendix 4) showed that the incidence trend from 2020 to 2023 remained nonsignificant, indicating that the sharp decline in 2024 did not fundamentally alter the overall conclusion of no sustained increase in incidence. Longer-term data are required to determine whether this decline represents a genuine epidemiological shift.

Though males retained higher absolute prevalence, females experienced faster escalation (+24.31% vs +22.16%), uncovering neglected vulnerabilities. Hypertension in pregnancy, postpartum hemorrhage, and changes in vascular biomarkers [35-37] in women during middle age are women-specific risk factors that increase the risk of stroke [38]. Women in rural areas and low-income families are more susceptible to chronic diseases such as hypertension and diabetes, which further increase the

XSL•FO
RenderX

risk of stroke [39]. Women are more susceptible to stress, depression, and psychological factors that increase the risk of stroke [35,40]. Sex differences in health literacy also affect stroke prevention and management. For example, 32% of rural women recognize the risk of high blood pressure, while 48% of men do [41]. These findings demand sex-specific prevention frameworks [35].

The analysis reveals a distinct and persistent north-south divergence in stroke burden across poverty-alleviated counties. Stroke prevalence demonstrates hyperendemic clusters in northern regions (notably the Hebei-Heilongjiang-Jilin-Inner Mongolia corridor), with a clear north-to-south decreasing gradient—exemplified by Tongjiang City in Heilongjiang recording the peak prevalence intensity in 2024. Similarly, incidence forms geographically anchored high-high clusters across these northern provinces, contrasting sharply with expansive low-low belts spanning southwestern regions such as Sichuan, Yunnan, and Qinghai. Three regional drivers likely contribute to this pattern of elevated stroke burden and high incidence in northern China's poverty-alleviated counties: (1) cold climate effects: prolonged indoor confinement during the harsh northern winters disproportionately affects residents in poverty-alleviated counties. This behavior correlates with elevated blood pressure [42] and increased exposure to particulate matter (PM2.5) from biomass heating [43], a common practice in these areas. (2) Dietary sodium overload: Northeastern diets average 11.2 g of salt per day [44], far surpassing the World Health Organization recommendation of 5 g—a key modifiable risk factor. This high sodium intake is a key modifiable risk factor that directly elevates blood pressure [2,45], creating a persistent and widespread driver of stroke risk within the local populace. (3) Health care delivery bottlenecks: Northeastern regions, such as Heilongjiang Province, have a relative lack of medical resources, especially in rural and remote areas, where medical conditions are poor and the poverty-alleviated population has insufficient awareness of stroke [46], leading to inadequate preventive and treatment measures. Despite the marked rise in prevalence, an important nuance emerges when examining incidence. Overall stroke incidence across the 832 counties remained largely flat throughout the study period until 2024. However, this aggregate stability masks localized intensification: significant rises were concentrated in only 12 counties, predominantly driven by populations aged 40 years and older. This pattern suggests that while the overall entry rate of new stroke cases was stable at the macro level, specific geographic clusters—particularly those with aging demographics—are experiencing a tightening grip of the epidemic. We hypothesize that the decline in Moran *I* in 2024 may reflect temporal variation in data reporting completeness or random fluctuation, but further observation is needed. This finding shifts the focus from a universal incidence surge to the identification of high-risk geographic and demographic pockets where primary prevention efforts may be failing or where demographic aging is exerting its strongest effect.

During the pivotal postalleviation transition (2019 - 2021), a striking disparity in the temporal dynamics of stroke prevalence emerged between poverty-alleviated and nonpoverty-alleviated regions. While the recorded age-standardized stroke prevalence in poverty-alleviated regions increased at an annual rate of 61.85% over 2 years, the concurrent increase in nonpoverty-alleviated regions was only 3.82%. We caution that the absolute prevalence estimates from the 2 data sources are not directly comparable due to fundamental methodological differences (see Limitations section). Therefore, only the direction and magnitude of temporal change (APC) are comparable between the 2 populations; any comparison of absolute rates or inference about confounding factors is not valid. Nevertheless, the markedly faster pace of increase in poverty-alleviated regions suggests a distinct epidemiological trajectory during the postalleviation transition period. This disparity can be understood as a "catch-up" phenomenon driven by 2 concurrent forces. First, the conclusive phase of the national poverty alleviation campaign (ending in 2020) significantly enhanced primary health care access and systematic screening in these regions, leading to improved detection and reporting of preexisting, previously undiagnosed cases [47]. Second, despite improved access, a relative lag in population-level stroke awareness and health literacy persists [48]. This lag likely results in delayed health care–seeking for transient ischemic attacks or minor strokes, allowing many cases to progress to a more severe or recordable stage before diagnosis, thereby contributing to the rising incidence of recorded prevalent cases. Thus, the steep upward trend does not merely represent a convergence toward the level observed in nonpoverty-alleviated regions but reveals a critical phase during which previously unmet health care needs became visible. Importantly, this surge should be interpreted primarily as a "detection catch-up" of previously unregistered cases, rather than as a mere epidemiological explosion.

In conclusion, this nationwide spatiotemporally explicit analysis reveals that the stroke burden in China's poverty-alleviated counties is not merely a residual challenge of the past but a dynamically evolving epidemic characterized by a sharp increase in recorded prevalence, alarming shifts toward younger adults, and stark geographical polarization. Our findings fundamentally recalibrate the postpoverty health narrative: economic advancement has not automatically translated into commensurate health gains. Instead, it may have unmasked or even accelerated latent epidemiological risks. The concentrated burden in northern "hotspots" and among the young working-age population signals specific failures in current primary prevention strategies. Therefore, moving beyond uniform, poverty-alleviation-era health policies is imperative. Future interventions must be geographically precision-targeted to the identified high-risk clusters—hotspot identification enables precision resource allocation under China's Rural Revitalization Health Initiatives—and demographically tailored to address the unique vulnerabilities of young adults and women. This shift is crucial for mitigating the impending wave of noncommunicable diseases and achieving equitable health outcomes in the post-poverty alleviation era.

## Limitations

Despite its comprehensive scope, this study has several limitations that should be considered when interpreting the findings. First, a fundamental limitation is the inability to distinguish the extent to which the observed surge in stroke

XSL•FO
RenderX

prevalence reflects a true increase in disease burden versus improved case ascertainment driven by poverty-alleviation policies. The national poverty-alleviation campaign (ending in 2020) substantially enhanced primary health care access and systematic screening in poverty-alleviated counties, likely leading to the detection and registration of previously undiagnosed prevalent cases. Consequently, the reported trends should be interpreted as a combination of genuine epidemiological change and policy-induced detection improvement. Second, reliance on retrospective surveillance data may introduce variability in diagnostic accuracy and case ascertainment across different counties and years. While we applied standardized case definitions, inconsistencies in medical record-keeping and reporting completeness, particularly in remote areas, could affect the accuracy of incidence and prevalence estimates. Third, the 832 poverty-alleviated counties are not a homogeneous group. Significant internal socioeconomic and ethnic heterogeneity exists within these counties, which our aggregate-level analysis could not dissect. Future studies should incorporate township-level data. Fourth, the comparative analysis between poverty-alleviated and nonpoverty-alleviated regions is constrained by the heterogeneity of data sources. The poverty-alleviated data were extracted from the NHPADMS (a policy-driven active registry), whereas the national comparator data were derived from the GBD 2021 study (a modeling-based estimate). These 2 sources differ substantially in case definitions, case ascertainment completeness, and population coverage. Therefore, absolute prevalence estimates are not directly comparable across the 2 datasets; the present analysis focuses only on comparing the rate of change (APC). No confounding factors (eg, age, sex, comorbidities, socioeconomic status) could be controlled for across the 2 datasets due to their heterogeneous designs. Therefore, readers should interpret any cross-dataset comparison with extreme caution, and only the temporal trend direction (APC) is considered reliable for comparative purposes. Fifth, this study did not differentiate between ischemic and hemorrhagic stroke subtypes. These 2 subtypes have distinct pathophysiological mechanisms, risk factor profiles (eg, hypertension is more strongly associated with hemorrhagic stroke, while atrial fibrillation and dyslipidemia are more linked to ischemic stroke), and treatment strategies. The NHPADMS database does not routinely record stroke subtype information, precluding subtype-specific analysis. Future studies should incorporate stroke subtype data to better tailor prevention and intervention strategies for poverty-alleviated populations.

## Conclusion

This study provides the first systematic evidence that the stroke burden in China's poverty-alleviated counties is dynamically evolving, characterized by a sharp increase in recorded prevalence, a pronounced shift toward younger adults (aged 20 - 39), and distinct geographic clustering in northern regions. These findings indicate a clear disconnect between economic advancement and health gains in the postpoverty transition era. Our high-resolution analysis thus furnishes critical evidence for precision public health, underscoring the imperative to shift interventions toward geographically targeted strategies for identified high-risk clusters and tailored prevention for younger populations to achieve equitable health outcomes.

## Acknowledgments

The author would like to express sincere gratitude to the China Population and Development Research Center for establishing the dataset, which provides researchers with high-quality data resources. The author declares that no generative artificial intelligence was used in the writing of this manuscript.

## Funding

This work was supported by the National Natural Science Foundation of China (72474220).

## Data Availability

The data on the impoverished population used in this research are obtainable by submitting a formal data request via email to info@cpdrc.org.cn to the China Population and Development Research Center under specific licensing agreements. To download Global Burden of Disease (GBD) data used in the analyses, please visit the GBD 2021 Results Tool.

## Authors' Contributions

MC and LZ developed the research aim and provided overall guidance. MC, DX, and WL analyzed the data and drafted the manuscript. JW, ZL, and JC contributed to data collection and preparation. All authors have critically reviewed and approved the manuscript.

## Abstract

**Background:** Geospatial analysis plays an essential role in informing targeted human immunodeficiency virus (HIV) intervention. The Dai-Jingpo Autonomous Prefecture of Dehong (hereinafter referred to as Dehong), located along the China-Myanmar border in the Yunnan province, has been heavily impacted by HIV infection. Given the complex local epidemic context, particularly frequent cross-border population movement, there is an urgent need to apply spatiotemporal analytical approaches to guiding resource allocation. Existing evidence has demonstrated the substantial spatial variations of newly diagnosed HIV infection this region. However, these spatiotemporal variations have not been fully explored at a finer geographic and temporal resolution.

**Objective:** This study aims to comprehensively investigate the spatiotemporal variations of newly diagnosed HIV infection at a finer scale in this border region to inform targeted interventions.

**Methods:** Data on newly diagnosed HIV cases at the township level in Dehong were collected from 2010 to 2022. The rate of newly diagnosis HIV cases was calculated annually. GeoDetector *q* statistics were performed to assess the spatially stratified heterogeneity of the rate of newly diagnosed HIV cases. The Bayesian space-time hierarchical model was applied to detect the spatiotemporal patterns of newly diagnosed HIV infection across the region.

**Results:** A total of 5045 newly diagnosed HIV cases were identified in Dehong from 2010 to 2022. The rate of newly diagnosed HIV cases decreased from 57.1 cases per 100,000 population in 2010 to 13.3 cases per 100,000 population in 2022, a decrease of 76.7% over the past 13 years. The overall temporal relative risk decreased from 2.11 (95% CI 1.84 - 2.41) in 2010 to 0.48 (95% CI 0.40 - 0.56) in 2022. There was substantial spatiotemporal heterogeneity in the risk of newly diagnosed HIV infection, with townships near the China-Myanmar border having a higher spatial relative risk. Notable spatially stratified heterogeneity in the rate of newly diagnosed HIV cases when stratified by the distance of townships to the China-Myanmar border was observed ($q$=0.27; $P$=.004). Among the 51 townships in Dehong, 22 (43.1%) hotspots and 22 (43.1%) coldspots were identified. Notably, in comparison to the overall declining temporal trend, 2 hotspots and 4 coldspots exhibited a slower declining trend, suggesting that these regions may require additional intervention efforts.

**Conclusions:** This study comprehensively estimated the spatiotemporal risk of newly diagnosed HIV infection across Dehong, revealing high-risk areas concentrated near the China-Myanmar border. Priority should be given to implementing targeted interventions to control cross-border HIV transmission, including the establishment of cross-border HIV control mechanisms, as well as the strengthening of management measures for cross-border populations. Furthermore, this study offers methodological insights into the use of routine surveillance data and Bayesian spatiotemporal modeling to better understand HIV transmission dynamics at finer geographic scales and to support precision-oriented HIV prevention services.

## Introduction

Since the acquired immune deficiency syndrome (AIDS) cases were first reported in 1981, there are now 40.8 million people living with human immunodeficiency virus (HIV) globally [1]. To prevent the transmission of HIV, the Joint United Nations Programme on HIV/AIDS (UNAIDS) has proposed the 95-95-95 targets, which aim to end HIV/AIDS as a public health threat by 2030 [2]. In China, impressive progress has been made to reduce new HIV infection and enhance the health quality of people living with HIV. The steadily increasing of antiretroviral therapy (ART) coverage in China has led to a significantly reduction in all-cause mortality, from 5.4% in 2013 to 2.7% in 2022 [3]. Achieving the goal of ending HIV/AIDS as a public health threat will increasingly depend on the implementation of precise and context-specific intervention strategies tailored to local epidemic characteristics.

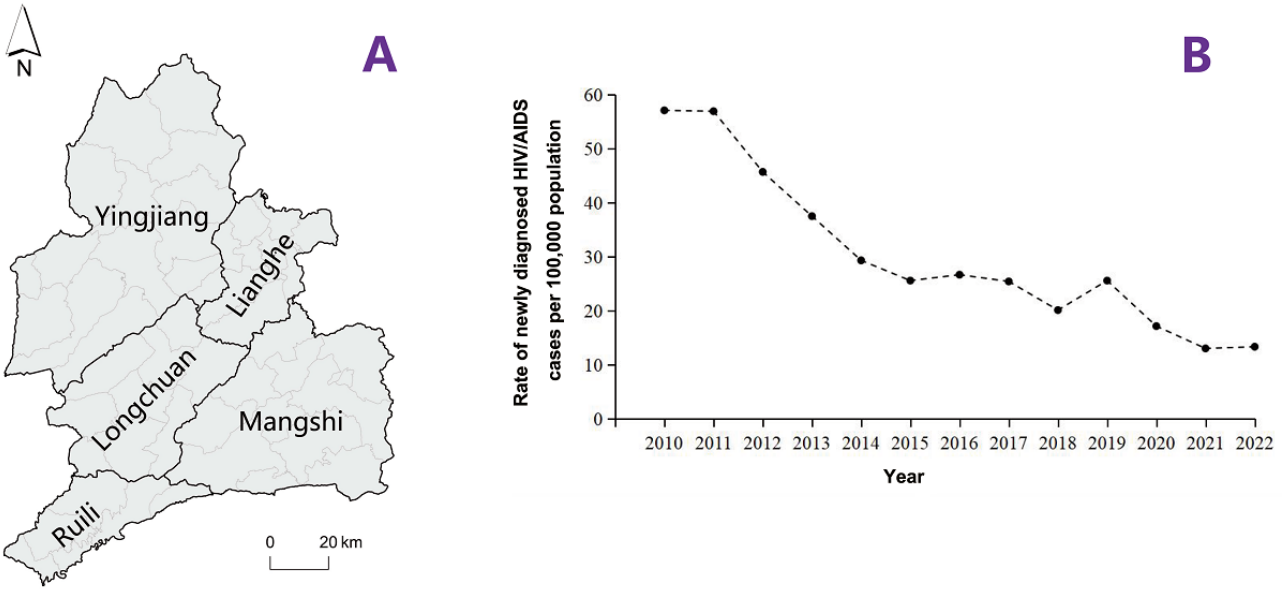
The Dai-Jingpo Autonomous Prefecture of Dehong (hereinafter referred to as Dehong) in the Yunnan province, located in the China-Myanmar border, is an area severely affected by HIV infection, where the first epidemic outbreak of HIV in China was recognized [4]. Located on major illicit drug-trafficking routes from the "Golden Triangle," a primary opium-producing area in Southeast Asia, early HIV transmission in this region was predominantly driven by injecting drug users (IDUs) [5]. After years of fighting illicit drugs and providing HIV harm reduction services to IDUs, such as syringe exchange programs and methadone maintenance treatment, sexual contact has become the dominant route of HIV transmission [6]. Consequently, the local HIV epidemic has become increasingly complex and concealed.

To achieve effective control of the epidemic, it is essential to accurately understand the current trends in HIV infection. Spatial analysis is often used to reflect the severity of the HIV epidemic at finer geographic scales and to inform the allocation of health resources and targeted interventions [7]. A previous study conducted in Dehong analyzed the spatial patterns of different years using HIV case data from 1989 to 2018 [8]. However, this previous study only performed purely spatial analyses based on annual newly diagnosed data and did not incorporate temporal terms. As local governments dynamically adjust policies and measures in response to evolving epidemic conditions, the risk and trends of HIV infection may vary over time across different regions of Dehong. Traditional spatial models, which only capture geographic variation, fail to integrate temporal dynamics of HIV transmission.

Understanding fine-scale spatiotemporal heterogeneity has become an increasingly important methodological challenge in HIV epidemiology, particularly in high-burden or highly heterogeneous settings. In this study, we employed a Bayesian space-time hierarchical model (BSTHM) to retrospectively analyze data of newly diagnosed HIV cases in Dehong from 2010 to 2022, enabling us to detect the spatiotemporal heterogeneity of HIV transmission. Compared to classical spatial analysis models, which are used to examine spatial autocorrelation and depict the spatial distribution of diseases, BSTHM is suitable for analyzing spatial data with continuous temporal variation. BSTHM effectively integrates spatiotemporal correlations and decomposes spatiotemporal data into 3 key components: common spatial patterns, common temporal patterns, and potential spatiotemporal interactions [9]. Therefore, BSTHM can be used to analyze the spatiotemporal heterogeneity and interactions of newly diagnosed HIV cases in Dehong from 2010 to 2022, providing more comprehensive and detailed data to reveal the trends of the HIV epidemic at both global and local levels over time.

This study aims to systematically describes the spatiotemporal distribution and changing characteristics of newly diagnosed HIV cases in Dehong. By applying a Bayesian spatiotemporal hierarchical modeling approach to routine HIV surveillance data, this study explores the potential of maximizing the utility of existing monitoring systems to characterize epidemic patterns at finer spatial and temporal scales. The findings will enhance the understanding of local epidemic characteristics, thereby guiding targeted interventions and resource allocation, further curbing the spread of the epidemic and effectively reducing new HIV infections in the area. In addition, this analytical approach may be applicable to understanding localized HIV transmission patterns and informing targeted intervention strategies in other regions.

## Methods



### Study Area

This longitudinal observational study was conducted in Dehong (Figure 1A), which has a population of approximately 1.3 million and an area of 11,526 $km^2$. The study region is divided into 5 districts (Ruili, Mangshi, Lianghe, Yingjiang, and Longchuan), encompassing 51 township-level districts (6 in Ruili, 12 in Mangshi, 9 in Lianghe, 15 in Yingjiang, and 9 in Longchuan).

RenderX

**Figure 1.** Administrative map and rate of newly diagnosed HIV/AIDS cases in the Dai-Jingpo Autonomous Prefecture of Dehong in the Yunnan province. (A) Administrative map. (B) The rate of newly diagnosed HIV/AIDS cases per 100,000 population from 2010 to 2022. AIDS: acquired immune deficiency syndrome; HIV: human immunodeficiency virus.

## Data Sources

Data on newly diagnosed HIV cases at the township level in Dehong were obtained from the national HIV/AIDS Comprehensive Response Information Management System (CRIMS) by the Dehong Center for Disease Control and Prevention. The data cover the period from January 1, 2010, to December 31, 2022, and include HIV cases that met the following criteria: (1) reported in Dehong; (2) resided in the specific townships within Dehong; and (3) of Chinese nationality. Township-level population data were obtained from the 2020 China Population Census [10]. All data were collected at the township level. The distance from each township to the China-Myanmar border was defined as the shortest distance between the township administrative boundary and the international border. Based on the calculated distances, all townships were classified into 4 distance-based groups according to proximity, which served as the stratification variable in the GeoDetector analysis. The rate of newly diagnosis HIV cases was obtained by dividing the number of newly diagnosed cases by the local resident population.

## GeoDetector *q* Statistics

As reported in previous studies, the HIV transmission in Dehong may be associated with cross-border population movements between China and Myanmar. We investigated the spatially stratified heterogeneity (SSH) of newly diagnosed HIV case rates, stratified by the distance of the township to the China-Myanmar border. The GeoDetector *q* statistics were calculated to measure the SSH of newly diagnosed HIV case rates across different township-level units in Dehong, and the formula is as follows [11]:

(1)$q=1-\frac{1}{N\sigma^2}\sum_{h=1}^{L}N_h\sigma_h^2$

In the formula (Eq. 1), N is the total number of townships in Dehong Prefecture, $\sigma^2$ denotes the variance of newly diagnosed HIV case rates across all townships, $N_h$ refers the number of townships in stratum h (1, 2, …, L), and $\sigma_h^2$ represents the variance of newly diagnosed HIV case rates within the stratum h. The *q* value ranges from 0 to 1, with a value of 0 indicating complete randomness and 1 representing perfect stratified heterogeneity.

## BSTHM Formulas

The Poisson and log link regression functions used to perform analyses were as follows:

(2)$y_{it} \sim Poisson(n_i r_{it})$

(3)$\log(r_{it}) = \alpha + S_i + U_i + (b_{0t}^* + v_t) + b_{1i}t^* + \varepsilon_{it}$

In the Poisson likelihood function (Eq. 2), $y_{it}$ represents the number of newly diagnosed HIV cases in township i at year t, $n_i$ denotes the total population in township i, and $r_{it}$ is the modeled risk of newly diagnosed HIV/AIDS cases in township i at year t.

In the log link regression function (Eq. 3) that describes the risk of newly diagnosed HIV infection, $\alpha$ is the overall log disease risk for the entire study period, and $(S_i+U_i)$ is the disease risk in township i. Specifically, $S_i$ captures the spatially structured component, and $U_i$ represents the spatially unstructured component. The term t* denotes the median time of the entire study period, with $(b_{0t}^*+v_t)$ and $b_{1i}t^*$ specifying the overall and local temporal trend in township i, respectively. Specifically, the term $b_{0t}^*$ captures the linear trend, while $v_t$ accounts for the nonlinearity in the overall trend pattern. Given the observed decrease in the newly diagnosed HIV cases rate of over the study period, if $b_{1i} < 0$, it indicates that the decreasing trend in township i is faster than the overall decreasing trend. Conversely, $b_{1i} > 0$ suggests a slower trend relative to the overall decrease. The Gaussian noise was captured by $\varepsilon_{it}$.

## Area Classification by BSTHM

The study area was classified into 9 categories (3 risk categories × 3 trend categories) based on the posterior probability of *P* (exp (Si) >1 |data) and *P* (b1i >0 |hi, data), following a specific

XSL•FO
RenderX

2-stage criteria [12]. In the first stage, townships were classified into 3 categories: hotspot, coldspot, and not cold/hot spot. A township is classified as a hotspot (hi=1) if *P* (exp (Si) >1 |data) is greater than 0.8, and as a coldspot (hi=2) if this probability is less than 0.2 [9]. The remaining townships were classified as not cold/hot spots (hi=3). In the second stage, temporal changes were categorized into 3 classes (faster decrease, common decrease, and slower decrease) according to *P* (b1i >0 |hi, data). A township was defined as exhibiting a slower decreasing trend compared to the overall decreasing trend if *P* (b1i >0 |hi, data) >0.8, a faster decreasing trend if *P* (b1i >0 |hi, data) <0.2, and a common decreasing trend if 0.2 <*P* (b1i >0 |hi, data) <0.8 [9]. Consequently, a total of 9 categories were established.

Hyperparameters for prior distributions were chosen following the approach of Li et al [9], which has been widely applied in BSTHM. Convergence of the Markov Chain Monte Carlo chains was evaluated using the Gelman-Rubin statistic, with values below 1.05 indicating satisfactory convergence. The variance partition coefficient was measured to assess model performance. All BSTHM analysis were conducted using WinBUGS 1.4.3.

### Ethical Considerations

This study was approved by the Institutional Review Board of the National Center for AIDS/STD Prevention and Control, Chinese Center for Disease Control and Prevention (approval number: X241028828). The data used in this study were from the CRIMS. No personally identifiable information was present in the data analyzed for this study.

## Results

### Characteristics of Newly Diagnosed HIV Cases

Between 2010 and 2022, a total of 5045 newly diagnosed HIV cases were reported in Dehong. Of these cases, 3235 (64.1%) were male, 2570 (50.9%) were aged between 31 and 49 years at the time of diagnosis, 2120 (42.0%) were of Han ethnicity, and 2937 (58.2%) had a primary school education or less (Table 1). More than half of the cases (n=2713, 53.8%) were married or cohabiting with a partner. In terms of the transmission routes, 4211 (83.5%) were infected through heterosexual contact, followed by 562 (11.1%) through injecting drug use, and 164 (3.3%) through homosexual contact.

## Dynamics of Newly Diagnosed HIV Infections

The rate of newly diagnosed HIV cases in Dehong decreased over time, from 57.1 cases per 100,000 population to 13.3 cases per 100,000 population, representing a 76.7% reduction over the past 13 years (Figure 1B). Furthermore, the proportion of townships with a rate of newly diagnosed HIV cases exceeding 60 cases per 100,000 population decreased from 52.9% (27/51) in 2010 to 3.9% (2/51) in 2022. Among the 51 townships in Dehong, the number of townships with more than 20 newly diagnosed cases decreased from 10 in 2010 to 1 in 2022 (Figure 2). GeoDetector analysis revealed notable SSH in the rate of newly diagnosed HIV case when stratified by the distance of townships to the China-Myanmar border ($q$=0.27; $P$=.004).

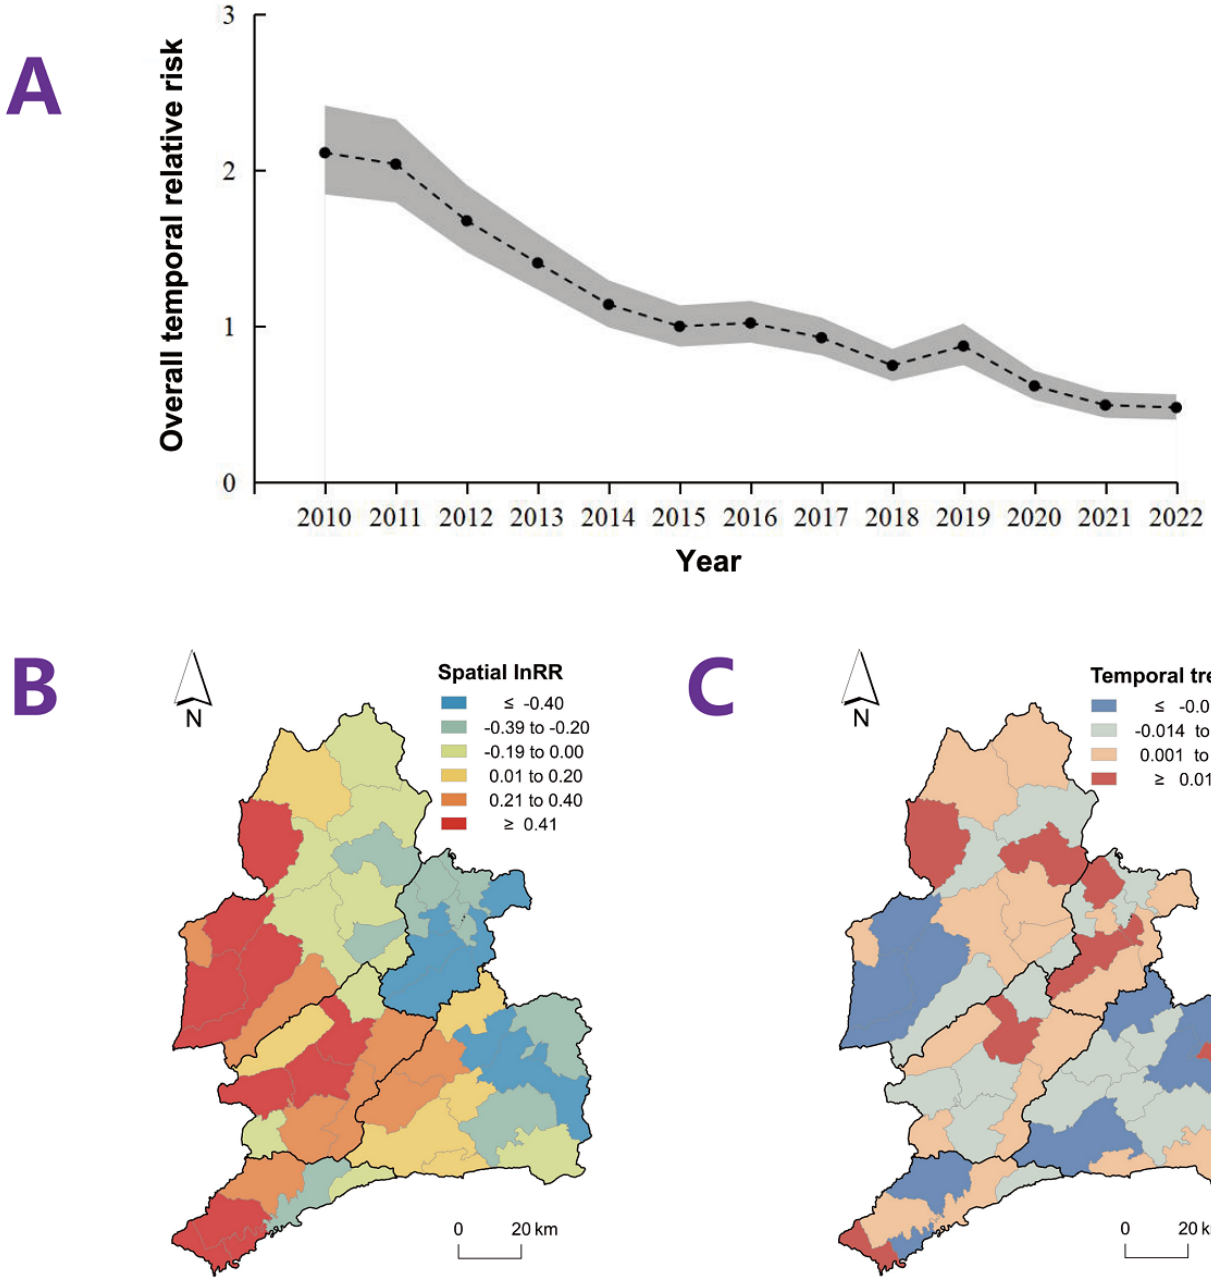
AIDS: acquired immune deficiency syndrome; HIV: human immunodeficiency virus.

## Bayesian Analysis of Newly Diagnosed HIV Infections



### *Overall Temporal Trend*

The variance partition coefficient for BSTHM was 91.3% (95% CI 85.8% - 95.5%). The BSTHM results indicate a declining trend in newly diagnosed HIV infection over the past 13 years, with the overall temporal relative risk decreasing from 2.11 (95% CI 1.84 - 2.41) in 2010 to 0.48 (95% CI 0.40 - 0.56) in 2022 (Figure 3A).

XSL•FO
RenderX

**Figure 3.** The characteristics of spatiotemporal relative risk of newly diagnosed HIV/AIDS cases in the Dai-Jingpo Autonomous Prefecture of Dehong in the Yunnan province, 2010 - 2022. (A) Overall temporal relative risk. The dots represent the estimated overall temporal relative risk [exp(b0t*+vt)], with the corresponding 95% credible intervals shown as the shaded area. (B) Spatial relative risk. The color intensity represents the estimated spatial relative risk (Si+Ui) without exponential transformation, where higher values (warmer colors) indicate a relatively higher risk in township i compared to the overall average risk in the study region. (C) Local temporal trend departure from the overall trend. The color intensity represents the estimated local departure trend (b1i) without exponential transformation, where the estimated lower value (cooler colors) indicates a faster declining trend compared to the overall declining trend. AIDS: acquired immune deficiency syndrome; HIV: human immunodeficiency virus; InRR: natural logarithm of the spatial relative risk.

### *Geographical Distribution*

Substantial geographical variations in the spatial relative risk of newly diagnosed HIV infection were observed across the study area (Figure 3B). Generally, the western region of Dehong experienced relatively higher risks. The estimated local slopes, which measure the departure of local trends from the overall declining trend, revealed that townships depicted in warm color (red and orange) exhibited slower declining trends compared to the overall trend (Figure 3C). Specifically, townships with slower local declining trends than the prefecture-wide level were predominantly located in Yingjiang, Longchuan, and Lianghe.

### *Area Classification*

Among the 51 townships, 22 (43.1%) were identified as hotspots, 22 (43.1%) as cold spots, and 7 (13.7%) as neither hot nor cold spots (Table 2, Multimedia Appendices 1 and 2). As shown in Figure 4, the 22 hotspots were mainly distributed in the southwestern part of Dehong Prefecture, near the China-Myanmar border. Among these hotspots, 1 township in Ruili and 1 in Longchuan exhibited a slower declining trend

XSL•FO
RenderX

compared to the overall trend. Conversely, 2 hotspots in Yingjiang, 1 in Mangshi, and 1 in Ruili showed a faster declining trend than the overall trend. Among the 22 cold spots, 2 townships in Lianghe, 1 in Mangshi, and 1 in Yingjiang showed a slower declining trend than the overall trend. Meanwhile, 2 cold spots in Mangshi exhibited a faster declining trend than the overall trend. There were 7 townships that were neither hot nor cold spots.

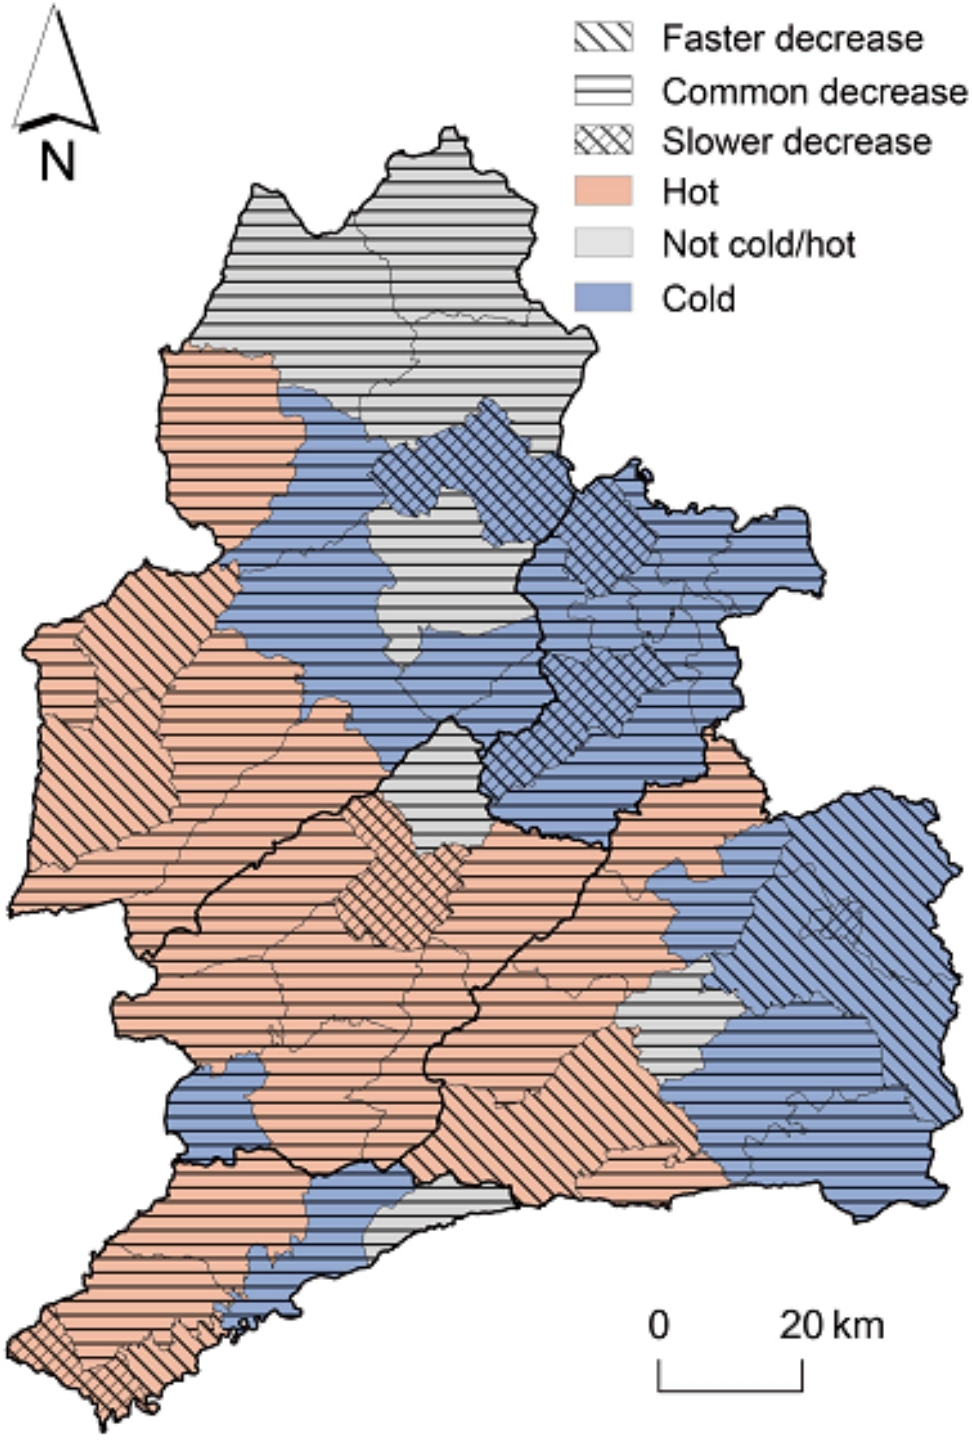


**Table .** Area classification based on the Bayesian space-time hierarchy model in the Dai-Jingpo Autonomous Prefecture of Dehong in the Yunnan province, 2010 - 2022.

| Area classification | Faster decrease | Slower decrease | Common decrease | Total, n (%) |
|---|---|---|---|---|
| Hotspots | 4 | 2 | 16 | 22 (43.1) |
| Coldspots | 2 | 4 | 16 | 22 (43.1) |
| Not hotspots/coldspots | 0 | 0 | 7 | 7 (13.7) |

## Discussion

### Principal Findings

In this study, using township-level data on newly diagnosed HIV infection in Dehong from 2010 to 2022, we quantitatively characterized fine-scale spatiotemporal patterns of HIV risk using BSTHM. The number of newly diagnosed HIV cases has declined significantly over the past 13 years, accompanied by notable SSH. Substantial spatiotemporal heterogeneity was observed in the risk of newly diagnosed HIV infection. By jointly modeling spatial structure and temporal dynamics, several townships were identified as areas that are likely to become or remain hotspots in the future.

In our analysis of newly diagnosed HIV infection from 2015 to 2022, IDUs accounted for 11.1% of cases, while heterosexual contact primarily dominated HIV transmission, responsible for

XSL•FO
RenderX

83.5% of cases. Since HIV was first identified among IDUs in Dehong in 1989 [4], the Chinese government has allocated massive resources to curb HIV transmission. At the provincial level, the Yunnan government has initiated multiple campaigns against HIV and illicit drugs, with remarkable achievements. A study incorporating HIV incidence assays to estimate the HIV incidence among IDUs in Dehong estimated that the HIV incidence among Chinese IDUs in Dehong decreased from 3.11% (95% CI 1.59% - 4.64%) in the 2009 - 2010 period to 0.58% (95% CI –0.06% to 1.04%) in the 2015 - 2017 period [13]. Furthermore, the proportion of IDUs among newly diagnosed male HIV cases in Dehong also showed a downward trend, decreasing from 46.7% in 2012 to 32.0% in 2016 [6]. These shifts reflect a structural transition in transmission dynamics, with heterosexual contact becoming the leading cause of local HIV infections, accounting for 84.7% of newly diagnosed HIV cases during the 2015 - 2017 period [14]. In 2017, the Yunnan government issued an implementation plan aimed at achieving the 90-90-90 HIV targets by the end of 2020. These unprecedented efforts to strengthen HIV prevention, testing, and treatment have resulted in a significant reduction of 76.7% in the rate of newly diagnosed HIV cases over the past 13 years.

Notable SSH was observed in newly diagnosed HIV cases rate across Dehong ($q$=0.27; $P$=.004). The spatial relative risk was apparently higher in townships closer to the China-Myanmar border and declined with increasing distance (Figure 3B). Consistent with the area classification analysis, most hotspots were concentrated in the cross-border region. Cross-border mobility and high HIV prevalence of Burmese individuals may play a significant role in HIV transmission. Due to lower income levels in Myanmar, many Burmese individuals migrate to China in pursuit of better economic opportunities, resulting in frequent interactions between the 2 populations. Previous studies have noticed the high HIV prevalence among Chinese-Burmese mixed couples [15,16]. Chen et al [17] recruited 617 Yunnan-Myanmar IDUs in 3 counties of Yunnan and conducted molecular transmission analysis on 117 (19.0%) people living with HIV. Their findings indicate that Yunnan-Myanmar IDUs play a pivotal role in the bidirectional cross-border HIV transmission [17]. Hu et al [18] further demonstrated the strong association between Burmese immigrants and HIV transmission in Dehong. According to a survey of 393 Burmese immigrants in Dehong in 2020, they had low levels of HIV knowledge, condom usage, and willingness to undergo HIV testing [19]. Consequently, the convergence of high background prevalence, frequent population mobility, and constrained access to HIV services likely contributes to the persistent elevated risk observed in border townships. Furthermore, in districts such as Ruili and Longchuan, where ports are in close proximity to main residential and commercial areas, the frequency of cross-border mobility and interactions is increased.

To control the cross-border transmission of HIV, several measures have been implemented in Dehong. These include strengthening comprehensive management of cross-border populations, providing free ART to Chinese-Burmese mixed couples or long-term resident immigrants living with HIV, and expanding HIV testing among immigrants engaged in long-term employment in Dehong. Nevertheless, the persistence of high-risk hotspots identified through BSTHM suggests that additional, more precisely targeted interventions are needed. The identification of these townships provides important epidemiological clues for prioritizing resource allocation. Further prevention and control measures are required for hotspot areas of cross-border HIV transmission. First, cross-border HIV prevention and control mechanisms should be established by strengthening bilateral collaborations between China and Myanmar. Second, programs should be implemented to improve health education, promote condom use, and increase HIV testing rates among Burmese immigrants. Third, appropriate HIV treatment programs should be explored for short-term Burmese immigrants, as they are currently ineligible for China's free ART program. Lastly, efforts should be made to explore ways to improve treatment adherence among HIV-infected immigrants to prevent treatment failure and the development of drug resistance.

In this study, we further estimated the local temporal trend of the spatial pattern using BSTHM, which can predict the spatial pattern shift in the future. The local trends were estimated by comparing their trend patterns with the overall trend pattern. In this study, we found that 2 hotspots exhibited a slower declining trend than the overall trend, while 4 coldspots with a slower declining trend showed a tendency to become "hot" (Table 2). These townships exhibited higher inclination of hotspots in the future and should be prioritized for targeted interventions. Further in-depth epidemiological investigations are warranted to explore the local drivers of transmission in these areas and to inform more precise and context-specific intervention strategies. To our knowledge, few studies in China have investigated the combined spatial patterns and temporal trends in the rate of newly diagnosed HIV infections. Previous spatial analysis studies primarily employed spatial autocorrelation analysis methods to examine the spatial distribution characteristics separately across different time periods [20-24] and used spatial scan statistics to detect cluster areas [21,25]. None of these studies incorporated spatiotemporal correlations. This study modeled spatial relative risk, overall temporal trends, and local temporal trends at the township level, thereby constructing a multifaceted picture of the evolving risk of newly diagnosed HIV cases across Dehong, representing a methodological advantage over traditional spatial analyses. This small area analysis has important implications for the allocation of resources in controlling HIV transmission in similar settings, as interventions and measures can be directly implemented in hotspots or potential hotspots to reduce new infections.

This study is subject to several limitations. First, since HIV diagnoses are not made immediately after HIV infection, the incidence rate could not be calculated in this study. Nevertheless, in the context of generally increasing HIV testing coverage in Dehong, the observed decline in newly diagnosed cases likely reflects, at least to some extent, a reduction in new HIV infections, indicating the effectiveness of local HIV control measures. Second, the analysis in this study was conducted at the township level; the macro-level factors potentially associated with the rate of newly diagnosed HIV infections were not investigated due to the data availability. Third, all analyses in

XSL•FO
RenderX

this study were restricted to newly diagnosed HIV cases of Chinese nationality, as data on foreign nationals were not available. Consequently, the findings primarily reflect HIV infection patterns among the local resident population and may underestimate the overall contribution of cross-border populations to the regional HIV epidemic.

## Conclusions

In conclusion, the rate of newly diagnosed HIV cases in Dehong has significantly decreased from 2010 to 2022. By applying a BSTHM framework to routine surveillance panel data, this study reveals substantial variations in the spatial distribution and temporal trends of the risk of newly diagnosed HIV infections within Dehong, with high-risk areas concentrated in townships near the China-Myanmar border. Future efforts should focus on exploring effective measures to reduce new infections in these high-risk areas. This analytical approach provides a new perspective for assessing local needs, guiding resource allocation, and developing targeted interventions to control HIV infection in other high-burden or highly heterogeneous settings.

## Abstract

**Background:** Acute hepatitis C virus outbreaks in California are identified by local health jurisdictions through the investigation of cases reported by laboratories and health care providers to the state's public health surveillance system. However, acute hepatitis C cases are widely underreported, limiting timely outbreak detection and early intervention. SaTScan (Space and Time Scan Statistics) has been proposed as a valuable tool to better detect disease clusters that may be missed by traditional surveillance, even when the disease is underreported, but it is not routinely used for acute hepatitis C surveillance. Timely outbreak detection enables prompt investigation, interruption of transmission networks, and expeditious access to treatment that prevents chronic hepatitis C progression.

**Objective:** We assessed the feasibility of using SaTScan to identify verified acute hepatitis C outbreaks using public health surveillance data by conducting a retrospective cluster analysis followed by a prospective, proof-of-concept (POC) analysis that simulated routine surveillance at a single time point using the preceding 2 years of available data.

**Methods:** We geocoded acute hepatitis C cases with an episode date between January 2022 and December 2023 that were reported to the California Department of Public Health (CDPH). Cases among people experiencing homelessness were included using proxy locations corresponding to their reporting jurisdiction. First, we applied a retrospective space-time permutation scan to determine if any detected significant clusters corresponded to a verified acute hepatitis C outbreak reported in California. We then performed a single prospective POC scan using surveillance data from August 2020 through August 2022 to simulate routine surveillance on August 28, 2022. Detection performance was evaluated based on whether the scan generated a signal corresponding to the known acute hepatitis C outbreak, measured using recurrence intervals.

**Results:** Of the 236 acute hepatitis C cases reported in California with an episode date between January 2022 and December 2023, 97.9% (n=231) were successfully geocoded. The retrospective scan identified 1 significant cluster that corresponded to a verified outbreak in Los Angeles County. The prospective POC scan detected the same outbreak 1 day after the second outbreak-related case was reported, based on symptom onset. The cluster exceeded the recurrence interval threshold (1.7 y), and 2 of 3 outbreak-related cases were identified.

**Conclusions:** SaTScan successfully identified a verified acute hepatitis C outbreak using both retrospective and prospective space-time permutation scans, demonstrating its potential to enhance real-time surveillance. However, detection performance depends on the timeliness and completeness of case reporting. Future research should explore the prospective use of SaTScan with real-time surveillance data to fine-tune signaling thresholds and scan statistic parameters and assess its broader applicability for acute hepatitis C outbreak detection.

## Introduction

Acute hepatitis C infection is defined as the 6-month period of disease onset following exposure to hepatitis C virus (HCV). Although patients with hepatitis C are often asymptomatic, symptoms after infection can include gastrointestinal issues (eg, abdominal pain, nausea, vomiting, dark-colored urine or clay-colored stools, and loss of appetite), fatigue, fever, and jaundice. Early diagnosis and treatment can prevent progression

XSL•FO
RenderX

to chronic hepatitis C among the 55% to 85% of people with acute hepatitis C infection who do not spontaneously clear the virus [1-4]. Chronic hepatitis C left untreated can lead to additional complications, such as hepatocellular carcinoma and death [5]. Outbreaks of acute hepatitis C arise in settings where there is a high risk of percutaneous exposure to infected blood and where sharps are shared, such as among people who inject drugs (PWID) and in health care facilities. HCV is highly infectious and can remain viable on dried surfaces and equipment for up to 6 weeks, which increases the time frame for possible transmission and occurrence of outbreaks [6]. Poor injection safety practices in an outpatient clinic [7] and a contaminated multidose medication vial after the suspected reuse of a needle or syringe at a pain management clinic [8] have caused recent acute hepatitis C outbreaks in California. Persistent acute hepatitis C outbreaks occur more often among PWID and incarcerated individuals, where limited access to hepatitis C prevention interventions, such as sterile injection and tattooing equipment and medication for opioid use disorder, enable ongoing transmission [9-12].

In California, local health authorities identify acute hepatitis C outbreaks by investigating hepatitis C infections reported by medical providers or diagnostic laboratories. Standard case investigations are labor-intensive, requiring extensive reviews of patient medical records and laboratory results, confirmation of symptoms, exclusion of other hepatitis causes (eg, alcohol use, toxins, and certain medications), and in-depth interviews with both patients and their providers [13]. These steps are critical to public health surveillance, as they identify behavioral, health care, or cosmetic-associated risk factors and detect clusters of acute hepatitis C infections or point-source outbreaks. However, local health jurisdictions often struggle with competing priorities and limited staffing, reducing their capacity to rapidly identify cases of concern or those linked to outbreaks. These efforts are further complicated when patients are lost to follow-up or cannot be located. Acute hepatitis C infections may also be asymptomatic or present with nonspecific symptoms, contributing to underdiagnoses and underreporting [14]. National estimates suggest that each reported case of acute hepatitis C may represent up to 13.9 actual infections [15]. When outbreaks are identified early, local health jurisdictions can investigate potential transmission networks, notify contacts, and identify individuals who may be unaware of their exposure. A systematic method for detecting outbreaks is needed, even when exposure and risk information data are incomplete, to enable effective public health response, reduce transmission, and prevent progression to chronic hepatitis C and related sequelae.

SaTScan (Space and Time Scan Statistics; Martin Kulldorff and Information Management Services Inc) is a spatiotemporal analysis software that can detect disease clusters based on spatial and temporal patterns of reported infections, independent of available exposure information [16]. The New York City Health Department has used SaTScan for routine surveillance of 35 reportable conditions since 2014 [17,18], including to identify and promptly respond to outbreaks of both legionellosis [19,20] and salmonellosis [21]. Other jurisdictions nationwide have shown that SaTScan significantly reduced the time required to detect legionellosis by eliminating the need for time-intensive manual case review [22,23]. During the COVID-19 pandemic, many jurisdictions started using SaTScan for cluster detection to enable early intervention [24], aid with the allocation of resources [25], and highlight social inequalities [26]. SaTScan has also detected spatiotemporal clusters of conditions commonly co-occurring with hepatitis C, such as opioid overdoses [27] and HIV [28], helping to characterize neighborhood-level risk factors and predict areas where transmission was likely to occur. Despite its broad application in public health surveillance, SaTScan's utility for acute hepatitis C remains underexplored.

We sought to test whether SaTScan could retrospectively identify outbreaks in noninstitutionalized, community settings across California among acute hepatitis C infections reported to the California Department of Public Health (CDPH). We also evaluated SaTScan's potential use as an early warning system for acute hepatitis C by assessing the timeliness and precision of outbreak detection. To do so, we ran a single prospective scan on historical data restricted to acute hepatitis C infections that would have been available at the time an outbreak occurred, mirroring how SaTScan would have performed in real-time surveillance.

## Methods

### Data Source

Acute hepatitis C is a reportable infectious disease in California per Title 17, Sections 2500 and 2505 of the California Code of Regulations (CCR; [29]), with cases reported through the statewide surveillance system, California Reportable Disease Information Exchange (CalREDIE). Cases are reported to one of California's 61 local health jurisdictions, comprising 58 counties and 3 city health jurisdictions (Berkeley, Long Beach, and Pasadena). However, for the purposes of this study, cases reported from city jurisdictions were counted in their respective county's boundaries. Cases are identified either through seroconversion (ie, documented negative HCV antibody, RNA, or genotype test followed by a positive HCV result) or a clinical diagnosis by a health care provider who recognizes symptoms of acute infection. All case events reported in California, including among people with acute hepatitis C infections classified according to the national surveillance case definition [30] or those pending investigation, with an episode date between January 1, 2022, and December 31, 2023 were included in this analysis. We excluded cases reported from prison, jail, and federal facilities to focus on community transmission.

### Geocoding

We attempted to geocode all eligible acute hepatitis C cases reported to CDPH to obtain the latitude and longitude of the individual's residential address. People experiencing homelessness (PEH) at the time of acute hepatitis C infection with no geocoded information were assigned to a synthetic location at the centroid of their reported jurisdiction and then shifted 10° west in longitude to position them outside populated areas. These displaced, centroid-based proxies served as artificial offshore "islands," ensuring that cases without a known address did not artificially contribute to clusters in populated areas where

XSL•FO
RenderX

the individual did not reside [18]. This approach enabled the retention of individuals experiencing homelessness, a population with increased prevalence of hepatitis C infection [31,32], in the spatial analysis, which would otherwise exclude them due to the absence of mappable residential address data.

## Criteria for Initiating Outbreak Investigations

Local health jurisdictions typically initiate outbreak investigations when 2 or more individuals with acute hepatitis C are identified in the same location (eg, the same health care facility, correctional setting, or other shared exposure site) within a 4-week period, when 1 individual with acute hepatitis C has no known risk factors (ie, sharing injection drug use or tattoo equipment, sexual contact with multiple partners, etc), or when 1 individual has health care–associated risk factors (ie, outpatient procedures, hospitalization, or organ transplantation).

## SaTScan Analysis

### *SaTScan Spatiotemporal Cluster Analysis*

We used SaTScan (version 10.1) to detect spatiotemporal clusters of acute hepatitis C infections using circular scanning windows in both retrospective and prospective space-time scans [33]. The prospective scan was designated as a proof-of-concept (POC) analysis because it aimed to evaluate whether selected parameter settings could detect a known outbreak using only data available up to the second reported outbreak-related case. In both the retrospective and prospective scans, a space-time permutation model was selected because it does not require population at risk data for acute hepatitis C infection [34], which is difficult to estimate because of variations in drug use patterns, disparities in access to health care, and stigma. Multiple circular scanning windows in the permutation scan statistic varied by spatial width (geographical area) and temporal height (time period of interest), comparing the observed number of cases within each window to the expected number under the null hypothesis of no space-time clustering.

### *Retrospective Analysis/Parameter Selection*

We conducted a retrospective space-time permutation scan on acute hepatitis C infections in California between January 2022 and December 2023. All acute hepatitis C cases classified as suspect, probable, or confirmed were included in the scan, regardless of the completeness of case investigations at the time of analysis. These inclusion criteria were intended to approximate case availability in real-time surveillance, when case classification may not yet be finalized. Initial SaTScan parameter settings were applied in the retrospective analysis to determine whether SaTScan could identify a known acute hepatitis C outbreak. Several parameters, including the space-time permutation model type, event types (eg, suspect, probable, or confirmed) for input data, maximum spatial cluster size, and secondary cluster reporting—were adopted directly from New York City Health Department guidance (Table 1) [18]. The maximum temporal cluster size, defined as the longest time period over which a cluster can occur, was set to 180 days to reflect the maximum incubation period for HCV (2 - 26 wk) infection [14]. In SaTScan, the maximum temporal cluster size parameter limits the height of the scanning window, ensuring that clusters do not span longer than the specified time. The study period spanned 2 years, which is at least three times the maximum temporal cluster size, consistent with guidance indicating diminishing returns in statistical power beyond this threshold and improved baseline stability with a longer observation period [18]. Individual cases were aggregated into consecutive 7-day intervals, consistent with the temporal aggregation used in SaTScan, to reduce sparsity in daily case counts and improve the stability of the Poisson approximation. Cluster start and end dates therefore correspond to the boundaries of these 7-day intervals. The scanning window with the maximum likelihood was designated as the most likely cluster, that is, the cluster least likely to have arisen by chance [33]. Following New York City Health Department recommendations, we also explored overlapping clusters whose centers did not fall within any other cluster [18] because more than one acute hepatitis C outbreak could occur in California at any given time. Default settings were applied for additional parameters. Each acute hepatitis C case had a temporal analysis date defined as the episode date, which was the earliest among the case report date, date of symptom onset, date of diagnosis by a clinician, and date of specimen collection for diagnostic testing. Detected clusters with $P<.05$ were considered statistically significant.

XSL•FO
RenderX

**Table .** Space and Time Scan Statistics (SaTScan) parameter settings for a retrospective space-time permutation model to identify clusters of acute hepatitis C cases in California, 2022 to 2023.

| Parameter | Setting | Justification |
|---|---|---|
| Study period | January 1, 2022, to December 31, 2023 | Reflects the most recent surveillance data available and provides adequate observation time for stable background estimation |
| Events included[a] | Suspect, probable, and confirmed acute hepatitis C cases reported to CDPH[b] | All reported events were included to approximate case availability in real-time surveillance, when case classification may be incomplete |
| Model type[a] | Space-time permutation | Requires only case data; adjusts nonparametrically for purely spatial or temporal trends and geographical variation in the occurrence, diagnosis, or reporting of disease |
| Scan areas[a] | High rates | Detects areas with a higher-than-expected case count based on the space-time permutation likelihood compared to the null distribution |
| Time aggregation | 7 days | Analysis run weekly |
| Maximum spatial cluster size (analysis)[a] | 50% of all cases during the study period | Common practice to allow detection of both small and large clusters while minimizing assumptions about true cluster size |
| Maximum temporal cluster size | 180 days | Maximum incubation period for acute hepatitis C infection |
| Maximum number of Monte Carlo replications[a] | 999 | Minimum number of replications required to avoid an unnecessary loss of power while balancing run time |
| Secondary cluster reporting criteria (output)[a] | No cluster centers in other clusters | Helps identify clusters in close proximity |

[a]Adapted from published guidance from the New York City Health Department [18].

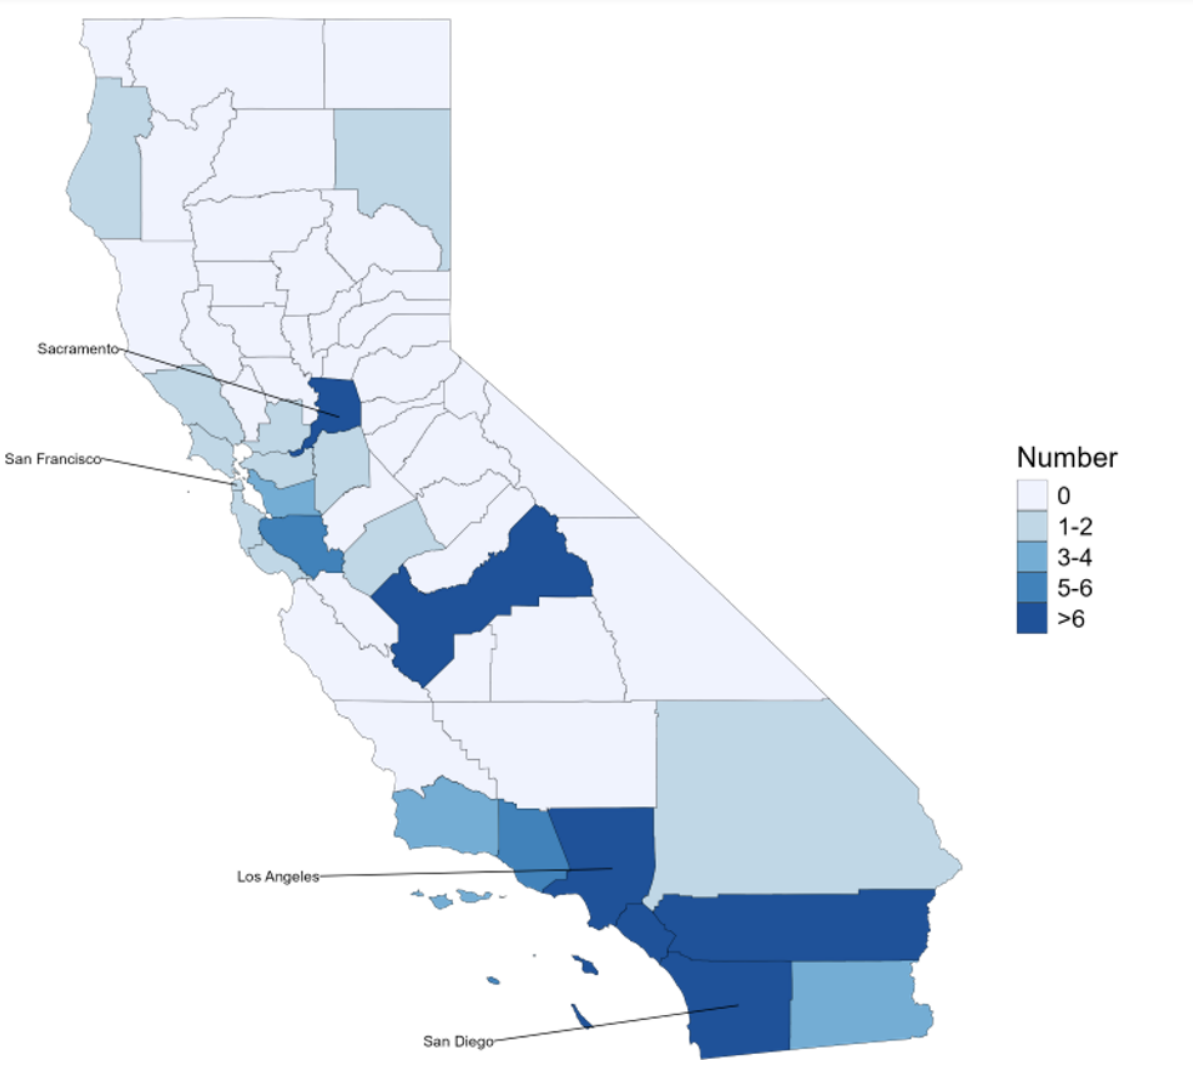
### *Prospective POC Analysis\Parameter Refinement*

We conducted a prospective POC analysis to simulate routine surveillance at a single time point and refine parameters for prospective outbreak detection. The analysis used surveillance data from August 2020 through August 2022 to mimic routine surveillance on August 28, 2022, prior to recognition of the outbreak identified in the retrospective space-time permutation scan. The same parameter settings described in the retrospective analysis were initially applied to the POC prospective scan (Table 1) to evaluate their detection performance. Recurrence intervals (RIs) are used in prospective scans; a greater RI indicates a lower likelihood that the cluster is due to chance alone. We set an RI signal detection threshold of at least 100 days, meaning that when the null hypothesis of no clustering is true, the expected number of clusters with an RI of at least 100 days occurring by chance during any 100-day period is 1. This threshold aligns with New York City Health Department guidance, which classifies clusters with an RI from 100 days to less than 365 days as weak, 365 days less than 5 years as moderate, 5 years to less than 10 years as strong, and at least 10 years as very strong [18]. Because this was an exploratory scan, we prioritized sensitivity by including weaker signals that might still warrant follow-up under real-time surveillance conditions. For each detected cluster, we determined whether it corresponded to the verified acute hepatitis C outbreak and the proportion of cases within the cluster that were epidemiologically linked to the outbreak.

We then conducted a sensitivity analysis, iteratively evaluating alternative prospective parameter settings, to assess their effects on the detection of the known outbreak and the resulting RI. Parameters evaluated included maximum temporal cluster sizes of 30, 60, 90, and 180 days (analysis>advanced>temporal window), maximum reported spatial cluster sizes (output>advanced>spatial output), and daily vs weekly temporal aggregation (analysis). When temporal aggregation was varied, prospective analysis frequency (analysis>advanced>miscellaneous) was set to the corresponding interval and was not evaluated independently. Final settings were selected by balancing signal strength with epidemiologic plausibility and suitability for routine surveillance rather than by selecting the configuration that maximized RI.

## Ethical Considerations

This study was designed as a secondary analysis of original data collected to investigate hepatitis C infections as part of routine public health surveillance and is considered “not research” under the Common Rule (45 CFR [Code of Federal Regulations] 46; [35]). This determination was made by CDPH under its institutional policy for classifying routine public health surveillance activities conducted pursuant to the department’s statutory authority to investigate and control reportable diseases (CCR, Title 17, Sections 2500 and 2505 [29]); no formal institutional review board protocol application was submitted, consistent with CDPH policy that such surveillance activities do not constitute human subjects research.



XSL•FO
RenderX

## Results

### Retrospective Analysis

Between January 2022 and December 2023, 409 acute hepatitis C cases with an episode date during the study period were reported to CDPH. Of these, 173 (42.3%) cases reported from prisons, jails, or federal facilities were excluded. Of the remaining 236 reported acute hepatitis C cases, 231 (97.9%) were geocoded and included in the retrospective scan, including 31 (13.4%) cases among PEH. Among the remaining 5 (2.2%) acute hepatitis C cases with missing geocoded information, all were male participants, 4 (80%) were Hispanic, 2 (40%) resided in the state's Central Coast region, and 3 (60%) resided in the Southern region of California. During 2022 and 2023, an average of 10 (SD 2.7) acute hepatitis C cases occurred each month (range: 4 - 14), with no notable temporal trends. This reflects a relatively low number of cases during the study period. The local health jurisdictions with the highest number of reported acute hepatitis C cases were San Diego (n=120), Los Angeles (n=33), Fresno (n=15), and Orange (n=12) counties (Figure 1). The retrospective space-time permutation scan identified 1 significant ($P$<.05) cluster of 5 cases in Los Angeles County (Figure 2). All these cases resided within the same 12-mile radius, with episode dates that ranged from August 15, 2022, to September 18, 2022 (Table 2). Two of the 5 (40%) cases in this cluster were linked to an August 2022 outbreak reported in Los Angeles County.

**Figure 1.** Number of acute hepatitis C cases reported to the California Department of Public Health (N=231) and included in the retrospective space-time permutation scan by local health jurisdiction, 2022 to 2023. All cases with geocoded information were included in the space-time retrospective scan. This includes cases among people experiencing homelessness (PEH) but missing a residential address, who were geocoded to their reported health jurisdictions. Shading indicates the number of reported acute hepatitis C cases by local health jurisdiction, with progressively darker shades of blue representing higher case counts (0, 1-2, 3-4, 5-6, and >6 cases).

XSL•FO
RenderX

**Figure 2.** Weekly occurrence of acute hepatitis C cases (N=231) included in the retrospective space-time scan, California, 2022 to 2023. Cases with episode dates from January 1, 2022, through December 31, 2023, were aggregated into consecutive 7-day periods consistent with the temporal aggregation used in the SaTScan (Space and Scan Statistics) analysis.

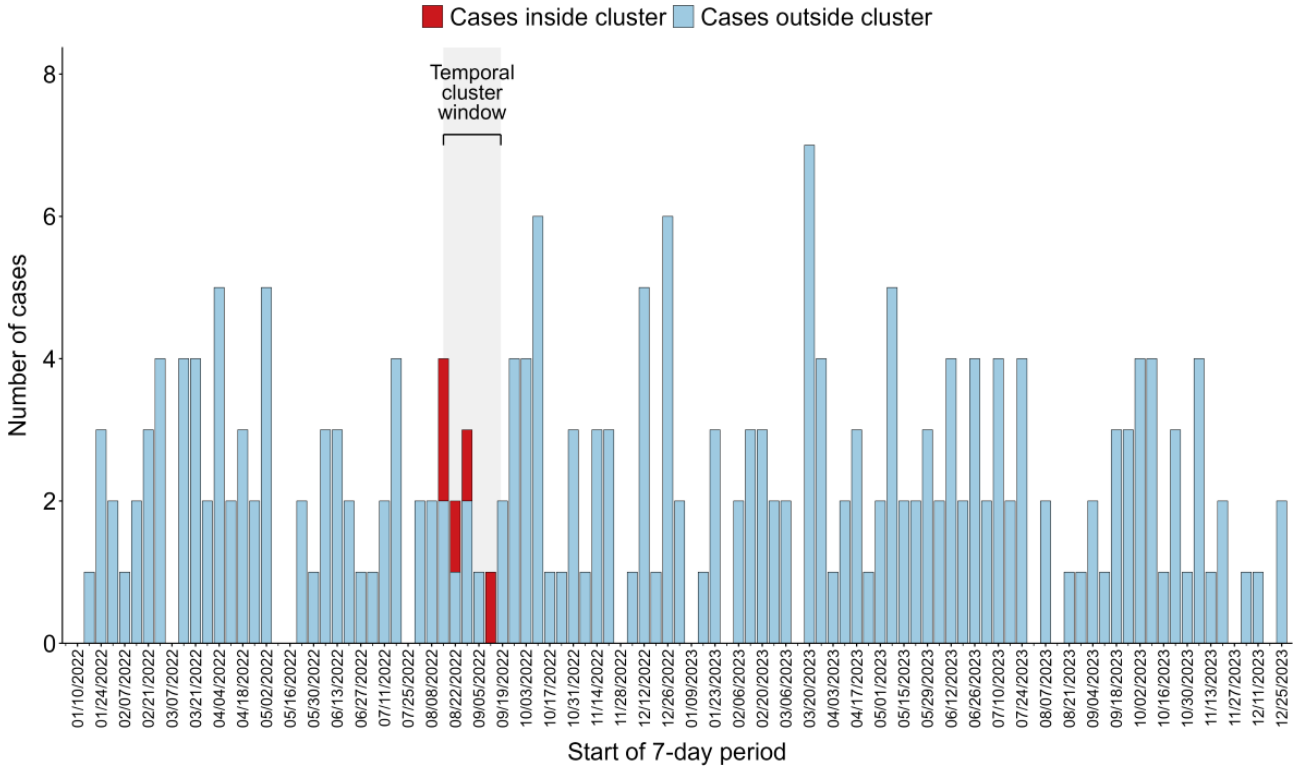


**Table .** Significant cluster of acute hepatitis C cases in California detected by SaTScan (Space and Time Scan Statistics) using a retrospective space-time permutation model between January 1, 2022, and December 31, 2023.

| Jurisdiction | Los Angeles County |
|---|---|
| Cluster time frame | August 15, 2022, to September 18, 2022 |
| Cluster radius size, km | 19.34 |
| Observed cases | 5 |
| Expected cases | 0.29 |
| Log likelihood ratio | 9.65 |
| *P* value | .02 |

## Historical Cluster Summary

The retrospective scan identified a historical outbreak of acute hepatitis C transmission in August 2022 at a pain clinic in Los Angeles County [8]. The outbreak was suspected to be caused by contamination of a multidose medication vial, possibly due to the reuse of a needle or syringe [8]. Two acute hepatitis C cases with onsets 12 days apart in late August 2022 were linked through visits to the pain clinic on the same day. To our knowledge, this pain clinic outbreak was the only verified acute hepatitis C outbreak identified in a noninstitutionalized, community setting, including among PEH, in California during the study period. Following an exposure notification sent by the Los Angeles County Department of Public Health to 140 patients who had visited the pain clinic and were considered at risk, a third acute hepatitis C case was linked to the same exposure event [8]. This case was initially reported in another county; however, the patient moved out of state and was subsequently classified as out-of-state in the surveillance system. Because out-of-state cases were excluded from the data, this case was not included in this analysis.

## Prospective POC Analysis

To simulate how a prospective scan might have performed at the time the second outbreak-related case was reported, we geocoded 157 cases with episode dates between August 28, 2020, and August 28, 2022. The prospective space-time permutation scan detected 3 new acute hepatitis C clusters (Figure 3). One cluster matched the Los Angeles County outbreak previously identified in the retrospective scan, with a start date of August 28, 2020, and an end date of August 28, 2022 (Table 3). This cluster included 3 acute hepatitis C cases; 2 were known to be associated with the outbreak; and the third had no known link to the clinic exposure but had shared injection equipment with a non–outbreak-related acute hepatitis C case. The RI for this cluster was 1.7 years (approximately 620 d), a moderate signal, indicating that a cluster of this magnitude or larger would be unlikely to occur by chance more than once

XSL•FO
RenderX

every 1.7 years. Because only 2 of the 3 cases were linked to the outbreak, the proportion of outbreak-related cases detected was 66.7%.

**Figure 3.** Weekly occurrence of acute hepatitis C cases (N=157) included in the prospective space-time scan, California, 2020 to 2022. Cases with episode dates from August 28, 2020, through August 28, 2022, were aggregated into consecutive 7-day periods consistent with the temporal aggregation used in the SaTScan (Space and Time Scan Statistics) analysis.

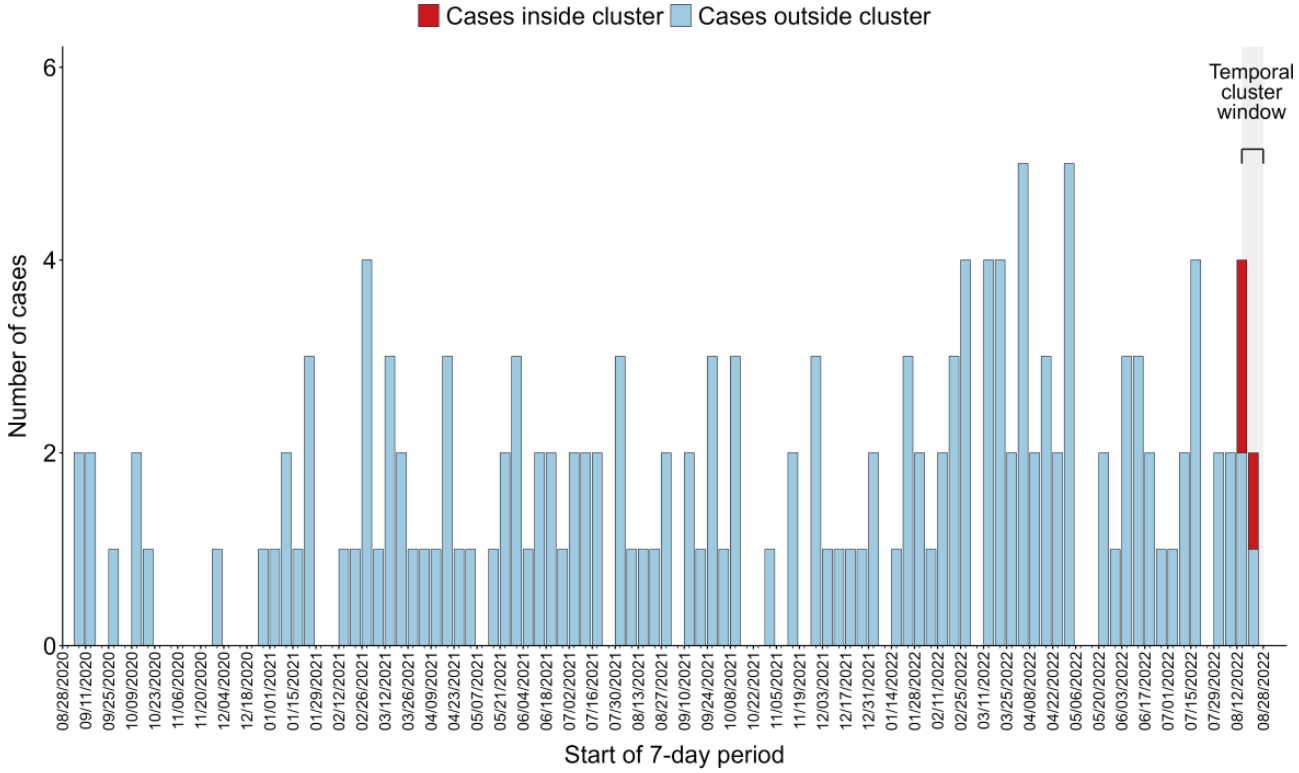

**Table .** Significant cluster of acute hepatitis C cases in California detected by SaTScan (Space and Time Scan Statistics) using a prospective space-time permutation model between August 28, 2020, and August 28, 2022.

| Jurisdiction | Los Angeles County |
|---|---|
| Cluster time frame | August 15, 2022, to August 28, 2022 |
| Cluster radius size, km | 19.34 |
| Observed cases | 3 |
| Expected cases | 0.11 |
| Log likelihood ratio | 6.93 |
| Recurrence interval, year | 1.7 |

Sensitivity analyses demonstrated that shorter maximum temporal cluster windows generally produced equal or stronger RIs for the known outbreak. For example, 30-day and 60-day windows produced RIs of approximately 2 years compared with 1.7 years using the 90-day and 180-day windows. Temporal aggregation had a larger practical effect on signal detection; changing from weekly to daily aggregation reduced the RI from 1.7 years to 77 days, below the prespecified at least 100-day signal threshold. Restricting the maximum reported spatial radius to 10 km similarly reduced the RI to 32 days, whereas 20-km and 30-km settings retained an RI of 1.7 years.

## Discussion

### Principal Findings

Our findings demonstrate that SaTScan was able to detect a known acute hepatitis C outbreak in both the prospective and retrospective space-time permutation scans, suggesting potential utility for supplementing real-time surveillance. We used both retrospective and prospective space-time permutation scans to evaluate SaTScan's utility in different contexts. Retrospective scans are useful for identifying historical outbreaks and informing initial parameter settings, while prospective scans can support routine monitoring for emerging clusters [36]. In the prospective POC analysis, the identified cluster met the predefined moderate RI threshold of at least 100 days and detected 2 outbreak-associated cases. Although 3 acute hepatitis C cases were ultimately linked to the outbreak, the third case

XSL•FO
RenderX

was classified as out-of-state in the surveillance system and therefore excluded from the analysis. Case information and classification may have differed had the scan been conducted in real-time; therefore, whether this case would have been included or the resulting signal would have differed under routine prospective surveillance is unknown.

The outbreak-related cases identified involved patients from geographically distinct areas, illustrating how spatial methods may help identify related cases that do not share addresses or known epidemiologic links. Although Los Angeles County initiated an investigation through comparison of a pain clinic's patient list to electronic lab reports, our prospective scan independently detected the same cluster using only routinely reported surveillance data. SaTScan identified the outbreak as a cluster of interest the day after the second outbreak-related case was reported, demonstrating how automated spatial methods could support near–real-time identification of clusters without requiring patient list matching to public health surveillance data. While Los Angeles County relied on a separate surveillance system during this study period and manually entered cases into CalREDIE, introducing reporting delays, this POC evaluation suggests that SaTScan could complement existing local workflows by systematically flagging clusters of concern when case ascertainment is timely. However, because only 1 verified community outbreak was available for evaluation, these findings demonstrate feasibility rather than the sensitivity or timeliness that could be expected across outbreaks more generally.

### Interpretation and Performance Considerations

Reported performance across previous SaTScan applications has varied, reflecting differences in disease epidemiology, case volume, and data quality. For legionellosis and salmonellosis, relatively moderate initial signals (eg, RIs of 1.4 y and 2.3 y) prompted targeted epidemiologic investigations and testing that ultimately confirmed point-source outbreaks [19,21]. Similarly, the present study identified a small, verified point-source outbreak with a moderate RI signal, demonstrating that epidemiologically meaningful outbreaks may produce relatively modest statistical signals. A simulation study of legionellosis found that an RI threshold of at least 100 days provided a balance between time to detection and positive predictive value, although a small, slowly developing simulated outbreak was not detected [22]. This limitation may also be relevant to acute hepatitis C, where small outbreaks developing gradually within populations with ongoing endemic transmission may produce less distinct spatiotemporal signals. Prospective legionellosis surveillance has also used an RI threshold of at least 100 days to identify clusters for further review [23]. Additionally, a COVID-19 application identified reporting delays and incomplete geocoding as limitations to the timeliness and completeness of prospective cluster detection [24]. These considerations are particularly relevant to acute hepatitis C, for which low case volume, incomplete ascertainment, and reporting delays may affect both the strength and timing of detectable signals. Other small acute hepatitis C outbreaks may also have occurred without being recognized or reported to CDPH and therefore could not be evaluated in this analysis. Together, these studies support the potential utility of prospective SaTScan for identifying signals warranting further investigation, while highlighting the importance of considering disease-specific epidemiology and surveillance data characteristics when selecting parameters and interpreting detected signals.

RI thresholds used to determine which clusters trigger alerts are suggested benchmarks and may be adapted based on epidemiologic and surveillance considerations [18]. Establishing useful thresholds may be particularly challenging when case volume is low because small clusters can be difficult to distinguish from expected variation [37,38]. Nevertheless, both space-time permutation analyses identified the known outbreak based on 2 eligible outbreak-associated cases, despite there being an average of only 10 (SD 2.7) acute hepatitis C cases reported statewide per month. Although this single outbreak cannot establish performance in other low-volume settings, it demonstrates that a small outbreak can generate a detectable signal even within sparse acute hepatitis C surveillance data.

While our findings suggest that SaTScan may have utility for detecting small, localized acute hepatitis C outbreaks, the approach has inherent constraints. Other cluster detection methods, such as flexible scan statistics [39], can identify irregularly shaped clusters and may capture more complex spatial patterns of transmission. However, these methods generally require greater computational and technical resources and are less commonly implemented in routine public health surveillance than SaTScan [40]. SaTScan itself also supports scanning along a user-defined network locations file, which can better accommodate irregularly shaped clusters than the circular scanning window used here; however, this approach requires aggregating cases to network nodes (eg, census tract centroids), introducing a trade-off between spatial flexibility and geographic precision. SaTScan has demonstrated comparable statistical power in many applications while requiring substantially less computation, making it a potentially practical tool for routine public health surveillance [41].

Sensitivity analyses demonstrated that parameter selection requires balancing statistical signal strength with epidemiologic plausibility and operational considerations. Although shorter temporal windows sometimes produced stronger signals, we retained the 180-day maximum temporal cluster size because it reflects the maximum incubation period for acute hepatitis C infection and allows detection of transmission occurring across the full biologically plausible interval. Similarly, restricting the spatial radius reduced signal strength, suggesting that overly narrow spatial windows may limit detection of epidemiologically related hepatitis C cases. This may be particularly relevant for point-source outbreaks, such as the outbreak detected in this study, because individuals sharing a common exposure may reside across a relatively broad geographic area. Hepatitis C transmission networks may also extend across geographically dispersed communities, particularly among PWID [42]. Thus, residential proximity does not necessarily reflect the geographic extent of a shared exposure or transmission network. Temporal aggregation also influenced signal strength, with weekly aggregation performing better than daily aggregation in these relatively sparse surveillance data. The space-time permutation model is based on a hypergeometric distribution conditioned on the observed spatial and temporal margins, but it currently

XSL•FO
RenderX

uses a Poisson approximation to calculate the likelihood ratio [34]. The accuracy of this approximation may be affected when case counts are very low [43]. However, in our sensitivity analysis, changing from weekly to daily aggregation reduced the RI signal when case counts were sparse. The appropriate aggregation interval should therefore be considered alongside case volume and signal stability when configuring routine surveillance.

### Methodological Strengths

One difference in our study from previous analyses was the use of residential locations of cases, the smallest available geographic unit, rather than spatially aggregated data to census tracts or zip codes. Aggregating data can dilute spatial signals and expand the scanning window to include unrelated cases, decreasing cluster precision [43]. We initially attempted cluster detection at the census-tract level; however, no significant clusters were identified, consistent with signal dilution resulting from spatial aggregation. Technical guidance from SaTScan developers indicated that, given the sparsity of acute hepatitis C cases, case-level coordinates were appropriate for the goals of this study. Use of case-level residential addresses may also improve the timeliness of detection among localized clusters of smaller sizes [44]. Additionally, we applied an approach to retain acute hepatitis C cases among PEH, a population that is often excluded from place-based analyses due to missing address information. By assigning PEH to an artificial centroid [18], we were able to include 13.4% (31/231) of reported acute hepatitis C cases that otherwise would have been excluded. Retaining PEH is important because housing instability is associated with increased risk of hepatitis C infection, especially among PWID [45]. While clusters involving PEH were not verified as known outbreaks, excluding PEH, who may also have limited access to hepatitis C screening and are underrepresented in public health surveillance data, would further reduce completeness of case ascertainment and impede early outbreak detection for a population disproportionately affected by hepatitis C infection [46]. As a sensitivity analysis, we evaluated alternative approaches for assigning cases among PEH, including placing them at the county centroid rather than shifting coordinates outside the study area. Although no PEH cases were included in the known outbreak cluster, centroid placement altered the strength of the detected cluster, reducing the RI estimate. Assigning multiple cases without residential addresses to the same county centroid creates artificial spatial concentration among individuals who may not have been geographically proximate. In the space-time permutation model, this artificial concentration can alter the expected spatiotemporal distribution of cases and consequently influence the statistical strength of other clusters in the surrounding area. These findings support caution when assigning cases with unknown residential locations to a common geographic point. In future applications, assigning PEH based on the location of testing or diagnosis may provide a more meaningful alternative to either central placement or coordinate shifting.

### Limitations

This study has several limitations. First, only 1 verified community outbreak was available to evaluate the approach. Consequently, this study cannot estimate the sensitivity, specificity, or overall performance of SaTScan for acute hepatitis C outbreak detection. The findings instead provide preliminary evidence that this approach can detect a verified outbreak using routinely collected California surveillance data. Evaluation against additional verified outbreaks and prospective implementation are needed to characterize performance more broadly. Second, although our prospective POC analysis was designed to simulate real-time surveillance, it was conducted retrospectively using historical surveillance data. By the time of analysis, most case investigations had been completed and case classifications finalized, resulting in fewer pending cases than would likely be encountered in real-time surveillance. In practice, a higher proportion of cases would be pending investigation, some of which may ultimately be determined not to meet the acute hepatitis C case definition, potentially increasing background noise and generating false-positive signals [47]. Routine prospective implementation could address this by rerunning scans as investigations are completed and surveillance data are updated. Scans using a lagged end date could also identify clusters that were not initially detectable because of incomplete case classification or reporting [48]. Third, surveillance bias influences acute hepatitis C case ascertainment. Asymptomatic cases are less likely to be tested and reported during the acute phase, contributing to underreporting. Misclassification also occurs when providers test for suspected acute infections but do not submit the required acute case report to the health department, resulting in these infections being automatically classified as chronic through routine laboratory reporting. As a result, reported acute hepatitis C cases likely underestimate the true burden and may not accurately represent its spatial distribution, limiting the ability of any cluster detection method to identify outbreaks. Surveillance bias could be reduced by capturing negative HCV antibody and liver enzyme laboratory results in surveillance systems, increasing case ascertainment by identifying markers of acute infections, such as HCV antibody seroconversions and higher-than-normal alanine aminotransferase and bilirubin results. At last, this analysis excluded people who were incarcerated, who have a higher incidence of acute hepatitis C compared with people in community settings [49,50]. Because cases within carceral facilities are concentrated at the same geographic location, residential coordinates provide limited spatial information for detecting transmission patterns. Institutional settings may therefore be better evaluated using more granular spatial approaches, such as building-level analyses [51].

## Conclusions

This study suggests that SaTScan may be helpful for enhancing acute hepatitis C surveillance, particularly for identifying geographic clusters in settings where underreporting and incomplete data hinder early detection. We used a retrospective scan to evaluate initial parameter settings and a prospective POC scan to fine-tune parameters while simulating real-time surveillance using historical data. SaTScan detected 1 verified acute hepatitis C outbreak in both analyses, providing an initial POC framework that public health jurisdictions may adapt to refine parameter selection based on local surveillance practices,

XSL•FO
RenderX

reporting patterns, and epidemiologic context. In practice, effective cluster detection depends on the timeliness and completeness of case reporting, as well as the granularity of the spatial information and the volume of case data available. Future research should evaluate SaTScan in real time to determine whether it consistently detects outbreaks early enough to support timely public health responses.

For implementation in California, SaTScan is planned to run automatically on a weekly basis, with epidemiology staff reviewing generated signals and communicating with local health jurisdictions when clusters exceed a predefined RI threshold of at least 100 days and warrant further investigation. Because scans can be automated, the primary ongoing staff effort is expected to involve the review and epidemiologic assessment of generated signals rather than manual execution of analyses. Beyond prospective implementation, validation against additional known outbreaks is needed to determine how well the approach performs across outbreaks with different spatial and temporal patterns, including more diffuse or network-associated transmission rather than a single point-source exposure. Other jurisdictions could use the parameters evaluated here as a starting point while adapting and validating them against their own surveillance data and epidemiologic context. Such evaluations will be important for determining the broader utility and generalizability of automated cluster detection for acute hepatitis C surveillance.

## Acknowledgments

The authors wish to acknowledge Alison Levin-Rector and her team at the New York City Department of Health and Mental Hygiene for offering technical assistance and troubleshooting guidance related to SaTScan. We also thank Dr Kristen Aiemjoy at the University of California, Davis, for her valuable comments and suggestions during manuscript development. The main author acknowledges the use of Claude Opus 5.5 (Anthropic) for editorial assistance, including language refinement and grammar correction. All scientific content, analyses, interpretations, and conclusions were developed and reviewed by the authors.

## Funding

The authors declared no financial support was received for this work.

## Data Availability

These data were collected and maintained by the California Department of Public Health (CDPH) for public health surveillance purposes under applicable state authority and contain confidential information that cannot be released publicly. Requests for access may be considered by CDPH in accordance with applicable laws, regulations, and data-sharing policies.

## Authors' Contributions

SN conceptualized the study, developed the methodology, conducted the analysis, curated the data, interpreted the findings, and drafted the manuscript. RM, RES, and BM-L provided critical review and editing of the manuscript. All authors reviewed and approved the final manuscript.

## Abstract

**Background:** Chronic diseases, including behavioral health topics, impose a significant burden on health systems, especially among rural and tribal communities. In response, federal agencies require reliable data-driven decision-support for investigating emerging needs, prioritizing responses, and conducting surveillance. Federal decision-support models may benefit from geo-analytic methods capable of integrating multicriteria evidence, interagency policy-driven parameters, and disparate jurisdictional interests.

**Objective:** This study aims to identify candidate federal priorities for intergovernmental and interagency cooperation using exploratory geo-analytic decision-support frameworks, specifically related to behavioral health risks and services among tribal populations.

**Methods:** We tested illustrative federal decision parameters within 3 exploratory geo-analytic frameworks using publicly available US data. These included alcohol-related and drug-related mortality data from 2018 to 2023 from the Centers for Disease Control and Prevention (CDC); facility locations, operating hours, and Euclidean-distance approximations of physical access to behavioral health services from the Indian Health Service (IHS); and federal transportation and rest stop data used to examine hypothesized interpersonal-risk conditions. Analyses were performed from February through August 2025.

**Results:** The exploratory analyses identified 78 counties across 13 states as prioritized investigation areas based on elevated and increasing alcohol-related or drug-related death rates. The 6-year pooled crude death rates ranged from 1197.8 to 1848.7 per 100,000 American Indian or Alaska Native (AI/AN) persons. Two regional analyses demonstrated methods for further prioritization. One analysis estimated that 22,029 and 234,852 AI/AN persons resided in low physical access areas for services during typical and nontypical business hours, respectively. Another analysis identified 12 potential interpersonal risk-exposure locations within a region of 28 rest stop facilities among 80 AI/AN communities.

**Conclusions:** Three exploratory geo-analytic frameworks demonstrate methodological feasibility for identifying candidate geographic priorities that could inform federal-tribal and interagency investigations, service access barriers, and interpersonal risk events. The recommendation is to validate and expand the methodology with rural and tribal systems, leading to a candidate federal decision-support model for future interagency initiatives.

## Introduction

In February 2025, Executive Order (EO) 14212 established a framework for refocusing federally funded scientific research, technology development, and health care delivery on mitigating the rising national rates of chronic disease [1]. The framework notes that 90% of the nation's 4.5 trillion dollars in annual health care expenditures are for people with chronic diseases, including mental health conditions. The federal guidance calls for the nation's health care systems to emphasize health promotion, not solely disease management.

Health care systems in the United States are largely based in urban areas, while 46 million Americans live in nonmetropolitan counties [2]. Rural communities experience greater barriers to accessing health services and higher morbidity and mortality rates from the nation's leading causes of death [3]. Among these

XSL•FO
RenderX

areas, American Indian or Alaska Native (AI/AN) persons engage with health systems operated by a mix of federally recognized tribes or tribal organizations, federal systems, and private rural systems. Consistently, AI/AN persons have lower life expectancy at birth, self-report high rates of fair or poor health (21.8%), and contend with significant burdens of heart disease, cancer, unintentional injuries, and chronic liver disease as leading causes of death [4]. Application of the new Health and Human Services (HHS) strategic framework for promoting health is therefore particularly germane to rural and tribal areas.

In this study, rural and tribal health systems are considered overlapping rather than mutually exclusive domains. Tribal members often reside within rural areas and may obtain care through a combination of tribal, federal, and other rural health systems. Their families and other members of the surrounding communities may also rely on the same regional health care infrastructure. Accordingly, rural and tribal areas are treated as combined areas of interest because service capacity, access constraints, and population health needs may extend across tribal and non-tribal jurisdictions. The principal analytic population in these demonstrations remains AI/AN persons; rural areas refer to the broader service geography in which many overlapping tribal, federal, and other health systems operate.

Health systems in rural and tribal communities tend to form and manage local and regional partnerships to achieve integrated service delivery and risk surveillance [5,6]. While such communities are often resilient and able to leverage insights that fit their unique contexts [7], they may be vulnerable to unexpected operational surges when complex health services are required. These cases tend to include the treatment of substance use disorders, violence-based injuries, mental illness, and debilitating chronic conditions [8]. Operational strain on local health systems can have broader social, economic, and safety consequences for communities. The ability to anticipate these surges and respond effectively is an essential rural health system capacity.

Relevant to both the HHS framework and the potentially overwhelming risks posed to rural and tribal communities, EO 14379 established the White House Great American Recovery Initiative [9]. The initiative enables federal agencies to explore and test decision-support capabilities in determining priorities in federal health service projects. Furthermore, EO 14332, Improving Oversight of Federal Grantmaking [10], encourages federal agencies to align discretionary awards with agency priorities and to establish clear benchmarks for measuring progress and success. Ideally, evidentiary methods should incorporate measurable necessity before issuing grants, as well as verify readiness for local and regional partnerships, opportunities for service innovations, and the soundness of proposed projects' investments. The HHS framework and the related EOs provide an opportunity for federal agencies to reexamine their methods of analyzing and prioritizing programs and projects. Analytic methods must be comprehensive and repeatable to provide a reliable foundation for negotiations among federal agencies, tribes, and tribal organizations.

Nationally, there are an estimated 2.8 million AI/AN persons associated with 575 federally recognized AI/AN tribes [11,12]. Tribal governments lead community health concerns, including the unique federal-to-tribal requirements and opportunities to plan cooperative analyses and initiatives. Federal law establishes government-to-government responsibilities for tribal participation, consultation, self-determination, and, where applicable, self-governance in the administration of Indian health services [13,14]. This government-to-government context creates a need for reliable and verifiable federal decision-support methods. These are foundations for organizing and negotiating initiatives that affect tribes, tribal members, and their cooperation with other health system partners, including regional rural health systems.

Within the scope of chronic diseases, we opted to demonstrate our methods with behavioral health topics. Our baseline analysis focuses on national alcohol-related and drug-related (ADR) deaths, with a regional example of potential barriers to accessing behavioral health services. Substance use disorders may coexist with social and behavioral conditions associated with vulnerability to interpersonal victimization. Accordingly, the study also examines an exploratory geographic framework for identifying locations where hypothesized interpersonal risk conditions could be investigated. Potential severe interpersonal risks include stalking, assault, abduction, human trafficking, and homicide [15]. Since AI/AN communities are disproportionately impacted by human trafficking [16], the study also examines methodologies for planning surveillance with tribal and local authorities.

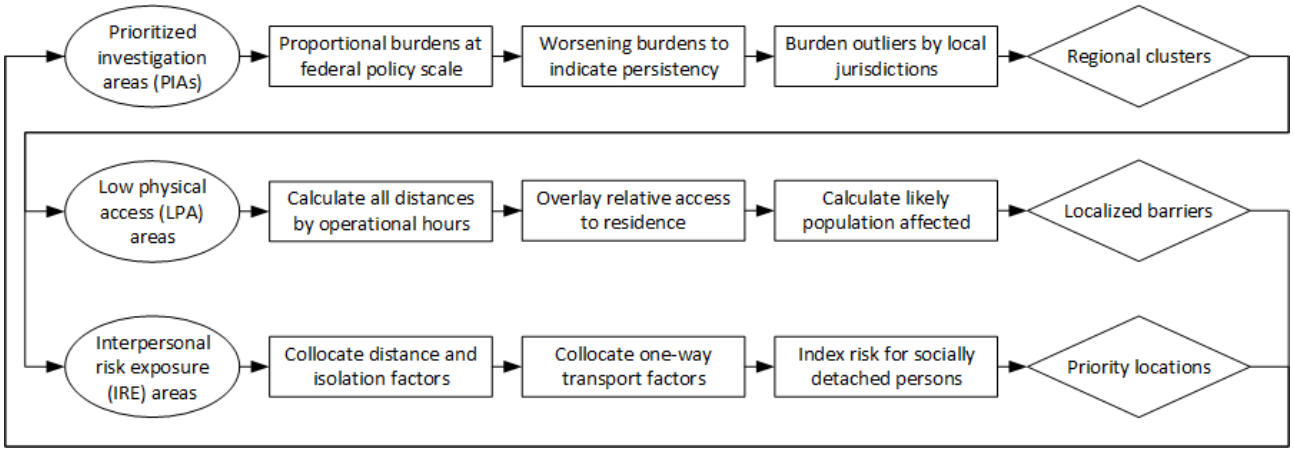
Geographic analysis can provide a common place-based framework for integrating evidence across jurisdictional interests. Herein, we explore the use of geographic sciences as an applicable set of decision-support methods for guiding the development of federal decision-support and surveillance tools. Because these methods rely on consistent location-based analyses, they are especially helpful in the context of coordinating strategic decision-making. These decisions involve actors operating across shared and overlapping geographies, including federal agencies, tribal governments, states, counties, and local health systems.

The field of geographic sciences includes place-based applied research for approximating useful patterns and anomalies, supporting hypothesis generation and, when combined with appropriate study designs, causal inference [17]. A subfield that is especially relevant to this study is medical geography [18]. This field specializes in the dynamic interactions among jurisdictional, economic, social, technological, political [19], and ecological factors [20]. These interactions inform measures of causal pathways in patient needs, community health needs [21], health system capabilities, and health outcomes [22]. Technologically, these methods are often performed through geographic information systems (GIS). GIS can provide efficiency in making repeated inquiries into multiple collocated or spatially diverse factors affecting health systems and patient experiences [23].

In combination, the GIS-based methods allow for multicriteria analyses that accommodate variability in both service objectives and local attributes that affect decisions among various interests [24]. The potential of geo-analytics in decision-support

XSL•FO
RenderX

frameworks is the ability to foster a dynamic research community in governments, academia, and industry, leading to robust methods in support of complex, scalable projects [25]. The same community is raising concerns about the repeatability, reproducibility, and replicability of these projects [26]. The rapid interdisciplinary influence of advanced geo-analytics and medical geography, as well as the potential geospatial AI (GeoAI), has stimulated an interest in expanding scientific oversight. Areas of concern include the development of effective curricula for analysts and researchers [27], anticipating shortcomings in scientific methods and ethical controls [28], and sustaining data quality to reduce information bias [29].



This study had two objectives: (1) to identify candidate federal priorities for intergovernmental and interagency cooperation in strengthening behavioral health services among AI/AN populations within overlapping tribal and rural service environments and (2) to demonstrate reproducible GIS frameworks that could contribute to a federal decision-support model for health-risk surveillance and service planning.

## Methods

### Overview

This study developed and tested 3 geo-analytic frameworks (Figure 1) using geographic sciences to enable future analytic integration and decision-support modeling. We investigated patterns of elevated and increasing ADR mortality, physical barriers to services, and locations with hypothesized interpersonal risk conditions. For purposes of these exploratory analyses, we followed a form of administrative decision-making and selected illustrative thresholds to demonstrate how policy-relevant parameters could be incorporated into federal decision support. Federal investment decisions often reflect a combination of statutory, administrative, practical, and policy considerations, not solely empirical evidence [30]. Analyses were performed in GIS in R (version 4.1.2; R Foundation for Statistical Computing) [31].

**Figure 1.** Conceptual structure of decision-support requirements, geo-analytic framework analyses, and initial analytic patterns to support the development of federal decision-support tools.

### National Prioritized Investigation Areas

The first geo-analytic decision framework enables the identification of prioritized investigation areas (PIAs, which are geographic areas that warrant prioritized investigation. We examined national ADR mortality data among AI/AN persons to locate PIAs based on geographically concentrated patterns of elevated and increasing mortality in AI/AN populations.

At the time of this analysis, we acquired 2018 to 2023 state-level and county-level mortality data from the Centers for Disease Control and Prevention (CDC) WONDER (Wide-Ranging Online Data for Epidemiological Research) database. We used the single race indicator for AI/AN, without restrictions. ADR deaths were identified using the National Center for Health Statistics Drug/Alcohol Induced Causes recode available in CDC WONDER. Analyses were restricted to deaths for which a drug-induced or alcohol-induced cause, as defined by the predefined *International Classification of Diseases, Tenth Revision (ICD-10)* [32] groupings, was listed as the underlying cause of death.

Using pooled crude mortality data from 2018 to 2023, we first identified states with greater than 1% of the aggregated death burden for the national AI/AN population. Within those states, we identified increases in death rates greater than 10% from 2018 to 2023. We then identified counties having 6-year pooled crude death rates exceeding the national non-AI/AN rate (958 deaths per 100,000 persons; 6-year pooled crude death rate) by 25%. The benchmark was calculated after excluding the count of AI/AN persons from the national rate. The national non-AI/AN rate was selected as an illustrative external benchmark for identifying AI/AN mortality burdens substantially exceeding the broader population burden; this comparator and the associated thresholds require sensitivity testing before operational use.

### Physical Access to Behavioral Health Services

The second geo-analytic decision framework facilitates potential characterization of local barriers to accessing health care. The analysis estimates physical proximity to behavioral health facilities serving AI/AN populations but does not determine individual eligibility for services at each facility. Eligibility may vary by facility, tribal affiliation, residence, and whether services are provided through Indian Health Service (IHS)–operated or tribally operated facilities. Accordingly, the measures represent

XSL•FO
RenderX

potential geographic access rather than confirmed individual service eligibility.

To demonstrate this framework, we examined time and distance factors in accessing ambulatory and urgent/emergency behavioral health services for AI/AN populations in the American Southwest. The region focuses on Arizona and New Mexico, with portions of neighboring states that border them, including portions of California, Colorado, Nevada, and Utah. A December 2024 IHS national file of AI/AN-serving facilities [33], managed by either federal or tribal authorities [34], identified a sample of 119 facilities. We excluded schools and inpatient facilities from the analysis, resulting in 86 facilities classified as behavioral health services. Through online searches, we confirmed site data on the seasonality of weekly operating hours, health services offered, and latitude/longitude. Data representing 2 or more unique but collocated health services were disaggregated to maximize data quality on operating hours without impacting the precision of distance estimates. Service hours were measured as a component of typical weekday business hours (Monday through Friday, 8 AM to 5 PM) and nontypical business hours (Monday through Friday, 5:01 PM to 7:59 AM, plus Saturday and Sunday).

We created raster maps illustrating the entire landscape as a set of pixels. Raster cells represented 1 square mile, and each cell stored the Euclidean distance to the nearest eligible facility. The color changes at 10-mile intervals (≤10, >10 - 20, >20 - 30, and >30 miles). Using the raster maps as a reference for relevant distances across the surface, we produced choropleth maps to illustrate the region's top 25% of census tracts by AI/AN population count. Population data are from the 2023 American Community Survey 5-year demographic and housing estimates [35]. The primary color code for the choropleth maps identifies census tracts completely within low physical access (LPA) areas, corresponding to locations greater than 30 miles from available services. The secondary color code identifies census tracts that were partial in these areas. All other areas, colored in white, represent tracts that were either beyond 30 miles of available services or excluded because they fell outside the top quartile by AI/AN population count.

### Anticipating Interpersonal Risk Exposure

The third geo-analytic decision framework is a proof of concept for identifying patterns of collocated factors as a potential interagency surveillance framework for informing human trafficking prevention. To demonstrate this approach, we analyzed collocated conditions representing hypothesized contextual conditions associated with interpersonal risk exposure (IRE). We selected Nevada for this exploratory analysis because we determined that it had the highest 2024 statewide per capita rate of reported human trafficking based on national hotline reports, which are supervised by federal agencies, at 7.2 cases per 100,000 people [36,37].

The exploratory analysis included a set of potentially interacting risk factors with weighted distance parameters as a candidate risk index measure. The parameters included straight-line (Euclidean) distances to major transportation routes, rest facility locations, and PIA borders. PIA proximity was included as an exploratory contextual indicator of home-area mortality burden, while transportation proximity represented potential mobility away from familiar social environments.

The framework assumes that vehicles traveling toward a major urban center may stop at rest facilities along the route. Conceptually, a rest facility may therefore serve as a point of confluence for possible victims and perpetrators [38,39]. The analysis is also informed by prior evidence linking mobility with changes in specific risk behaviors among some populations of people who use drugs [40]. Theoretically, transportation features may facilitate rural-to-urban mobility in circumstances in which people might be socially unaccompanied or detached, which the exploratory framework treats as a hypothesized context for possible exposure to interpersonal violence.

Data on rest facilities were accessed through the US Department of Transportation's Bureau of Transportation Statistics, which identifies rest stops that accommodate commercial motor vehicles engaged in interstate transportation [41]. We acquired community locations and transportation routes for LPA and IRE analyses through the US Census 2023 TIGER (Topologically Integrated Geographic Encoding and Referencing)/Line Shapefiles [42].

For purposes of demonstration, we used 25 km (15.5 miles) as an initial distance of interest and weighted the factors according to a theoretical emphasis on proximity to a PIA and proximity to locations where exposure to exogenous risk is theoretically possible. These weights were selected a priori for proof-of-concept demonstration and were not empirically estimated or validated. The resulting score was calculated as follows:

IRE = 5 (PIA within 25 km) + 2 (route within 25 km) + 1.5 (rest facility within 25 km). A community receives the maximum score of 8.5 when it is within 25 km (15.5 miles) of all 3 features.

### Ethical Considerations

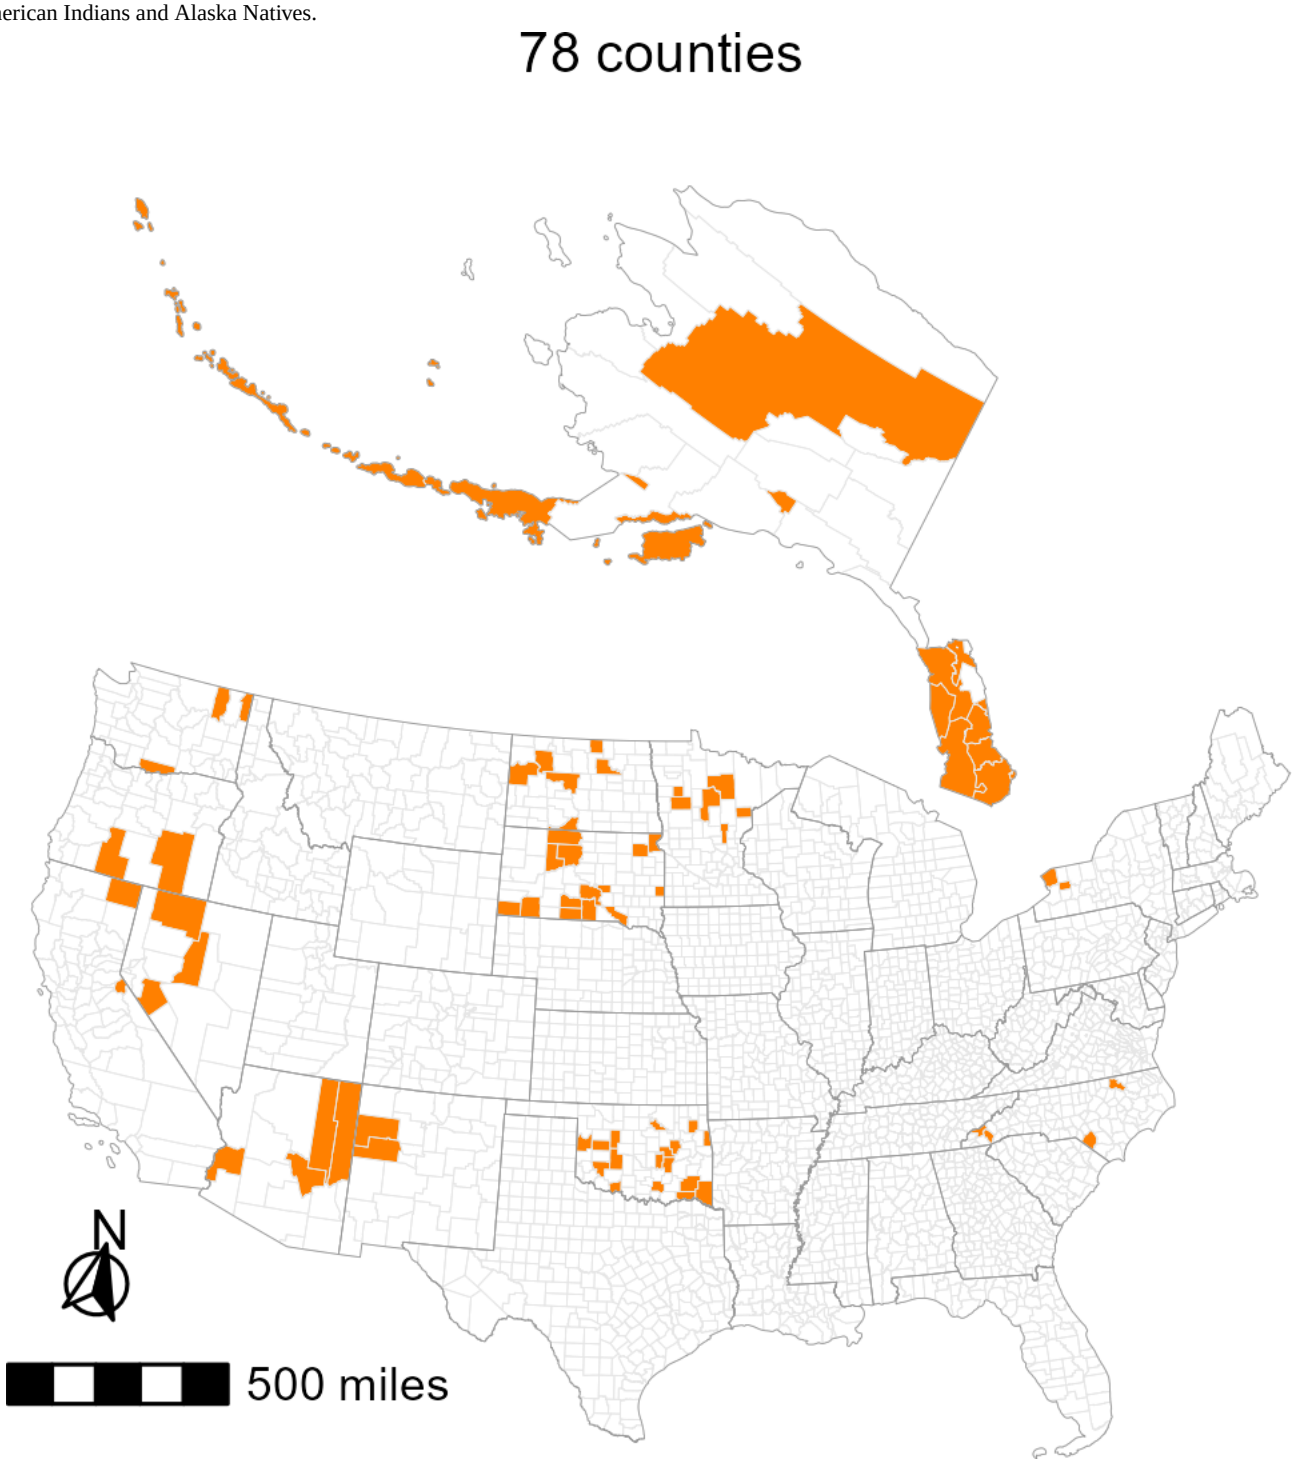
The Albuquerque Area Indian Health Board provided guidance on avoiding stigmatization, focusing on structural issues, and protecting Tribal data sovereignty. The IHS Institutional Review Board determined on July 1, 2026, that review was not required because the study used publicly available, aggregate data and did not constitute human-subjects research, as defined in 45 Code of Federal Regulations (CFR) § 46.102 [43]. The restriction of tribal identifiers was additionally used as an ethical safeguard against stigmatization [44]. Because applicable federal Indian health law requires active and meaningful tribal consultation for actions under the Indian Health Care Improvement Act (25 United States Code [USC] § 1602.5) [14], the decision parameters examined here are hypothetical and would require appropriate tribal consultation before operational adoption.

## Results

### National PIAs

Our analysis identified 20 states that represented at least 1% of the total ADR deaths among AI/AN persons from 2018 to 2023, ranging from 1.2% to 14.6%. We identified a subset of 14 states

XSL•FO
RenderX

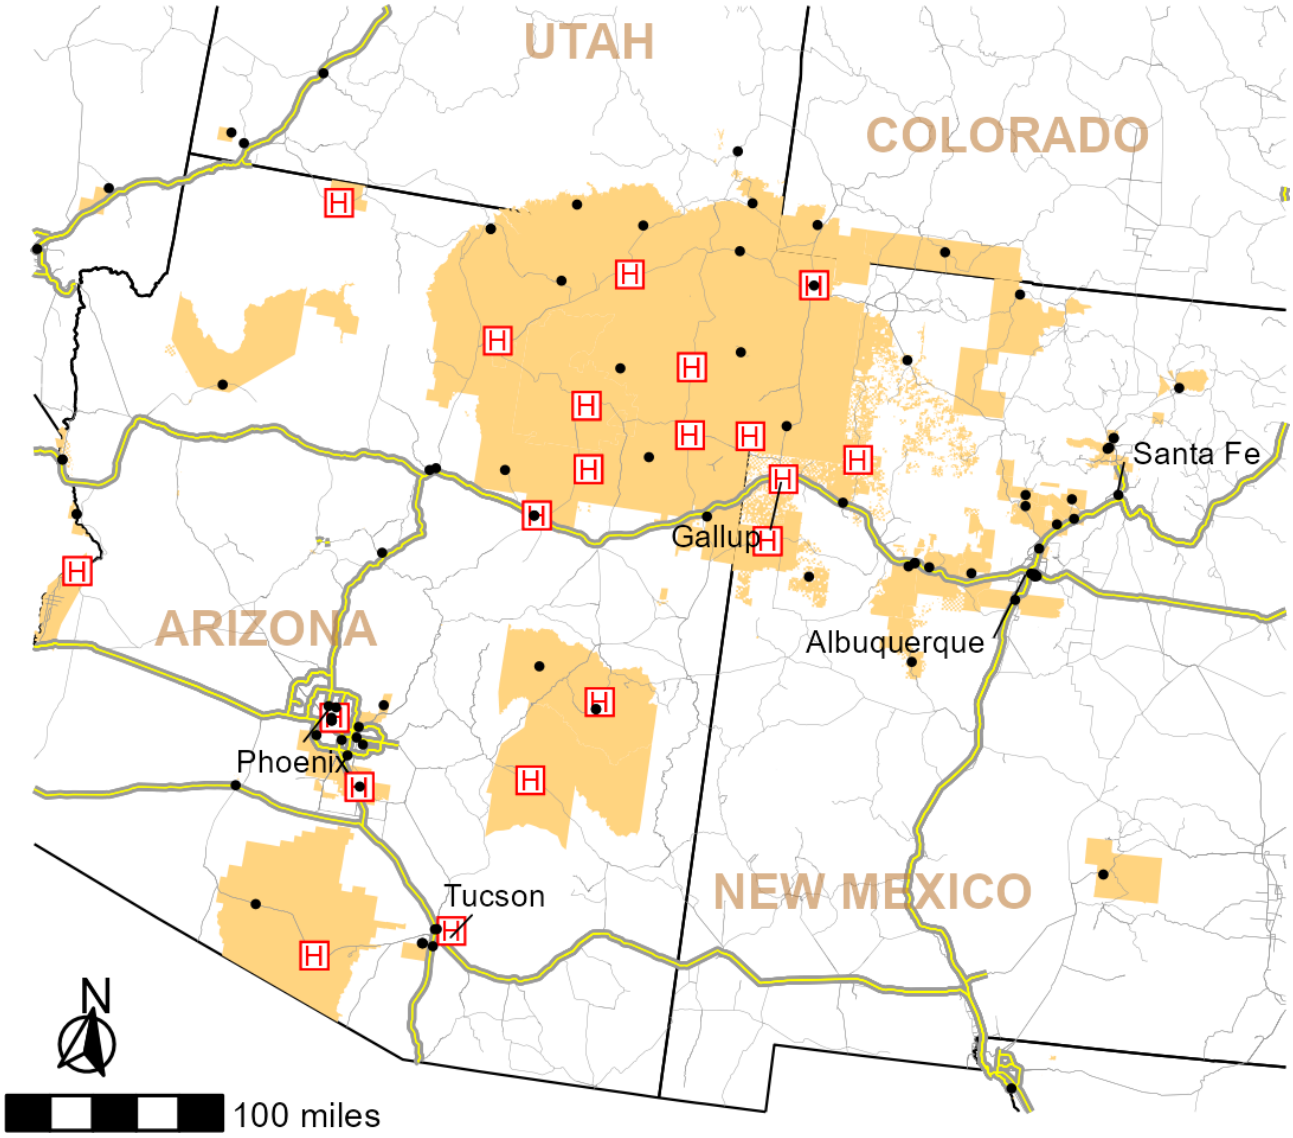


in which the 2023 ADR rate was at least 10% higher than the 2018 rate, as an indicator of increasing death burden. Percentage increases in ADR rates ranged from 11% to 36% for 14 states, representing 107,954 deaths over the 2018 to 2023 period. Within those 14 states, 78 counties met the PIA criterion of having a 6-year pooled crude ADR death rate at least 25% higher than the national non-AI/AN benchmark of 958 deaths per 100,000 persons. Across the 78 PIAs, 6-year pooled crude ADR death rates among AI/AN persons ranged from 1197.8 to 1848.7 per 100,000.

The distribution of the 78 PIAs (counties) was greatest in Oklahoma, with 17, followed by 14 in South Dakota, 13 in Alaska, 6 in Minnesota, and 6 in North Dakota. Arizona and North Carolina had 4 PIAs. Nevada and Washington had 3 PIAs. California, New Mexico, New York, and Oregon had 2 PIAs. One of the 14 states, Colorado, had no counties meeting this level of burden, or PIAs. There were 34,783 ADR deaths among the 78 PIAs, accounting for 32.2% (34,783/107,954) of the total sample of ADR deaths. Six PIAs accounted for 55.8% (19,400/34,783) of all ADR deaths among PIAs. Three Southwest PIAs accounted individually for 11.0% (3841/34,783), 11.9% (4133/34,783), and 12.5% (4339/34,783) of all ADR deaths occurring in the 78 PIAs. The remaining 3 of the 6 highest-burden PIAs were in South Dakota, Alaska, and North Carolina, with ADR deaths among all PIAs of 2.9% (1024/34,783), 6.1% (2106/34,783), and 11.4% (3957/34,783), respectively. Figure 2 identifies all 78 PIAs by states, illustrating apparent geographic concentrations of PIAs that cross state boundaries.

XSL•FO
RenderX

**Figure 2.** National distribution of prioritized investigation areas (PIAs) based on initial analyses of alcohol-related and drug-related death rates among American Indians and Alaska Natives.



## Physical Access to Behavioral Health Services

Concentrating on the example of the American Southwest, Figure 3 illustrates the distribution of ambulatory and emergency behavioral health service facilities and tribal lands. Figure 4 is a raster map of the ambulatory facilities operating during typical business hours. These depict straight-line distances from each facility, at 10-mile intervals, as an approximation of travel distances. Large areas beyond a 30-mile radius, representing LPA areas, are shown in red. Figure 5 identifies the distances to facilities operating during nontypical business hours. In this map, the area shown in red is much larger, indicating a substantially larger LPA area during nontypical business hours for AI/AN persons.

XSL•FO
RenderX

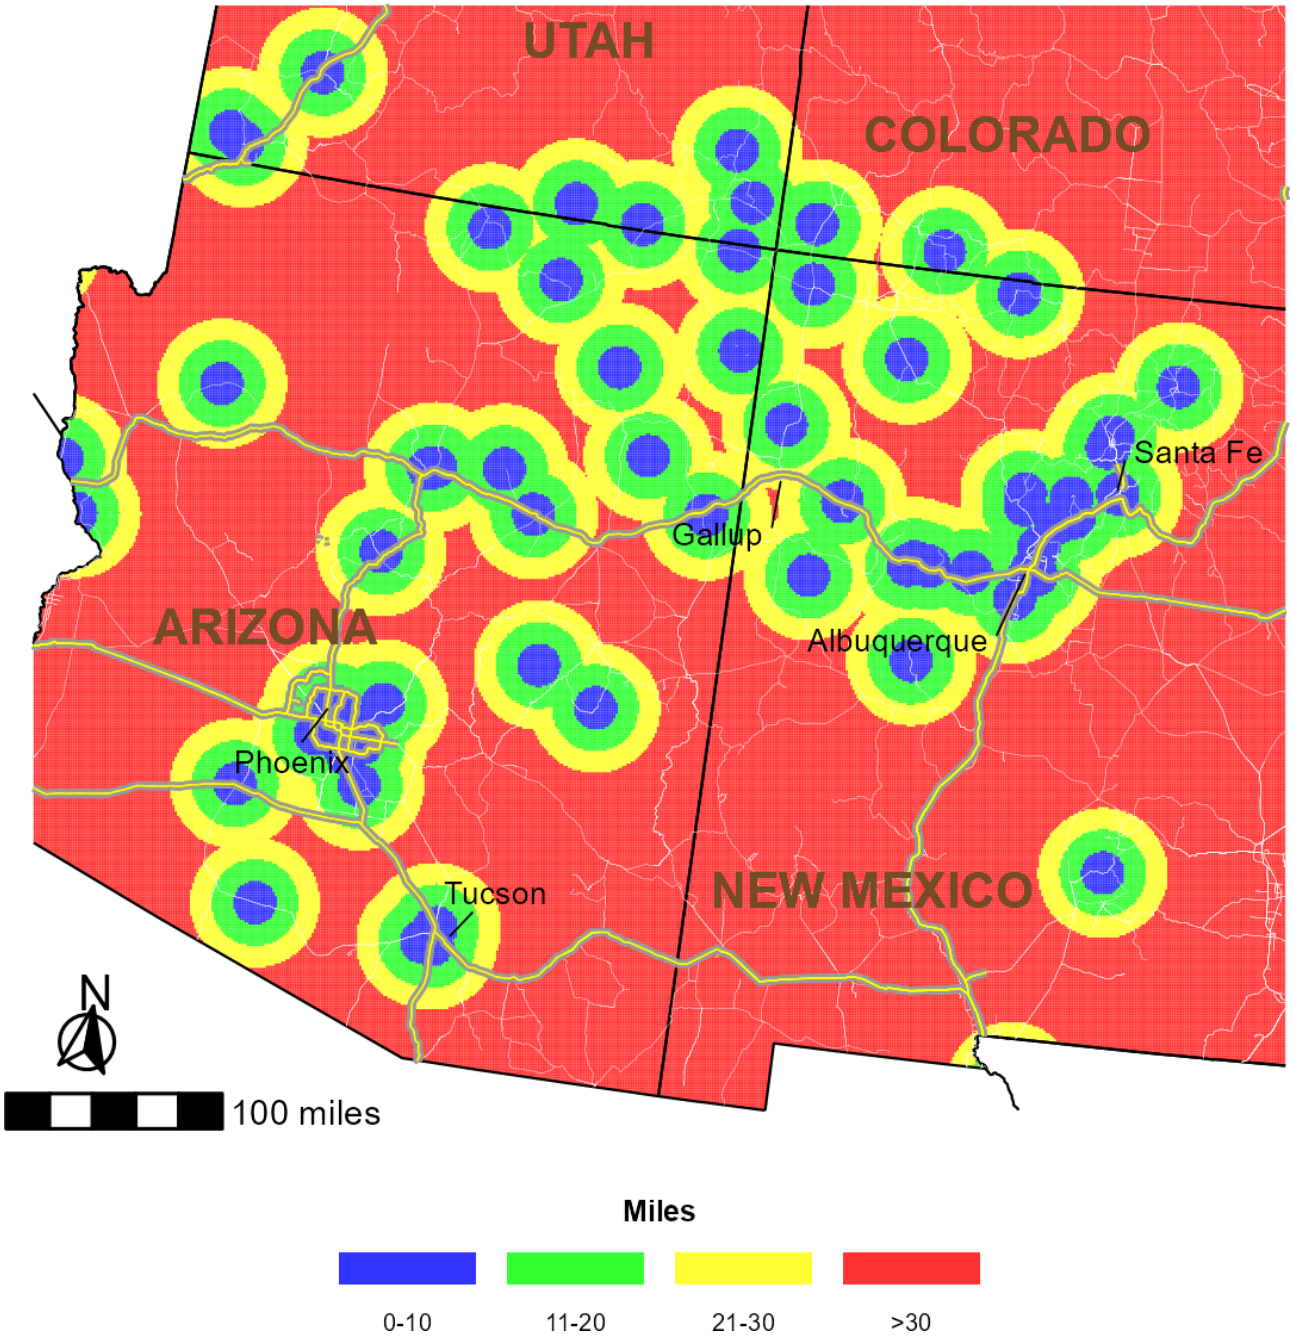


**Figure 3.** American Southwest tribal lands and the distribution of 119 ambulatory and emergency behavioral health service facilities that may be available to American Indians and Alaska Natives.

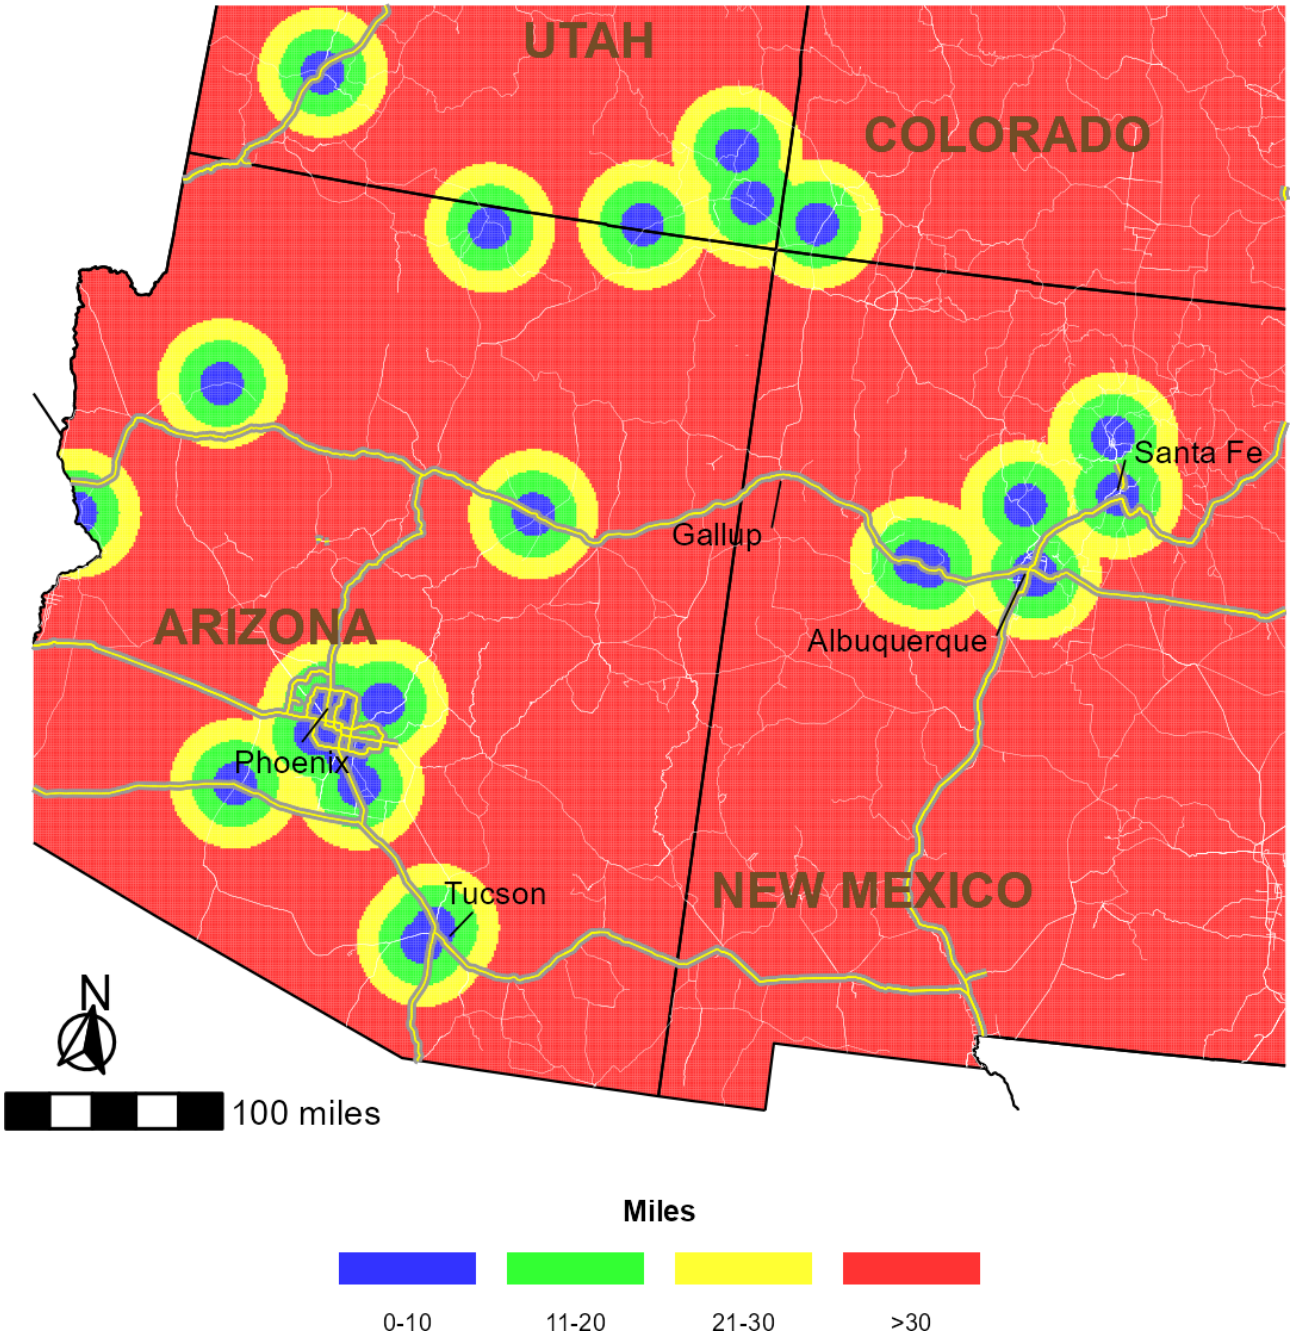
XSL•FO
RenderX

**Figure 4.** Raster map of American Southwest ambulatory facilities that may be available to American Indians and Alaska Natives, operating during typical business hours (Monday through Friday, 8 AM to 5 PM) and interval straight-line distances away from each facility.

XSL•FO
RenderX

**Figure 5.** Raster map of American Southwest ambulatory facilities that may be available to American Indians and Alaska Natives, operating during nontypical business hours (Monday through Friday, 5:01 PM to 7:59 AM, plus Saturday and Sunday) and interval straight-line distances away from each facility.



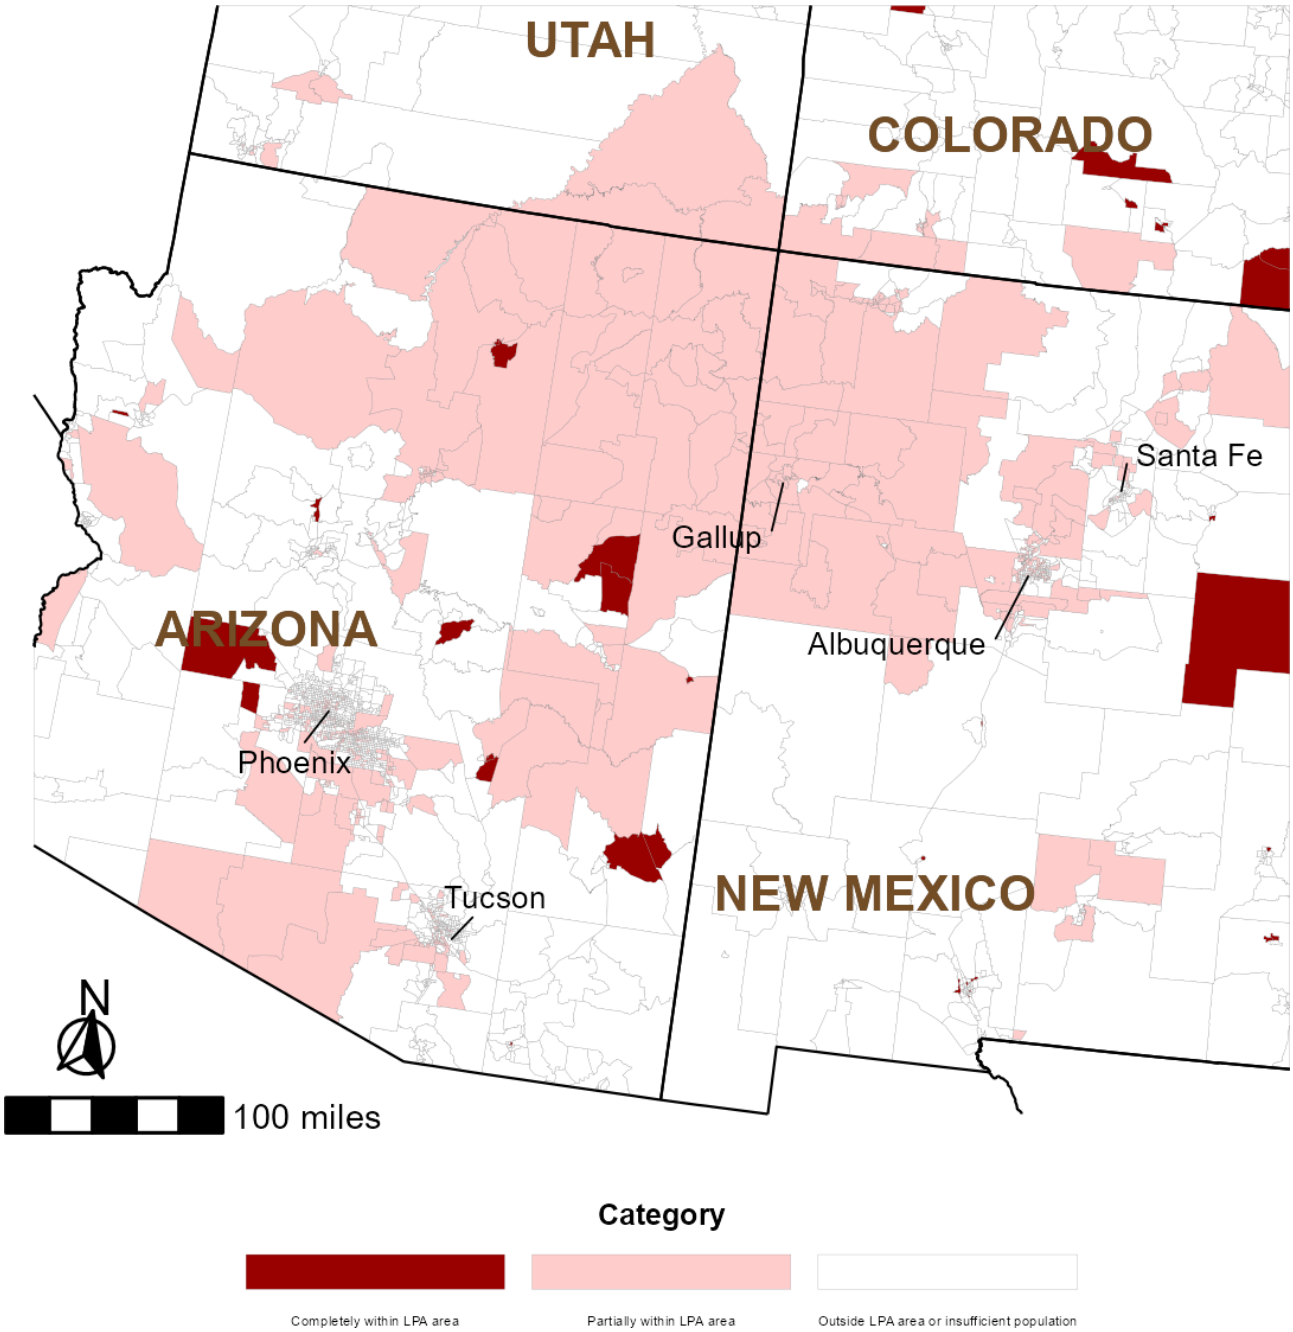


Figure 6 and Figure 7 are maps that illustrate possible LPA areas, relative to distance and facility operating hours. Both maps include a white area that represents tracts that were either beyond 30 miles from available services or were excluded because they fell outside the top quartile by AI/AN population count. This white area includes an estimated 171,311 AI/AN persons, 24.1% of the total regional AI/AN population, which was approximately 710,111 AI/AN persons. The 2 maps illustrate the possible LPA areas for an estimated 538,800 AI/AN persons. Figure 6 illustrates that during typical business hours, an estimated 22,029 (3.1%) AI/AN persons reside in census tracts completely within LPAs, while tracts partially overlapping LPAs contain an estimated 516,771 (72.8%) AI/AN persons. In contrast, Figure 7 illustrates that during nontypical business hours, an estimated 234,852 (33.1%) AI/AN persons reside in census tracts completely within LPAs, while tracts partially overlapping LPAs contain an estimated 303,948 (42.8%) AI/AN persons.

XSL•FO
RenderX

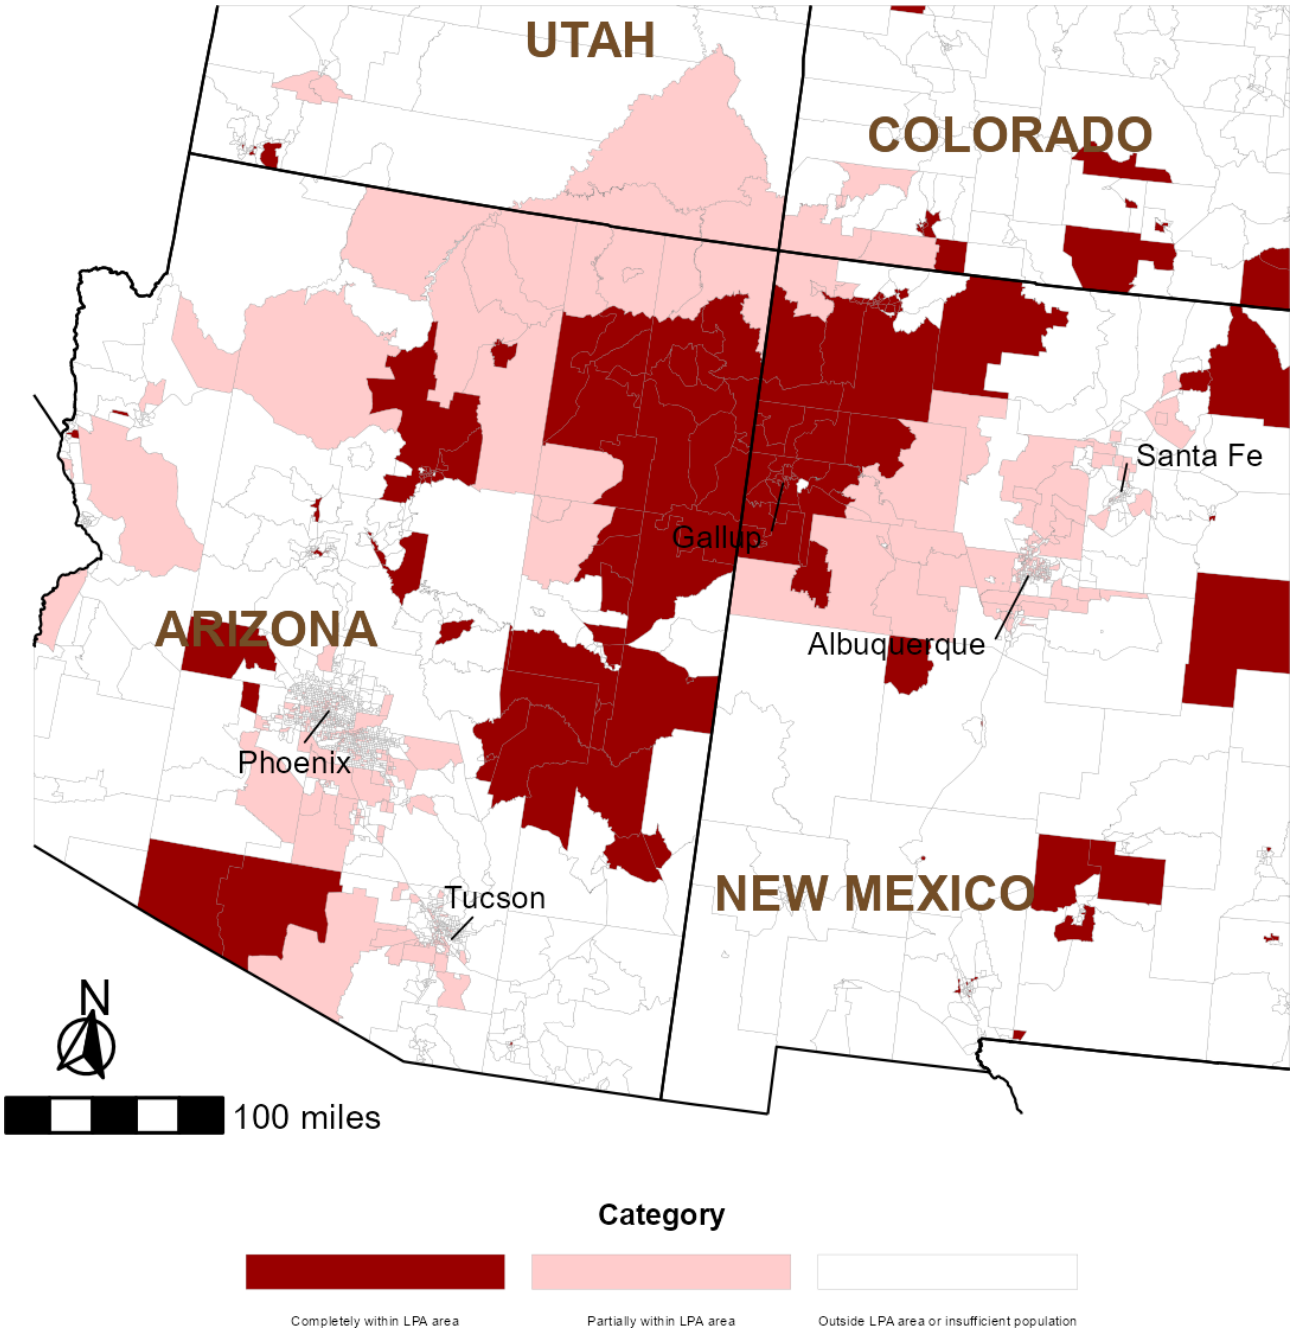

**Figure 6.** Census tracts in the top quartile by American Indian and Alaska Native population count are classified as completely or partially overlapping low physical access areas during typical business hours (Monday through Friday, 8 AM to 5 PM) for facilities that may be available to American Indians and Alaska Natives.

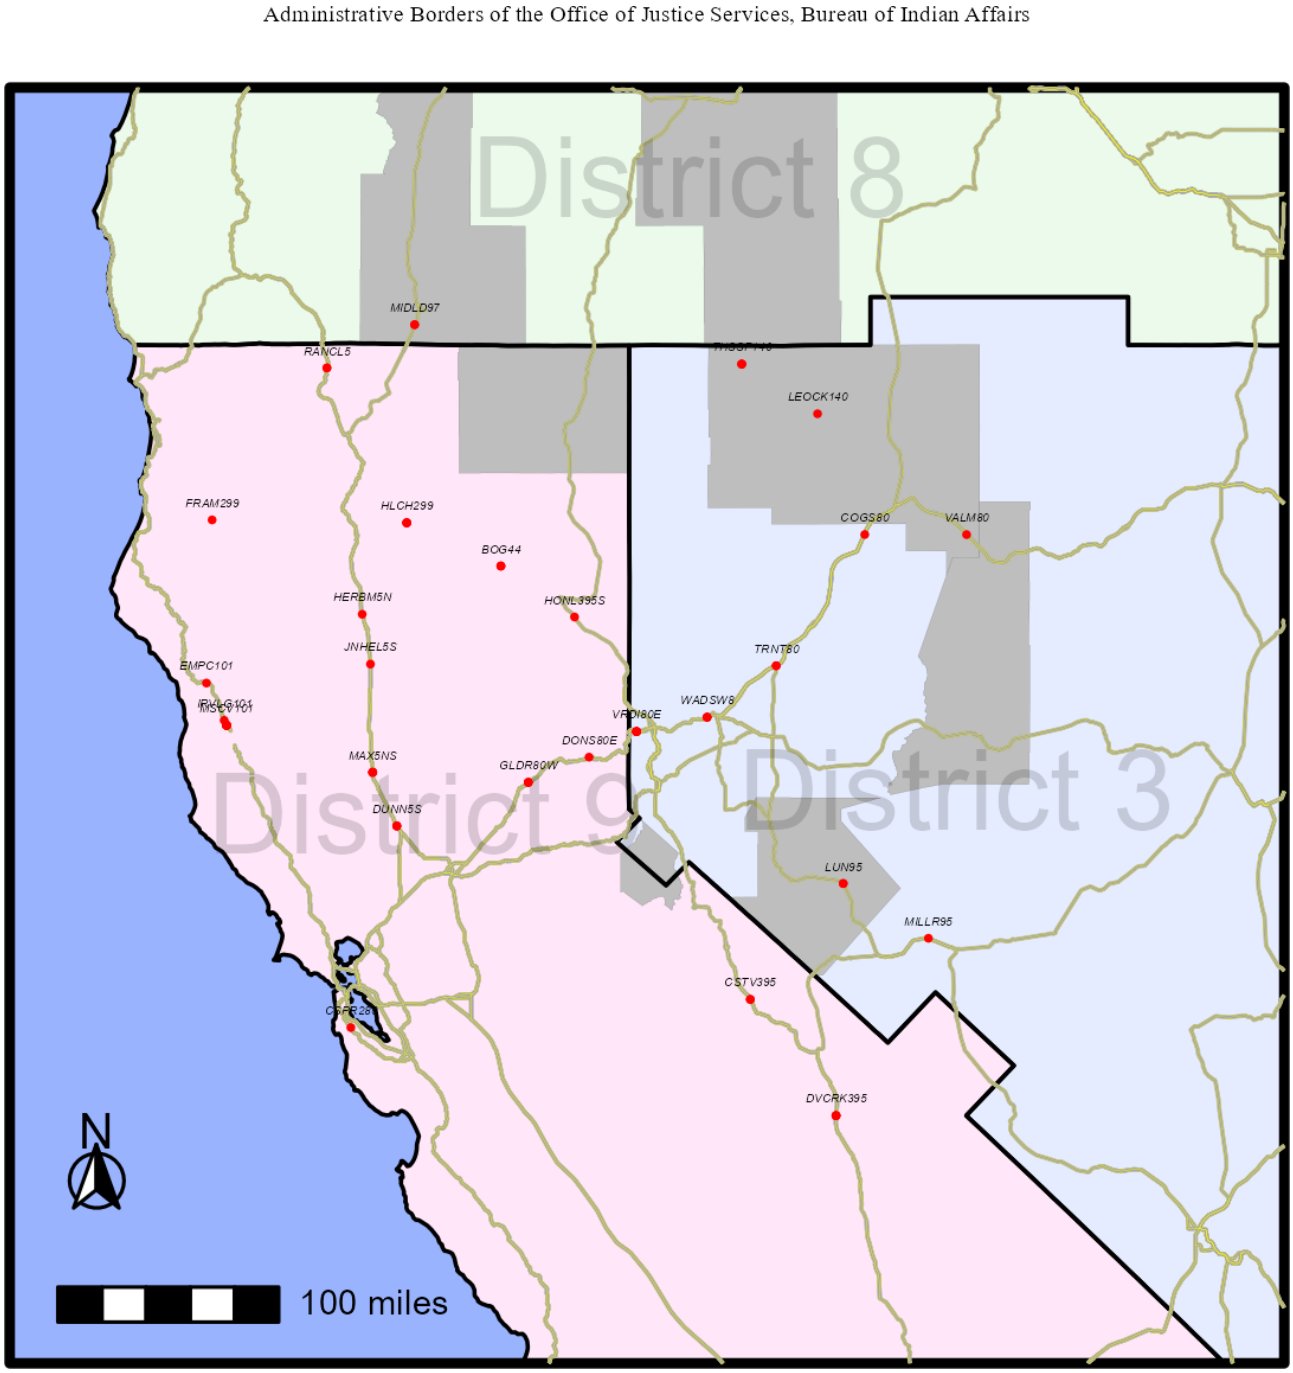
XSL•FO
RenderX

**Figure 7.** Census tracts in the top quartile by American Indian and Alaska Native population count are classified as completely or partially overlapping low physical access areas during nontypical business hours (Monday through Friday, 5:01 PM to 7:59 AM, plus Saturday and Sunday) for facilities that may be available to American Indians and Alaska Natives.



## Anticipating IRE

As a means for visualizing the hypothesized contextual factors potentially relevant to human trafficking risk, Figure 8 illustrates a 300-mile radius of AI/AN communities surrounding Reno, Nevada. The figure shows how Reno is a hub for a north-south transportation corridor intersecting with east-west interstate highways that span rural counties. The analysis produced a candidate IRE index for prioritizing locations for field validation of hypothesized risk conditions. We calculated an IRE score for each of 80 communities. Of these, 56 (70%) received an IRE score of at least 1.5 and 20 (25%) received an IRE score of 5 or higher. The candidate prioritized surveillance sites are 12 rest stop facilities that were located within 25 km (15.5 miles) of the 80 communities. To protect the identities of tribal communities, their IRE scores are not reported publicly. Likewise, the 12 facilities designated as candidate field-validation locations are not distinguished from the 28 facilities shown herein. Figure 8 illustrates the transportation routes and rest stop facilities (n=28; red squares) that are relevant to the production of IRE indexes and the hypothesized convergence of risk conditions among the 80 AI/AN communities in the study territory.

XSL•FO
RenderX

**Figure 8.** Transportation corridors and 28 rest stop facilities included in the exploratory IRE analysis within a 300-mile radius of Reno, Nevada. Twelve locations met the exploratory candidate field-validation criterion; candidate locations are not distinguished publicly to protect Tribal community identities.

## Discussion

### Principal Findings

The study produced 2 principal findings. First, 3 exploratory geo-analytic frameworks identified candidate priorities for federal, tribal, and regional investigation in 3 domains: elevated and increasing alcohol-related or drug-related mortality, geographic gaps in access to behavioral health services, and locations where hypothesized interpersonal risk conditions could be field-validated. Second, the study demonstrated that routinely updated federal datasets and reproducible GIS methods are technically feasible components of a multicriteria federal decision-support framework. Underlying these findings were 3 sets of study observations. Nationally, 78 counties were identified across 13 states as PIAs. These counties had alcohol-related or drug-related death rates among AI/AN persons at least 25% above the specified national non-AI/AN benchmark, with 6-year pooled crude death rates ranging from 1197.8 to 1848.7 per 100,000. Those 78 counties accounted for 34,783 deaths or 32.2% (34,783/107,954) of the deaths in the analytic sample. In a regional analysis, only 3.1% (22,029/710,111) of the AI/AN population was estimated to be entirely within LPA areas during typical business hours, but this increased to 33.1% (234,852/710,111) during nontypical hours. In another regional analysis, the IRE framework identified 12 candidate field-validation locations from 28 rest stop facilities evaluated within a study region containing 80 AI/AN communities. The

XSL•FO
RenderX

factors included transportation corridors, rest stop facilities, and proximity to PIAs.

### Comparison to Prior Work

The PIA analysis provides a repeatable empirical method of organizing and extending the scope of evidence previously developed to support national research on AI/AN behavioral health policy. Etz et al [45] articulated broad principles for the field, emphasizing heterogeneity among Tribal communities, community-oriented approaches to health, and the formation of meaningful partnerships and community benefits. Novins et al [46] operationalized related principles through a national framework that examines geographic samples of tribal communities, service structures, and governance. Luger et al [47] applied similar principles at local and regional scales to develop community-defined research agendas. Collectively, these studies contribute approaches for establishing research priorities, validating local conditions, planning federal initiatives, and developing federal-tribal behavioral health partnerships and plans.

These studies were not designed, however, to provide a routinely updatable analytic mechanism for federal planning across multiple jurisdictions. The PIA analysis is methodologically complementary to this prior work because it provides a reproducible process for identifying geographic areas in which population-level mortality conditions warrant further investigation. In this way, the framework can help organize subsequent cooperative investigations, validation of local conditions, and, where appropriate, negotiations concerning the development of projects or investment priorities.

The PIA framework is also consistent with prior applications of geo-analytics for determining surveillance priorities. Das et al [48] applied spatial analysis to prioritize national sentinel sites for surveillance of ADR medical cases. The PIA methodology applies a related county-level prioritization strategy specifically for AI/AN mortality and demonstrates how sequential policy-relevant thresholds can be incorporated into a broader multicriteria framework. Similarly, the US Environmental Protection Agency used geo-analytics as an initial national decision-support framework for prioritizing local investigations of lead exposure hotspots, where direct surveillance data are limited [49]. Although that analysis focused on identifying hotspots for a specific exposure, the PIA framework demonstrates how multiple morbidity categories can be combined to characterize a broader potential service burden within communities. The PIA approach also illustrates how multiple policy-relevant criteria can be incorporated into the prioritization process, including parameters relevant to federal, state, and local decision-making.

Other investigators have developed multicriteria geographic approaches to health surveillance using vulnerability indices. Daza-Torres et al [50] developed criteria for prioritizing the geographic allocation of wastewater monitoring sites in California. Riggins et al [51] used social vulnerability measures to identify areas in Illinois with elevated priority for preventing sudden unexpected infant deaths. These studies demonstrate the value of reproducible multicriteria geo-analytics for informing recurring government decision-making. Our work extends this general approach by examining multiple analytic domains through geo-analytic frameworks (Figure 1).

The frameworks are designed to permit future geographic integration when federal decisions require intergovernmental or interagency coordination across domains. For example, we identify places where potential service-seeking populations are in LPA areas and areas with conditions for potential IRE. Each of these analyses can function as a unique framework for the respective health domain and can also be integrated with PIA analyses when decisions involve multiple behavioral health risks, service burdens, or resource requirements.

Federal multicriteria geo-analytics may need to combine epidemiological evidence with statutory, administrative, operational, and policy considerations. This is important because the units of federal program decisions are often organizations, jurisdictions, or projects rather than individual patients. Zhan et al [52], for example, used multicriteria geo-analytics in support of prioritizing investments in federally qualified health centers serving populations at high risk for colorectal cancer. Their criteria included policy and program thresholds alongside population-based data. Our LPA analysis follows a similar decision-support logic by combining characteristics of available services, travel distances, and hours of operation, with the geographic distribution of the population of concern, namely AI/AN persons.

Prior research on behavioral health services in AI/AN communities has documented access barriers related to nontypical operating hours, work and family obligations, and transportation arrangements [53]. Our LPA findings are also consistent with research showing that health service access reflects both spatial and nonspatial factors [54]. Operating hours interact with other dynamic dimensions of service accessibility, including staffing, travel conditions, appointment availability, the availability of traditional healing practices, and telehealth and other digital technologies for as-needed access [55-59]. The LPA analysis extends prior federal efforts to characterize LPA to behavioral health services [60] by explicitly incorporating temporal availability into the geographic assessment. The finding that estimated LPA changes substantially between typical and nontypical operating hours illustrates why facility location alone may provide an incomplete representation of service accessibility.

The IRE framework builds on prior geographic and analytic work concerning interpersonal risk, especially in human trafficking [61]. Its underlying spatial logic is consistent with studies examining relationships between proximity, mobility, crime, and victimization. Consistent with prior crime-geography research, the IRE framework incorporates spatial mobility as a hypothesized contextual factor [62]. In contrast to studies that primarily document the prevalence or consequences of victimization among AI/AN persons [63-67], the IRE framework provides a method of identifying locations where hypothesized risk conditions could be investigated and, if validated, where targeted surveillance planning might be considered. The IRE approach is also consistent with recommendations for interagency coordination of risk information involving transportation, public safety, and tribal jurisdictions [68]. If

XSL•FO
RenderX

validated through field research, the framework could support federally funded studies and federal-tribal partnerships aimed at preventing human trafficking, consistent with concerns and priorities previously raised by tribal researchers and leaders [69,70].

## Limitations

Several limitations are common to all 3 frameworks. The parameter thresholds and weights used in these exploratory analyses have not been validated, the analyses rely primarily on secondary public datasets, and the resulting measures support area-level rather than individual-level inference. The analyses do not incorporate potentially important covariates, such as workforce availability and service capacity, that may influence future algorithmic designs [71].

Accordingly, the PIAs, LPAs, and IRE locations should be interpreted as priorities for further investigation rather than as validated determinations of community-level or individual-level risk. All 3 frameworks will require sensitivity testing and validation with tribal and local partners before operational use.

In addition, the PIA analysis identifies worsening ADR mortality from 2018 to 2023, a period that overlaps substantially with the COVID-19 pandemic. Pandemic-related changes in mortality, service availability, social conditions, and use of health services may therefore have influenced the observed geographic patterns. Future analyses could incorporate additional indicators, such as the prevalence of active substance use disorders and geographically associated criminal or behavioral events, to better characterize local risk conditions. However, the use of such data would raise individual privacy, tribal data sovereignty, and governance considerations requiring specialized protection and appropriate tribal consultation. The PIA analysis is also limited by its reliance on mortality data. County-level estimates may be unstable when AI/AN population denominators or death counts are small, and misclassification of AI/AN race on death certificates may bias mortality estimates. In addition, the state-level decision thresholds may exclude small-population jurisdictions that nevertheless experience high mortality rates.

The LPA analysis is limited by its use of straight-line distance as an approximation of physical access. This measure does not account for road networks, terrain, seasonal conditions, or other geographic factors that can affect travel time. The analysis also does not incorporate several operational characteristics of facilities, including workforce availability, appointment capacity, or variation in service levels. Incorporating road-specific travel times and locally validated operational data could improve the precision and geographic applicability of future LPA analyses. Facility-specific eligibility may affect access to services, despite their locations being in proximity to AI/AN persons. For tracts partially overlapping with LPAs, population counts describe the tract population and should not be interpreted as the number of individuals residing specifically within the low-access portion of the tract.

The IRE analysis is the most exploratory of the 3 frameworks. Although it may be sufficiently developed to inform initial interagency and tribal field-validation studies, it is not yet appropriate for scalable policy, predictive, or operational use. Its parameters and weights are theoretical and require empirical validation. Future analyses will also require localized data to characterize interpersonal risk conditions, mobility patterns, and the prevalence and distribution of injurious events. The state-level Hotline data used to select the demonstration region represent reported and identified cases rather than population-based estimates of trafficking incidence; geographic differences in reporting or identification may therefore affect comparisons among states.

## Conclusions

The 3 geo-analytic frameworks demonstrate complementary methods for identifying geographic priorities for the investigation of behavioral health risks and service conditions among AI/AN populations within overlapping tribal and rural health service environments. The PIA analysis provides a repeatable method for identifying areas where observed mortality patterns warrant further investigation and local validation. Its national application also illustrates opportunities for cooperative investigations across jurisdictions, including refinement of measures in which small population denominators may affect estimates.

The LPA analyses demonstrate how geographic access measures can incorporate both the location and temporal availability of services. In the American Southwest, the estimated proportion of the AI/AN population residing completely within LPA areas increased from 3.1% (22,029/710,111) during typical operating hours to 33.1% (234,852/710,111) during nontypical hours. This difference suggests that measures based solely on facility location may substantially understate physical access constraints when operating hours are not considered. LPA analyses can therefore help identify potential service gaps that warrant further investigation and may inform subsequent service planning and negotiations.

The IRE framework provides a third, more exploratory application by identifying locations where hypothesized interpersonal risk conditions may warrant field investigation. Rather than predicting interpersonal violence or trafficking events, the framework demonstrates how multiple geographically coincident conditions can be organized to prioritize locations for validation and potential surveillance through interagency and federal-Tribal cooperation.

Taken together, the PIA, LPA, and IRE analyses demonstrate the methodological feasibility of a reproducible, multicriteria geo-analytic approach to federal decision support. Each framework addresses a distinct domain, and the analyses are designed to permit future geographic integration when decisions involve multiple behavioral health risks, service-access constraints, jurisdictional interests, or resource considerations. Because the methods use routinely updated federal datasets or datasets supervised by federal agencies and repeatable GIS procedures, they can provide a basis for iterative analyses in which policy-relevant parameters can be modified, tested, and reviewed as conditions change.

Such reproducible methods may be particularly useful for federal decisions that require coordination among agencies [72], Tribal governments, state and local health systems, and other partners.

XSL•FO
RenderX

Federal policy already emphasizes improved data governance, program evaluation, and interoperability of geographic information [73,74]. A common geo-analytic framework could contribute to these objectives by providing a transparent evidentiary basis for identifying priorities, comparing conditions across geographic scales, organizing cooperative investigations, and forming geo-analytic communities of practice [75]. Longer-term development could incorporate more dynamic data and GeoAI capabilities to support increasingly complex and repeatable place-based analyses through shared services [76,77].

Standardization of analytic methods, however, should not imply uniform selection of parameters across tribal communities. Field validation, sensitivity testing, tribal consultation, and, where appropriate, tribal approval or codevelopment are necessary before these frameworks are used for operational decisions. Federal decision-support methods should therefore provide a common analytic structure while allowing parameters and interpretations to reflect locally relevant conditions, governance requirements, and tribal priorities.

This study demonstrates the feasibility of using routinely available federal data and reproducible GIS methods to identify geographic priorities for investigating behavioral health risk, service accessibility, and hypothesized interpersonal risk conditions among AI/AN populations. With appropriate validation and tribal and local engagement, these exploratory frameworks could contribute to a common evidentiary foundation for federal-tribal research, interagency planning, and multicriteria decision support across complex jurisdictional settings and federal service domains [77].

## Acknowledgments

The authors thank Ayn Whyte (Albuquerque Area Indian Health Board [AAIHB] Executive Director) for her guidance on ethics, Rachael Tracy for technical support during institutional review board consideration, Ramsey Hawasly for federal policy guidance, and Carlynne Worsham for assistance with accessing Indian Health Service facility data. We also appreciate the feedback provided by the members of the AAIHB, whose comments strengthened the manuscript. The findings and conclusions in this article are those of the authors and do not necessarily represent the official position of the US Department of Health and Human Services (HHS) or any of its agencies or those of the Albuquerque Area Southwest Tribal Epidemiology Center (AASTEC) or AAIHB. The authors used ChatGPT (OpenAI; GPT-5.5/GPT-5.6) under human supervision to assist with literature searching, reference formatting, proofreading, and language revision. All analyses, interpretations, methodological decisions, source verification, and final manuscript content were reviewed and approved by the authors.

## Funding

The authors received no financial support for this work.

## Data Availability

Source data were obtained from publicly available national and federal datasets, including Centers for Disease Control and Prevention (CDC) WONDER (Wide-Ranging Online Data for Epidemiological Research), the US Census Bureau, the Indian Health Service (IHS), the US Department of Transportation, and the National Human Trafficking Hotline. Facility operating-hour information was additionally verified by the authors and included into IHS dataset updates. Derived analytic data are not available due to tribal data sovereignty policies.

## Abstract

**Background:** Social determinants of health continue to drive persistent disparities in perioperative care. Our team has previously demonstrated racial and socioeconomic disparities in perioperative processes, notably in the administration of antiemetic prophylaxis, in several large perioperative registries. Given how neighborhoods are socially segregated in the United States, we examined geospatial clustering of perioperative antiemetic disparities.

**Objective:** The study aimed to determine whether disparities in perioperative antiemetic prophylaxis exhibit geographic clustering based on neighborhood-level disadvantage and whether patients from disadvantaged communities are more likely to be undertreated after adjusting for individual postoperative nausea and vomiting risk.

**Methods:** We conducted a retrospective cohort study of anesthetic records from the University of Utah Hospital involving 19,477 patients who met the inclusion criteria. We geocoded patient home addresses and combined them with the census block group–level neighborhood disadvantage, a composite index from the National Neighborhood Data Archive. We stratified our patients by antiemetic risk score and calculated the number of antiemetic interventions. We used Poisson spatial scan statistics, implemented in SaTScan (Information Management Services, Inc), to detect geographic clusters of undertreatment.

**Results:** We identified 1 significant cluster ($P$<.001) of undertreated perioperative antiemetic prophylaxis cases. The relative risk of the whole cluster was 1.44, implying that patients within the cluster were 1.44 times more likely to receive fewer antiemetics after controlling for antiemetic risk. Patients from more disadvantaged neighborhoods were more likely to receive below-median antiemetic prophylaxis after controlling for risk.

**Conclusions:** To our knowledge, this is the first geospatial cluster analysis of perioperative process disparities; we leveraged innovative geostatistical methods and identified a spatially defined, geographic cluster of patients whose home address census-tract level neighborhood deprivation index predicted disparities in risk-adjusted antiemetic prophylaxis.

## Introduction

### Background

Social determinants of health (SDOH) continue to drive disconcerting health care disparities [1-4]. SDOH are defined as "the societal circumstances in which we are born and grow up, learn and mature, and work and age," and also includes race, ethnicity, education, wealth, insurance coverage, and health literacy; they impact equitable perioperative processes and outcomes as fundamental causes of disease [1,3-5]. Disparities can concern access to care, care processes, and health care outcomes. We focus on care processes, as the means to intervene [2,3,6]. To precisely target the underlying causes and to create, test, and implement specific countermeasures, we need to define the exact granular mechanisms leading to disparities in processes [4,5,7-10].

### Health Care Disparities in Anesthesiology and Perioperative Medicine

Disparities in care processes lead to subpar health outcomes in minoritized, marginalized, and migrant populations; differences in care processes based on race and ethnicity or socioeconomic status rather than patient risk factors and comorbidities have been a longstanding and troubling aspect of care delivery in the United States [1,3]. In outpatient settings, racial and ethnic disparities impact care for diabetes, asthma, and heart disease [11,12], as well as veterans' care. For inpatients, race-based process-of-care surgical disparities [13] have been described, especially within neonatal and obstetric care [7,13-15]. Macario et al [16] and our team previously demonstrated process variability in anesthesiology, possibly tied to unconscious bias and negative stereotypes [2,5], as well as disparities in access to chronic pain treatment [10]. We previously demonstrated that individual clinicians provide fewer antiemetics to people who identify as Black, to those with lower health insurance, and to patients living in zip codes with lower median income [2,5]. One hypothesis is that this arises from the clinicians' prejudice towards their patients [17]: clinicians (sub)consciously detect the social status of their patients in their interaction, and therefore become less likely to diligently elicit for, document, and treat risk factors of postoperative nausea and vomiting (PONV) [2,5]. We discussed possible concrete drivers leading to PONV disparities elsewhere [4]. Given how neighborhoods are socially segregated in the United States, the patient's home address can provide a proxy for socioeconomic status and race [5,9]. This motivates our more granular geospatial analysis of perioperative process disparities in anesthesia care, [9]: Our primary question is whether we can identify clusters of neighborhoods with elevated social deprivation scores whose inhabitants receive less antiemetic prophylaxis after controlling for PONV risk [2,18].

### Geospatial Analysis to Investigate Health Care Disparities

The use of geospatial analysis to understand social and environmental influences on perioperative outcomes is a promising emerging science, with studies suggesting zip code may predict health outcomes better than a patient's DNA [2,10]. Figure 1 illustrates the various data that can be leveraged for geospatial analysis (eg, spatial accessibility, air quality, and neighborhood deprivation). We discussed the promise and pitfalls of geospatial analysis for health systems and disparity research and the pertinent concepts previously [9]. While more mainstream in public health, very few studies have applied these innovative techniques to perioperative disparities research, especially in conjunction with large-scale perioperative registry data, such as the Multicenter Perioperative Outcomes Group (MPOG), a leading US perioperative electronic health record registry [18,19]. The integration with census-tract and block group level social determinants of health derived from publicly available databases (eg, the National Neighborhood Data Archive) further augments the power of granular electronic health registries [9]. Not only is geographically informed health care disparity research ideally suited to studying the impact of patients' SDOH on their perioperative trajectory, but the information can also be leveraged to provide individual clinicians, teams, and institutions with actionable insights on how to improve care processes [4,7,9]. While northern Utah and the Salt Lake region have a reputation for homogeneity, the National Equity Atlas ranks Salt Lake County at 208 out of 430 US counties ranked, with a diversity index of 0.95 (diversity index is a measure of racial or ethnic diversity, with a maximum score of 1.95 if all ethnic groups are equally represented), while the United States as a whole ranges from 0.22 to 1.58, making our study population comparable to a broad swath of midsize US counties [20].

Our innovation was to apply a novel geostatistical method (Poisson spatial scan statistic) [21] to identify neighborhood-level clusters of systematic under-treatment after adjusting for PONV risk. As this methodology represents an alternative statistical approach to classical statistics, we provided Table S1 in Multimedia Appendix 1 to aid readers in interpretation of our results. We chose to use geospatial clustering, widely used in disease and crime surveillance [22,23], to explore its use of this technique in the service of health care equity. We hypothesized that patients living in neighborhoods with higher levels of social disadvantage are more likely to receive fewer perioperative antiemetics after adjusting for antiemetic risk factors, and that such neighborhoods would be found to cluster geographically [2,18,24].

## Methods

### Overview

We performed a retrospective cohort analysis of the University of Utah local MPOG electronic health registry (supplemented with University of Utah Health Epic database), enriched with geocoded SDOH for the year 2021 [25]. We adhered to the Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) statement and principles (Checklist 1) [26]. All authors approved the statistical analysis plan before analyses began. We describe patient demographic characteristics, PONV risk, and perioperative antiemetic prophylaxis in Table 1.

Table 1 details characteristics of our population before and after applying exclusion criteria and filtering of data to the Wasatch Front for the purpose of our geographic analysis. Characteristics of the final study set with home addresses in the target area are listed in the final cohort data. It should be noted that the "unknown" category is unable to be disaggregated due to limitations in the underlying dataset.

Most patients in the final cohort had a median age of 48 (IQR 63-34) years and received a general anesthetic of more than 1-hour duration, including the administration of opioid medication. Their risk classification according to the American Society of Anesthesiologists (ASA) was mostly 1-3. Only 10% reported a history of PONV, and most were nonsmokers. For a median of 4 PONV risk factors, they received on average about 2 prophylactic antiemetic interventions.

The focus on the Wasatch Front area shrunk the total number of patients from 51,809 to 19,477 in the final cohort analyzed and increased the relative proportion of non-White patients (typically clustered in urban areas in Utah); the prevalence of risk factors and the number of interventions also changed. Percentages have been rounded to the nearest 10th place with some factors being described by the mean, SD, median, and IQR of the data represented.

## Ethical Considerations

This study was considered exempt on February 9, 2023, by the institutional review board at the University of Utah (reference: 00142167). All patients at the University of Utah agreed to secondary data use as part of their consent to care, and therefore, no additional informed consent was required for this retrospective study. All data were stored on secure servers at the University of Utah consistent with university policy, and no data were transmitted outside the University firewall for geocoding, as this was done using locally installed geocoding servers. No patients were compensated for this study and no identifiable data were included in this paper.

## Geocoding SDOH

Patient home addresses were obtained from Epic and then geocoded to latitude and longitude with ArcGIS (ESRI, Inc) [9,27] and spatially matched to census block group (CBG), the boundaries of which were obtained from US Census TIGER/Line (Topologically Integrated Geographic Encoding and Referencing System) 2020 CBG boundaries layer. Any incomplete address information was excluded. We extracted neighborhood disadvantage (ND), a composite index of neighborhood deprivation, from the National Neighborhood Data Archive, a publicly available database, and used this as our independent variable [28]. ND is an average of 5 US Census indicators, including proportion of the following: non-Hispanic Black, female-headed families, households with public assistance or on food stamps, income below the federal poverty level, and unemployment, all derived from the US Census American Community Survey 5-year estimates from 2016 to 2020. ND is an average of these proportions; therefore, as this value increases, the relative disadvantage or social stress increases.

## Inclusion and Exclusion Criteria

Following the MPOG Anesthesiology Performance Improvement and Reporting Exchange (ASPIRE) quality metric PONV05 Inclusion Criteria [29], and using information obtained from the Utah local Epic and MPOG instances, we excluded cases with ASA Physical Status Classification of 5 or 6, aged <18 years, ICU transfers, and cases performed without general anesthesia (including obstetrics, ECT electroconvulsive therapy, and bronchoscopy procedures). We limited our study area further to the Wasatch Front, a densely populated metropolitan area served by the University of Utah hospital in Salt Lake City, Utah, as this better enables geospatial clustering analysis and is more generalizable to urban areas in the United States.

## Risk-Adjusted Antiemetic Prophylaxis

The novel geostatistical method (Poisson spatial scan statistic) required a characterization of patients as receiving relatively more (+1), similar (0), or fewer (−1) antiemetic interventions compared to their peers with similar PONV risk factors, leading us to define a 3-level ordinal variable of risk-adjusted antiemetic prophylaxis (RAAP), similar to the MPOG PONV-05 quality metric; RAAP is discussed in the later sections.

### *Antiemetic Interventions*

The response variable was the administration of appropriate numbers of antiemetic prophylactic interventions. We counted up to 6 antiemetic interventions (0 - 1, 2, 3, 4, 5, and 6+) [4,24]. These interventions included the number of and class of antiemetic prophylaxis (1 point per each), and the use of total intravenous anesthesia, as the presence of a propofol infusion, as defined in PONV05, a performance metric developed by MPOG [25].

### *PONV Risk*

Risk factors for PONV likely mediate RAAP; as they could be unevenly distributed among different racially, ethnically, and geographically defined groups; PONV risk factors could confound the analysis of equitable antiemetic administration [2,4,30]. All PONV risk factors were extracted from our local MPOG instance. We categorized the PONV risk score into 6 ordinal levels (0 - 1, 2, 3, 4, 5, and 6+), following the PONV05 standard of MPOG [29]. These PONV risks are defined by PONV05 and follow widely accepted guidelines including female sex (assigned at birth), history of PONV or motion sickness, nonsmoker, opioid use (either intraoperative or postoperative), duration of inhalational anesthesia greater than 1 hour, aged <50 years, and certain select procedures known to cause PONV.

### *Characterizing RAAP*

First, we stratified our patients by antiemetic risk [4,24]. Within each stratum of risk, we calculated the median number of antiemetic interventions. We defined RAAP to describe above median, median, and below median RAAP. Finally, we assigned the 3 levels (below median, median, and above median) RAAP contingent on the number of prophylactic antiemetic interventions received: a high RAAP for an above median number, a median RAAP for cases with an intermediate number, and a low RAAP for cases with a below median number of antiemetic prophylactic interventions compared to other cases in the same PONV risk stratum. With RAAP, we sought to *contrast* different levels of antiemetic prophylaxis *despite* similar PONV risk, ie, process disparity driven by neighborhood-level social determinants of health [4]. Hence, RAAP serves to characterize the relative intensity of antiemetic prophylaxis after controlling for risk (not as a measure of guideline adherence) [4]. This was due to guideline variability and the use of adherence to guidelines could obscure underlying disparity within our practice, which includes physicians who trained outside of the United States, which runs counter to the purpose of the investigation.

## Cluster Analysis

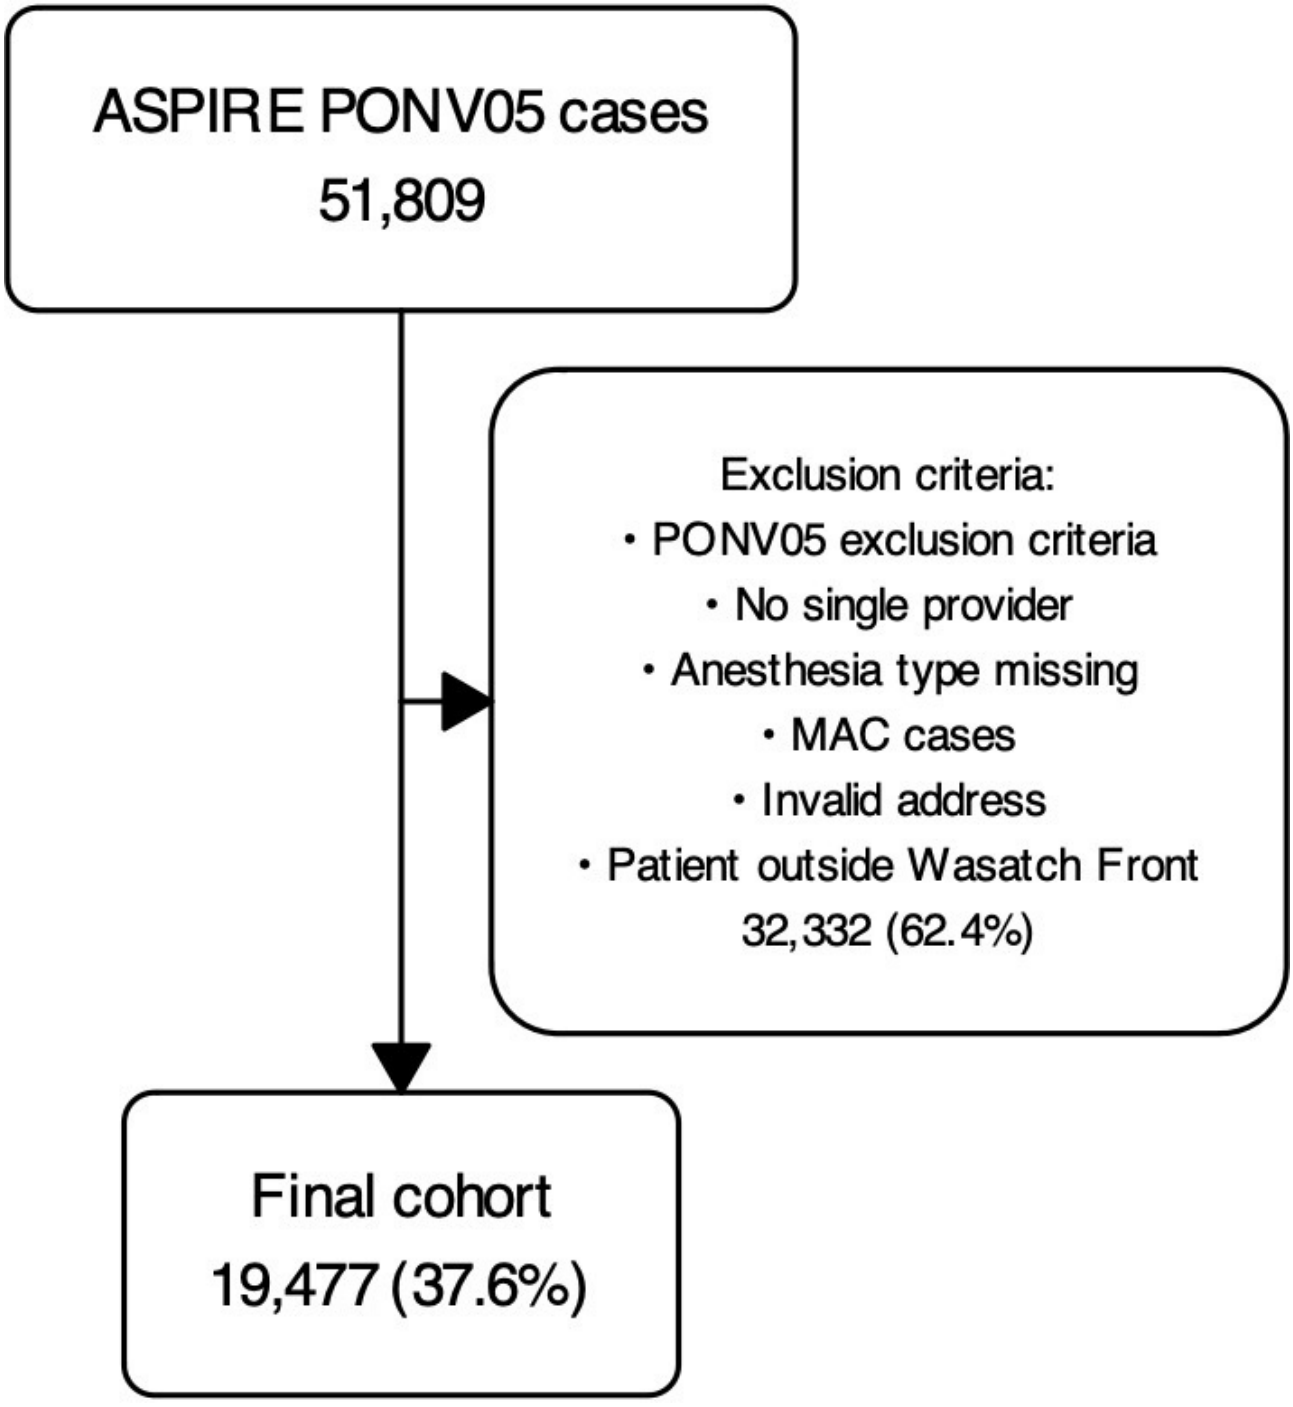
We used the Poisson spatial scan statistic [21,31] implemented in SaTScan (Information Management Services, Inc) [32] to detect the clusters of undertreated perioperative antiemetic prophylaxis cases in the Wasatch Front. In this study, we focused specifically on detecting clusters of low RAAP incidence, as identifying areas with undertreatment is of particular relevance for targeting systemic interventions to improve perioperative care. A cluster contains a set of neighboring regions which collectively have higher incidence

XSL•FO
RenderX

(of low RAAP) rates than expected if the low RAAP cases were evenly distributed across the study area. The Poisson spatial scan statistic uses a likelihood ratio test combined with Monte Carlo simulations to determine whether any detected clusters represent a significantly higher or lower incidence than would be expected by chance. Thus, we identify clusters only when there is statistically significant evidence of an unusually high or low rate of under-treatment relative to the expected distribution under the null model.

We used univariate and multivariate logistic regressions to investigate the characteristics of the CBG in the identified low RAAP cluster. The outcome was a binary variable indicating whether the CBG belongs to the high-rate low RAAP or not. We tested previously described or suspected social determinants of health as predictors of disparities: [2,5] percentage of non-White population, percentage of population with education less than high school, percentage of population below poverty rate, percentage of population married, percentage of older people (aged >65 y), and percentage of renters. Finally, the presence of spatial autocorrelation was tested by calculating the Moran I statistic for the residuals of the multivariate model.

## Results



### Description of the Population and Study Flow Diagram

A total of 51,809 anesthetic case records of patients undergoing surgery at the University of Utah were extracted from the Utah MPOG 2021 dataset. After excluding cases with missing data, a final dataset of 19,477 cases was analyzed in the cluster analysis, as detailed in Figure 2 with missing data noted therein. Table 1 lists detailed characteristics of the original cohort as well as the final analysis cohort after applying our exclusions criteria.

XSL•FO
RenderX

**Figure 2.** Cohort selection flow diagram of 51,809 cases with exclusions and final analytic cohort of 19,477 cases. ASPIRE: Anesthesiology Performance Improvement and Reporting Exchange; MAC: monitored anesthesia care (excluded); MPOG: Multicenter Perioperative Outcomes Group; PONV: postoperative nausea and vomiting.

The median age in the final cohort was 48 (IQR 34 - 63) years; 94.9% (18,491/19,477) of patients underwent a general anesthetic, often lasting longer than 1 hour (7838/19,477, 40.2%); the administration of opioid medication was almost always part of the anesthetic plan (19,176/19,477, 98.5%). ASA class was mostly 1 - 3 (2411/19,477, 12.4%; 9157/19,477, 47.0%; and 7222/19,477, 37.1%, respectively). Approximately one-tenth of patients reported a history of PONV. Most patients were nonsmokers (19,208/19,477, 98.6%). The median number of PONV risk factors was 4 (IQR 3 - 4), and patients received a median of 2 (IQR 2 - 3) prophylactic antiemetic interventions.

The final cohort had approximately the same percentage of White patients (41,189/51,809, 79.5% original vs 14,223/19,477, 78.2% final; standardized mean difference [SMD] 0.03), similar sex distribution (28,871/51,809, 55.7% female original vs 10,908/19,477, female 56.0% final; SMD 0.01) and similar smoking status (51,112/51,809, 98.7% nonsmoking original vs 19,208/19,477, 98.6% nonsmoking final; SMD 0.00) while the final cohort had slightly more risk factors (3.46 vs 3.79; SMD 0.29), interventions (1.88 vs 2.44, SMD 0.55), and higher prevalence of a lower ASA (ASA1-2: 25,654/51,809, 50% original vs 11,568/19,477, 59% final; SMD 0.27).

### Uni- and Bivariate Analysis

In total, we found 2260 low RAAP cases, 7358 median RAAP, and 9589 high RAAP cases in our final dataset. The association between socioeconomic neighborhood-level and demographic patient factors and RAAP is presented in a bivariate tabulation (Table 2).

Table 2 demonstrates how home address and race predicted RAAP in a descriptive, bivariate comparison. Levels of RAAP are tabulated in 3 columns: below median, median, and above median, which reflect disparities. The ND scores in the rows were separated into quartiles, with the 1st quartile Q1 being the lowest score (meaning the least disadvantaged) and the 4th quartile being the highest disadvantaged score (meaning the most disadvantaged). Populations living in more disadvantaged neighborhoods (eg, Q4=ND 4th quartile) on average received fewer antiemetic interventions after adjusting for risk, with 17.1% (835/4869) of Q4 receiving low RAAP versus 14.2% (692/4870) low RAAP for Q1 (most affluent) and similarly 41.1% (2001/8850) of Q4 receiving high RAAP versus 49.1% (2390/8850) of Q1 receiving high RAAP; hence, they were relatively undertreated compared to patients living in more affluent neighborhoods (Q1). In addition, people who self-identified as White mostly received many antiemetic interventions after controlling for risk (only 933/8850, 10.5% low RAAP) compared with unknown patients who more often received fewer interventions after controlling for risk (470/2986, 15.7% low RAAP) and non-White patients (897/7641, 11.7% low RAAP).

**Table .** Association of neighborhood disadvantage and race with risk-adjusted antiemetic prophylaxis (RAAP).

| Category | RAAP | | | Total, n (%) |
|---|---|---|---|---|
| | High RAAP, n (%) | Median RAAP, n (%) | Low RAAP, n (%) | |
| Quartile | | | | |
| Q1 | 2390 (49.07) | 1788 (36.71) | 692 (14.21) | 4870 (25) |
| Q2 | 2331 (47.87) | 1858 (38.16) | 680 (13.96) | 4869 (25) |
| Q3 | 2128 (43.70) | 1962 (40.29) | 779 (16.41) | 4869 (25) |
| Q4 | 2001 (41.09) | 2033 (41.75) | 835 (17.14) | 4869 (25) |
| Total | 8850 (45.43) | 7641 (39.23) | 2986 (15.33) | 19,477 (100) |
| Race | | | | |
| Non-White | 5990 (78.39) | 754 (9.86) | 897 (11.74)[a] | 7641 (39.23) |
| White | 7097 (80.19) | 820 (9.26) | 933 (10.54)[b] | 8850 (45.43) |
| Unknown | 2136 (71.53) | 380 (12.73) | 470 (15.74)[a] | 2986 (15.33) |
| Total | 15,223 (78.15) | 1954 (10.03) | 2300 (11.81) | 19,477 (100) |

[a]*P*<.001

[b]*P*=.003

Finally, an asymptotic generalized Pearson chi-squared test was performed to compare the distribution of RAAP values between all pairwise race categories (White, non-White, and unknown). The associated *P* values are as follows: White versus non-White (*P*=.003), White versus unknown (*P*<.001), and non-White versus unknown (*P*<.001).

Patient self-identified race predicted RAAP. Living in more disadvantaged neighborhoods (eg, Q4=ND 4th quartile) was associated with receiving fewer antiemetic interventions after adjusting for risk (835/4869, 17.1% low RAAP); in other words, compared to patients living in more affluent neighborhoods (Q1=1st ND quartile with 2390/8850, 49.0% high RAAP), clinicians administered fewer antiemetic interventions, even after adjusting for risk, in cases of patients living in CBGs with higher ND scores, which represent neighborhoods with higher proportions of non-Hispanic Black, female-headed families, households with public assistance or on food stamps, income below federal poverty level, and unemployment. In addition, after controlling for PONV risk, patients who self-identified as White received more antiemetic interventions (7097/8850, 80.1% high RAAP; *P*=0.003), and rarely fewer antiemetic interventions (only 933/8850 10.5% low RAAP; *P*<.001) while non-White patients more often received fewer interventions after controlling for risk (470/2986, 15.7% low RAAP; *P*<.001), compared to White patients in similar PONV risk strata. These associations are congruent with the results of our more complex statistical models.

The bivariate analyses showed that all the variables of interest, except age, were significantly related to being inside the cluster, with the percentage of non-White, percentage of male, percentage of education less than high school, percentage of population below poverty level, and the percentage of renter being positively related to belonging to a high-rate cluster, while the percentage of married population being negatively related to belonging to a cluster.

### Geospatial Analysis

We identified 1 significant cluster (*P*<.001) of low RAAP cases in Wasatch Front (Multimedia Appendix 2), comprising 101 CBGs. The cluster was located around the geographic center of Salt Lake City, and included West Valley City, South Salt Lake, and Taylorsville. The cluster had a total of 1934 included

XSL•FO
RenderX

participants residing within it, or approximately 9.93% of the study population. The relative risk (RR) of the whole cluster was 1.44 ($P$<.001), implying that the risk of receiving less (low RAAP) was 1.44 times higher for patients living *within* the cluster than for those living in other CBGs along the Wasatch Front. The CBG level RR within the cluster ranged between 0 and 3.73 (with RR>1 being a high relative risk), meaning the highest risk of low RAAP was 3.73 times higher living in CBGs within versus outside the cluster.

After adjusting for all listed covariates, we found that percentage of age >65 years in a CBG cluster became highly significantly associated with a low RAAP cluster, which would represent guidance-congruent care as age protects against PONV. However, we similarly demonstrated that the percentage of non-White people in a geographic area was also associated with low RAAP, which represents an unexplained process disparity. The larger the percentage of age >65 years and the percentage of non-White, which in West Valley City is over 42% Hispanic [33], the more likely the CBG belonged to the low RAAP cluster. In addition, the percentage of males was positively related to belonging to a low RAAP cluster, but with borderline statistical significance (again indicating guidance-congruent care, as female sex is positively associated with PONV risk). The Moran I statistic (Moran I=0.003; $P$=.79) indicated no evidence of spatial autocorrelation in the model residuals.

## Discussion

### Principal Findings

In our retrospective cohort of patients at the University of Utah local MPOG electronic health registry [25], we leveraged a novel geostatistical method to identify a spatial cluster of patients receiving less RAAP than peers in similar PONV risk strata [32]. We identified one significant cluster ($P$<.001) of low RAAP cases in the Wasatch Front (Multimedia Appendix 2), comprising 101 CBGs.

The cluster identified is an area of low RAAP cases with a high ND score (reflecting structural neighborhood features such as female-headed families, households with public assistance or on food stamps, income below the federal poverty level, and unemployment), and a relatively higher percentage of Hispanic and non-White patients. Low RAAP, defined in the methods, reflects process disparities in RAAP. Our findings are consistent with a direct association between ND and RAAP. Our results remained statistically significant in multivariate analysis, where we demonstrated that non-White individuals received lower RAAP than self-identified White participants. Uni- and bivariate tabulation of our data (Table 2) corroborated our principal geospatial analysis, while the association of male sex and older age in CBGs with low RAAP was consistent with guidance-congruent care, as both patient characteristics are associated with lower PONV risk.

### Interpretation of Principal Findings

Only individual patient-level PONV risk factors should be the guiding principle of RAAP [2,4,5,24]; neither patient race and ethnicity, nor ND should impede equitable RAAP [2,18,24]. By identifying geographic clusters of low RAAP, representing populations experiencing disparities in antiemetic prophylaxis after adjusting for risk, we visualized how geographically defined SDOH drive health care process disparities within anesthesiology [9]. Our finding that those within a disadvantaged geographic area, in this case the Hispanic-dominated West Valley region of Salt Lake County (where West Valley City has over 42% identify as Hispanic) [33], are over 40% less likely to receive RAAP is troubling, and it reinforces the use of geospatial analysis to identify populations at risk of process disparities. It should be further noted that the use of the spatial scan statistic examines individual CBGs in the context of neighboring CBGs: the ability to analyze beyond administrative boundaries can capture broader area characteristics, an advantage when examining subdivisions within a broader area of disparity.

### Significance of Geospatial Process Disparities in the Literature

Why would a patient's home address determine how many antiemetics they receive, as we demonstrated in this geospatial analysis? Geographic analyses in perioperative medicine have been sparse [34-36], and prior work tended to focus on patient *outcomes* rather than on *process* disparities. Geographic clusters of disparities in care have been well-documented in various areas of medicine, including diabetes, asthma, heart disease, veterans care, surgical care, as well as neonatal care [7,11-15]. Our findings also build on process outcomes in pediatric anesthesiology and our own work in obstetric care pain medicine, where cancellation rates were found to be higher in communities with lower socioeconomic status [10,19,35,37,38]. Our findings also add to our prior research on disparities in RAAP driven by patient- and neighborhood-level social determinants of health (patient race, insurance, and median income in zip code) [2,5]. Our results are consistent with these prior findings but examine perioperative process disparities through a geospatial lens with granular geostatistical methods, considering proximity statistically [9,21]. In addition, compared to previous work, the cluster analysis used here offers 2 key advantages. First, zip codes, designed primarily for mail delivery, are often misaligned with meaningful health behaviors or risk boundaries and can introduce bias when used as analytic units [39,40]. Second, by applying spatial scan statistics to pinpoint geographic clusters of suboptimal perioperative care, we move beyond coarse aggregation to directly identify and quantify localized disparities. The geospatial granularity empowers public health officials to deploy interventions (eg, quality improvement initiatives, tailored community outreach, and provider education) focused precisely on those areas where care gaps are statistically significant, thus enhancing the effectiveness of efforts to improve perioperative outcomes.

### Promise of Geospatial Analysis of Disparities

The innovation of our study is to perform a geospatial analysis of perioperative process disparities, leveraging equitable RAAP as a case study [2,5]. This represents an important step forward in terms of ability to ameliorate disparities, as geospatial drivers can be reevaluated over time, for example, after mitigation measures are put in place to address disparities [9]. The benefits of exploring process differences by neighborhood were also noted in studies in Scotland and California [41]; identifying

XSL•FO
RenderX

specific neighborhood clusters provided for targeted outreach to improve diabetes care.

Our analysis of local catchment areas with disparities in care *processes*, for which we are individually accountable as clinicians [5], can make for a different conversation within a department and among clinicians about potential modifications to practice patterns; these may ultimately drive many outcome disparities which some may have traditionally considered beyond our direct influence and scope of practice [7]. Outcome differences may be influenced by environmental factors (eg, pollution) while differences in risk-adjusted processes, under the primary domain of the individual anesthesia provider in the operating room, leave fewer excuses [4], though our findings are based on aggregate patterns and should not be interpreted as direct evidence of bias at the individual provider level. Despite this limitation, a focus on process provides greater insight into clinician behaviors and relationships with patients, with neighborhood structural factors potentially leading to care disparities potentially shaping the provider-patient relationship in the high-stakes and brief time of the preoperative anesthesia assessment and contributing to cumulative disadvantage. It also identifies, in our instance, an area where language barriers (due to Hispanic, Spanish-speaking population) may impede recognition of PONV risk factors and thus opens the door to potential novel avenues to improve care [4,10]. In our institution, identifying that a Hispanic, Spanish-speaking predominant neighborhood is potentially experiencing disparities is a unique way that geospatial clustering uncovers actionable, neighborhood-targeted hypotheses for intervention.

Studies from Taiwan and the United Kingdom National Health Service system show a complex interplay between care disparities and socioeconomic status of the neighborhood, demonstrating that even in systems with near-universal health care coverage, socioeconomic status can drive disparities in the delivery of care [42,43]. In contrast, other studies have suggested that neighborhood characteristics have only a modest impact on some care processes and outcomes [44], while the influence of race may overshadow neighborhood characteristics.

### Limitations and Potential Bias in Our Methods

Our study is not without its limitations. First, limiting generalizability, we confined the study population to the catchment area of the University of Utah Hospital, limited to 1 health system and 1 group of anesthesiologists. However, our prior studies around race have examined multiple hospitals in the large perioperative electronic health registries with analogous disparities identified [2,5]. Furthermore, the racial and ethnic diversity of populations varies across the United States, somewhat limiting the external validity of our study to states with lower minority representation. Low RAAP areas had low socioeconomic status and higher rates of Hispanic populations. This could result in autocorrelation and bias, as it is possible that neighborhood socioeconomic status and geographic factors were less salient than race but could not be fully separated in our model due to our small patient cohort. Expanding our approach to include areas of economic diversity among the Hispanic or other minoritized populations (eg, Texas, South Florida, and California) would further elucidate this relationship. The MPOG registry and our local dataset do not provide data on the race, sex, or ethnicity of the *clinicians* assigned to a particular anesthetic case. We were therefore unable to investigate if congruence of identity characteristics between patients and clinicians for a given case had an impact on clinician adherence with the best antiemetic practices. Furthermore, the assignment of staff to specific clinical locations could introduce bias in our results, especially if a single subgroup regularly practices at a given location; however, as the vast majority of cases take place at the main University of Utah clinical campus, the potential for this bias is minimal.

Another limitation, inherent in all geographic epidemiological retrospective studies, is the ecological fallacy [9,45]; we did not have individual self-identified race for all patients, as our local instance of MPOG and Epic provides inconsistent information on race and ethnicity, thus this is a data quality gap that constrains our interpretation. Our most reliable information is aggregate data at the neighborhood CBG level. Despite joining some individual data with group-level data, the risk of ecological bias, while mitigated, is still present. We acknowledge potential *missing data bias*, since we were only able to identify 93.1% of patients' addresses to the level of the street point address, (which is, however, consistent with other geocoding results) [9,46]. We also acknowledge that limiting the study area to the Wasatch Front, which was done to ensure contiguous CBGs for geospatial clustering analysis, may have resulted in the exclusion of rural disparities. We also did not examine the race of clinicians or perform any analysis by clinician characteristics [4]. A few outliers could have skewed the cohort, though this is unlikely given the inclusion of over 100 anesthesiologists. More detailed strengths and weaknesses of our geospatial analysis approach are discussed in Multimedia Appendix 1.

## Conclusions

Demonstrating the use of a novel geostatistical method in a retrospective cohort of anesthesia case records from the local MPOG electronic health registry at the University of Utah, we identified a spatial cluster of patients in the West Valley area of Salt Lake City, Utah, receiving less RAAP (Multimedia Appendix 2); they also represented a population from CBGs with relatively high neighborhood deprivation. Our results are consistent with prior work that demonstrated disparities in antiemetic prophylaxis based on *patient*-level factors (eg, race) [2], but adding a *neighborhood*-level, spatial dimension to perioperative health care disparities and health systems research, with many potential applications to elucidate geographic, social, and environmental drivers of the health care process and outcome (Figure 1) [9].

## Acknowledgments

The authors would like to acknowledge Beca Chacin of the Department of Anesthesiology, University of Utah for her contribution to creating Figure 1. During the preparation of this work, the authors used ChatGPT 4, from OpenAI, in order to edit the manuscript

## Abstract

**Background:** Tuberculosis (TB) remains a major public health concern. Despite improved diagnostic tools, delays in TB diagnosis persist and hinder control efforts.

**Objective:** This study aims to investigate the spatiotemporal patterns of TB diagnostic delay and identify individual and spatial risk factors in Jiangsu Province, China, from 2011 to 2021.

**Methods:** This study included 332,091 patients with TB who reported in Jiangsu Province from 2011 to 2021, using data obtained from the Jiangsu TB Information Management System, and diagnostic delay was defined as an interval of more than 28 days between symptom onset and diagnosis. Logistic regression was used to evaluate individual-level factors associated with delayed status, while a Bayesian spatiotemporal Beta model was used to analyze county-level TB diagnostic delay rates and assess spatial correlation using the global Moran *I*. The panel Granger causality analysis explored the temporal dynamics of delay rate transitions.

**Results:** Male patients, educators, and those diagnosed at the local Centers for Disease Control and Prevention had lower odds of diagnostic delay, whereas the older adults, agricultural workers, migrants, clinically diagnosed cases, and those diagnosed at community health centers had higher odds of delay. Spatial clustering in TB diagnostic delay rates was significant from 2015 onward (Moran $I$=0.110-0.193; all $P$<.05), excluding 2018 when Moran $I$ was 0.054. The Bayesian spatiotemporal Beta model, which accounted for 31.8% of the total variation due to spatial structure, indicated that for each 1-unit increase in the proportion of local patients and for each 100,000-person increase in resident population, the TB diagnostic delay rate decreased by 33.9% (95% CI 0.128-0.498) and 2% (95% CI 0.005-0.033), respectively. The panel Granger causality analysis indicated that TB incidence and health care technicians significantly influenced temporal changes in delay rates.

**Conclusions:** TB diagnostic delays in Jiangsu were influenced by both individual and spatial factors, with the proportion of local patients and resident population size contributing significantly to spatiotemporal variation. Tailored interventions targeting high-risk groups and health care settings are needed.

## Introduction

Tuberculosis (TB) is a chronic infectious disease caused by *Mycobacterium tuberculosis* and is primarily transmitted via airborne particles [1]. In 2022, TB was the second leading cause of death from a single infectious agent, surpassed only by COVID-19 [2]. Globally, an estimated 10.8 million new TB cases occurred in 2023, with an incidence rate of 134 per 100,000 population, posing a grave threat to public health [3]. As the country with the third highest TB burden [4], China has made significant efforts in TB control over recent decades, increasing the case detection rate from 30% in the 1990s to 80% by 2005 and thereby effectively reducing transmission and

XSL•FO
RenderX

incidence [5,6]. In Jiangsu Province, China, TB remains a critical public health challenge, consistently ranking second among reported class A and B infectious diseases [7].

The World Health Organization (WHO) End TB Strategy emphasized the importance of early diagnosis and timely treatment for TB control and prevention, as well as reducing treatment costs [8]. However, most national TB control programs primarily rely on passive case finding, a practice often resulting in treatment delays exceeding 1 month in approximately 42% of patients [9]. The extent of these delays varies globally due to socioeconomic and health care disparities, with particularly severe delays observed in less developed regions. For instance, reported median total delays range significantly from 68 days in France to 104 days in Ghana and up to 366 days in Afghanistan [10]. Therefore, identifying the key factors contributing to delays in specific regions is essential for developing targeted TB interventions and control measures.

Extensive research has examined risk factors contributing to TB diagnostic delays, which arise from complex interactions of individual behaviors, social determinants, and health care system challenges [11]. The declining clinical awareness of TB among health care workers, especially in low-incidence settings, combined with the nonspecific nature of typical TB symptoms, such as persistent cough and sputum production, often leads to early misdiagnosis as common respiratory infections [12]. Meanwhile, misdiagnosis and missed cases are exacerbated by urban-rural disparities in medical resources and surges in diagnostic pressure during peak health care demand periods, such as holidays or influenza seasons [4]. Socioeconomically vulnerable populations, including migrant workers and older adults, often experience delays in seeking medical care due to limited access to health care insurance, language barriers, and varying levels of education [13,14].

Although previous analyses have identified key risk factors, they have generally failed to sufficiently account for the spatial and temporal dependence inherent in TB diagnostic delays [15,16]. Past research using descriptive statistics has highlighted spatial heterogeneity, for instance, by revealing median delays of 30 days in eastern or central China versus 41 days in the west [6] and identifying regional disparities in Portugal [17]; these studies often overlook spatial autocorrelation. To address this limitation, the Bayesian spatiotemporal model provides a rigorous framework that incorporates explanatory variables to capture large-scale trends while also accounting for residual dependencies to reveal robust spatial patterns and potential risk factors [18]. Furthermore, by integrating prior knowledge to quantify uncertainty, this approach enhances both the accuracy and interpretability of findings [19,20]. The integrated nested Laplace approximation (INLA) algorithm offers an efficient approach for implementing Bayesian inference in such complex models [21]. Notably, the spatiotemporal patterns of TB diagnostic delay have been rarely investigated using this Bayesian approach, representing a critical research gap that this study aims to address.

This study used Bayesian spatiotemporal analysis to investigate TB diagnosis delays, capturing spatiotemporal dependencies and examining patterns of temporal and spatial variation. We have the following three research goals: (1) assess the existence of spatial and temporal autocorrelation in TB diagnostic delays within Jiangsu Province, China; (2) identify individual-level risk factors associated with delayed diagnosis; and (3) determine county-level determinants of diagnostic delay rates, while accounting for potential temporal and spatial random effects.

## Methods

### Data and Variables

We obtained TB surveillance data from the Jiangsu Tuberculosis Information Management System (TBIMS), spanning January 1, 2011, to December 31, 2021. The original dataset contained 354,274 infection cases reported in Jiangsu Province during this period, including patient information such as names, ages, sex, occupations, sources of patients, types of diagnosis, tracking status, types of hospital, dates of birth, onset dates, diagnostic dates, and so on. A total of 332,091 patients were analyzed in this study following exclusion criteria: (1) patients diagnosed and reported between January 1, 2011, and December 31, 2021, at health care institutions outside Jiangsu Province (n=8010); (2) patients with missing critical information (n=12,889); and (3) patients whose standardized *z* value for the total diagnostic delay that exceeded 3 (ie, more than 3 SD from the mean; n=1266) [22].

Total diagnostic delay, defined as the interval from the onset of TB symptoms to formal diagnosis, comprises both patient delay and health system delay [13,23]. Patient delay refers to the time between symptom onset and the first medical consultation, while health system delay spans from the time of the first health care visit to diagnosis. This study focused exclusively on total diagnostic delay, as the dataset lacked information regarding the date of the first medical visit. At the individual level, the outcome was defined as the diagnostic delay status, which indicated whether a patient's total diagnostic delay exceeded 28 days, a commonly adopted threshold for total TB diagnostic delay based on previous studies [13]. At the county level, the outcome was the TB diagnostic delay rate, which was calculated by dividing the number of delayed patients (ie, those with more than 28 d of total diagnostic delay) by the total number of patients in each county each year.

In addition to the individual-level TB surveillance data from Jiangsu TBIMS, a total of 9 annual county-level explanatory variables were included, categorized into three distinct domains: (1) demographic factors, comprising the annual proportions of older adult patients (≥60 y), male patients, local patients, and agricultural-worker patients among reported cases; (2) socioeconomic and health care indicators, including gross domestic product (GDP) per capita (adjusted to the 2021 Consumer Price Index), resident population size, TB incidence rate (per 1000 population), and the health care technicians (professionals per 1000 population); and (3) pandemic period, a binary variable (1=2020 - 2021; 0=2011 - 2019) introduced to adjust for the potential impact of social isolation policies and health care resource diversion during the COVID-19 pandemic. Data regarding health care technicians, GDP, and resident population were sourced from annual county statistical

XSL•FO
RenderX

yearbooks, while other variables were aggregated directly from the TB surveillance data.

### The Bayesian Spatiotemporal Model

To explore the spatial correlation of the TB diagnostic delay rate across 89 districts and counties in Jiangsu Province from 2011 to 2021, we calculated the global Moran *I* to measure the spatial correlation [24,25]. When the result for Moran *I* is statistically significant, a positive value for Moran *I* suggests spatial clustering, while a negative value suggests spatial dispersion. The closer the value of *I* is to 1 or −1, the stronger the spatial association, while a value near 0 indicates a random spatial distribution of TB diagnostic delay rates.

Prior to the spatiotemporal modeling, multivariable binary logistic regression was used to identify risk factors associated with individual diagnostic delay status (binary outcome: 1 if total delay >28 d, 0 otherwise). Subsequently, a logit-link Bayesian Beta regression model was then applied, incorporating fixed effects for the proportion of older adult patients, proportion of male patients, proportion of local patients, proportion of agricultural-worker patients, GDP, TB incidence rate, number of health care technicians, and resident population, along with spatial and temporal random effects.

Specifically, let y(s,t) denote the TB diagnostic delay rate in year *t* over district or county *s*, with values ranging from 0 to 1. Here, *t*=1, 2, ..., 11 represents the years 2011 to 2021, and *s*=1, 2, ..., 95 represents the 95 counties or districts in Jiangsu Province, China. We further assumed that y(s,t) follows a β distribution with mean μ(s,t)∈(0,1) varying over time across counties or districts, and a constant precision parameter φ>0. Namely,

$$\text{logit}\ \mu(s,t)=xT(s,t)\beta+\delta t+us+(s,t),$$

where the vector x(s,t) represents the regional-level variables in Table 3. The (s,t) term is an unstructured random effect in the model. We employed the first-order Gaussian random walks (RW1) model and the Besag-York-Mollié 2 model to capture the overall temporal random effect δt and spatial random effect us [26].

The Besag-York-Mollié 2 model was used to capture spatial random effects by combining structured and unstructured spatial components through a mixing parameter [27]. The spatial effect for area i is expressed as:

$$bi=1\tau b(1-\varphi vi*+\varphi ui*),$$

where τb is the overall precision, ui∗ is a standardized intrinsic conditional auto-regressive component capturing structured spatial dependence, and vi∗ is a standardized Gaussian noise term representing unstructured spatial variability. The mixing parameter φ∈[0,1], is a spatial smoothing parameter, measuring the proportion of the marginal variance explained by the structured random effect.

As a latent effect implemented in the R-INLA package, the first-order Gaussian random walk was used to model temporal dependence [26]. For a latent Gaussian field u=(u1,…,un)T, it is a random walk of order 1 if the increments Δui=ui−ui−1 are independent and identically distributed Gaussian random variables with zero mean and precision τ>0 (inverse variance).

Based on the delay rates estimated from the Bayesian spatiotemporal Beta model, we dichotomized at the median and then fitted a Bayesian spatiotemporal binomial model to identify factors associated with a higher likelihood of diagnostic delay. Furthermore, to explore the temporal dynamics and potential drivers of delay rate, we conducted a panel Granger causality analysis [28].

All statistical analyses were conducted using R software (version 4.4.1; R Foundation for Statistical Computing). The *INLA*, *stats*, and *lmtest* packages were used to conduct the Bayesian spatiotemporal modeling, logistic regression, and the Granger causality analysis, respectively, with default prior distributions specified for the INLA hyperparameters.

### Ethical Considerations

Anonymized data were obtained from the Jiangsu TBIMS, with all personal identifiers (eg, name and ID number) removed prior to analysis. The study protocol was reviewed by the ethical review board of the Jiangsu Provincial Center for Disease Control and Prevention (Jiangsu CDC) and granted an official exemption (acceptance: SL2025-B030-01), as the study was deemed retrospective and the data were deidentified. Data access and usage were strictly governed by a formal Data Usage Agreement between the Jiangsu CDC and the study authors. Informed consent was not required for this retrospective study using anonymized data.

## Results

### Descriptive Statistics

Table 1 summarizes the demographic and clinical features of patients with TB with delayed (≥28 d) and nondelayed (<28 d) diagnoses, respectively, in Jiangsu Province (2011-2021). Among all patients, the majority were male participants (239,692/332,091, 72.18%), working in agriculture (204,983/332,091, 61.72%), and reported by general hospitals (148,960/332,091, 44.86%), with a high proportion of local residents (239,440/332,091, 72.10%).

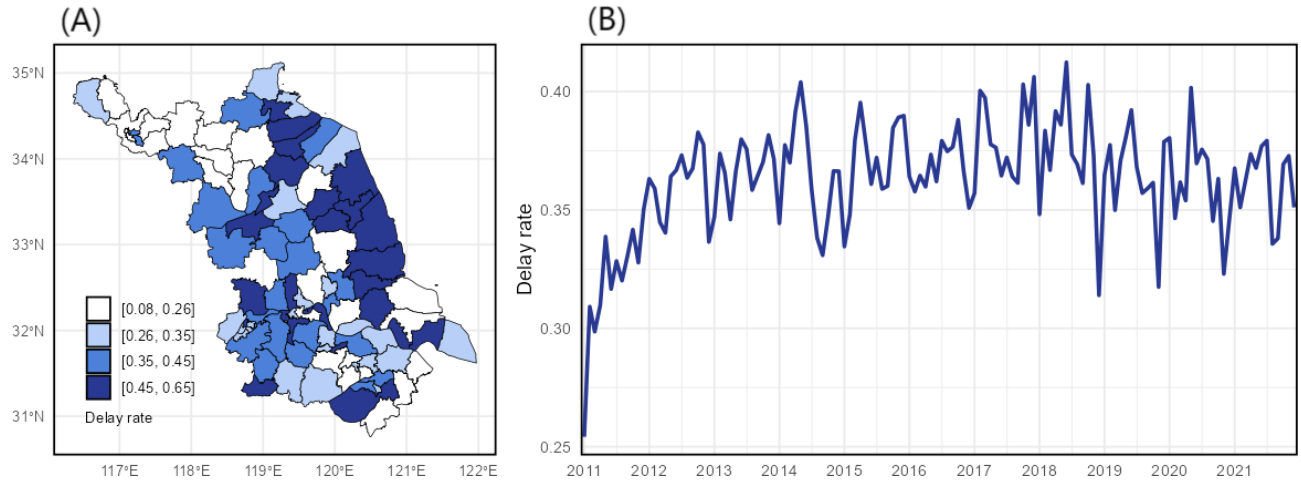

Figure 1A shows the spatial distribution of average TB diagnostic delay rates in Jiangsu Province over the period from 2011 to 2021. The cities of Yancheng and Huaian generally exhibited the highest delay rates, and the Binhai district in

XSL•FO
RenderX

Yancheng recorded a peak delay rate of 93.35% in 2016. Figure 1B illustrates the temporal trend across all 95 counties. An increasing trend was evident from 2011 to 2014, followed by a plateau. Notable distinct declines in the average delay rate were observed in specific months, including December 2018, November 2019, and November 2020.

**Figure 1.** Annual average spatial distribution across 95 counties (A) and monthly provincial average temporal trends (B) of tuberculosis delayed diagnoses in Jiangsu Province, 2011-2021.

## Analysis at the Individual Level

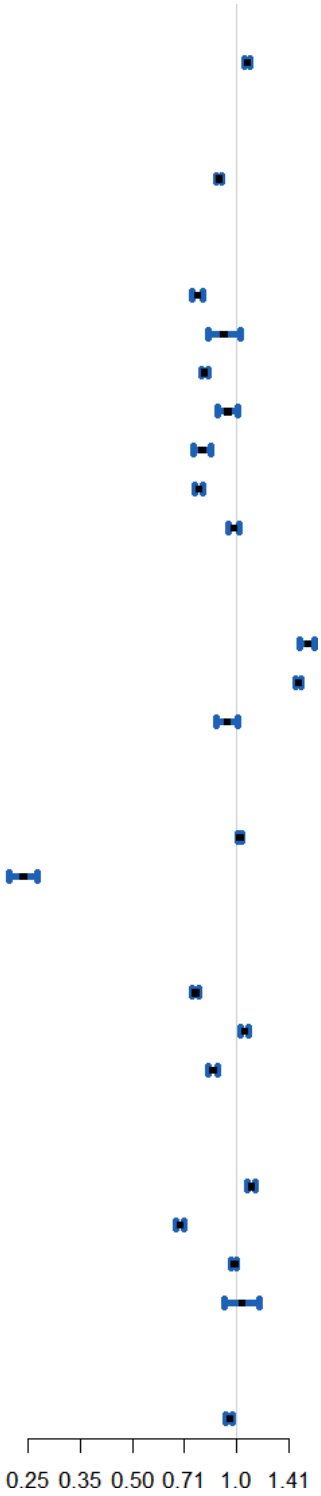

Figure 2 presents the results of a logistic regression analysis used to investigate potential risk factors associated with individual TB diagnosis delay status. Specifically, males had significantly lower odds of experiencing delayed TB diagnosis compared to females (odds ratio [OR] 0.891, 95% CI 0.874-0.906), while patients older than 60 years had slightly higher odds of delayed TB diagnosis compared to those who were younger than 60 years (OR 1.070, 95% CI 1.053-1.088). We also found that patients who worked in agriculture had higher odds of delayed TB diagnosis than patients in other occupations. Particularly, the differences between patients working in agriculture and patients of occupations in education (OR 0.769, 95% CI 0.740-0.799), housekeeping (OR 0.807, 95% CI 0.791-0.824), service (OR 0.794, 95% CI 0.749-0.843), and worker (OR 0.778, 95% CI 0.757-0.800) were statistically significant. Local patients (from the same county/district) had significantly lower odds of delayed TB diagnosis than patients from different counties (OR 1.598, 95% CI 1.525-1.675) or cities (OR 1.508, 95% CI 1.480-1.536) in Jiangsu. Regarding types of diagnosis, the suspected cases had significantly lower odds of delayed TB diagnosis compared to the confirmed cases (OR 0.242, 95% CI 0.221-0.266), while the clinically diagnosed cases had significantly higher odds of delayed TB diagnosis (OR 1.021, 95% CI 1.003-1.037) compared to the confirmed cases. Patients diagnosed at community health centers (CHCs) had higher odds of delayed diagnosis compared to those diagnosed at designated TB hospitals (OR 1.103, 95% CI 1.075-1.133). However, patients diagnosed at local CDCs had considerably lower odds of delayed diagnosis than those diagnosed at designated TB hospitals (OR 0.687, 95% CI 0.668-0.707). Finally, the COVID-19 period was associated with significantly lower odds of diagnostic delay (OR 0.954, 95% CI 0.933-0.975).

## Analysis at the County Level

Table 2 presents the global Moran *I* indices for TB diagnostic delay rates from 2011 to 2021. From 2011 to 2014, the Moran *I* values were close to zero (all *P*>.05), indicating no significant spatial autocorrelation. However, a marked increase in Moran *I* was observed from 2015 onwards, suggesting the emergence of substantial spatial clustering. Consequently, the Bayesian spatiotemporal Beta model was used to fully account for the spatial autocorrelation found in TB diagnostic delay rates across the years.

RenderX

**Table .** Global Moran *I* index for tuberculosis diagnostic delay rate in Jiangsu Province, 2011-2021.

| Year | Moran *I* | *P* value |
|---|---|---|
| 2011 | 0.018 | .33 |
| 2012 | 0.079 | .08 |
| 2013 | 0.047 | .19 |
| 2014 | 0.040 | .22 |
| 2015 | 0.193 | <.001 |
| 2016 | 0.167 | .003 |
| 2017 | 0.161 | .004 |
| 2018 | 0.054 | .16 |
| 2019 | 0.113 | .03 |
| 2020 | 0.110 | .03 |
| 2021 | 0.085 | .07 |

Table 3 presents the fixed effect estimates for the proportion of older adult patients, proportion of male patients, proportion of local patients, proportion of agricultural-worker patients, GDP, TB incidence rate, number of health care technicians, and resident population from the Bayesian spatiotemporal Beta model. For each 1-unit increase in the proportion of local patients, the TB diagnostic delay rate decreases by 33.9% (1−exp[−0.415], 95% CI 0.128-0.498). Additionally, each 100,000-person increase in resident population is associated with a 2% (95% CI 0.005-0.033) decrease in TB diagnostic delay. For random effects, the precision parameter τb was estimated as 3.411, indicating a moderate degree of spatial variation in the diagnostic delay rates across counties. In addition, the mixing parameter φ was estimated as 0.318, meaning that the structured spatial component accounts for 31.8% of the total spatial variation in TB diagnostic delay rate.

**Table .** The result of the Bayesian Beta spatiotemporal model of TB[a] diagnostic delay rate at the county level in Jiangsu Province, 2011-2021.

| Variables | Mean (SD) | 0.025 quantile | 0.975 quantile |
|---|---|---|---|
| Fixed effect | | | |
| Proportion of older adult patients (%) | 0.234 (0.261) | −0.281 | 0.747 |
| Proportion of male patients (%) | −0.002 (0.014) | −0.030 | 0.026 |
| Proportion of local patients (%) | −0.415 (0.140) | −0.691 | −0.138 |
| Proportion of agricultural-worker patients (%) | 0.187 (0.184) | −0.176 | 0.548 |
| GDP[b] (thousand yuan per person) | 0.061 (0.037) | −0.014 | 0.135 |
| TB incidence rate (%) | 0.055 (0.062) | −0.068 | 0.180 |
| Health care technicians (per 1000 residents) | −0.008 (0.008) | −0.024 | 0.007 |

[a]TB: tuberculosis.

[b]GDP: gross domestic product.

[c]BYM2: Besag-York-Mollié 2.

Figure S1 in Multimedia Appendix 1 illustrates the spatiotemporal distribution of the estimated TB diagnostic delay rate obtained from the Bayesian spatiotemporal Beta model. Higher estimated delay rates were concentrated in the northern coastal cities such as Huaian, Yancheng, and Lianyungang, while lower rates were observed in Xuzhou and Suzhou in the southern region. Among the 95 districts and counties over the 11-year period, Qingjiangpu of Huaian ranked among the top

XSL•FO
RenderX

3 with the highest estimated delay rates, with values of 0.648 in 2021, 0.645 in 2014, and 0.644 in 2018. Meanwhile, from 2011 to 2013, the delay rate exhibited an increasing temporal trend, which was particularly evident in Suqian. In contrast, Figure S2 in Multimedia Appendix 1 presents the observed delay rates, which show much larger fluctuations, reflecting random noise and potential instability due to small-area sample variation. The differences between Figures S1 and S2 in Multimedia Appendix 1 arise because the Bayesian spatiotemporal Beta model smooths random noise and incorporates both spatial and temporal dependencies. By integrating relevant covariates and modeling residual correlation through random effects, it effectively adjusts for unobserved dependence and confounding, producing spatially coherent and statistically reliable estimates.

The median of the estimated TB diagnostic delay rate was 0.352. Based on the obtained median, the results from the Bayesian spatiotemporal binomial model (Table S1 in Multimedia Appendix 1) show that counties with a higher proportion of agricultural workers and higher GDP were more likely to experience high diagnostic delays. Conversely, counties with larger shares of local patients, larger resident populations, and the COVID-19 period were associated with a lower risk of high delays. Furthermore, Table S2 in Multimedia Appendix 1 indicated that GDP, TB incidence, and health care technicians had significant Granger causal effects on the temporal changes in the delay rate ($P$<.05).

### Sensitivity Analysis

The sensitivity analysis confirmed the consistency of our main results. We applied penalized complexity priors to spatial and temporal model parameters to constrain model complexity and prevent overfitting (Tables S3-S6 in Multimedia Appendix 1) [29]. Across these analyses, the direction and statistical significance of the main variables remained consistent, with a slight change in the magnitude of some coefficients. To examine the impact of risk factors associated with TB diagnostic delays over shorter periods, we divided the study period into 2 subperiods (2011 - 2015 vs 2016 - 2021), representing China's 12th and 13th Five-Year Plans for Tuberculosis Prevention and Control (Table S7 in Multimedia Appendix 1) [30]. We found that the significant associations between diagnostic delay and residency or occupation observed in the first subperiod disappeared in the second subperiod, likely due to expanded health care access and continuous public health developments in Jiangsu.

## Discussion

This research analyzed 332,091 patients with TB in Jiangsu Province from 2011 to 2021, combining individual-level analysis with county-level spatiotemporal modeling to enhance understanding of diagnostic delay risk factors and their spatial and temporal patterns. At the individual level, we found that all 7 risk factors (ie, age, sex, occupation, patient source, type of diagnosis, tracking status, and type of hospital) were significant. At the county level, significant spatial clustering was observed from 2015. Drawing on such spatial dependence, we found that the proportion of local patients and the resident population were significantly and negatively associated with the TB diagnostic delay rates. Counties with higher proportions of older adults and agricultural-worker patients were more likely to experience high diagnostic delays. Moreover, GDP, TB incidence, and health care technicians exhibited significant effects on temporal changes in the delay rate.

Various individual characteristics were found to be significantly associated with the status of TB diagnostic delay. The odds of experiencing a TB diagnostic delay were significantly lower for males, consistent with the findings of previous studies [31,32]. A study in Portugal suggested that the higher overall TB burden in males (male-to-female ratio 2:1) could increase clinical suspicion and expedite diagnosis when men seek care [33]. The odds of experiencing TB diagnostic delay for education industry workers were also significantly lower, potentially attributed to strict TB screening programs for students and higher health management standards in Jiangsu and elsewhere [34]. We found older adult patients had higher odds of experiencing TB diagnostic delay, mainly due to factors such as lower education levels, poorer health awareness, lack of knowledge on TB prevention and treatment, economic difficulties, and insufficient social support [35,36]. Regarding the type of hospital, patients diagnosed by CHCs had higher odds of experiencing TB diagnostic delay, likely because these CHCs have limited resources and clinical experience [37]. For example, an artificial intelligence–assisted diagnostic platform was launched in Jiangsu Province in 2023, but this system has not been implemented at CHCs [38]. In contrast, patients diagnosed by CDCs had much lower odds of experiencing delay, underscoring the specialized knowledge needed for early TB diagnosis and thus the critical role of CDCs in TB detection. Finally, the significantly lower odds of diagnostic delay during the COVID-19 pandemic likely reflect how rigorous respiratory screening, targeting basically the same symptoms (eg, fever and cough), prompted earlier identification of TB cases that might be otherwise overlooked [2].

The spatial distribution of TB diagnostic delay exhibited clear characteristics of spatial clustering in Jiangsu Province. The global Moran $I$ index showed no significant spatial autocorrelation in TB diagnostic delay rates from 2011 to 2014. Starting in 2015, however, significant spatial clustering emerged (Moran $I$=0.110-0.193; $P$<.05 for 2015-2017 and 2019-2020), indicating that the delay rates formed a stable spatial dependence pattern across counties or districts [25,39]. The mixing parameter of the Bayesian spatiotemporal Beta model was estimated at 0.318, indicating that a substantial portion of the spatial variation was attributable to structured spatial effects, also reflecting interdependency in the delay-risk patterns of neighboring areas. A possible explanation for this is the promotion of rapid drug-resistant TB molecular biological testing equipment in Jiangsu Province, which has improved TB diagnostic efficiency but may be disproportionately allocated across counties/districts due to a limited supply [40].

Our research revealed significant associations between the key factors and the TB diagnostic delay rate. For each unit increase in the proportion of local patients, the TB diagnostic delay rate decreased by 33.9%. This suggested that patients who lived permanently within the county might have had better access to

XSL•FO
RenderX

local health services, greater familiarity with the health care system, or improved continuity of care, all of which could have facilitated earlier diagnosis [41]. Additionally, each increase of 100,000 residents was associated with a 2% decrease in the TB diagnostic delay rate. Larger populations were typically found in more urbanized or economically developed counties, which tended to have better health care infrastructure, higher diagnostic capacity, and more accessible TB services [42]. When counties were classified using the median estimated delay rate, those with larger older adult populations were consistently identified as high-delay areas, which was consistent with the individual-level associations. A higher proportion of agricultural-worker patients was likewise linked to greater diagnostic delays, reflecting structural barriers such as limited health care access, seasonal labor patterns, and insufficient disease awareness [43]. Panel Granger causality tests further indicated that GDP and health care technician density were key drivers of temporal fluctuations in diagnostic delay. Higher GDP likely supported more advanced diagnostic infrastructure and resource allocation, while greater technician density enhanced diagnostic capacity and accelerated case detection [44,45].

The significance of this study lies in three main aspects. First, there had been a lack of large-scale, population-based investigations into diagnostic delay in TB in Jiangsu Province. Based on a comprehensive surveillance system covering 332,091 patients with TB, the study identified several key risk factors associated with TB diagnostic delay in the general population of Jiangsu, providing an essential empirical basis for targeted interventions. Second, the analysis confirmed the existence of spatial correlation and random effects in TB diagnostic delay rates, thereby underscoring the necessity of using a Bayesian spatiotemporal modeling approach to capture the underlying spatial and temporal dependence appropriately. Third, we conducted statistical analysis at both the individual and county levels, which accounts for geographic disparities while estimating the risk factors associated with TB diagnostic delay rates. This approach leads to more targeted and synergistic public health strategies for reducing regional TB diagnostic delay rates, as well as individual chances of experiencing TB diagnostic delays.

Our study also has several limitations. First, while diagnostic delay may affect the temporal alignment between symptom onset and reporting, the calculation of TB incidence rate was not adjusted for such delays and thereby may be biased [46]. Second, due to data limitations, this study focused on the total diagnostic delay, making it impossible to distinguish between patient delay and health system delay. Future studies with more detailed health care-seeking information are needed to explore these 2 components separately. Third, continuous socioeconomic development over the decade may introduce temporal heterogeneity in the impact of risk factors, limiting the findings to this specific developmental stage.

In conclusion, a multifaceted and targeted approach is essential for effectively reducing diagnostic delays in TB. First, efforts should be made to promote proactive health-seeking behaviors among individuals, particularly among high-risk populations such as agricultural workers, older adults, and female individuals. These groups are more vulnerable to pulmonary diseases and often underrepresented in passive case detection strategies [47]. Second, from a health system perspective, it is necessary to enhance TB screening and testing protocols for migrants by improving access to care and removing systemic barriers that can delay their diagnoses, should they have TB [48]. Third, more resources should be allocated to CHCs to enhance their diagnostic capacity and knowledge of TB, as they are often the first point of contact for patients with TB, especially in underdeveloped areas [49].

## Acknowledgments

The authors thank the editor and reviewers for their valuable comments and suggestions, which greatly improved the manuscript. While preparing this work, the authors used ChatGPT (OpenAI) to assist with language editing and improve readability. The authors critically reviewed and revised the artificial intelligence–generated content to ensure accuracy and adherence to scientific standards. The authors take full responsibility for the final manuscript.

## Funding

This study was supported by the following funding sources: National Natural Science Foundation of China (82574173 and 82003516), Jiangsu Provincial Natural Science Foundation (BK20251958), and Jiangsu Provincial Medical Key Discipline (ZDXK202250).

## Data Availability

The data analyzed during this study are not publicly available due to restrictions imposed by the Jiangsu Provincial Center for Disease Control and Prevention in eastern China. However, access to the data can be requested from the corresponding author, LZ, upon reasonable request and with appropriate approval.

## Authors' Contributions

TL, LZ, and YT developed the methodology and conceptualization. YT prepared the initial draft of the paper and programmed the code. YT and TL analyzed the main results. CC, QL, and LZ conducted the survey and data collection. YL, YT, MC, KW,

## Abstract

**Background:** Despite major biomedical advances in HIV testing, prevention, and treatment, annual HIV transmissions in the United States remain above 30,000. Geographic access to pre-exposure prophylaxis (PrEP) is critical to HIV prevention efforts, particularly in regions with high HIV burdens, such as metro-Atlanta. Community-based organizations (CBOs) play a central role in delivering culturally competent prevention services, yet many rely on federal funding that is increasingly unstable. Understanding the potential impact of CBO closures on geographic access to PrEP is essential for anticipating inequities and informing policy.

**Objective:** The aim of this study was to estimate how hypothetical closures of federally funded CBOs providing PrEP affect geographic access to PrEP clinics by car and public transit across metro-Atlanta and to assess whether impacts differ by community racial/ethnic composition.

**Methods:** We identified 71 PrEP-providing clinics in metro-Atlanta (August 2025), including 12 CBOs. Using 3 simulated closure scenarios in which 25% of CBOs were randomly closed, we calculated one-way travel times from 2466 census block group (CBG) centroids to the nearest PrEP-providing clinic. Travel times were estimated for car and public transit across 3 weekdays and timepoints and then averaged per CBG. Two-sided paired *t* tests were used to compare the change in travel time compared to baseline. Logistic regression assessed associations between racial/ethnic plurality and increased travel times.

**Results:** Under baseline conditions, 100% of CBGs had car access to a PrEP clinic within 30 minutes compared to only 41.6% (1027/2466) via public transit. Across closure scenarios, 732 CBGs (29.6%; representing over 1 million residents) experienced increased transit times (mean increase 1.2 minutes; range 0.0-11.6; $P<.001$), and 7 CBGs lost transit access entirely. For car travel, 1184 CBGs (48%; representing approximately 1.7 million residents) experienced increased drive times (mean increase 0.5 minutes; range 0.0-6.4; $P=.03$). Black-plurality CBGs had higher odds of increased drive times compared to White-plurality CBGs (odds ratio 1.37, 95% CI 1.15-1.63).

**Conclusions:** Even limited closure of CBO PrEP providers meaningfully reduces geographic access to HIV prevention services, disproportionately affecting communities already experiencing transportation and HIV-related vulnerabilities. Sustained federal investment in CBOs is essential to preserve equitable PrEP access and prevent avoidable HIV infections.

## Introduction

We have arrived at a point in the HIV epidemic in the United States where we arguably have all of the biomedical tools we need to end the epidemic [1]. There are multiple options for HIV screening, including self-testing [2]; multiple formulations and regimens for pre-exposure prophylaxis (PrEP) to prevent HIV infection; and effective treatments that result in full healthy lives for people living with HIV and, for people living with HIV who are virally suppressed, eliminating the risk of onward transmission through sex [3]. Despite these biomedical advances, annual HIV transmissions in the United States remain above 30,000 [4].

The realties of bringing these foundational tools to scale in a coordinated response has proven to be a substantial challenge of implementation and has resulted in increased attention to and funding for implementation science approaches [5-7]. Geographic access to HIV prevention services, including PrEP, is foundational to the "Prevent" pillar of the National HIV/AIDS Strategy [8]. We have previously explored geographic access to HIV prevention and care issues during a time of more certainty and consistency about the funding mechanisms for HIV prevention and care [9-11]. We have found that inequities in geographic access to HIV prevention and care services, and often, commute times disproportionately impact communities of color for whom car ownership may be less [12,13] and for whom public transportation access and route frequency may be more limited [14,15].

As we consider the structural and socioeconomic factors that impact geographic access to HIV prevention services, we are now in an era where federal funding for HIV services is declining or under threats of future reduction or elimination [16-19]. HIV prevention services in the United States are supported through a patchwork of federal funding mechanisms, including direct service delivery grants from the Centers for Disease Control and Prevention, funds administered through the Health Resources and Services Administration like the Ryan White HIV/AIDS Program, the Ending the HIV Epidemic initiative, Title X, Medicaid reimbursement for clinical PrEP services, and time-limited federal demonstration and implementation grants. These funding streams vary in stability, allowable services, and eligibility criteria, creating differential vulnerability to funding reductions across delivery settings. Although most PrEP prescriptions in the United States are provided through traditional health care clinics, community-based organizations (CBOs) contribute disproportionately to PrEP access among marginalized populations through direct provision, partnerships with prescribing clinicians, and intensive navigation services [20]. Given that many CBOs that provide HIV prevention services are supported, at least in part, by federal funding, it is important to consider how reductions in federal funding that lead to the closure of existing prevention providers might impact geographic access to HIV prevention services. Further, given the disparities in new HIV diagnoses related to acquisitions risks (eg, men who have sex with men), racial/ethnic minority groups (eg, Black and Hispanic or Latinx people) and geographic region (eg, the US South), it is important to assess whether gaps in geographic access to prevention services are differential by these population characteristics. To address these gaps, we used public data about the locations of HIV PrEP providers and previously described methods for estimating commute times to HIV prevention care services [10] to model the potential impact of federal funding cuts on geographic access to PrEP in Atlanta, Georgia.

## Methods

We examined how the closing of CBOs that provide HIV prevention services may impact access to PrEP by both car and public transit across the four counties that encompass metro-Atlanta: DeKalb, Cobb, Fulton, and Gwinnett (all of which are "Ending the HIV Epidemic"–prioritized counties for HIV prevention).

### Ethical Considerations

This study used publicly available, deidentified census and clinic location data. No human participants were involved, and therefore, no reviews or approvals by an ethics committee or institutional review board were required.

### Clinic Data and Closure Scenarios

We identified all PrEP-providing clinics in the metro-Atlanta area as of August 2025 by using the Centers for Disease Control and Prevention's National Prevention Information Network PrEP Locator directory [21]. Clinics in the database are screened for eligibility if they have at least one health care professional (eg, physician, nurse practitioner, physician assistant) who is qualified to prescribe PrEP and if they have confirmed that they actively prescribe it. In addition to geographic data, each clinic is categorized by its funding type (federally qualified health center, public health department, hospital, CBO, etc). Of the 71 clinics in metro-Atlanta, 12 were designated as a CBO. To simulate potential impacts of federal funding reductions that disproportionately affect CBOs, we created 3 separate closure scenarios. In each scenario, 3 CBOs (approximately 25% of all Atlanta-area CBO PrEP clinics) were randomly selected for closure, and analyses were rerun to estimate the resulting changes in geographic access.

### Origin and Destination Specification

Census block groups (CBGs) served as the unit of analysis for travel time estimation. Origin coordinates were defined as the population-weighted centroid of each CBG, representing where residents are most likely to live. CBG-level sociodemographic data were obtained from the American Community Survey 5-year estimates [22]. CBGs were categorized by the racial or ethnic plurality of residents. Destination coordinates were the locations of PrEP-providing clinics identified above. This approach captures area-level variation in accessibility rather than individual travel patterns.

### Travel Time Estimation

We estimated one-way travel times between each CBG centroid and the 10 nearest PrEP clinics by using the Google Maps Distance Matrix application programming interface accessed through R [9]. The application programming interface was used to calculate the shortest available route under two transportation

XSL•FO
RenderX

modes: public transit and private vehicle. For both modes, travel times were calculated across 3 weekdays (Tuesday, Friday, and Saturday) and 3 time points (8 AM, noon, and 3:30 PM).

The shortest one-way travel time for each day-time combination was selected and then averaged to provide one estimate per mode for each CBG for each closure scenario. CBGs with no available public transit route to any PrEP clinic, defined as a walking distance of more than 30 minutes to the nearest transit stop, were coded as having no transit access. Transit time estimates included walking time to any transit stops, waiting time, boarding/transfer time, and time in transit.

### Statistical Analysis

We used descriptive statistics to describe mean one-way travel times to the nearest PrEP clinic before and after simulated closures, separately for car and public transit. The mean change in travel time (minutes) was averaged across the 3 closure scenarios and compared using a 2-sided paired *t* test. CBGs were dichotomized into those that saw increased travel times compared to no change for both car and public transit. We then used simple logistic regression to model associations between race/ethnicity and increased travel times. All analyses and visualizations were conducted in R software (version 4.3.2; R Foundation for Statistical Computing).

## Results

### Descriptive Results

A total of 2466 CBGs across metro-Atlanta were included in the analysis. More than half of the CBGs (n=1361, 55.2%) had a White plurality. An additional 943 (38.2%) CBGs had a Black plurality, 155 (6.3%) had a Hispanic/Latinx plurality, and only 2 (<1%) CBGs had a plurality of another race or ethnicity. Under baseline conditions, all CBGs had access to at least one PrEP-providing clinic by car within 30 minutes, while only 1027 (41.6%) CBGs had access via public transit within 30 minutes. A total of 567 (22.9%) CBGs did not have access to PrEP via public transit.

### Public Transit Changes in Access

Across the 3 simulated CBO closure scenarios (N=2466), 732 (29.6%) CBGs experienced longer average public transit times to the nearest PrEP clinic compared with current access. These CBGs represented approximately 1,024,900 residents or about 27.8% of Atlanta's total population. The average change in one-way transit time was 1.2 (range 0.0-11.6) minutes, which was significantly longer than the baseline ($P$<.001). Seven CBGs lost access to a PrEP clinic or CBO via public transit in the modeled closure scenarios. Compared to CBGs with a White plurality, the odds of experiencing increased transit times under the CBO closure scenarios were significantly lower for CBGs with a Hispanic plurality (odds ratio [OR] 0.61, 95% CI 0.40-0.95) but no different for CBGs with a Black plurality (OR 0.99, 95% CI 0.81-1.20).

### Drive Time Changes in Access

Across the 3 simulated CBO closure scenarios (N=2466), 1184 (48%) CBGs experienced longer average drive times to the nearest PrEP clinic compared with current access. These CBGs represented approximately 1,698,000 residents or about 46.4% of Atlanta's total population. The average change in one-way drive time was 0.5 (range 0.0-6.4) minutes, which was significantly longer than baseline ($P$=.03). Compared to CBGs with a White plurality, the odds of experiencing increased drive times under the CBO closure scenarios were significantly higher for CBGs with a Black plurality (OR 1.37, 95% CI 1.15-1.63) but no different for CBGs with a Hispanic plurality (OR 0.90, 95% CI 0.64-1.28).

## Discussion

Our research explores the potential impact of federal funding cuts on geographic access to PrEP in Atlanta, Georgia. Whereas previous research in this area was proposed to identify geographic areas within cities that would be important locational targets for new services to decrease travel times to care [23-25], we argue that this expansion-oriented framing must be complemented by models of the closing of existing facilities due to cuts in HIV prevention funding to better understand PrEP service availability and the risk of new HIV infections. Our data suggest that increases in travel times related to the closure of community providers were greater for people who used public transit, underscoring the importance of evaluating modal dimensions of transportation time to health care facilities. This is especially relevant given that communities most vulnerable to HIV are also most likely to rely on public transportation [12,26].

Although the differences in travel times might seem modest in some settings, such differences represent meaningful barriers to seeking care among marginalized groups already facing transportation disadvantages. A given level of change in commute time may result in different willingness to travel for people who use different modes of transportation or for people who do not have employment benefits that include paid time for seeking health care [26,27]. It is also important to acknowledge that HIV prevention service providers have both located their facilities in areas with high needs for prevention services, and clinics that provide services in areas with fewer community and economic resources are often set up to meet multiple care and social service needs [28]. Colocation of PrEP services with other health and social services may facilitate engagement in prevention by reducing logistical barriers, normalizing HIV prevention within broader care settings, and leveraging established trust between providers and communities. Such organizations spend decades building trusting relationships with communities, fostering trusting relationships [29,30]. Depending on which facilities close, it is foreseeable that populations with multiple medical and social service needs might lose access to a variety of services that would increase their vulnerability to HIV and other health threats.

Other aspects of our analysis reinforce the stakes in terms of health and equity considerations that would attend closures of existing PrEP-prescribing organizations. Although any licensed medical provider can provide PrEP, CBOs are disproportionately located in high-need areas and serve populations often excluded from traditional health care systems [31]. Thus, the loss of such facilities would create a double impact on PrEP accessibility:

XSL•FO
RenderX

it might create a longer commute time to the nearest PrEP provider, and it might mean that the nearest PrEP provider would be less likely to have culturally competent services [32-34]. Further, it is unclear whether existing clinics that survive the closure would have sufficient clinical capacity to provide PrEP to more patients even if prospective PrEP users are able to commute longer distances to continue to access PrEP [35,36]. Lastly, while our analysis focused on neighborhood level demographics, we know that PrEP-seeking patterns differ across multiple identity groups. For example, White men who have sex with men are more likely to access PrEP though traditional health care systems [37], while Black cisgender women and other groups with high HIV transmission tend to rely more often on community-based and safety-net providers [38]. Therefore, the loss of CBO-based PrEP services may disproportionately impact more marginalized groups.

The eventual impact of closures on the coverage of PrEP and the impacts of limitations on PrEP services are not easy to predict with confidence. However, it is clear that there are limitations to how far people will drive to obtain services for nonemergent health problems (eg, preventive services); several publications suggest that 30 minutes is a common threshold of willingness [39,40]. In any case, distance to receipt of care has an important and converse relationships with receipt of nonurgent health care, including preventive care [41]. A recent analysis suggests that even small decreases in PrEP coverage among people with indications could have substantial impacts on new HIV infections and health care costs. For example, just a 3% reduction in PrEP coverage is forecast to result in over 8000 preventable infections, with lifetime medical costs for HIV care exceeding US $3.6 billion for those infections [42].

Our findings, while empirically derived and reflective of real-world challenges to transportation to PrEP care services, have several limitations. First, we present one-way estimates of transit times, so the actual additional transportation burden to seeking PrEP care would be double the one-way estimates presented in the analysis. Simulated closures may not reflect actual likelihoods of closure; in the absence of empiric, publicly accessible data about organization-specific funding portfolios, we were unable to weight closures by likelihood and instead selected organizations randomly in the simulation. Future work incorporating such data could identify especially high-risk providers and communities. Conversely, we did not consider the likelihood of other types of organizations that provide PrEP closing; so, our estimates of impact on PrEP service might not reflect the true additional travel burden associated with the closure of facilities. Further, our analysis did not collect new data on, or consider the service capacity of, clinics; so, even if potential PrEP users were willing to travel longer distances, it is possible that existing clinics might not be able to handle an increase in the patient load.

According to our data, the closure of even a small number of current PrEP providers would have important impacts on physical access to HIV prevention services and would be predicted to increase commute times, decrease engagement in PrEP care, and result in avoidable new HIV infections and associated care costs. Therefore, our findings support sustained investment in CBOs as critical access points for HIV prevention services.

## Abstract

**Background:** Ambient ozone ($O_3$) exposure has been found to be associated with gestational hypertension, which, in turn, increases the risk of term low birth weight (LBW). As such, gestational hypertension acts as a potential mechanism mediating restricted fetal growth; however, few epidemiological studies have quantified this specific mediation pathway.

**Objective:** This study aims to examine whether gestational hypertension serves as a mediator of the association between prenatal $O_3$ exposure and term LBW.

**Methods:** We conducted a population-based cohort study using the Cheeloo Lifespan Electronic Health Research Data-library, including 3,394,739 singleton term live births in Shandong Province, China, from January 1, 2016, to December 31, 2022. We used high-resolution spatiotemporal models based on residential addresses for exposure assessment. In addition to term LBW, we examined term small for gestational age (SGA) to capture fetal growth restriction while accounting for gestational age at birth. Given the low prevalence of these outcomes, we used logistic regression models where odds ratios approximated relative risks. A 4-step mediation analysis using logistic regression was conducted, followed by a counterfactual-based causal mediation analysis, to test the mediating role of gestational hypertension.

**Results:** The mean (SD) $O_3$ concentration was 113.90 (13.03) μg $m^{-3}$. Each IQR increase in $O_3$ was positively associated with the risks of term LBW (relative risk 1.055, 95% CI 1.034-1.077) and term SGA (relative risk 1.037, 95% CI 1.026-1.048). Using the traditional approach, gestational hypertension mediated 19.94% of the risk for term LBW and 13.41% for term SGA. Under the counterfactual framework, the contribution rates were 38.82% (term LBW) and 19.96% (term SGA) when excluding exposure-mediator interaction, and 35.15% (term LBW) and 18.82% (term SGA) when accounting for such interaction.

**Conclusions:** Our findings showed that gestational hypertension was a significant mediator of the association between $O_3$ exposure and risks of term LBW. Consequently, a multitiered strategy—encompassing stricter air quality standards, integrating $O_3$ risk education into routine prenatal care, and taking proactive measures to minimize personal exposure—is essential to prevent potential adverse impacts on developing fetuses and mothers.

**KEYWORDS**

ozone exposure; low birth weight; small for gestational age; gestational hypertension; causal mediation

## Introduction

Low birth weight (LBW) is one of the major markers of fetal growth and stands as a predominant factor contributing to neonatal mortality and morbidity [1-3]. LBW infants are about 20 times more likely to die than heavier infants. Additionally, LBW is associated with adverse consequences in later life, such as neurobehavioral issues and respiratory, cardiovascular, cerebrovascular, and metabolic diseases [4-7]. LBW, which brings about a considerable disease burden and high medical costs, has presented significant challenges to health care systems. Consequently, it has been incorporated into the Sustainable Development Goals [8]. Nevertheless, despite years of strenuous efforts, merely a slight reduction in the prevalence of LBW has been noted [9], and factors such as multifetal pregnancy and maternal malnutrition, while recognized

XSL•FO
RenderX

contributors, cannot fully account for the persistent prevalence of fetal growth restriction leading to LBW.

In recent years, regions with a high prevalence of LBW often face severe air pollution. A series of investigations noted that exposure to air pollution, such as particulate matter (PM), could plausibly be involved in LBW via higher oxidative stress levels [10,11]. Compared to PM, ozone ($O_3$) is a pollutant endowed with more potent oxidative stress-inducing properties and is more challenging to mitigate through individual behavioral measures [12]. Thus, it is sensible to postulate that $O_3$ exposure might potentiate susceptibility to LBW. However, little is known about the association between $O_3$ exposure during pregnancy and the risk of LBW. Five studies have reported a positive and significant association between $O_3$ exposure and LBW [13-17], whereas findings from another 5 studies were inconsistent or mixed [18-22]. Exposure misclassification might, to some extent, account for the variability in the results, which stems from regionally specific evaluations of pollution exposure [13-15,20,22]. Several recent studies further used satellite retrieval data to attenuate exposure misclassification to a certain degree [16,18,19,21]. However, most of these studies failed to account for several fundamental covariates such as gestational temperature exposure, maternal BMI, and the smoking status of the husband, which may lead to biased results [13,14,16,18-21]. Thus, more information may be needed in future studies.

Another pressing question is through which mechanisms $O_3$ exposure during pregnancy affects fetal development in utero. Unlike acute and abruptly occurring conditions, the influence of $O_3$ on fetal development unfolds gradually throughout pregnancy. In this chronic process, $O_3$ can slow the development of the early placental vasculature and ultimately may promote maternal cardiovascular abnormalities later in gestation or intrauterine growth deficiency [23]. A wide range of studies has demonstrated that air pollution exposure could be involved in the development of hypertension through oxidative stress [24,25]. Three empirical studies focusing on the relationship between $O_3$ exposure and the risk of gestational hypertension achieved similar results [26-28]. Gestational hypertension is evidenced by a reduction in placental perfusion [29,30], and the occurrence of intravascular coagulation [31,32], which is considered to precipitate placental dysfunction and subsequently lead to LBW [33]. Given the pairwise associations, we propose that gestational hypertension may mediate the associations between $O_3$ and the risks of LBW and small for gestational age (SGA), which has yet to be studied.

To address the above gaps, our study estimated the independent effects of maternal $O_3$ exposure on term LBW and SGA based on a broad and highly representative sample, while controlling for a range of covariates. Additionally, we examined, for the first time, the mediating effects of gestational hypertension to provide evidence regarding the underlying mechanisms.

## Methods

### Study Population

This is a retrospective cohort study based on the extended version of the Cheeloo Lifespan Electronic Health Research Data-library in Shandong Province, China (Multimedia Appendix 1). Shandong is a coastal province in eastern China (34°22.9′–38°24.01′N, 114°47.5′–122°42.3′E) with approximately 100 million inhabitants and substantial geographic and socioeconomic heterogeneity across coastal and inland areas. The foundation of our data infrastructure is the Shandong Province Birth Certificate System, a national government–administered registry that integrates birth information reported by medical institutions at multiple levels across the province. This system captures standardized demographic and administrative information for nearly all newborns and their parents, including place of residence (eg, municipality or township of residence). Additional data sources include linked electronic medical records (EMRs) and electronic health records, which provide complementary information on maternal health conditions, clinical encounters, and other relevant characteristics. A unique deidentified personal identification code is systematically applied across all databases; therefore, linkage of these records enables the construction of a large population-based birth cohort. During the study period, birth records were continuously available from 16 cities and 1840 township-level administrative units across the province.

We initially identified 7,141,641 live births recorded in Shandong Province between January 1, 2016, and December 31, 2022. Among these, 6,099,731 were singleton live births. Neonatal information was routinely verified by designated quality-control personnel at delivery institutions, and data underwent consistency and range checks, with obvious logic inconsistencies corrected when possible. To improve comparability and focus on a relatively homogeneous population, we restricted the cohort to singleton firstborn live births among women aged 20 to 45 years and further limited analyses to term births (gestational age 37 - 45 wk) to reduce confounding related to prematurity, resulting in a total of 5,720,445 eligible births. We excluded records with incomplete hospitalization records or residential address information (n=2,130,147), unmarried women (n=125,465), missing $O_3$ exposure (n=70,066), and implausible birthweight values (n=28). The final analytical sample included 3,394,739 births (Multimedia Appendix 2).

### Term LBW and SGA

Our key interests were term LBW and SGA. Term LBW was defined as birth weight less than 2500 g and gestational age greater than 37 weeks. In addition, term SGA was used in the analysis because it takes gestational length into consideration. Term SGA was determined as birth weight below the 10th percentile and gestational age greater than 37 weeks according to the INTERGROWTH-21st (International Fetal and Newborn Growth Consortium for the 21st Century) fetal growth standards [34].

XSL•FO
RenderX

### $O_3$ Exposure

Daily concentrations of $O_3$, with a spatial resolution of 1 km × 1 km, were sourced from the CHAP (China High Air Pollutants) dataset. The ground-level 8-hour maximum daily average $O_3$ concentration was predicted through an ensemble learning approach using the space-time extremely randomized trees model, which incorporated solar radiation intensity, surface temperature, remote sensing products, and ground-based observations. The 10-fold cross-validation results for $O_3$ demonstrated a coefficient of determination ($R^2$) of 0.87 and a root mean square error of 17.10. Detailed information about the prediction is available elsewhere [35]. Address information for each participant was gathered and geocoded into longitude and latitude coordinates. We calculated the $O_3$ exposure levels throughout the entire pregnancy for each subject based on their home address, the date of their last menstrual period, and the date of delivery. We also calculated pregnancy exposure to PM≤2.5 µm in aerodynamic diameter ($PM_{2.5}$), PM≤10 µm in aerodynamic diameter ($PM_{10}$), nitrogen dioxide ($NO_2$), sulfur dioxide ($SO_2$), and carbon monoxide (CO) concentrations using similar methods.

### Gestational Hypertension

Gestational hypertension was identified based on the *International Classification of Diseases, Tenth Revision* (ICD-10) [36] codes documented in integrated outpatient and inpatient medical records throughout pregnancy, which were derived from EMR. Specifically, the diagnosis was determined using ICD-10 diagnostic codes O13 (gestational [pregnancy-induced] hypertension), O14 (pre-eclampsia), and O15 (eclampsia), as well as the keyword "hypertensive disorders of pregnancy." In addition, as a nationally implemented program, China's National Essential Public Health Services includes standardized maternal follow-up management, during which pregnant women are routinely assessed for pregnancy complications such as gestational hypertension. This framework may support more complete case ascertainment across health care settings, including resource-limited areas, and help mitigate potential under-ascertainment and information loss.

### Covariates

Using a directed acyclic graph (Multimedia Appendix 3) informed by the literature [37], we selected confounders that are associated with both $O_3$ exposure and birth outcomes and that, when adjusted for, remove all backdoor paths between the exposure and the outcome while minimizing overadjustment [38]. The models were adjusted for maternal age, maternal occupation (such as farmer, clerk, housewife, worker, and other categories), infant sex, gestational diabetes, and the smoking status of the husband (the prevalence of active smoking among pregnant women in China is exceptionally low) [13,18]. In addition, given the close association between temperature and $O_3$ concentration, temperature exposure during pregnancy was included. Monthly ambient temperature was obtained from the Global Surface Summary of the Month data files provided by the National Oceanic and Atmospheric Administration (NOAA), with a spatial resolution of 10 km × 10 km [39].

### Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the ethics committee of the Shandong University School of Public Health (LL20240334). The requirement for informed consent was waived because all data were anonymized.

### Statistical Analysis

We used logistic regression models to estimate the associations of an IQR increase in $O_3$ concentration with term LBW and SGA. Given the low prevalence of these outcomes in our study population (typically <10%), the odds ratios (ORs) derived from logistic regression were considered reasonable approximations of relative risks (RRs) [40]. Consequently, we reported the results as RRs and 95% CIs. To ensure the robustness of our findings, 3 sensitivity analyses were conducted. First, Cox proportional hazards models were fitted using gestational age (wk) as the time scale to incorporate time-to-event data. Second, 2-pollutant models were established by adjusting for $PM_{2.5}$, $PM_{10}$, $NO_2$, $SO_2$, and CO to isolate the independent effect of $O_3$. Third, maternal BMI was added to control for nutritional status; missing BMI data were imputed using the "*missForest*" algorithm prior to analysis (Multimedia Appendix 4). Fourth, to address potential biases arising from (1) incomplete residential addresses or failed hospitalization record linkages and (2) nonrandom missingness of $O_3$ exposure data, and to improve the representativeness of the analytic sample, we used a weighted logistic regression model supplemented by robust variance estimation. We first derived calibration weights for records with complete residential address and hospitalization information. These weights were constructed by calibrating the distribution of key demographic variables (eg, maternal age, infant sex, and gestational age) in our complete-case sample to the eligible population, thereby adjusting for potential bias due to missingness in these essential identifiers [41]. Next, to account for nonrandom missingness in $O_3$ exposure assessment (eg, dependent on geographic location), we estimated inverse probability of selection weights (IPSWs) [42]. The IPSWs were derived from a logistic regression model predicting inclusion in the exposure-assessed analytic sample based on maternal age, infant sex, gestational diabetes, the smoking status of the husband, and maternal occupation. The final analytic weight for each participant was obtained by multiplying the calibration weight and the IPSW. To ensure numerical stability and facilitate variance estimation, the composite weights were normalized to sum to the actual sample size (ie, mean weight=1). Additional details are provided in Multimedia Appendix 5.

Stratified analyses were conducted based on (1) maternal age (<30 y vs ≥30 y, with the latter marking the initial decline in fecundity and ovarian function [43]; (2) infant sex (female vs male) [44]; and (3) coastal residence (coastal vs inland) to account for geographic environmental differences [45,46].

The hypothesis that the association of $O_3$ exposure with term LBW and SGA would be mediated by gestational hypertension was tested using a 4-step analysis. The method involved testing the total effect (TE) of $O_3$ exposure with term LBW and SGA and then estimating how much the association was reduced by

XSL•FO
RenderX

the inclusion of gestational hypertension. Using a logistic regression model, the TE, represented as the RR of term LBW or SGA linked to an IQR rise in $O_3$ exposure, was divided into direct and indirect effects in line with the methodology described by Buis [47]. The mediating role of gestational hypertension was quantified and evaluated within the framework of a Cox proportional hazards model.

To gain a deeper understanding of the underlying causal processes, a mediation approach based on the counterfactual framework for causal inference was adopted. In contrast to traditional methods, this framework defines mediation effects using counterfactual scenarios. This enables a more precise exploration of how the exposure and the potential mediator jointly affect the outcome [48,49]. In this counterfactual framework, the TE was defined as the RR of term LBW or SGA related to an IQR increase in $O_3$ exposure, comparing the 75th percentile to the 25th percentile. This was calculated while adjusting for covariates and allowing gestational hypertension to occur naturally. Following Pearl's [50] approach for the risk difference scale, the TE was expressed as the product of the ORs for the natural direct effect and the natural indirect effect (NIE) [49]. The natural direct effect was estimated by comparing $O_3$ exposure at the 75th percentile versus the 25th percentile, while keeping gestational hypertension at the level it would have been under the 25th percentile of $O_3$ exposure. The NIE was defined as the change in odds resulting from gestational hypertension when $O_3$ exposure increased by an IQR. It represents the part of the causal pathway from exposure to outcome that was mediated by gestational hypertension. The proportion mediated was computed as log(NIE)/log(TE), following the method of Imai et al [51]. The details of the analysis are presented in Multimedia Appendix 6.

All statistical analyses were conducted using R (version 4.4.0; R Foundation for Statistical Computing) and Stata (version 17.0, StataCorp LLC). Bias-corrected standard errors and 95% CIs were estimated using bootstrapping with 1000 replications. All statistical tests were 2-sided, with a significance level set at $\alpha$=.05.

## Results

### Descriptive Results

Table 1 presents the descriptive characteristics of the study population. Among the 3,394,739 term births included in this study, 1,615,993 (47.6%) were female. The overall prevalence of term LBW and SGA infants was 0.89% and 3.34%, respectively. Notably, a higher incidence of both term LBW and SGA was observed among mothers diagnosed with gestational hypertension. Regarding the air pollution levels during the study period, the summary statistics are shown in Table 2. The mean (SD) $O_3$ concentration during pregnancy was 113.90 (13.03) μg $m^{-3}$. Furthermore, $O_3$ exposure was correlated with other pollutants, with the Pearson correlation coefficients ranging from –0.47 to 0.75.

## Association Between $O_3$ Exposure and Term LBW or SGA

Table 3 illustrates the associations of $O_3$ exposure with term LBW and SGA across various adjusted models. Based on logistic regression models, each IQR increase in $O_3$ concentration was significantly associated with elevated risks of term LBW (RR 1.055, 95% CI 1.034-1.077) and SGA (RR 1.037, 95% CI: 1.026-1.048). The median (IQR) $O_3$ concentration was 112.70 (19.93) μg/m$^3$. These results were corroborated by Cox proportional hazards models, yielding hazard ratios of 1.071 (95% CI 1.049-1.093) and 1.081 (95% CI 1.069-1.092) for term LBW and SGA, respectively. Sensitivity analyses adjusting for maternal BMI (original and imputed) and co-pollutants confirmed the robustness of our findings. The weighted model produced RRs consistent with the main model (term LBW: RR 1.055, 95% CI 1.032 - 1.077; term SGA: RR 1.033, 95% CI 1.022 - 1.044). Additionally, stratified analyses showed stable positive associations across subgroups of maternal age, infant sex, and coastal residence (Multimedia Appendix 7).

**Table .** Associations between maternal ozone exposure and the risks of term low birth weight (LBW) and term small for gestational age (SGA) among singleton term births in Shandong Province, China, 2016 - 2022[a].

| Model | RR[b] (95% CI) | |
|---|---|---|
| | Term LBW (n=3,394,739) | Term SGA (n=3,394,049) |
| Main model[c] | 1.055 (1.034-1.077) | 1.037 (1.026-1.048) |
| Cox model[d] | 1.071 (1.049-1.093) | 1.081 (1.069-1.092) |
| Main model adjusted for maternal BMI[e] | 1.051 (1.021-1.082) | 1.033 (1.018-1.049) |
| Main model adjusted for imputed maternal BMI[f] | 1.056 (1.034-1.078) | 1.040 (1.029-1.051) |
| Main model adjusted for $PM_{2.5}$[g] | 1.058 (1.034-1.082) | 1.072 (1.060-1.085) |
| Main model adjusted for $PM_{10}$[h] | 1.051 (1.028-1.074) | 1.063 (1.051-1.075) |
| Main model adjusted for $NO_2$[i] | 1.056 (1.033-1.079) | 1.048 (1.036-1.060) |
| Main model adjusted for $SO_2$[j] | 1.040 (1.017-1.063) | 1.047 (1.035-1.059) |
| Main model adjusted for CO[k] | 1.061 (1.038-1.085) | 1.057 (1.045-1.069) |
| Main model adjusted for gestational hypertension | 1.034 (1.013-1.055) | 1.029 (1.019-1.040) |
| Weighted model [l] | 1.055 (1.032-1.076) | 1.033 (1.022-1.044) |

[a]Effect estimates were expressed per IQR increase in $O_3$. The median (IQR) $O_3$ concentration was 112.70 (19.93) μg/m³.

[b]RR: relative risk.

[c]Main model: single-pollutant model for $O_3$ adjusted for maternal age, infant sex, temperature, maternal occupation, gestational diabetes, and the smoking status of the husband.

[d]Cox proportional hazards model (time scale: gestational age): adjusted for maternal age, infant sex, temperature, maternal occupation, gestational diabetes, and smoking status of the husband. Results are presented as hazard ratios (HRs) with 95% CIs.

[e]The sample size of maternal BMI was 1,556,480.

[f]Missing values were imputed using the missForest algorithm.

[g]$PM_{2.5}$: fine particulate matter with a diameter of 2.5 μm or smaller.

[h]$PM_{10}$: particulate matter with a diameter of 10 μm or smaller.

[i]$NO_2$: nitrogen dioxide.

[j]$SO_2$: sulfur dioxide.

[k]CO: carbon monoxide.

[l]Adjusted for maternal age, infant sex, gestational diabetes, maternal occupation, smoking status of the husband, and temperature category. Final weights were calculated as ranking weights multiplied by inverse probability of selection weight (IPSW) truncated at the 99th percentile.

Notably, while $O_3$ exposure remained significantly associated with adverse outcomes after adjusting for gestational hypertension, the effect estimates were slightly attenuated (term LBW: RR 1.034, 95% CI 1.013-1.055; term SGA: RR 1.029, 95% CI 1.019-1.040), suggesting a potential mediating pathway, as shown in Table 4.

| Mediation effect (%) | 35.15 | 18.82 |

[a]The use of the bootstrap was proposed to estimate standard errors.

[b]RR: relative risk.

### The Mediation of Gestational Hypertension

Exposure to $O_3$ was correlated with an elevated risk of developing gestational hypertension, with an OR of 1.162 (95% CI 1.149-1.175). Additionally, individuals who experienced gestational hypertension were more likely to deliver babies with term LBW (RR 6.499, 95% CI 6.300-6.706) and term SGA (RR 2.767, 95% CI 2.703,2.832; Multimedia Appendix 8). Table 4 presents the indirect contribution of gestational hypertension in the association between $O_3$ exposure and term LBW or SGA. We found that gestational hypertension partly mediated these associations. Gestational hypertension accounted for 19.94% and 13.41% of the association between $O_3$ exposure and term LBW or SGA, respectively. Under the framework of Cox proportional hazards models, consistent results were observed, with mediation proportions of 31.28% for term LBW and 11.35% for term SGA (Multimedia Appendix 9).

Under the counterfactual framework, the contribution of gestational hypertension to the association between prenatal $O_3$ exposure and term LBW was 38.82% when excluding exposure-mediator interaction, and 35.15% when accounting for such interaction. For term SGA, the corresponding contribution rates were 19.96% (without interaction) and 18.82% (with interaction), respectively.

## Discussion

### Principal Findings

To our knowledge, this is the first study to investigate the mediation effects of gestational hypertension in the associations of $O_3$ exposure during pregnancy with term LBW and SGA. Based on a birth cohort of 3,394,739 samples in China, this study provides novel findings by demonstrating the independent effect of $O_3$ exposure on term LBW and SGA. Additionally, mediation analysis revealed that the proportion of the effect of $O_3$ exposure on term LBW and SGA mediated through gestational hypertension ranges from 13.41% to 19.94%. This study holds significant implications for the surveillance and management of maternal blood pressure during prenatal care and contributes to our comprehension of the underlying mechanisms regarding the associations of $O_3$ exposure with term LBW and SGA.

### Associations Between Prenatal $O_3$ Exposure and Term LBW

Previous studies have revealed that PM exposure might impact fetal growth through elevated oxidative stress levels [10,11]. As another major ambient air pollutant, $O_3$, with more powerful oxidative stress-eliciting characteristics [12], may act indirectly on the fetus by inducing oxidative stress, inflammatory responses, and hormonal imbalances in the mother [52]. These maternal states, over time, may disrupt normal placental function and fetal development, ultimately resulting in LBW [23]. Our study indicated a similarly notable association between $O_3$ exposure during pregnancy and term LBW as well as term SGA. This is consistent with nationwide studies conducted in the United States with 2,179,040 participants and Iran with 4,030,383 participants [13,16]. However, some recent studies have reported conflicting findings [18-22], which may be

XSL•FO
RenderX

attributed to differences in study design and the statistical models used.

It is well-known that variability in exposure assessment approaches is an important source of variability in effect estimates between different studies. Unlike previous studies that estimated exposure based on data from fixed monitoring stations, we used $O_3$ concentrations retrieved from satellite remote sensing to calculate individual $O_3$ exposure levels throughout pregnancy. This approach enables a more reliable estimation of the impact of $O_3$ exposure on adverse birth outcomes. Additionally, by leveraging enriched indicators from EMRs and electronic health records, this study incorporated maternal and paternal information into the analytical models based on an extensive sample covering the period from 2016 to 2022. These factors have been demonstrated to potentially confound the associations under investigation [53]. A series of robust analyses further validates the reliability and significance of our results. Our findings provide justification for addressing air pollution-related adverse birth risk to achieve Sustainable Development Goals.

### Gestational Hypertension Mediated Partly the Associations Between Prenatal $O_3$ Exposure and Term LBW

Fetal growth and development in utero are a continuous process, indicating that the impact of air pollution during pregnancy is likely to be long-term and chronic. Consequently, pregnancy complications and the associated physiological changes in the mother may play a crucial role in mediating these effects. Several studies have used effect modification to explore the mechanisms by which air pollution exposure affects birth outcomes, although the process through which air pollution exposure causes LBW remains elusive. Recent studies, including ours, have suggested that $O_3$ or $PM_{2.5}$ exposure in the first trimester is associated with gestational hypertension [26-28,54]. There is also evidence that gestational hypertension increases the risk of LBW [55,56]. Exposure to $O_3$ may not only contribute to gestational hypertension but may also generate intergenerational effects, resulting in term LBW and SGA. However, none of these studies have explored whether gestational hypertension could link $O_3$ exposure to adverse birth outcomes.

This present study found that gestational hypertension significantly mediated 13.41% and 19.94% of the association between $O_3$ exposure and term LBW or SGA, respectively. These findings provide strong evidence that gestational hypertension occurring in later pregnancy, along with associated placental perfusion abnormalities, significantly mediates the effect of $O_3$ exposure on fetal growth restriction. After entering the body, $O_3$ primarily affects the respiratory and circulatory systems, where it induces oxidative stress and disrupts vascular tone regulation [57]. Mechanistically, $O_3$-related oxidative stress and inflammation may impair endothelial function and activate vasoactive pathways, including the renin-angiotensin system (eg, angiotensin-converting enzyme/angiotensin II) and endothelin-1 signaling, thereby contributing to elevated blood pressure [58]. These changes may provoke enhanced sympathetic activity, thereby augmenting the risk of gestational hypertension [59]. Supporting evidence from pregnant animal models shows that mid-gestational $O_3$ exposure can induce a mild but significant increase in maternal arterial blood pressure [57]. Gestational hypertension may adversely affect placental blood supply, leading to suboptimal perfusion [31,32,60]. This impairment restricts the delivery of oxygen and nutrients to the fetus [30]. Ultimately, such deprivation significantly increases the risk of low birth weight. In addition, experimental studies indicate that prenatal $O_3$ exposure can increase circulating soluble fms-like tyrosine kinase-1 and elevate uterine artery resistance, accompanied by placental transcriptional changes consistent with preeclampsia-related pathways, providing biological plausibility for placental vascular maladaptation [61]. Beyond circulatory effects, $O_3$ exposure may contribute to fetal growth disturbances through maternal chronic inflammation. Some inflammatory mediators, including interleukin-17A, have been shown to cross the placental barrier and potentially influence fetal developmental regulation [62].

To further quantify this mediation pathway, causal mediation analysis was conducted. When allowing for exposure-mediator interaction, the mediation effects were 35.15% for term LBW and 18.82% for term SGA. These findings suggest that, beyond acting through independent primary pathways, $O_3$ exposure and gestational hypertension may also exert synergistic effects that exacerbate intrauterine fetal development impairments. Moreover, the mechanisms underlying these associations appear to be more complex than previously understood. Taken together, interventions or policies addressing $O_3$ exposure should coordinate the health risks for mothers and neonates. Efforts to reduce the risks of LBW should be tailored to focus on mothers with gestational hypertension, while recognizing early warning signs of $O_3$ exposure.

Collectively, we propose a multitiered strategy to mitigate the adverse effects of $O_3$ exposure. At the policy level, stricter enforcement of air quality standards and the development of pregnancy-specific health warning systems are essential. Within the health care system, $O_3$ risk education should be integrated into routine prenatal care, particularly for high-risk populations. At the individual level, we recommend that pregnant women monitor air quality indices, minimize outdoor activities during peak pollution, use indoor air purifiers, and maintain an antioxidant-rich diet. Synergistic efforts across these sectors are required to effectively protect maternal and fetal health.

### Contributions and Limitations

This study enriches the growing body of literature in 2 aspects. First, it evaluates the associations between $O_3$ exposure and the health risks faced by mothers and neonates, thereby enhancing understanding of the intergenerational impacts. Second, it reveals the mediating role of gestational hypertension within the aforementioned association, aiming to comprehensively illustrate the mechanisms underlying these associations.

However, our study has several limitations. First, exposure misclassification was a potential issue in our research. Specifically, using a single address to estimate $O_3$ exposure

XSL•FO
RenderX

may not accurately reflect personal exposure, as individuals may commute to workplaces during the day. Due to data limitations, indoor air pollution was not accounted for. However, given the large sample size, the impact of exposure misclassification primarily manifests as a dilution of the study's effect, making it unlikely to fundamentally reverse the association we observed. Second, gestational hypertension was ascertained using ICD-10 codes from pregnancy-related outpatient and inpatient EMRs, which may have under-captured milder or undiagnosed cases, particularly in rural or medically underserved settings. Such under-ascertainment could underestimate the prevalence of gestational hypertension and bias the estimated associations toward the null. Nevertheless, China's National Essential Public Health Services include standardized maternal follow-up management, during which pregnant women are routinely assessed for conditions such as gestational hypertension, which may support more complete case ascertainment across health care settings. Future studies could link more granular clinical data (eg, serial blood pressure measurements and proteinuria indicators) to construct a more sensitive phenotyping definition, thereby validating and potentially refining the effect estimates reported here. Third, although covariates were selected a priori using a directed acyclic graph, residual confounding from unmeasured factors (eg, diet or other environmental exposures not available in our database) cannot be completely ruled out. Fourth, we recognize that the process of constructing the analytic sample may have introduced selection bias, potentially affecting the generalizability of our findings. Approximately 40% of eligible births were not included in the analytic sample, largely due to unsuccessful linkages to hospitalization records, incomplete residential addresses, and non-random missingness in $O_3$ exposure data. Compared with the eligible population, the average maternal age in our analytic sample was slightly lower (29.85 y, SD 4.82 vs 30.16 y, SD 4.91), with a small standardized mean difference of 0.062. Infant sex was nearly identical (female 47.6% in the analytic sample vs 47.7% in the eligible population; standardized mean difference=0.003). The limited imbalance in measured age and sex distributions suggests our sample is representative. Additionally, evidence from prior hospital-based birth cohorts in China [63] suggests that excluding participants with missing address data or failed geocoding does not correlate with a higher risk of adverse birth outcomes. In summary, while selection bias cannot be entirely ruled out, its impact is likely minimal. To reduce the potential bias, a weighting analysis has been applied. Sensitivity analyses using weighting methods yielded consistent estimates, thereby reinforcing the validity and robustness of our primary conclusions. In future studies, we will refine the data collection process by strengthening multisource record linkages and improving the precision of residential history tracking to further enhance data completeness and minimize potential selection bias. Fifth, our study was restricted to Shandong Province, China; therefore, caution is warranted when extrapolating the findings to regions with different climatic conditions, demographic structures, health care access, or pollutant concentrations, which may yield heterogeneous associations. Shandong spans substantial east-west variation and shares several natural and socioeconomic characteristics with China overall, providing a reasonable basis for examining the health implications of $O_3$ exposure. Subgroup analyses also support the robustness of this study. However, the exposure distribution in our cohort was dominated by relatively high ambient $O_3$ levels. Accordingly, applying these estimates to areas with lower $O_3$ concentrations should be done cautiously, as the underlying exposure distribution may differ from that of our study population.

## Conclusions

This study provides, for the first time, robust evidence quantifying gestational hypertension as a significant mediator between prenatal $O_3$ exposure and adverse birth outcomes—19.94% for term LBW and 13.41% for term SGA. Using a counterfactual mediation framework, we clarify a key biological pathway linking air pollution to impaired fetal growth. These findings highlight the need to integrate $O_3$ pollution control into prenatal health guidance and strengthen blood pressure monitoring during pregnancy. Future research should validate these associations across diverse populations and investigate underlying biological mechanisms, such as oxidative stress.

## Abstract

**Background:** Air pollution continues to impose a substantial health and economic burden in China. Despite recent improvements, national annual average PM2.5 (fine particulate matter) concentrations remain substantially above the levels deemed safe by the World Health Organization (WHO), underscoring the need for more stringent air quality control.

**Objective:** This study aims to quantify the projected health and economic benefits of reducing PM2.5 concentrations in China under the Healthy China 2030 plan.

**Methods:** Using the 2020 ground-level PM2.5 data as a baseline, we projected cause-specific mortality and morbidity outcomes for 337 prefecture-level cities in China from 2020 to 2030 under four policy scenarios: (1) Healthy China 2030 (10% reduction by 2025; 25 μg/m³ by 2030) and the WHO targets of (2) 15 μg/m³, (3) 10 μg/m³, and (4) 5 μg/m³ by 2030. Mortality for noncommunicable diseases, lower respiratory infections, stroke, ischemic heart disease, lung cancer, and chronic obstructive pulmonary disease was estimated using the Global Exposure Mortality Model. Hospitalizations were modeled using log-linear models based on national evidence.

**Results:** In 2020, PM2.5 concentrations across the 337 cities ranged from 7 to 63 μg/m³, with a national annual mean of 32.6 μg/m³. Higher concentration levels were observed in eastern China, particularly in the eastern and southeastern regions. Overall, our analysis accounted for nearly 70% of the total population of China in 2020. Our analysis shows that maintaining PM2.5 at 2020 levels was projected to result in 9.04 million (95% CI 7.70 - 10.67 million) attributable deaths, compared with 8.63 million (95% CI 7.42 - 10.30 million) under the policy scenario, corresponding to 0.41 million premature deaths averted under the 14th Five-Year Clean Air Plan. Over 2021 - 2030, PM2.5-attributable deaths declined from 17.76 million (95% CI 14.21 - 20.95 million) under baseline conditions to 15.96 million (95% CI 12.85 - 19.15 million) under the policy scenario. Achieving WHO targets would further reduce attributable deaths to 13.99 million (95% CI 11.25 - 15.25 million) at 15 μg/m³, 12.86 million (95% CI 10.85 - 14.85 million) at 10 μg/m³, and 11.49 million (95% CI 8.96 - 13.45 million) at 5 μg/m³. The annual average hospitalizations declined by 21,422 cardiovascular and 26,545 respiratory admissions under the policy scenario, increasing to 41,690 and 51,681 at 15 μg/m³, 51,884 and 64,333 at 10 μg/m³, and 62,146 and 77,073 at 5 μg/m³, respectively. Subsequently, total economic gains reached US $123.7 billion under the policy scenario and increased to US $185.7 billion, US $240.7 billion, and US $306.5 billion under the 15, 10, and 5 μg/m³ scenarios, respectively.

**Conclusions:** Our findings suggest that while the Healthy China 2030 Plan offered substantial health gains, achieving stricter WHO air quality targets could yield 2-3 times greater benefits. These findings will support the future development of stricter evidence-based national air quality standards.

## Introduction

Ambient air pollution represents a major global environmental health challenge. In 2019, the World Health Organization (WHO) estimated that exposure to outdoor air pollution was responsible for more than 4.2 million premature deaths worldwide [1]. In particular, there is a growing body of epidemiological evidence linking exposure to fine particulate matter (PM) with increased risks of cardiovascular and respiratory diseases, lung cancer, and premature mortality [2-6]. In addition to the substantial health burden, exposure to PM2.5 also imposes considerable economic costs, including direct health care expenditures from air pollution–induced illnesses, increased hospitalizations, and indirect losses from reduced workforce productivity [7]. In particular, the burden falls disproportionately on low- and middle-income countries, where around 80% of individuals exposed to unsafe annual PM2.5 concentrations reside and nearly 90% of air pollution–related premature deaths occur [1,8]. Recognizing the increasing health and economic burden associated with exposure to elevated levels of PM, many low- and middle-income countries have introduced national policies aimed at reducing PM levels. For example, countries in Southeast Asia, such as Indonesia, Vietnam, and Thailand, have implemented mitigation strategies to varying degrees, including the establishment of ambient air quality standards, the introduction of emission controls across key sectors, such as transport, industry, and energy, and the strengthening of air quality monitoring systems, with the aim of reducing both emission levels and population exposure [9-11]. In India, the National Clean Air Program has been associated with substantial improvements in urban air quality, with declines in PM10 concentrations across 20 major cities, and is estimated to have averted approximately 62,219 excess mortalities in 2021 compared to 2018 [12].

In China, ambient air pollution remains a critical public health issue, contributing to an estimated 1.67 million premature deaths nationwide in 2020 [13]. Exposure to PM is the nation's fourth leading risk factor for overall mortality and disability-adjusted life years [14]. Overall, this contributes substantially to both the health and economic burden, with several studies estimating associated annual economic losses ranging from 0.92% to 3.6% of the national gross domestic product (GDP) within the past decade [13,15,16]. The Chinese government introduced the Air Pollution Prevention and Control Action Plan in 2013, setting ambitious targets to reduce pollution levels [17]. The plan aimed to lower PM concentrations in prefecture-level cities and above by at least 10% from 2012 levels by 2017. Consequently, the annual average PM2.5 concentration in 74 major cities declined by 33.3%, from 72.2 μg/m³ in 2013 to 47.0 μg/m³ in 2017 [18]. This improvement has resulted in substantial health benefits, including the reduction of 47,240 deaths and the prevention of 710,020 years of life lost [18].

In 2021, the WHO updated its air quality guidelines, lowering the recommended annual average PM2.5 concentration to 5 μg/m³ [19]. This revision reflects a growing body of epidemiological evidence demonstrating that both short-term and long-term exposure at low threshold levels to PM can still result in adverse health effects [3,4,20]. Despite significant improvements in air quality, PM2.5 levels in 2020 remained 7 times higher than the updated recommended limit. Han et al [21] estimated that long-term exposure to ambient PM2.5 above the new WHO guideline was associated with approximately 1.4 million premature deaths and US $1006.9 billion in the total value of statistical life annually. As part of its commitment to building a "Beautiful China," the government introduced a new set of air quality standards under the latest Clean Air Action Plan, aiming to reduce the annual mean PM2.5 concentration by 10% between 2020 and 2025 and achieving the interim target of 25 μg/m³ by 2030 [22,23]. This initiative underscores China's ongoing efforts to mitigate the health and economic burdens associated with air pollution.

Currently, much is known about the national health and economic disease burden associated with PM2.5 exposure. For example, Maji et al [13] estimated the disease burden associated with PM2.5 across 338 cities, reporting that PM2.5-attributable mortality reached 0.964 million in 2016, accounting for 9.98% of total reported deaths in China that year. Other national-level estimates since 2010 have ranged from 1.02 to 2.20 million deaths [24-28]. Additionally, several studies have also retrospectively examined the benefits of previous air quality guidelines or policies, either nationally or at a regional level. Xu et al [29] assessed the health and economic impacts of clean air policies in the Beijing-Tianjin-Hebei region, estimating a reduction of 24,000 premature deaths and associated economic benefits of US $60 billion. Zhang et al [30] compared the benefits of the previous 5-year Clean Air Action Plan with its implementation costs, reporting that the public health benefits of air quality improvements were 1.5 times greater than the mitigation costs. However, the understanding of the potential benefits of future air quality improvements, particularly those projected under the latest clean air policies, remains limited. Given the significant gap between current national air quality standards and WHO recommendations, evaluating the health and economic impacts of national air policies is essential for supporting evidence-based decision-making as China advances toward its Healthy China 2030 goals. To bridge this dearth of evidence, we modeled the attributable health and economic outcomes associated with achieving the latest national regulations from 2021 to 2030, as well as the additional benefits associated with reaching the more stringent WHO targets of 15, 10, and 5 μg/m³ over the same period from a health system perspective.

## Methods

### Policy Scenarios and Model Period

We projected cause-specific mortality and morbidity outcomes for 337 prefecture-level cities in China from 2020 to 2030 under several air quality improvement scenarios. These include (1) a 10% reduction in PM2.5 by 2025, targeting 25 μg/m³ by 2030, representing the policy scenario under the current clean air action plan; (2-3) a stepwise reduction to WHO interim targets, with annual PM2.5 concentration levels reaching 15 μg/m³ (Interim Target III), and 10 μg/m³ (Interim Target IV) by 2030, respectively; and (4) achieving the WHO's recommended air quality guideline of 5 μg/m³ by 2030. To account for population

XSL•FO
RenderX

changes, age-specific and sex-specific baseline population data were projected for the modeled period under shared socioeconomic pathways for each of the air quality scenarios. Table S1 in Multimedia Appendix 1 presents the matrix summarizing the air quality scenarios and population projections considered in this analysis.

### Statistical Analysis

We used the widely used health impact function to model mortality and morbidity outcomes under the policy scenarios [31]. Specifically, the health impact function is given as follows:

$$\Delta y = x0 \times (RR - 1)RR \times Pop$$

where the health end point attributable to PM2.5 Δy) is a function of the baseline incidence rate x0, the population attributable risk [(RR-1)/RR], and the population at risk (Pop). Mortality outcomes included the combined category of noncommunicable diseases and lower respiratory infections (NCD + LRI), alongside 5 specific causes: stroke, ischemic heart disease (IHD), chronic obstructive pulmonary disease (COPD), lung cancer (LC), and LRIs. Morbidity outcomes assessed included hospital admissions related to cardiovascular and respiratory conditions.

### Mortality Attributable to PM2.5 Exposure

Mortality attributable to PM2.5 exposure under baseline and policy scenarios was estimated using the global exposure mortality model (GEMM), which provides age-specific and cause-specific hazard ratios for nonaccidental mortality [32]. The GEMM is a multivariate random effects model that synthesizes evidence from 41 cohort studies globally to characterize the exposure-response relationship between ambient air pollution and nonaccidental mortality and has been widely applied in health assessment studies of ambient air pollution internationally. Details of the model have been described elsewhere [32]. In brief, the GEMM characterizes the exposure-response relationship as:

$$GEMM(z) = \exp\{\theta \log(z\alpha + 1)/(1 + \exp\{-(z - \mu)/\nu\}\}, \text{where } z = \max(0, PM25 - 24)$$

where θ, α, $\mu$, and ν are parameters that define the shape of the relationship. We selected the GEMM as it provides the most up-to-date risk estimates for the relationship between ambient air pollution and mortality globally, incorporating risk information from high-pollution regions, such as China. Additionally, the GEMM has demonstrated that mortality estimates attributable to PM exposure may be several times higher compared to those derived from other previously used risk functions, which integrate exposure data from multiple sources, including both indoor and outdoor environments [32,33]. Table S2 in Multimedia Appendix 1 provides details on the parameters of the GEMM.

### Morbidity Attributable to PM2.5 Exposure

Cardiovascular and respiratory disease–specific hospital admissions attributable to PM2.5 exposure were estimated using log-linear models. Log-linear models have previously been used in the literature for the assessment of PM2.5-related mortality and morbidity outcomes, particularly in high pollution regions, such as China [13,34,35]. Specifically, the function is defined as follows:

$$RR(z) = \exp[\beta(z - z0)]$$

where β denotes the exposure-response coefficient, representing the change in the incidence of the disease-specific outcome for each μg/m³ increase in PM2.5 concentration, and z0 is the threshold concentration. Consistent with recent epidemiological evidence demonstrating that PM2.5 exposure can have adverse health effects even at low concentrations, no threshold concentration was applied in this analysis. Table S3 in Multimedia Appendix 1 provides an overview of the disease-specific mortality and morbidity outcomes assessed in this study, along with the corresponding exposure-response coefficients derived from national and international studies.

### Estimating Health and Economic Benefits

To estimate the economic impact of reductions in mortality and morbidity, we used the value-of-statistical life (VSL) and cost-of-illness (COI) methods. Briefly, VSL represents the monetary value assigned to reducing the risk of mortality, offering a quantitative basis for informing government decisions on environmental and health policies [36]. The estimate is derived from survey-based assessments of individuals' stated willingness to pay for incremental reductions in mortality risk [37]. To ensure the estimates adequately reflected the risk and income specific to the Chinese context, we used VSL values derived from a recent national-level study, estimated at US $689,659 [38]. To quantify morbidity benefits, we used the COI method, which estimates the economic burden of disease [39]. Reductions in direct costs were estimated by multiplying the average hospitalization costs for cardiovascular and respiratory diseases by the projected decrease in hospital admissions under improved air quality scenarios. Baseline figures in 2020 were projected using time series regression, assuming that historical trends continued over the modeled period. We use a 5% discount rate, consistent with China's economic evaluation guidelines [40].

In our reporting, we adhered to the GATHER (Guidelines for Accurate and Transparent Health Estimates Reporting) guidelines (Checklist 1).

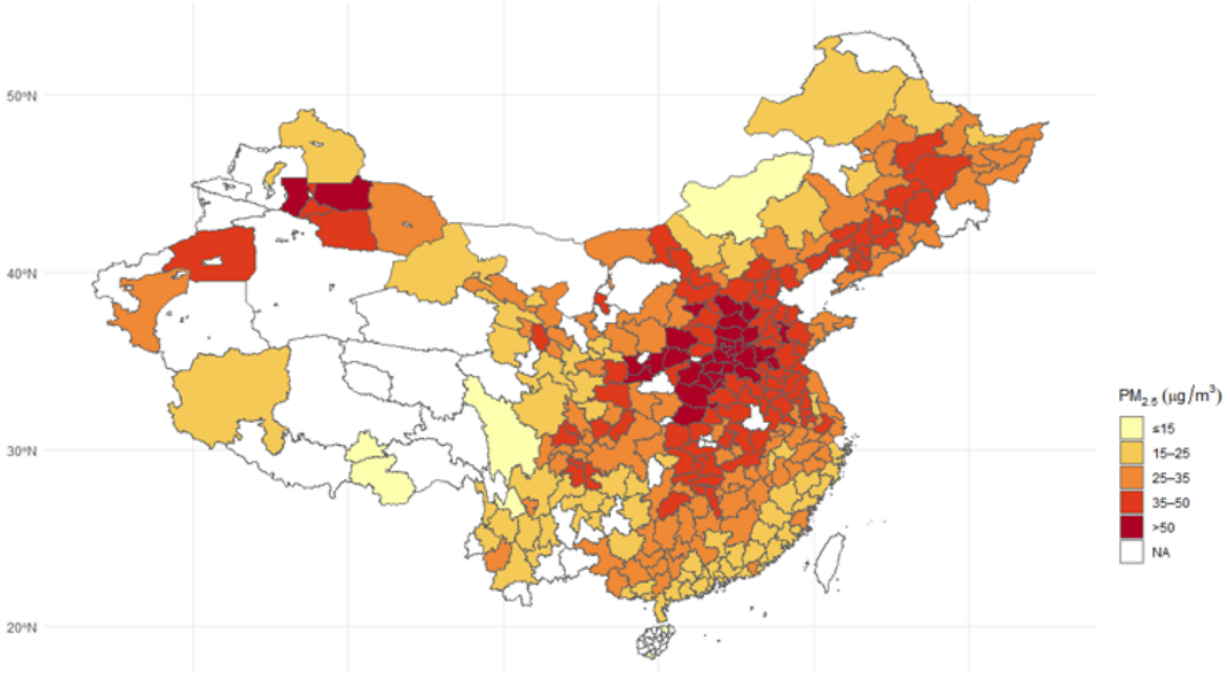
### Data Source

Air quality monitoring data between January 1 and December 31, 2020, were collected from the National Environmental Monitoring Center, which contain hourly PM2.5 concentrations collected from 1497 monitoring sites in 338 Chinese cities at the prefectural level and above. In our analysis, the annual mean PM2.5 concentrations at the city level were obtained by aggregating hourly monitoring data to annual averages at each station and subsequently assigning these values to the corresponding administrative city unit by averaging across stations within each city. For baseline age-specific and cause-specific mortality in 2020, national-level estimates disaggregated by region (western, central, and eastern China) were utilized in the absence of city-level data. These estimates were derived from the Centers for Disease Control and Prevention's mortality surveillance system, a national death registry covering over 605 counties and districts (21.1% of all counties and districts in China) [41]. Baseline mortalities under the business-as-usual scenario were projected for the modeled period using estimates from an existing study, which assessed

XSL•FO
RenderX

risk factor exposures and associated noncommunicable disease mortality trends based on Global Burden of Disease data through 2030 [42]. For morbidity, baseline cardiovascular and respiratory hospitalization incidences and hospitalization costs were sourced from national and provincial statistical yearbooks and projected forward based on historical trends [43]. Moreover, age-specific and sex-specific baseline demographic data for 337 cities in 2020 were also extracted from statistical yearbooks. Table S4 in Multimedia Appendix 1 presents the primary data sources used in our health prediction model, while Table S5 in Multimedia Appendix 1 summarizes the key assumptions underlying our analyses.

### Ethical Considerations



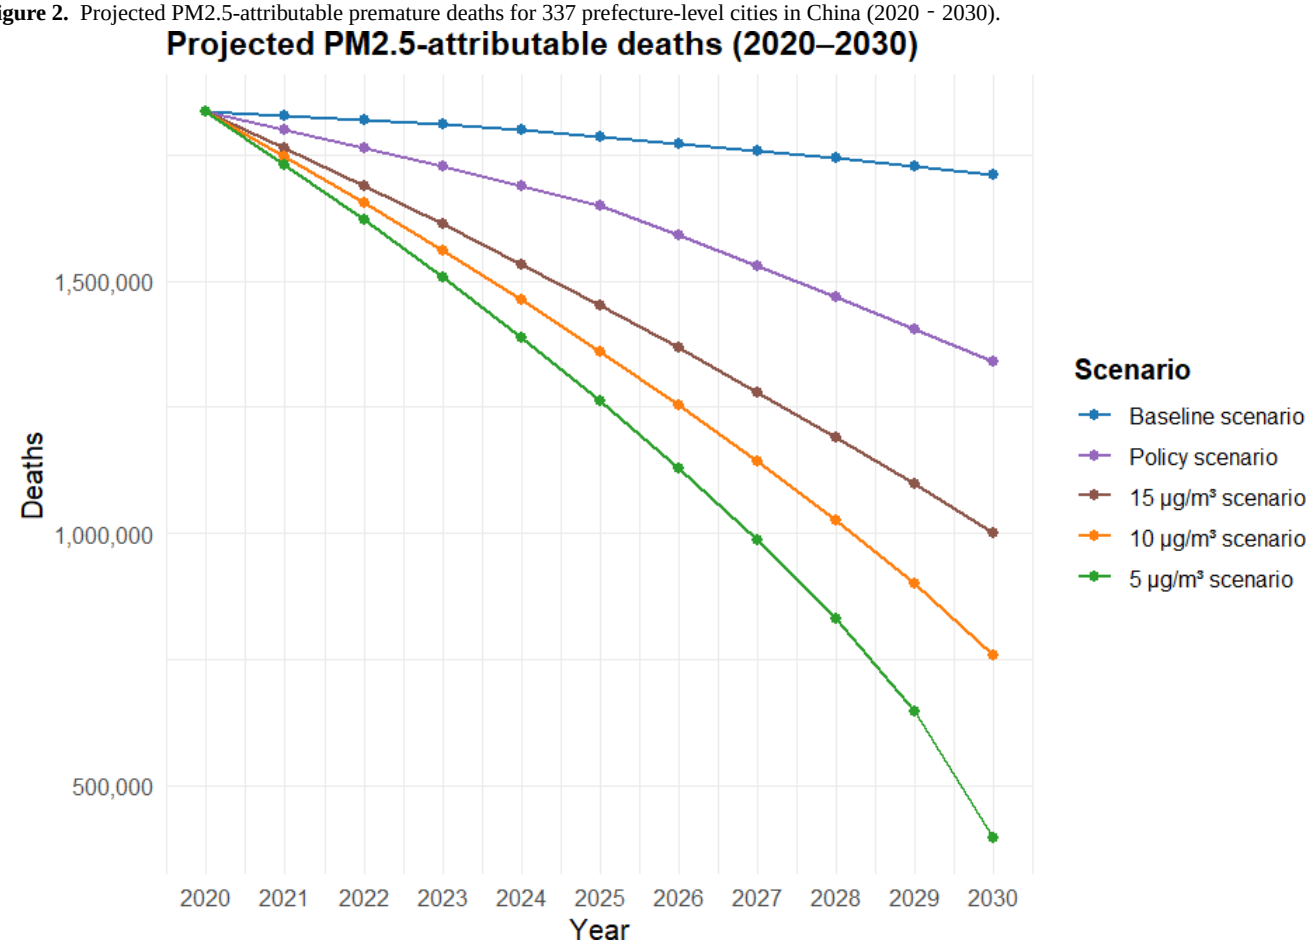
This study is a secondary analysis of preexisting, aggregate-level data obtained from publicly available sources, including the *China Statistical Yearbook* [43] and the *China Health Statistical Yearbook* [44]. These datasets are compiled and released by the National Bureau of Statistics of China as part of routine national statistical and health surveillance. The data are reported at an aggregated city-level and do not contain individual-level data or personal identifiers. Therefore, ethics approval and informed consent were not required as it did not involve direct human participation. Permission to use the data was granted through public access, and all data were used in compliance with the terms and conditions specified by the respective data providers [44].

## Results

### PM2.5 Concentrations

Figure 1 illustrates the spatial distribution of PM2.5 levels across 337 cities. In 2020, PM2.5 concentrations across 337 cities ranged from 7 to 63 μg/m³, with a national annual average of 32.6 μg/m³, falling below the 35 μg/m³ national guidelines but exceeding the WHO-recommended target of 5 μg/m³ by more than 6-fold. Higher concentrations were observed in the east compared to the west, with densely populated regions such as the Beijing-Tianjin-Hebei (BTH), Fenwei Plain (FP), and Yangtze Delta (YDR) reporting PM2.5 levels of 50.7, 47.8, and 36.7 μg/m³, respectively. Overall, our analysis accounted for nearly 70% of the total population of China in 2020.

**Figure 1.** Annual average PM2.5 concentrations across Chinese prefecture-level cities in 2020. PM: particulate matter.



### Mortality

Figure 2 presents the estimated burden of premature mortality attributable to PM2.5 exposure across the modeled scenarios, based on the Shared Socioeconomic Pathway 2 (SSP2) population trajectory. Between 2021 and 2025, under the baseline scenario in which PM2.5 concentrations remained at 2020 levels, exposure was projected to contribute to 9.04 million (95% CI 7.70 - 10.67 million) attributable deaths. Under the policy scenario, where concentrations were reduced by 10% from 2020 to 2025, this estimate declined to 8.63 million (95% CI 7.42 - 10.30 million), corresponding to an additional 0.41 million premature deaths averted under the 14th Five-Year Clean Air Plan. Over the full modeled period from 2021 to 2030, the total number of PM2.5-attributable deaths was estimated at 17.76 million (95% CI 14.21 - 20.95 million) under the baseline scenario, while the policy scenario resulted in a lower estimate of 15.96 million (95% CI 12.85 - 19.15 million). If PM2.5 concentrations were further reduced to the WHO's more stringent targets, the estimated number of attributable deaths would decline correspondingly to 13.99 million (95% CI 11.25 - 15.25 million) under a 15 μg/m³ scenario, 12.86 million (95% CI 10.85 - 14.85 million) under a 10 μg/m³ scenario, and 11.49 million (95% CI 8.96 - 13.45 million) under a 5 μg/m³ scenario, respectively.

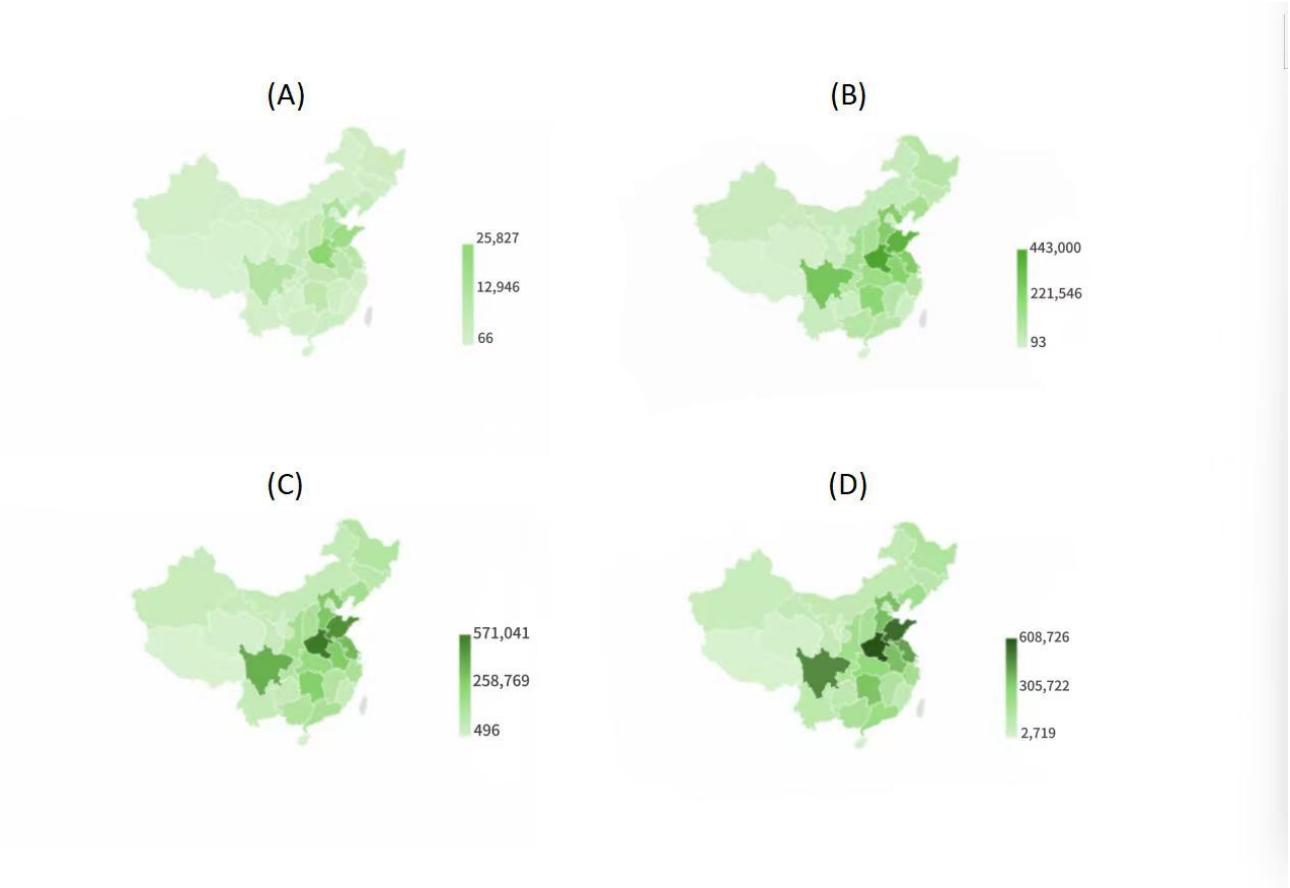
XSL•FO
RenderX

**Figure 2.** Projected PM2.5-attributable premature deaths for 337 prefecture-level cities in China (2020‐2030).

The spatial distribution of the annual average reduction in total premature deaths across provinces for each modeled scenario is shown in Figure 3. The greatest reductions in mortality were observed in the eastern and southeastern regions, particularly in highly populated and heavily polluted areas such as the BTH, FP, and YDR regions, compared to the west. Under the policy scenario, the estimated reduction in average annual premature deaths over the 10-year period was 13,879 for the BTH region, 7,009 for the FP region, and 6,895 for the YDR region. Similar spatial patterns of avoided premature deaths were observed under the WHO scenarios. In the most polluted regions (BTH, FP, and YDR), the estimated annual average benefits of reaching 15 μg/m³ corresponded to 237,580, 165,989, and 142,120 deaths averted, respectively. For the 10 μg/m³ scenario, these estimates increased to 283,878, 217,406, and 171,727, while for the 5 μg/m³ scenario, the reductions in premature deaths reached 338,916, 279,313, and 206,993, respectively.

XSL•FO
RenderX

**Figure 3.** Spatial distribution of reductions in PM2.5-attributable premature deaths across Chinese prefecture-level cities under improved air quality scenarios for 2021 - 2030: (A) policy scenario, (B) 15 μg/m³ target, (C) 10 μg/m³ target, and (D) 5 μg/m³ target. PM: particulate matter.



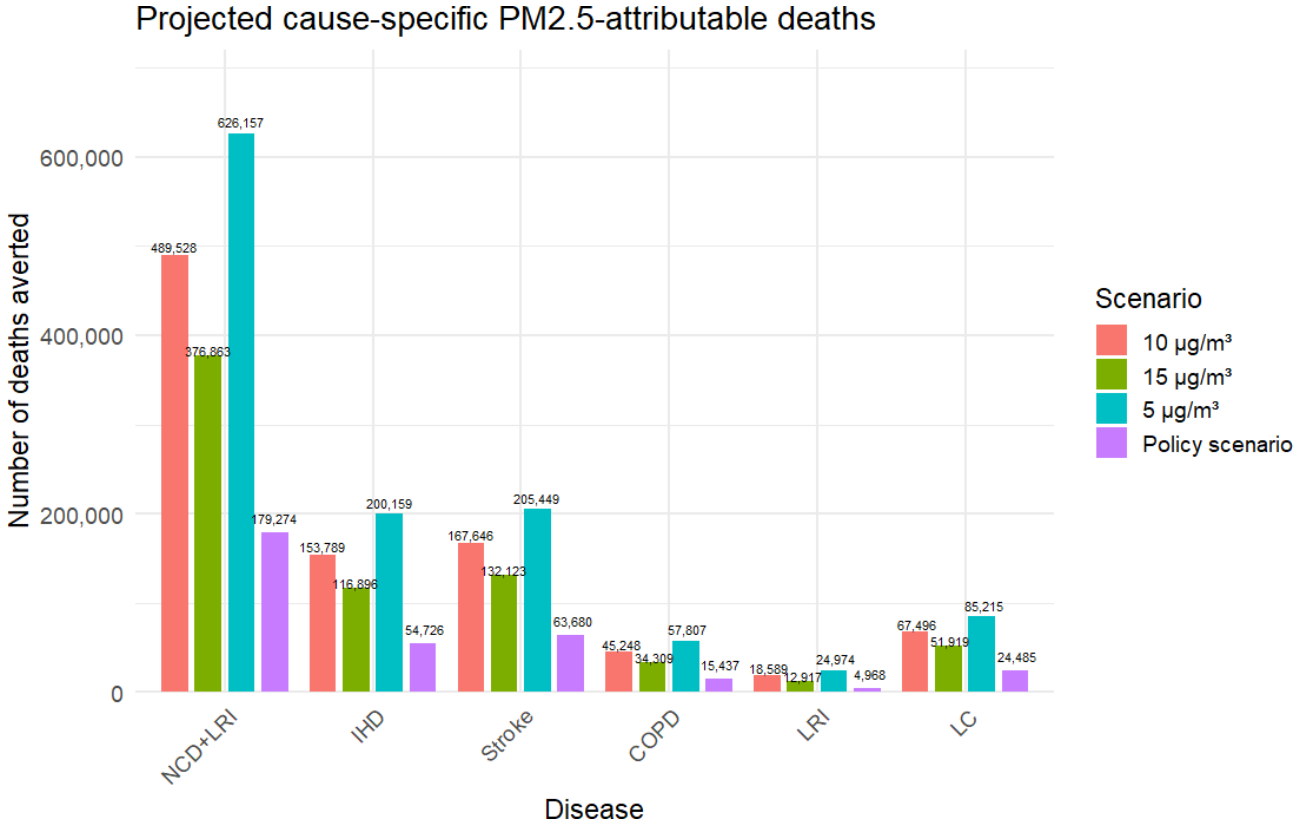


Figure 4 presents the annual average reduction in cause-specific premature deaths attributable to improved air quality for each modeled scenario under the SSP2 pathway. Under the policy scenario, a 10% reduction in PM2.5 concentrations by 2025, followed by a further reduction to 25 μg/m³ by 2030, is projected to result in an average annual reduction of 179,274 premature deaths. This includes 54,726 deaths from IHD, 63,680 from stroke, 15,437 from COPD, 4,968 from LRI, and 24,485 from LC. If PM2.5 concentrations were further reduced to the WHO's interim and final targets (15.10 and 5 μg/m³), the estimated annual reductions in total premature deaths would increase to 376,863, 489,528, and 626,157, respectively. The corresponding reductions in cause-specific mortality would range from 116,896 to 200,159 for IHD, 132,123 to 205,449 for stroke, 34,309 to 57,807 for COPD, 12,917 to 24,974 for LRI, and 51,919 to 85,215 for LC.

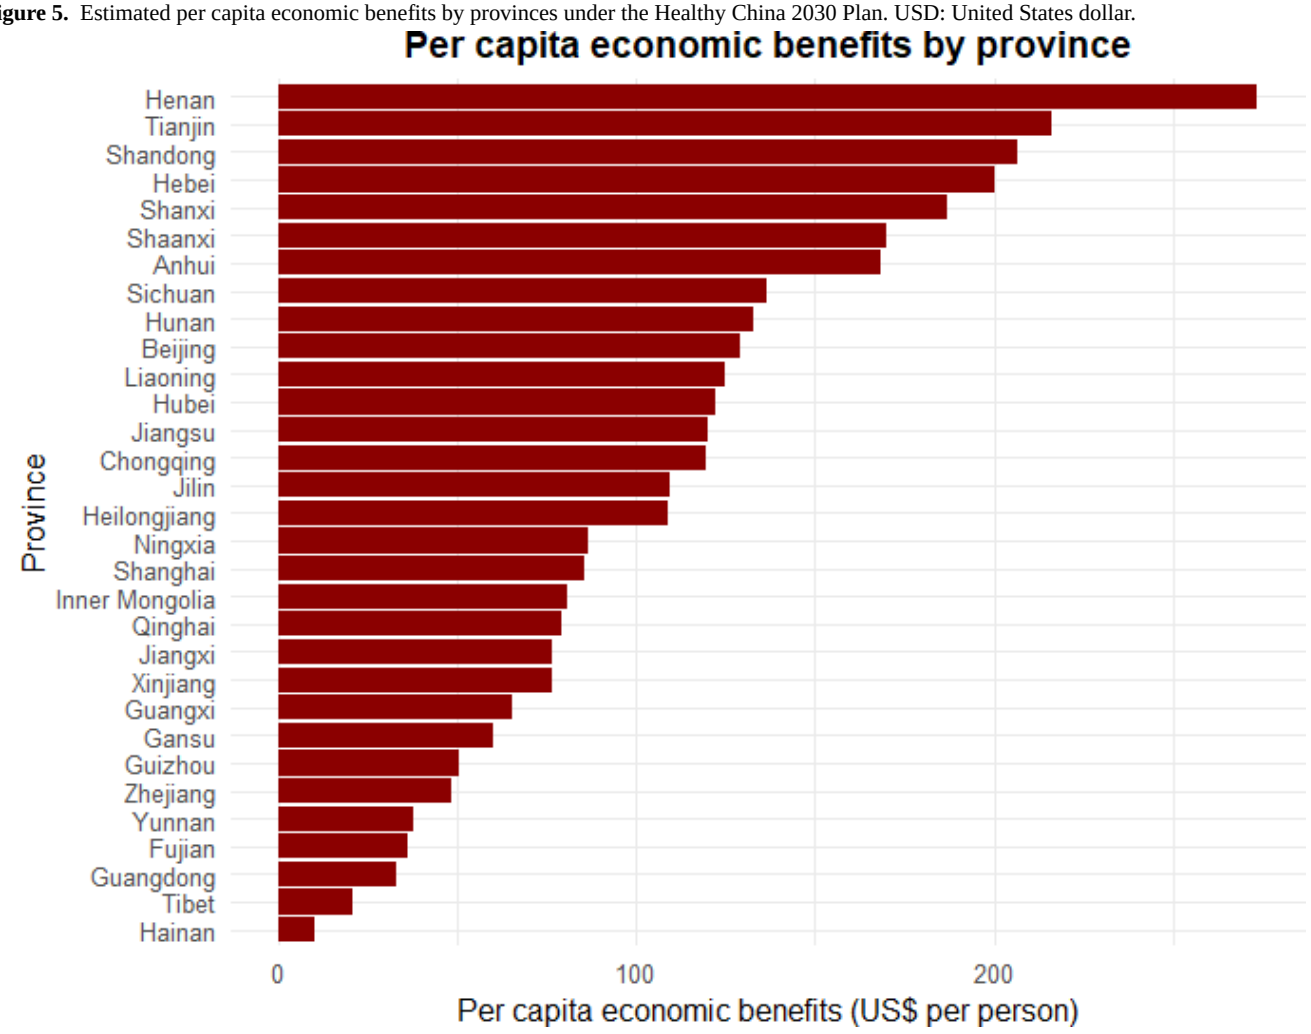
XSL•FO
RenderX

**Figure 4.** Projected annual average premature deaths by cause in China under improved air quality scenarios (2021 - 2030). COPD: chronic obstructive pulmonary disease; IHD: ischemic heart disease; LC: lung cancer; LRI: lower respiratory infections; NCD: noncommunicable disease.

## Morbidity

Table S6 in Multimedia Appendix 1 presents the annual average estimates of PM2.5-associated morbidity outcomes for the baseline scenario and the projected benefits under improved air quality scenarios. Under the policy scenario, the annual average morbidity benefits included 21,422 fewer cardiovascular disease admissions and 26,545 fewer respiratory disease admissions. These estimates increased to 41,690 and 51,681 cases under the 15 µg/m³ scenario, 51,884 and 64,333 cases under the 10 µg/m³ scenario, and 62,146 and 77,073 cases under the 5 µg/m³ scenario, respectively.



## Economic Benefits

Figure 5 illustrates the estimated per capita annual average economic benefits associated with the modeled scenarios under SSP2 at the provincial level. Under the policy scenario, the annual average economic benefits were estimated at US $123.7 billion, corresponding to approximately US $122.7 per person per year, comprising US $123.5 billion from reductions in premature mortality and US $175.5 million in annual savings from hospitalization costs. With the adoption of more stringent air quality targets of 15, 10, and 5 µg/m³, total annual savings were projected to increase to US $185.7 billion, US $240.7 billion, and US $306.5 billion, respectively. Further, the spatial distribution of economic benefits closely followed PM2.5 concentration patterns, with eastern and southeastern provinces experiencing the most substantial gains, while western regions observed relatively lower benefits. Specifically, under the policy scenario, the per capita annual average economic benefits ranged from US $10.1 in Hainan to US $273.5 in Henan, with other provinces such as Shandong (US $206.4) and Hebei (US $200.5) also realizing substantial gains. Under the more stringent targets, the average economic benefits across all 31 provinces increased progressively under similar distribution patterns, with projected benefits ranging from US $51.1 per person in Hainan to US $644.6 per person in Henan under the most stringent 5 µg/m³ target.

XSL•FO
RenderX

**Figure 5.** Estimated per capita economic benefits by provinces under the Healthy China 2030 Plan. USD: United States dollar.

### Scenario Analysis

Tables S7-S10 in Multimedia Appendix 1 provide summary estimates of the mortality and morbidity outcomes under different population trajectories. Annual reductions in total premature deaths ranged from 177,857 (under SSP4) to 180,500 (under SSP3) under the policy scenario, aligning closely with the SSP2 “middle of the road” estimates. The average annual reduction in morbidity was the highest under SSP3 (48,284 cases) and lowest under SSP5 (47,588 cases). Further reductions in premature deaths were observed when achieving lower PM2.5 targets of 15, 10, and 5 μg/m³, with estimated reductions ranging from 373,985 - 379,377 deaths, 485,767 - 492,843 deaths, and 621,288 - 630,487 deaths, respectively. Annual reductions in hospitalizations corresponded to 92,661 - 93,967 cases for 15 μg/m³, 115,333 - 116,965 cases for 10 μg/m³, and 138,159 - 140,119 cases for 5 μg/m³. The estimated annual economic benefits under the policy scenario ranged from US $123.1 billion to US $124.9 billion, further increasing to US $184.3 to US $186.8 billion for 15 μg/m³, US $238.9 to US $242.2 billion for 10 μg/m³, and US $304.2 to US $308.5 billion for 5 μg/m³.

## Discussion

### Principal Findings

In this study, we modeled the health and economic benefits of air quality improvements in China under several population and PM2.5 concentration scenarios. Our analysis suggests that attaining China’s current national policy, which aims to reduce PM2.5 levels by 10% from 2021 to 2025 and reach 25 μg/m³ by 2030, would prevent an annual average of approximately 179,274 premature deaths and 47,967 hospitalizations, translating to economic benefits totaling US $123.7 billion (US $122.7 per capita). This would represent approximately 0.6% of China’s national GDP in 2020. Under this policy scenario, the annual average reduction in premature deaths accounted for roughly 10% of the total PM2.5-attributable deaths estimated in 2020. Reductions in deaths from IHD and stroke accounted for most of these benefits, comprising 31.4% and 34.2% of the total annual average averted deaths, respectively. Under the VSL of US $689,659, monetized mortality benefits were overwhelmingly the largest source of economic gain, comprising over 99% of the total. The greatest benefits were observed in regions with high PM2.5 concentrations and population densities, such as the BTH, FP, and YDR region. At the provincial level, Shandong, Henan, and Hebei yielded the highest estimated annual benefits, equating to 1.0%, 1.6%, and 1.4% of their respective 2020 GDPs. Moreover, our model

XSL•FO
RenderX

estimates suggested that substantially greater health and economic benefits could be realized under more stringent air quality targets. Specifically, the additional annual average economic benefits were projected to be approximately 2.1, 2.7, and 3.5 times higher under the 5, 10, and 15 μg/m³ targets, respectively, compared to the national policy scenario. These results underscore the substantial potential for improved health and economic outcomes through more stringent air quality control, supporting the national government's ongoing efforts to enhance air quality and emphasizing the necessity to set more ambitious future guidelines.

Our study contributes to the literature in several ways. First, it provides an updated analysis to support identifying at-risk populations and future policy design by projecting health and economic outcomes in the future at the national level. Limited evidence exists in this area of research. Previously, Wang et al [45] quantified the health benefits for 100% and 50% improvements in air quality based on 2010 levels, reporting a reduction in the number of PM2.5-related premature deaths in China by approximately 129,278 by 2020 and 217,988 by 2030, compared with 2010. Since then, China has significantly reduced PM2.5 concentrations, with an annual average of 32.6 μg/m³ in 2020. With the introduction of its latest 14th 5-Year Action Plan and Healthy 2030 Plan, China is set to reach the target of 25 ug/m$^3$ by 2030 [22]. Additionally, in 2021, the WHO updated its air quality guidelines, recommending several updated interim and final targets to reflect the growing body of updated epidemiology evidence [19]. These updates in policies and air quality guidelines both nationally and internationally necessitate an updated analysis to support identifying at-risk populations and informing future policy design. Additionally, in this analysis, we use the GEMM to estimate mortality. Evidence shows that GEMM predicts mortality estimates over 120% higher than other established exposure-response functions, such as the WHO's Integrated Exposure-Response model or the log-normal model by considering for epidemiological evidence specific to ambient air pollution, as well as including evidence from high pollution regions [32]. Third, our findings further contribute to the global evidence demonstrating the substantial health and economic benefits of significant reductions in ambient air pollution, particularly in highly polluted countries. For example, research from India has shown significant reductions in excess mortality for both urban and rural populations following national actions to reduce PM [12,46]. Collectively, this body of evidence encourages governments in South and South-East Asia, which already bear a disproportionate burden from high PM exposure, to establish and strengthen effective national air quality regulatory standards. Fourth, we provide an economic perspective by quantifying the potential economic benefits of air quality improvements. Using both willingness to pay and COI estimates, our analysis translates health gains into monetary terms to better inform policy and facilitate decision-making.

Several limitations and future research questions should be acknowledged. As with all modeling analyses, the accuracy of our estimates is constrained by simplifying assumptions. First, we assumed that annual average PM2.5 concentrations serve as a proxy for long-term exposure, despite individual exposure being influenced by spatial-temporal variability, socioeconomic factors, and personal health behaviors [47,48]. Second, our economic valuation heavily relied on the VSL estimate, despite the lack of a nationally recognized figure. Previous VSL studies have reported values ranging from US $23,745 to US $614,805, highlighting the significant variability [38]. In our analysis, we opted for a recent VSL figure estimated in multiple cities representative of the national population. Third, due to the absence of city-level data on age-specific population trajectories, baseline mortality, morbidity, and health care utilization, we relied on provincial and regional data from statistical yearbooks and national death registries. Fourth, future advancements in health care services could significantly alter hospitalization rates and costs, yet our projections are based on historical trends. Further, a broader societal perspective on the benefits of reducing PM2.5 could be considered. For example, this study did not incorporate indirect benefits, such as avoided productivity losses. Additionally, previous studies have indicated that air pollution mitigation can involve substantial costs, including direct abatement costs and broader social and economic impacts [30,49]. Although these were beyond the scope of this study, they may affect the overall net economic benefit of such policies and warrant further investigation. Fifth, in our analysis, although population growth was projected using the shared socioeconomic pathways, we assumed that the population age structure remained unchanged over time. This is a notable limitation in the context of China's rapidly aging population, as epidemiological evidence indicates that older adults are more susceptible to the adverse health effects of PM [32]. Consequently, our estimates may underestimate the future disease burden attributable to air pollution and the corresponding health benefits achievable through air quality improvements. Finally, we assumed a steady decline in PM2.5 concentrations over our modeled period, while in reality, PM2.5 reductions occur through a nonlinear process.

## Conclusion

We modeled the potential health and economic benefits of improving air quality in China from 2021 to 2030. Achieving a 10% reduction in national PM2.5 concentrations by 2025, with a target of 25 μg/m³ by 2030, was estimated to prevent an average of 179,274 premature deaths and 47,967 hospital admissions annually, corresponding to US $123.7 billion in annual average economic benefits. However, more ambitious targets could yield substantially greater benefits, with annual death reductions of 376,863, 489,528, and 626,157 and hospitalization reductions of 93,371, 116,217, and 139,219, under 15, 10, and 5 μg/m³ targets, respectively, representing a 2-fold to 3-fold increase compared to the national target. Our findings underscore the substantial additional health and economic benefits of stricter air quality policies and support the development of future evidence–based national air quality guidelines.

## Abstract

**Background:** The range expansion of ticks transmitting zoonotic diseases in Canada poses challenges for public health surveillance. Active monitoring of where tick populations are emerging helps inform public health responses, but is resource intensive and logistically complex. Crowdsourced data may provide a cost-effective approach to augment surveillance. In this study, we assessed the value of crowdsourced data from eTick, a platform whereby the public submits tick photographs for expert identification.

**Objective:** We aimed to (1) characterize spatial patterns of eTick submissions and identify socioecological factors associated with their occurrence and frequency, and (2) assess the ability of indicators derived from eTick to predict census subdivisions (CSDs) with established tick populations.

**Methods:** We conducted a retrospective ecological assessment (2020 - 2023) for the effectiveness of crowdsourced data to detect established blacklegged tick (*Ixodes scapularis*) populations in Quebec, Canada. First, we applied a spatial scan approach to assess significantly high submission rates in human- and animal-origin data separately. Then, using zero-inflated regression models, we assessed socioecological factors associated with the occurrence and counts of tick submissions. Next, we used logistic regression models to assess the value of using eTick surveillance data to predict the presence of established tick populations, as documented by active surveillance. Finally, we calculated thresholds for eTick submissions to maximize sensitivity, specificity, or a balance of both metrics for detecting established tick populations, and developed scenarios to interpret linear predictors of submission counts across different socioecological contexts.

**Results:** No clusters in submissions were detected for human and animal-origin data. However, high concentrations of ticks found on humans corresponded with areas reporting a high risk of Lyme disease. Tick submissions of animal origin extended beyond endemic areas, highlighting their complementary surveillance value. Zero-inflated models identified socioeconomic, climatic, and land cover factors significantly associated with submission rates. Logistic regression models, including significant socioecological factors, performed best to identify CSDs with established tick populations. Predictive performance was similar for ticks from humans (area under the curve [AUC] 0.86), animals (AUC 0.83), and all submissions combined (AUC 0.85). Using the best model adjusted for population size, median income, median age, and cumulative degree days above 0 °C, an optimal threshold of 3.32 crowdsourced tick submissions allowed the detection of CSDs with established tick populations while maximizing sensitivity and specificity (both 0.76).

**Conclusions:** This work introduces a framework for analyzing crowdsourced surveillance data by correcting for participation bias and benchmarking against active surveillance. Unlike approaches relying on traditional or unadjusted data, it incorporates socioecological factors associated with reporting. We show that crowdsourced data can yield reliable inferences about vector distributions and provide a methodological approach that could be applied across species and regions. Applied to eTick, it supports

integration into surveillance systems to improve early detection, targeting interventions, and cost-effective monitoring of emerging risks by public health.

## Introduction

Tick-borne diseases represent a growing public health concern in Canada. In recent decades, several tick species have expanded their geographic ranges and population sizes, largely driven by climate and land use changes [1,2]. Notably, *Ixodes scapularis*, the primary vector of the agent of Lyme disease (LD), the most commonly reported vector-borne illness in Canada, has seen significant range expansion [3-5]. Geographic ranges of other species transmitting various pathogens, such as *Ixodes cookei* and *Dermacentor* spp., are also expanding, thereby increasing current and future risks of tick-borne diseases in Canada [1,6,7]. In this context, national and provincial public health authorities across Canada have implemented surveillance programs to identify where tick populations are spreading and to monitor disease incidence trends. These efforts identify where tick-borne disease risk is occurring, allowing targeted promotion of public awareness of risk and prevention methods and providing guidance to health care professionals [8]. However, tick presence and disease risk vary regionally due to ecological and environmental factors, including the availability of suitable hosts for ticks and pathogens, climate and habitat suitability for tick survival, and human exposure [1,9]. Canada's vast territory and diverse environments present major challenges for conducting consistent nationwide tick surveillance [10]. Tick-borne diseases demonstrate the importance of a One Health approach, as disease risk emerges from interactions among environmental conditions, animal hosts, and human behavior. While tick occurrence depends on climate, habitat, and wildlife hosts, exposure of humans and domestic animals is shaped by patterns of outdoor activity and contact with suitable tick habitat [11]. Domestic animals, which are frequently exposed to ticks, can serve as sentinels of local tick presence, underscoring the value of integrated surveillance approaches that integrate data from multiple sources (ie, humans, pets, and wildlife) and the environment [11-14].

Traditional methods for tick surveillance include active and passive surveillance conducted by public health organizations. In active surveillance, field teams perform standardized environmental sampling, generally involving drag sampling to collect questing ticks [10]. This approach provides strong scientific rigor because it allows the collection of tick abundance data, ensuring repeatability and comparability across sites due to standardized protocols for sampling and site selection [15,16]. However, this approach is also labor-intensive, and its inherent high costs limit its use geographically and temporally [17]. In passive surveillance, wider geographic coverage is possible at a lower cost, as ticks are voluntarily submitted to public health laboratories by the general population via health care professionals, medical clinics, or veterinary clinics. These laboratories undertake tick species identification and molecular screening for targeted pathogens [18]. Historically, passive surveillance has played a central role in detecting the emergence of new tick populations in Canada, providing early warning signals [18-20]. However, it has been gradually phased out in most regions across Canada due to insufficient laboratory resources to handle the increasing submission volumes associated with both higher numbers of ticks in endemic regions and expanding tick species distributions [16,21,22]. Consequently, an alternative passive surveillance framework is needed to ensure continued monitoring of emerging tick species and tick-borne diseases and to enable long-term data collection critical for understanding the spread of tick-borne diseases [23].

Citizen science approaches such as crowdsourcing-based data are increasingly used to complement field observations to estimate species distributions [24]. Crowdsourcing-based tick data collection is an emerging approach that engages the public to contribute to monitoring efforts via web platforms and applications [25]. Numerous examples from Europe and North America demonstrate the utility of such participatory approaches in complementing traditional tick surveillance methods [26-30]. The benefits of these approaches for public health include access to large volumes of data, broad geographic coverage, timely observations, and increased public engagement and risk awareness [31]. In 2017, eTick was launched as the first crowdsourcing platform dedicated to tick data collection in Canada. The general public, veterinarians, and health care professionals are invited to submit digital images of ticks found on people, on animals, or in the environment for free professional identification using a validated method [32]. When submitting a tick, users mark the location on a map to identify the presumed location of acquisition and provide additional information about recent travel. Submitters receive tick species identification results along with health prevention recommendations within 2 business days, and the municipalities where ticks were found are displayed on a publicly accessible map.

Multiple factors are thought to influence the data structure in citizen science and passive tick surveillance initiatives and must be identified and accounted for if the data are to be unbiased and useful for driving public health actions. Participation varies with age and sex [33-36], personal values, intrinsic interest, and a sense of belonging to a community [31,37-39], as well as education, income, and ethnicity, which may either encourage participation through increased awareness and risk perception or represent barriers to participation [31,34,36,37,39-41]. In tick-borne disease initiatives, pet owners are typically the most

XSL•FO
RenderX

represented group, along with people living in houses with yards and those regularly doing outdoor recreational activities [35].

Geographical biases in sampling are a common issue with crowdsourced data. Areas that are more accessible and that offer higher recreational interest, such as public parks and protected areas, may yield more observations [42,43]. Most tick submissions tend to be associated with peridomestic exposures [44], but these are influenced by the degree with which human settlement is juxtaposed with wildland [45]. The geographic scope of tick surveillance is limited by the geographic scope of the human populations. Tick submission numbers are proportional to the size of the participating human population and must be accounted for in data analysis [18-20,40,41]. Furthermore, expectations of spatial accuracy of tick encounter locations identified in passive surveillance must be realistic, as ticks can remain attached to their hosts for several days and often go unnoticed [21,46]. If possible, tick data from submitters with a recent history of long-distance travel should be eliminated from analysis [47].

A significant potential weakness of crowdsourced data is that, for some species, individual specimens may be found outside their geographic range due to their dispersion by migratory animals [48]. Crowdsourced data from these species require careful analysis and processing to avoid overestimating geographic ranges and ecological niches. For many tick species, ticks found by the public do not necessarily indicate locations where annually reproducing tick populations have become established. Many tick species are dispersed over long distances from their source populations by hosts (particularly migratory birds), and these ticks can survive to molt and feed as the next instar on hosts, including humans and their pets [48]. Locations where submitted ticks comprise only these “adventitious ticks” must be distinguished from locations with established tick populations [20]. The primary method for making this distinction involves determining a threshold number of submitted ticks per geographic unit based on statistical comparisons of the submission rates from locations with and without established populations identified through “gold standard” active surveillance [20]. Including environmental data that determine where tick populations can persist (habitat, host densities, and climate [1,9,49,50]) in analyses of passive surveillance data can help discriminate ticks coming from established populations versus adventitious ticks [20].

This study aimed to develop robust, evidence-based indicators for assessing the risk of tick population establishment using crowdsourced tick surveillance data. Specifically, our objectives were to (1) characterize spatial patterns in eTick submission rates and identify socioecological factors influencing their occurrence and frequency and (2) assess the ability of indicators derived from eTick data to predict census subdivisions (CSDs) with established tick populations. We focused on *I scapularis* in Quebec, Canada, where long-term active surveillance provides a reliable benchmark for validation. By leveraging Quebec’s extensive dataset, this study generated practical, scalable insights to improve tick surveillance and risk assessment frameworks across Canada and in comparable international contexts.

# Methods

## Study Design and Setting

In this study, we conducted a retrospective ecological assessment for the effectiveness of crowdsourced data to detect established tick populations in Quebec, Canada, from 2020 to 2023. Here, an established tick population refers to a locally reproducing population considered persistent over time. The criteria used to infer establishment followed the *Institut national de santé publique du Québec’s* (INSPQ) risk classification approach [51], itself based on [52] (see section Active Tick Surveillance for details). The unit of analysis was the municipality, defined as CSDs, totaling 1282 across the province [53], representing the finest spatial scale at which all relevant data were available. Approximately 80% of the province’s population of 8 million lives in metropolitan areas, concentrated in the south, with the most populated being Montréal, Québec City, and Sherbrooke [54]. The province has seen ticks and LD emerging gradually over the last two decades. The most endemic regions, with the longest history of emergence, are the southernmost regions of Montérégie and Estrie, near the US border [55,56]. Since initial emergence, endemic regions have progressively expanded across southern Quebec, and human LD cases have been constantly rising. The dominant forest types are deciduous and mixed forests, and the potential exposure to ticks varies depending on land use and human activities, ranging from peridomestic and rural environments to recreational areas, such as natural parks in urban settings.

## Data Sources and Variable Construction

### *Active Tick Surveillance*

Active surveillance data were obtained from the INSPQ for 2014 to 2023. The INSPQ is Quebec’s public health expertise and reference center, playing a key role in the surveillance and prevention of LD and other tick-borne diseases. Active surveillance was conducted at sampling sites located in public nature parks or on private lands with owner authorization. Site selection was based on habitat suitability for ticks (eg, deciduous or mixed forests) and signals of emerging risk, such as reported human LD cases or *I scapularis* collected through active and passive surveillance. Sampling took place between May and August under conditions without rain and with dry soil. At each site, a standardized drag sampling protocol was used. A team of 2 field technicians sampled each site, using a 1-$m^2$ flannel cloth dragged horizontally along 2 transects: one along the trail edge and one 25 m into the forest, parallel to the trail. Each technician sampled 1000 $m^2$, for a total sampled area of 2000 $m^2$ per site. The flannel cloths were inspected every 25 m for ticks. Ticks were removed with tweezers, placed in tubes containing 70% ethanol, and sent to the Quebec Public Health Laboratory (*Laboratoire de santé publique du Québec*) for species identification using taxonomic keys and pathogen testing [57]. Counts of the 3 life stages of *I scapularis* (larvae, nymphs, and adults) were calculated for each site visit and used to classify CSDs as having established tick populations or not. A CSD was considered established if at least six ticks of any life stage or at least two different life stages were collected within the same year in the municipality. If the indicator was met for at least 1

XSL•FO
RenderX

year during our study period, the municipality was considered as having an established *I scapularis* population [52,58].

### *Crowdsourced Tick Surveillance*

Crowdsourced tick surveillance data were obtained from the eTick platform. We extracted all submissions identified as *I scapularis* for 2020 to 2023 in Quebec. Although eTick was launched in 2017, this time frame was considered representative of a stable period for analysis, following an initial phase of increasing familiarity and adoption of the eTick platform by the public. Retrospective analysis of the number of tick submissions suggested that the COVID-19 pandemic did not have a large effect on submissions, possibly due to limited restrictions on peridomestic activity and outdoor pursuits. Furthermore, the launch of the mobile eTick application in early 2020, just prior to lockdown, likely facilitated engagement and sustained user participation.

Data reported by users for each submission included the geographic location where the tick was found (ie, users marked the presumed location of acquisition on a zoomable map, from which the research team extracted coordinates), the date it was found, and whether the tick was found attached to an animal, attached to a human, or unattached (eg, crawling on a host or free in the environment), which is referred to as the origin of the tick throughout the paper. Additionally, for cases where the tick was attached to a human, users reported the age and gender of the individual. Users also reported whether they had traveled outside their municipality within 2 weeks prior to finding the tick. Starting in 2023, data collection also included information from the submitting individual regarding their profession (health care professional, veterinarian, or general public participant). Finally, additional details were provided by eTick's professional entomologist team: the tick life stage and sex, and unique unidentifiable user IDs. A public map is available on the platform, displaying tick submission locations, along with the tick species, locality, date of observation, origin, and tick pictures. All other information provided by users remains confidential.

The total number of individual submissions per user was calculated, and the distribution of the number of submissions per user was inspected graphically to detect potential outliers (ie, superusers). Superusers were defined a priori as users with submission counts exceeding the 99.9th percentile of the distribution.

Total tick submissions by origin type and overall (including unknown origins) were summed at the CSD level, given submission locations found within CSD boundaries. These counts were calculated both with and without the superuser outliers. Ticks that could have been acquired during travel were excluded from the analysis to reduce potential bias from submissions not representing the geographic location of tick exposure [19,20].

### *Socioecological Factors*

Here, socioecological factors refer to demographic and socioeconomic characteristics that may influence community participation and environmental conditions known to affect tick populations. Corresponding variables were constructed and considered as predictors or confounders in the statistical models described below (see section Analysis for Details).

CSD statistics for human population size, median age, and median household income were obtained from the 2021 census [53,59]. All monetary values are reported in Canadian dollars. The conversion rate at the time of the study was CAD $1=US $0.72. Missing data occurred for these variables at the CSD level, primarily due to census data suppression or nonrelease resulting from confidentiality rules, low population counts, or high nonresponse rates [60]. These missing data largely occurred in remote or Indigenous CSDs, which represent subpopulations that differ from the population relevant to this study (ie, potential users of the eTick platform). CSDs with missing values for any of these variables were therefore not included in the analysis (194 CSDs excluded, representing 15% of Quebec's 1282 CSDs).

A variable derived from Google Trends was used to account for CSD-level participation toward eTick [61,62]. Google Trends is an open-access tool to extract information about Google search trends [63]. We assumed that Google searches that included keywords "ticks" and "Lyme disease," in either English or French, represented interest in ticks and LD, and thus served as a proxy to contribute to eTick. Google Trends data for the study variable were extracted at the municipal level for 2020 to 2023. Municipalities were then matched to their corresponding CSD based on name. The returned data use a relative scale from 0 to 100, where 100 represents the highest proportion of keyword searches relative to the total searches in a given region and period, and 0 represents the lowest level of interest [64].

A variable representing human exposure to tick habitats was derived as the proportion of interface zones between human settlements and wildlands. Data from the global wildland-urban interface (WUI) [65] were used to compute the WUI proportion per CSD. The calculation included all WUI categories dominated by forest, shrub, and wetland types, including both intermix and interface zones. The full methodology used to produce this layer has been published [65]. In brief, the WUI classifies areas into 2 categories: intermix and interface. The intermix WUI has ≥6.17 buildings per km² and ≥50% wildland vegetation. The interface WUI has ≥6.17 buildings per km² and <50% wildland vegetation but is located within 2.4 km of a large patch (≥5 km²) of wildland with >75% vegetation cover.

Finally, to compute annual values of cumulative degree days (DD) >0 °C, we used the Daymet dataset [66], which provides daily meteorological data at a 1 km spatial resolution across North America by integrating data from weather stations and other supporting sources through interpolation methods. This variable served as a proxy for 2 factors. First, the yearly exposure duration to host-seeking ticks [41], and second, a determinant of the potential for tick population establishment, given an approximate constraint of 2843 DD >0 °C to maintain populations [67,68]. Yearly CSD values were calculated as the mean 1-km resolution of pixel values whose centroids fell within CSD boundaries.

## Ethical Considerations

The eTick platform collects routine passive surveillance data on ticks in Canada. On the basis of the nature of the data collected and the collection process, and acknowledging that no formal research question was specifically formulated to acquire these data, the Bishop's University Research Ethics Board stated that no ethical review is required for data collection through the eTick platform (Multimedia Appendix 1). Here, we make a secondary use of nonidentifiable data; individuals cannot be identified from any images or materials in the paper or supplementary files, a case defined in the Canadian research ethics guidelines for research involving humans (TCPS 2) as not requiring ethical review [69].

Before submission, all eTick users must consent to the use of their deidentified data for surveillance purposes and for future unspecified research [70]. Personal information (name, username, email address) is collected exclusively for communication purposes and visible only to site administrators. Data extracts used for surveillance or research do not include personal information in their data fields. No compensation was provided to participants.

## Analysis

All analyses were conducted in R version 4.5.1 (R Foundation for Statistical Computing) [71].

### *Objective 1: Spatial Patterns and Socioecological Factors Associated With eTick Submissions*

#### Assessing for Clusters in Tick Submissions

Spatial patterns in tick submissions were analyzed separately for tick submissions originating from humans and animals. The total CSD-level submissions for both types of submissions over the study period were visualized as rates normalized by CSD population size. Rates were calculated as: (number of submissions in the CSD/CSD human population)×100,000 and then mapped using QGIS (version 3.44.1).

The spatial scan statistic assessed for significantly high rates in the number of submissions at the CSD level [72]. CSD locations were represented by the centroid coordinates. The method used a circular scanning window that moved across the study area, varying in size from 0% to 50% of the study population, to identify potential windows in which submission rates are significantly higher than in surrounding areas [73]. Prior to the scan, overdispersion in submission counts was assessed using the Dean test [74]. As significant overdispersion was present, spatial scan analyses were conducted under a negative binomial distribution, implemented in the *DCluster* package in R [75]. As shown by Loh and Zhu [76], this approach is appropriate for overdispersed count data and reduces the risk of detecting false-positive clusters driven by extravariability rather than true spatial clustering [73]. The statistical significance of each potential cluster was evaluated using Monte Carlo simulation with 999 random permutations. Clusters were considered statistically significant at $P \geq .05$. The spatial scan analysis was performed separately for human- and animal-origin data.

#### Identifying Socioecological Factors Associated With Tick Submission Occurrence and Counts

We assessed for socioecological factors associated with the occurrence and counts of tick submissions, at the CSD-year levels, using zero-inflated regression models.

Logarithmic transformations were first applied to normalize skewed predictor variable distributions, then all predictors were centered and scaled to ensure appropriate model behavior (ie, reduce multicollinearity, help produce reliable model estimates, and facilitate interpretation of model estimates). Collinearity among variables was verified using Pearson correlation coefficients and the variance inflation factor (using maximal thresholds of 0.7 and 3, respectively [77]). Significant overdispersion was detected based on the dispersion ratio, and the presence of excess zeros was confirmed through the Vuong test.

A zero-inflated negative binomial model was fitted using the *pscl* package, version 1.5.9 [78]. These models have 2 distinct components: a logistic component that models the probability of having structural zeros (ie, populations not at risk; in our case, regions unsuitable for the presence of tick populations) and a count component that models the number of events (including zero counts) in the at-risk population (in our case, regions suitable for tick presence, where tick submissions may or may not occur). A backward stepwise selection procedure was used for final variable selection [79].

Model fit was assessed through graphical inspection of the residuals. Cook distance was calculated to identify potential outliers with a threshold of 1. When outliers were detected, models were refitted excluding the outlier CSDs. Observations were considered influential if their associated difference in beta exceeded the conventional threshold ($2/\sqrt{n}$) for any key coefficient or if their removal altered the statistical significance of predictors [80]; such CSDs were excluded; otherwise, they were retained. The presence of residual spatial autocorrelation, which could bias the results, was assessed using the global Moran I test on standardized Pearson residuals with the *ape* package in R.

## Objective 2: Ability of eTick Indicators for Detecting Established Tick Populations

### *Detecting Established Tick Populations*

Logistic regression models were used to assess the value of using eTick surveillance data to predict the presence of an established tick population in a CSD. Observed tick establishment status was determined using INSPQ active surveillance data, following the criteria described in section Active Tick Surveillance, and including CSDs with at least one active surveillance visit since 2014 (n=343). Model building was conducted separately for 3 types of eTick indicators: number of submissions of (A) human origin, (B) animal origin, and (C) all origins combined. Three model structures were assessed for each indicator: (1) a global model including the respective eTick indicator and all socioecological factors identified as significant in objective 1 (models A1, B1, and C1), (2) a reduced model including the eTick indicator and CSD population size (models

XSL•FO
RenderX

A2, B2, and C2), and (3) a basic model including only the eTick indicator (models A3, B3, and C3).

We used the same variable data transformation and model building approaches as described for objective 1. Backward stepwise selection based on Akaike information criterion was used to identify the best model for the global model structures. We compared the explanatory power of the nested models using the likelihood ratio test, and assessed model performance using area under the curve (AUC) and Akaike information criterion. Finally, model fit was evaluated using the Hosmer-Lemeshow test, along with graphical inspection and outlier detection as described earlier in objective 1.

### *Identifying Thresholds of Submissions Optimizing Tick Population Detection Accuracy*

Thresholds for eTick submission data were calculated to maximize sensitivity, specificity, or a balance between both metrics for detecting established tick populations. Analyses focused on submissions from all origins, with thresholds derived from the linear predictors of models C1, C2, and C3. Optimal cutoffs for the linear predictors were determined using the *OptimalCutpoints* package in R [81]. The first 2 methods maximize sensitivity and specificity separately, while maintaining the other parameter at a minimum threshold [82-84]. For instance, in the method optimizing sensitivity, we set specificity to 0.5 and maximized sensitivity under this condition. The third method sought a balance between sensitivity and specificity by minimizing the absolute difference between them [85-87].

To facilitate interpretation of the resulting linear predictor thresholds, illustrative scenarios were subsequently developed. These scenarios were not intended for inference, but rather to translate the model-derived thresholds into interpretable submission counts, by fixing covariates at representative values reflecting different socioecological contexts within the study area. To this end, CSDs were grouped according to the 2 most influential covariates affecting the relationship between submissions and tick population presence: climate suitability and human population size. CSDs were first classified according to their climatic suitability for tick establishment, using the threshold of 2843 DD>0 °C [67]. Within climatically suitable CSDs, a population threshold of 100,000 inhabitants was applied to distinguish large population centers from medium and small population centers [88]. As climatically unsuitable CSDs generally have smaller populations, we used the small population center threshold (30,000 inhabitants [88]) in this group to improve descriptive stratification. In each group, the number of submissions corresponding to each optimized cutoff of the linear predictor was calculated while holding model covariates at their mean values.

## Results

### Objective 1: Spatial Patterns and Socioecological Factors Associated With eTick Submissions

### *Characteristics and Spatial Patterns of Tick Submissions*

A total of 2668 photographic submissions to eTick were identified as *I scapularis* collected in Quebec during the study period, including 429 (16.1%) submissions in 2020, 722 (27.1%) in 2021, 855 (32.1%) in 2022, and 662 (24.8%) in 2023.

Of these, 313 (11.7%) submissions were excluded from the analysis because users reported travel outside their municipality of residence within the 2 weeks prior to submission.

Among the 2355 included submissions, most (n=1594, 67.7%) submitted ticks were found attached to animals, whereas 28.6% (n=673) were found attached to humans and 3.7% (n=88) were found from the environment (Table 1). Most submitted ticks were adult females (1639/1955, 83.8%), followed by adult males (270/1955, 13.8%) and nymphs (46/1955, 2.4%). The life stage could not be distinguished for 400 (17%) of 2355 submissions. Among submissions with reported submitter profession (this question was introduced in 2023 and was therefore missing for 1,524/2355, 64.7%, submissions), most were submitted by members of the public (719/831, 86.5%), with smaller proportions of submissions from veterinary professionals and human health care professionals (Table 1).

XSL•FO
RenderX

**Table .** Distribution of blacklegged tick (*Ixodes scapularis*) submissions reported through the eTick crowdsourcing passive surveillance platform in Quebec, Canada, between 2020 and 2023, categorized by tick, host, and submitter characteristics[a].

| Variables and characteristics | Submissions, n (%) |
|---|---|
| Tick stage and sex[b] (n=1955) | |
| Nymph | 46 (2.4) |
| Adult (male) | 270 (13.8) |
| Adult (female) | 1639 (83.8) |
| Origin of the tick (n=2355) | |
| On a human | 673 (28.6) |
| On an animal | 1594 (67.7) |
| In the environment | 88 (3.7) |
| Age of the human host (y; n=671)[c] | |
| 0 - 20 | 185 (25.6) |
| 21 - 40 | 131 (19.5) |
| 41 - 60 | 229 (34.1) |
| ≥61 | 126 (18.8) |
| Submitter profession[d] (n=831) | |
| Member of the public | 719 (86.5) |
| Veterinary professional | 101 (12.2) |
| Human health care professional | 11 (1.3) |

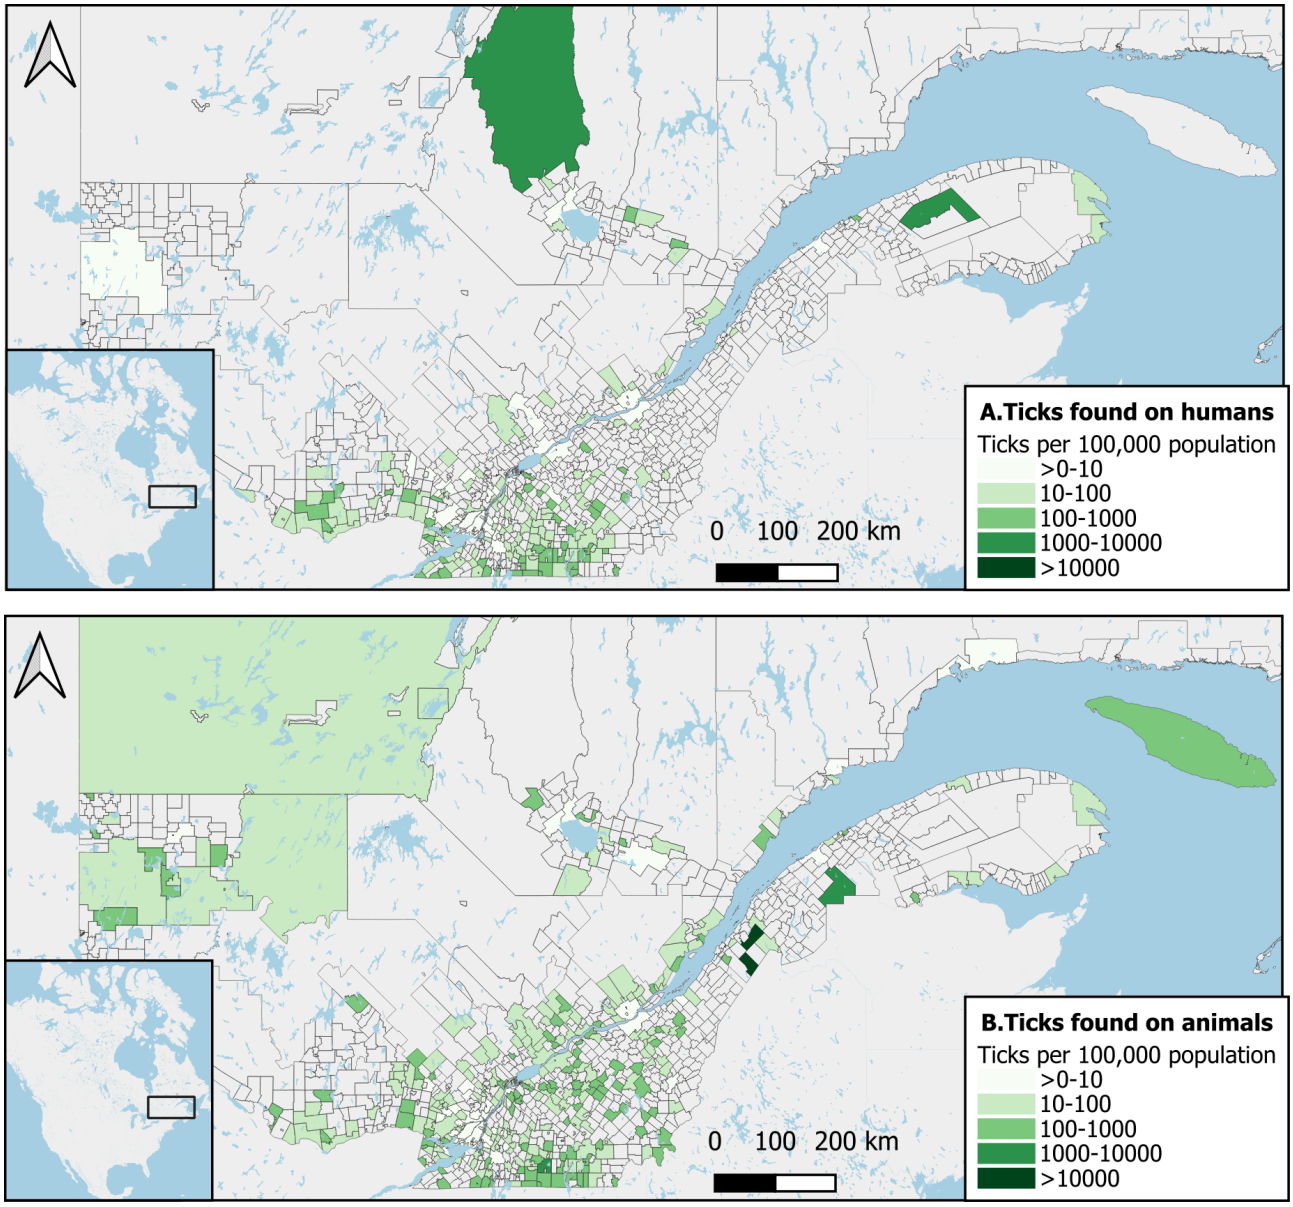
[a]Only considering the submissions for which the user did not report travel history within the previous 2 weeks (n=2355).

[b]Was missing in 400 (17%) of 2355 cases because not all ticks could be identified to a life stage from the submitted picture.

[c]Was missing in 1684 (71.5%) of 2355 cases because not all users reported this information.

[d]Was missing in 1524 (64.7%) of 2355 cases because it has been only added to the eTick questionnaire in 2023. For users who submitted before 2023 and later returned, their profession was retrieved and added to their earlier submissions.

Most (1600/1789, 89.4%) users made only one submission to the platform, with an average of 1.49 (SD 7.38) submissions per user. Among users who made multiple submissions, 2 were outliers regarding submission frequency (submitting 137 and 264 times) and were therefore excluded from the subsequent analysis. After removing these outliers, the average number of submissions per user was 1.27 (SD 2.38), and the number of submissions ranged from 0 to 148 per CSD, with a mean of 1.56 (SD 6.82) submissions per CSD.



Of the 1282 CSDs, 454 (35.4%) had at least one tick submission. Among these tick-positive CSDs, 210 (46.3%) were identified exclusively through submissions of ticks found attached to animals, 85 (18.7%) were identified through submissions of ticks found attached to humans, and 150 (33%) were identified through both categories of submissions. Strong overdispersion was detected in CSD-level submission counts for both human and animal-origin ticks (Dean test, $P<.001$). Spatial scan analyses accounting for overdispersion did not identify any statistically significant spatial clusters for either human- or animal-origin submissions. Spatial patterns are therefore described qualitatively.

For both categories, the submissions were geographically distributed across municipalities in southern Quebec (Figure 1). Submissions of ticks found attached to humans accounted for 29% of all submissions and were predominantly reported from the southern regions of Quebec, particularly Estrie, Outaouais, and Montérégie. Additional areas with higher submission rates for human-origin ticks were observed in Centre-du-Québec and Chaudière-Appalaches. Ticks found attached to animals represented 68% of all submissions and showed a broader geographic distribution. Additionally, higher submission rates for animal-origin ticks were observed in more northerly regions, including Abitibi-Témiscamingue, Mauricie, Capitale-Nationale, and Centre-du-Québec.

RenderX

**Figure 1.** Blacklegged tick (*Ixodes scapularis*) submission rates reported through the eTick crowdsourcing passive surveillance platform, in Quebec, Canada, from 2020 to 2023, showing the spatial distribution of ticks found attached to (A) humans and (B) animals at the census subdivision level.

### *Socioecological Factors Associated With Tick Submissions*

The human population size of CSDs was the strongest predictor of both the likelihood (Table 2) of tick submissions and their count (Table 3). Each unit increase in the log-transformed population was associated with a 2.04-fold increase in submission counts (incidence risk ratio [IRR] 2.04, 95% CI 1.86 - 2.25; *P*<.001) and a reduction in the odds of structural zeros (odds ratio [OR] 0.13, 95% CI 0.05 - 0.31; *P*<.001). The log-transformed proportion of WUI zones significantly influenced both components of the model. CSDs with higher WUI proportions had more submissions (IRR 1.43, 95% CI 1.26 - 1.63; *P*<.001), but they were also associated with greater odds of being a structural zero (OR 2.65, 95% CI 1.21 - 5.79; *P*=.01). The number of DD>0 °C significantly reduced the odds of structural zeros (OR 0.10, 95% CI 0.04 - 0.24; *P*<.001). Socioeconomic factors also positively influenced submission counts. Higher median household income and median age were associated with increases in submissions (IRR 1.35, 95% CI 1.20 - 1.52; *P*<.001; and IRR 1.45, 95% CI 1.26 - 1.67; *P*<.001, respectively). One CSD, Lac-Brome in the Estrie region, was identified as an outlier for submission counts (n=148) and excluded from the model fit. No residual spatial autocorrelation was detected (*P*=.60), supporting the robustness of the model.

## Objective 2: Ability of eTick Indicators for Detecting Established Tick Populations

### *The Detection of Established Blacklegged Tick Populations*

In all 3 sets of models, the more complex models that incorporated socioecological factors outperformed the simpler models, which included submissions with population size or submissions alone (Table 4). The model using submissions of ticks found attached to humans and socioecological covariates (model A1) performed best among all models (AUC 0.86). The model using all types of submissions (model C1) had lower performance (AUC 0.85) compared to the model using submissions of ticks found attached to humans only (model A1), followed by the model using submissions of ticks found attached to animals only (model B1, AUC 0.83).

XSL•FO
RenderX

**Table .** Performance of logistic regression models predicting the presence of established blacklegged tick (*Ixodes scapularis*) populations at the census subdivision (CSD) level in Quebec, Canada, between 2020 and 2023, using eTick crowdsourced surveillance indicators[a].

| Model[b] | Set of covariables included for each candidate model | AIC[c] | ΔAIC[d] | AUC[e] |
|---|---|---|---|---|
| A1 | Submissions of ticks found attached to humans, population size, income, age, proportion of WUI[f], and DD[g] >0 °C | 289.24 | 0.00 | 0.86 |
| C1 | All tick submissions, population size, income, age, and DD >0 °C | 295.82 | 6.58 | 0.85 |
| B1 | Submissions of ticks found attached to animals, population size, income, age, and DD >0 °C | 312.26 | 23.02 | 0.83 |
| A2 | Submissions of ticks found attached to humans and population size | 366.99 | 77.75 | 0.70 |
| A3 | Submissions of ticks found attached to humans | 370.23 | 80.99 | 0.67 |

The number of human-attached submissions to eTick was significantly associated (OR 3.34, 95% CI 2.30 - 4.86; *P*<.001; Table 5) with an increased likelihood of finding established tick populations through active surveillance. Socioecological factors influencing tick presence or population participation in crowdsourced surveillance improved model performance. Positive effects were observed for the log DD >0 °C (OR 4.73, 95% CI 2.97 - 7.52; *P*<.001) and for the proportion of WUI (OR 1.37, 95% CI 1.03 - 1.83; *P*=.03). Negative effects were observed for the log of population size (OR 0.37, 95% CI 0.24 - 0.56; *P*<.001), median income (OR 0.42, 95% CI 0.28 - 0.63; *P*<.001), and median age (OR 0.62, 95% CI 0.42 - 0.92; *P*=.02).

### *Thresholds of Submissions Optimizing Tick Population Detection Accuracy*

Thresholds of tick submissions calculated using the linear predictor from the most complex model (C1) outperformed those from the simpler models across all optimization methods. A cutoff of −2.30 optimized sensitivity at 0.96, while a cutoff of 0.26 optimized specificity at 0.91 (Table 6). These optimizations were achieved while ensuring that the opposite parameter did not fall below 0.50. When optimizing both parameters simultaneously, sensitivity and specificity were balanced at 0.76 with a cutoff of −0.66. The method that minimized the overall error rate was the one optimizing specificity, resulting in an error rate of 0.22.

XSL•FO

| Optimization of the balance between sensitivity and specificity | | | | |
| C3. Model using all submissions | 0.55 | 0.61 | 0.41 | −0.81 |
| C2. Model using all submissions and population size | 0.63 | 0.63 | 0.37 | −0.90 |
| C1. Model using all submissions, population size, income, age, and DD >0 °C | 0.76 | 0.76 | 0.24 | −0.66 |

[a]The minimum value tolerance for specificity is 0.50.

[b]DD: degree days.

[c]The minimum value tolerance for sensitivity is 0.50.

The CSDs grouped by climatic suitability and human population showed diverse environmental and demographic characteristics (Table 7). Across the study region, for a typical area with an average DD >0 °C of 3199 and an average human population of 19,838, the optimal submission threshold for detecting an established tick population—balancing sensitivity and specificity—is estimated at 3.32. This threshold increases to 7.54 when optimizing specificity and decreases to 0.51 (rounded to 1 submission in practice) when optimizing sensitivity. When analyzing CSDs by group, climatically unsuitable medium population centers had the highest threshold values, followed by climatically suitable large population centers, climatically unsuitable small population centers, and, finally, climatically suitable small and medium population centers.

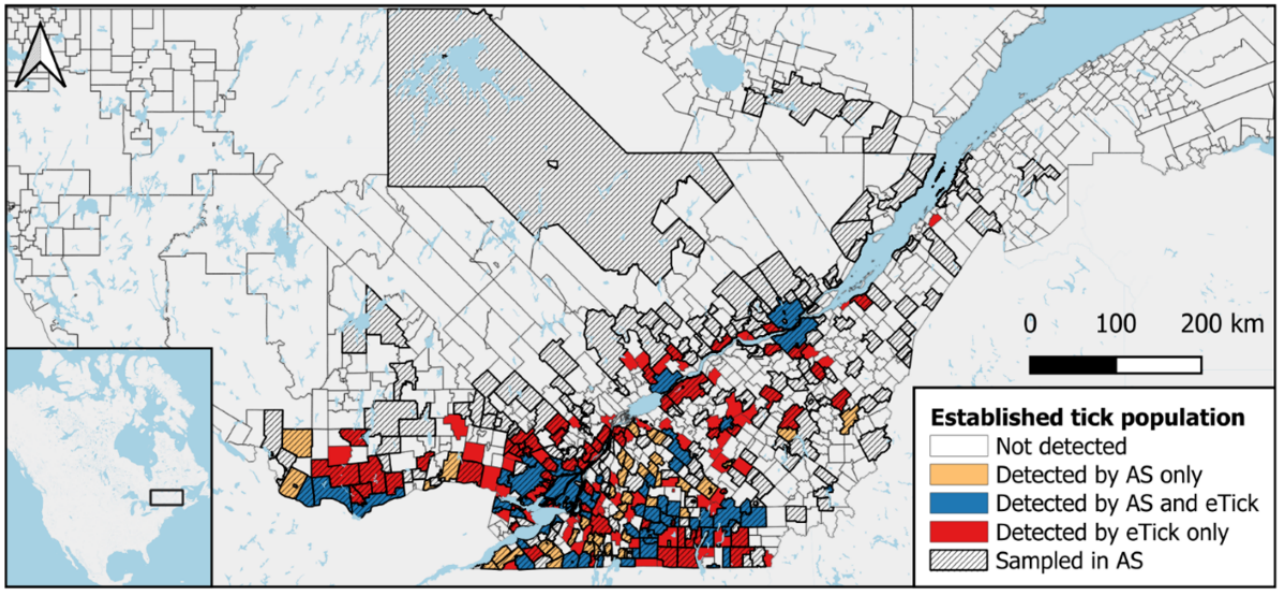
| Climatically suitable small and medium population centers (>2843 DD >0 °C; <10,000 population; n=247) | 3344 | 9202 | 77,717 | 46.4 | 1.92 | 4.76 | 0.02 |
| Climatically unsuitable medium population centers (<2843 DD >0 °C; ≥30,000 population; n=3) | 2769 | 97,172 | 61,300 | 50.2 | 64.40 | 128.16 | 21.90 |
| Climatically unsuitable small population centers (<2843 DD>0 °C; <30,000 population; n=74) | 2684 | 3478 | 68,129 | 51.7 | 11.87 | 24.41 | 3.51 |

[a] For ease of interpretation, the cutpoints are calculated for typical CSDs grouped by climate suitability and population size, with demographics and environmental covariates fixed at their mean values within each CSD group.



[b]DD: degree days.

According to the active surveillance criteria for the presence of established blacklegged tick populations and the eTick indicator based on submission thresholds, all CSDs with established populations are located in the southern part of the province, up to the approximate 47˚N latitude of Quebec City (Figure 2). Among the 343 CSDs sampled through active surveillance, 248 (72.3%) were identified as positive for the presence of established tick populations by at least one of the 2 indicators. Of these 248 positive CSDs, 45 (18.1%) were identified by the active surveillance criterion only, 148 (59.7%) were identified by the eTick indicator only (using thresholds ranging from 2 to 64 submissions, as detailed in Table 7), and 55 (22.2%) were identified by both indicators (Figure 2).

XSL•FO
RenderX

**Figure 2.** Comparison of established blacklegged tick (*Ixodes scapularis*) populations at the census subdivision (CSD) level in Quebec, Canada, between 2020 and 2023, based on active surveillance (AS) criteria (n=343 CSD sampled) and the eTick thresholds. Based on AS data, an *I scapularis* population is considered established if either 6 or more ticks have been found or at least two different life stages are found within the same year in a municipality. The eTick thresholds represent the number of submissions optimizing the balance between sensitivity and specificity and are derived from the top-performing model (C1) predicting established blacklegged tick populations using the eTick crowdsourced surveillance indicator, including all origins combined and socioecological factors. Thresholds are applied to CSDs according to climate suitability and population size, as detailed in Table 7. Depending on the CSD, thresholds range from 2 to 64 submissions to be considered indicative of an established population.

## Discussion

### Principal Findings

This study demonstrates that crowdsourced eTick data can be used to develop robust, evidence-based indicators of blacklegged tick population establishment in Quebec. Although we did not detect spatial clusters in submission rates, we found that the rates were associated with socioecological factors, including climate suitability, population size, landscape configuration, and population socioeconomic characteristics. The results also highlighted key sources of variation that must be accounted for when deriving indicators from crowdsourced surveillance data. Building on these findings, we developed and tested indicators based on eTick submissions that were effective in detecting CSDs with established tick populations while accounting for confounding factors. Overall, the results support integration of crowdsourced surveillance data into the Canadian tick-borne disease surveillance framework as a complementary tool to traditional active surveillance. Previous studies using eTick data have applied different approaches to predict tick distribution or public health risk, providing useful points of comparison for the present findings. Bowser et al [89] assessed whether early eTick data (2018 - 2020) could predict LD risk at the CSD level, in an endemic region of Quebec, Canada. They reported weaker associations and poorer model fit when eTick submissions were used as LD risk predictors compared to other indicators, attributing these results to the novelty of the platform at the time and variable levels of public adoption and participation. More recently, Westcott et al [90] used eTick submissions with other citizen science datasets to develop niche models predicting the current and future distribution of *I scapularis*. Both studies relied on raw submission data and did not explicitly account for socioecological factors influencing participation and reporting intensity, which may have limited risk signal detection in Bowser et al [89] and biased habitat suitability estimates in Westcott et al [90]. While these studies illustrate the potential utility of crowdsourced surveillance data, the lack of consideration of these factors may represent an important limitation. Indeed, results from this study indicate that eTick submission counts are influenced by both human and environmental factors, including population size, socioeconomic characteristics, and habitat suitability affecting tick occurrence and abundance. Submission rates likelihood reflect exposure risk among humans and companion animals as driven by behavior and tick presence and density, as well as factors influencing the decision to submit samples to eTick. Accordingly, the value of these data for contributing to surveillance programs depends on accounting for biases affecting submission rates.

Submissions to eTick were distributed across southwestern and central Quebec, corresponding to the known distribution range of *I scapularis* in the province [91]. Although no statistically significant spatial clusters were detected, there was geographic heterogeneity in submission rates for both submission types. Submission of ticks found attached to humans were mostly reported in the southernmost regions of the province, which are also the highest risk regions for LD (Outaouais, Montérégie, and Estrie [92]). In contrast, submissions of ticks found attached to animals were distributed across a wider geographic area, including regions located outside the currently defined endemic zones. Several of these regions include municipalities with lower risk levels for LD or are not considered endemic for LD according to the provincial risk classification [91]. Under this classification, municipalities are considered endemic when they meet one or more criteria regarding the number of declared human LD cases, the number of ticks collected through passive

XSL•FO
RenderX

surveillance, or the number and stages of *Borrelia burgdorferi*–infected ticks collected in active surveillance [93]. Taken together, these patterns highlight the broader geographic scope of detections obtained through animal-origin submissions and suggest that combining submissions from both origins may provide complementary information for surveillance of tick presence beyond established endemic areas. As eTick data continue to accumulate over time, there may be sufficient statistical power to detect higher than expected submission rates, if present, which could help identify and test for currently unknown local factors (human and pet population, or tick) affecting exposure risk.

### Socioecological Factors Associated With Tick Submissions

In zero-inflated negative binomial models analyzing the factors associated with tick submissions, the total human population of CSDs was the strongest predictor of both submission likelihood and count, indicating that more populated areas are more likely to report tick presence. This result aligns with previous studies, which have shown that submission counts are generally proportionate to population size, where the odds of submission increase with the number of potential contributors [18-20,40,41]. These findings reinforce the importance of accounting for population size when analyzing passive surveillance data [18,19]. Additional socioecological factors also influenced submission occurrence and counts.

First, municipalities that accumulated more annual DD >0 °C were more likely to have tick detections. Ticks require ambient temperatures above 0 °C to quest for hosts, with warmer conditions accelerating interstadial development [94]. Globally warmer conditions throughout the year are thought to accelerate the completion of their life cycle and facilitate their establishment. Indeed, previous modeling and field studies have shown that a threshold of approximately 2800 DD >0 °C is needed for ticks to establish viable populations [67,95]. While DD >0 °C was a determinant of the presence of tick populations, it did not significantly affect submission counts once populations were established. This suggests that once tick populations are well established, other factors such as host densities, human-tick encounters, or participation behavior may drive the numbers of submissions to eTick.

The proportion of WUI in CSDs was positively associated with tick submission counts. This variable measures the degree to which human settlements (ie, neighborhoods where people live, infrastructures where people work, or roads providing access to the territory) are surrounded by natural areas, including woodlands, ecotones, and prairies, which may be suitable habitats for ticks and their hosts [65]. Results indicate that CSDs with higher WUI represent higher tick exposure risk areas [45]. Conversely, the WUI indicator was negatively associated with the occurrence of tick submissions (as denoted by a significant positive relationship with the likelihood of structural zeros), which is a surprising result that warrants further analysis. Here, we studied a region that may not be entirely suitable for tick establishment, with very different biomes across the territory [5]. It is unknown, for example, if boreal forest provides a habitat where *I scapularis* populations can become established [96]. Consequently, this result may reflect another underlying relationship not captured by our current indicators or may relate to the coarse ecological nature of the indicator, which is aggregated at the municipal level and includes all types of natural habitats. Moreover, ticks require specific ecological conditions regarding habitat type, host availability, and landscape connectivity at fine spatial scales, which likely could not be detected at the municipal scale used in this work [45,97,98].

Finally, CSDs with higher median household income and age were associated with more submissions. This aligns with other findings that citizen science initiatives tend to predominantly attract middle-aged and older groups and those with greater access to educational and financial resources [35,37]. This is a common point of critique [37,99] and an area where improvement is needed through initiatives aimed at reaching more diverse groups. Doing so would help ensure that the benefits of participation are more equitably distributed across the population [31] and that the indicators derived from these data are more representative of all areas and population profiles. Our proxy of general population awareness of ticks and LD, constructed using Google Trends data, showed a weak but positive relationship with submission counts in CSDs. This aligns with expectations that public awareness of the problematics under focus is generally associated with higher participation in citizen science initiatives [31,37,100]. However, several limitations inherent to Google Trends may have contributed to the weak association observed. Keyword-based indicators rely on specific search terms and may not capture the broader range of queries related to tick information seeking [101]. Additionally, Google search activity can be strongly influenced by short-term, media-driven attention, which may not reflect sustained awareness or a durable willingness to engage with surveillance initiatives such as eTick [101]. More broadly, public health intelligence derived from open-access, user-generated sources, such as Google Trends, is subject to participation bias, with contributions disproportionately originating from populations with greater internet access and digital literacy. As a result, these data may not accurately represent the population at risk to the public health threat [102,103]. Furthermore, Google Trends data can be unstable or imprecise when analyzed at small spatial scales or in areas with low population sizes, such as many CSDs, in the study area [104]. Collectively, these limitations may reduce the validity of this indicator as a proxy for awareness, as noted in previous studies [101]. Integrating complementary data from diverse sources, ranging from traditional public health surveillance systems to nontraditional data, such as open-access social media, may help strengthen signal detection and mitigate participation biases [102].

### The Detection of Established Blacklegged Tick Populations

To evaluate the ability to detect established *I scapularis* populations, we built and compared models using 1 of 3 crowdsourced surveillance indicators based on tick origin: ticks found attached to humans, animals, and from all origins combined. For each indicator, we compared simple models with more complex ones that accounted for socioecological factors

XSL•FO
RenderX

associated with submissions in objective 1. In all cases, the complex models significantly outperformed simpler alternatives, including those accounting for population size or only using submission counts. While simple models can be useful for ease of interpretation and indicator development for public health use [18], the loss in performance here would be too high to justify this approach. This result highlights the relevance of analytically considering socioecological covariates when using passive or crowdsourced data, consistent with findings and approaches from other studies [20,41,44].

The 3 top-performing models yielded similar results: model A1, based on ticks found attached to humans and socioecological factors; model B1, based on ticks found on animals and socioecological factors; and model C1, based on all tick origins combined with socioecological factors. Given these similar performances and the complementarity observed in the geographic distributions of both submission types, we pursued subsequent analyses using the submissions from all origins to identify the threshold optimizing the detection of established tick populations. By doing so, we also ensured that all data collected by users were leveraged.

These analyses showcase a methodology for indicator development that can be adapted according to the objectives of the surveillance or research program and the epidemiological context. Previous Canadian passive surveillance studies have shown that ticks recovered from animals, particularly dogs, were effective at providing early signals and wider geographical extent of emerging tick populations [18-20,105]. This relationship has been attributed to differences in exposure, as dogs are generally more directly in contact with vegetation and leaf litter, where they are more likely to be bitten by questing ticks, even with low tick densities [13,14]. However, ticks recovered from animals may be less specific indicators than those from humans, as very low tick densities detected through animals may reflect adventitious ticks transported by migratory birds rather than established tick populations [18,19]. On the other hand, our analyses suggest that ticks from animals can be efficient at detecting emerging tick populations where active surveillance may not be possible or may be insufficient. Although active surveillance remains the most standardized method available for tick surveys, its efficacy depends on multiple factors, including vegetation type and weather conditions before and during sampling [106-108]. Drag sampling may be less effective for detecting emerging tick populations in northern Quebec, where coniferous forests and dense understory vegetation dominate, compared to deciduous forests in southern Quebec [106-109]. This highlights that both active and crowdsourced surveillance indicators may have strengths and limitations and that we would benefit from both by developing integrated indicators [15,100,110].

### Thresholds of Submissions Optimizing Tick Population Detection Accuracy

To identify submission thresholds that optimize tick population detection, we searched for cutpoints that maximized sensitivity, specificity, or both, using models based on submission types. In the best-performing model, a threshold of 3 submissions (rounded from 3.32) maximized both sensitivity and specificity for detecting tick populations. At this threshold, both sensitivity and specificity reached 76%. These levels are comparable to those of a previous study conducted in Quebec, which used passive surveillance to predict the presence of established *I scapularis* populations, as measured by active surveillance carried out from 2007 to 2008 [20]. That study identified an optimal threshold of 0.073 (Predicted Linear Index), which predicted the presence of ticks in the environment with 74.19% sensitivity and 73.68% specificity, using a similar methodology that maximized both indicators. Their model included passive surveillance data, an index of environmental suitability based on cumulative annual DD >0 °C, and an index estimating the number of ticks arriving on migratory birds. Overall, our results of crowdsourced surveillance shared similar characteristics and limitations with comparable traditional passive surveillance datasets from other Canadian studies: more adult female ticks were submitted than immature ticks, more ticks were recovered from animals than from humans, and similar factors affected the submission data [14,18-20]. The predictive performance of this dataset in identifying established tick populations, as confirmed by active surveillance, was consistent with that of traditional passive surveillance. Therefore, our analysis supports the validity of crowdsourced data as a complement to traditional active and passive surveillance. We believe these approaches should remain complementary, as each provides distinct information. Active surveillance provides standardized measures of tick density and confirmation of locally reproducing populations, while crowdsourced data offer broader geographic coverage and rapid detection of emerging areas [111], and traditional passive surveillance also more readily enables pathogen testing, which is generally not feasible with crowdsourced submissions. Future work should include an assessment of how these data should be used to build indicators that are adaptive to evolving epidemiological context, such as the one prevailing in Canada [11,105].

The optimal thresholds of submissions maximizing tick population detection accuracy were highly variable across the study area. This variability reflects the province's pronounced heterogeneity regarding population size, land cover, climate, and socioeconomic characteristics. To facilitate interpretation, we exemplified what these thresholds would be across different groups of CSDs, regrouped by population size and climate suitability. Climatically suitable regions for ticks are concentrated in the southern parts of Quebec. These areas are well-known endemic zones for *I scapularis* and LD, including the highest incidence regions of Estrie and Montérégie [56]. Most CSDs in these regions have small population sizes and are suburban or rural. These areas also have a high proportion of WUI, meaning there is significant overlap between tick-suitable natural environments and human habitation. In such contexts, only a very small number of tick submissions was sufficient to indicate the likely presence of an established tick population. This suggests that even limited crowdsourced surveillance signals in these areas should raise awareness about possible reproducing tick populations and emerging risk of tick-borne disease [112]. In contrast, large population centers in climatically suitable areas required a higher threshold of submissions to balance sensitivity and specificity. In climatically unsuitable regions, a similar threshold was identified for small

XSL•FO
RenderX

population centers, while the highest one was identified for medium population centers. These findings suggest that in emerging areas, a high number of ticks must be submitted before suspecting an established population, which may indicate that adventitious ticks are detected well before actual establishment occurs. Alternatively, it could reflect a mismatch between active and passive surveillance data in these regions. For example, active surveillance may fail to detect ticks in more northern environments due to limitations in sampling sensitivity, especially in the dense understory vegetation of coniferous forests [106,108], or because of lower sampling effort deployed in these areas. In contrast, passive surveillance may be less affected by these limitations, as it relies on ticks encountered by the public or professionals across a wider range of habitats and conditions.

This study has several limitations that should be considered when interpreting its findings. First, the spatial accuracy of eTick submissions implies an inherent level of uncertainty, as reported locations reflect the user's presumed site of tick acquisition and cannot be assumed to be exact. These locations remain subject to recall and information bias, as users may have incomplete recollection of where exposure occurred or may infer locations based on routine activities. Spatial accuracy is expected to be higher when ticks are detected promptly after exposure or when individuals perform regular tick checks and are aware of their recent movements [28]. Excluding submissions from users reporting recent travel history mitigated the impact of this source of uncertainty; however, it was not possible to fully control for this limitation with the available data. Second, uncertainty in indicator precision may arise from spatial aggregation at the CSD level and from the use of active surveillance as an imperfect reference standard. Ecological processes relevant to tick establishment operate at finer spatial scales than those captured here, and active surveillance may fail to detect established populations under certain environmental or sampling conditions. Together, these limitations reflect the challenge of relying on relatively coarse spatial indicators. Likewise, although we attempted to account for participation biases to which crowdsourced initiatives are subject by including sociodemographic covariates in our modeling framework, residual bias likely remains. Finally, the generalizability of the proposed indicators beyond Quebec and over time will require further evaluation. Differences in surveillance systems, population engagement, ecological contexts, and public awareness across provinces or countries may affect indicator performance. Over time, the usefulness of a crowdsourced approach such as eTick depends on sustained participation from both the general public and professionals [113]. Since future engagement is unknown and may not remain stable over time, the continued usefulness of this surveillance method cannot be guaranteed. Regular reassessment will therefore be necessary to ensure data quality and long-term relevance.

## Conclusions

In this study, we analyzed the patterns in blacklegged tick submissions to the platform eTick in Quebec, Canada. This work introduces a rigorous analytical framework for interpreting crowdsourced surveillance data by comparing submission rates with long-term active surveillance. A novel contribution is using a socioecological approach to adjust for potential participation bias in eTick submission rates. Unlike prior Canadian tick passive surveillance studies, which rely primarily on traditional surveillance methods or that use unadjusted crowdsourced data, our approach explicitly incorporates socioecological factors associated with reporting into the modeling framework. This work demonstrates that crowdsourced surveillance data, when appropriately modeled, can yield reliable inferences about disease vector distributions. It provides a methodological approach applicable to other medically important vector species and geographic contexts, and contributes to improving the robustness of ecological inference of vector distributions. Specifically, our findings show that eTick can effectively complement traditional passive surveillance methods for detecting established blacklegged tick populations. Although this analysis focused on *I scapularis*, eTick allows the collection of all tick species and could therefore support monitoring of other medically important species in Canada, such as *Ixodes cookei*, *Dermacentor variabilis*, *Rhipicephalus sanguineus*, or *Amblyomma americanum*. These contributions have practical implications for public health practice. More confident identification of tick distributions supports targeted public health actions and improved surveillance strategies. The broad geographic coverage of eTick makes it well suited for early detection of emerging tick-borne diseases in undersurveyed regions. Integrating eTick data into formal surveillance systems could significantly enhance Canada's capacity to detect those emerging risks in a cost-effective way. Future work should focus on expanding the analytical framework to other tick species and pathogens, conducting field validation of predicted tick populations using active surveillance, and improving the representativeness of reporting populations across diverse and historically excluded communities.

## Acknowledgments

We thank Jeremie Bouffard for assistance in managing the eTick program and all participants who submitted specimens to eTick. We also thank Ariane Adam-Poupart for facilitating the data agreement between Institut national de santé publique du Québec and Public Health Agency of Canada. The authors confirm that no generative AI tools were used in the preparation of this manuscript.

## Funding

This study was funded by the Public Health Agency of Canada through internal operational research funds.

## Abstract

**Background:** Rheumatic heart disease (RHD) is a sequela of recurrent, untreated group A *Streptococcus* infections. RHD disproportionately affects children and young adults in the Global South. Intermittent mass screening of early RHD by using affordable tools in these disease-endemic regions is essential for effective prevention.

**Objective:** This study examined multimodal physiological data for assessing the prevalence of early RHD in a cohort of asymptomatic, at-risk students in rural Ethiopia.

**Methods:** A total of 584 asymptomatic children aged 10 to 20 years were randomly selected for screening and stratified into 2 groups (≤14 and >14 years). Electrocardiogram, phonocardiogram, and echocardiography screening were performed, with diagnoses based on the 2012 World Heart Federation criteria.

**Results:** After excluding 1.4% (8/584) of the children, who had nonrheumatic findings, 576 participants were analyzed, including 334 (58.0%) female and 242 (42.0%) male children. The mean age was 16.1 (SD 2.4) years (95% CI 15.9-16.3). Echocardiographic screening identified 19 cases of RHD (n=10, 52.6% borderline and n=9, 47.4% definite). Female children accounted for 68.4% (13/19) of cases, and the association between female sex and RHD was not statistically significant (odds ratio 1.59, 95% CI 0.60-4.25; *P*=.35). The estimated prevalence of RHD was 32.5 per 1000 population (95% CI 18.1-46.9; SE 7.4; 19/576, 3.3%), which was significantly higher than the most recent multicenter prevalence estimate of 19 per 1000 population (95% CI 13.9-23.4; odds ratio 2.12; *P*=.03). Mitral regurgitation was the predominant lesion (16/19, 84.2%), followed by mitral stenosis (2/19, 10.5%) and aortic regurgitation (1/19, 5.3%). Phonocardiogram analysis showed mitral regurgitation (10/19, 52.6%), mitral stenosis (2/19, 10.5%), and subclinical findings in the rest of patients with RHD. Prolonged PR intervals were observed in 10.5% (2/19) of the RHD-positive participants.

XSL•FO
RenderX

**Conclusions:** This study confirms persistent high prevalence of asymptomatic RHD among students in rural regions of Ethiopia. Although there was a female predominance in RHD incidence, the difference between the sexes was not statistically significant.

## Introduction

Rheumatic heart disease (RHD) arises from a systemic immune response to β-hemolytic streptococcal throat infections, particularly affecting children younger than 15 years [1]. Untreated infections can lead to acute rheumatic fever (ARF) and subsequent cardiac damage resulting in RHD [2], which often remains asymptomatic in the early stages [3]. RHD has been a global health priority since 2018. It disproportionately affects low- and middle-income countries (LMICs) and socioeconomically marginalized populations despite being a preventable disease [4-6]. A recent World Health Organization report [7] stated that approximately 55 million people worldwide are affected by the disease, resulting in over 360,000 deaths each year. While the burden of RHD has decreased significantly to almost none in high-income countries over recent decades, it remains a critical public health issue in the Global South, particularly in regions with high rates of ARF. The prevalence of RHD in LMICs has increased by nearly 50% since 1990, with projections suggesting that this trend will continue until 2030 [8].

Epidemiological studies conducted in Ethiopia indicate that chronic RHD ranks among the most commonly diagnosed cardiovascular conditions, with valvular heart disease constituting 40% of annual cardiac cases—80% of which are linked to RHD [9]. However, accurate estimates of prevalence of RHD remain challenging due to variations in screening methods, demographic characteristics of the participants, and sampling techniques. An echocardiography-based overall pooled national prevalence estimate in students suggests approximately 27 cases per 1000 individuals [4]. A multicenter study involving 3238 students in regional cities reported definite RHD cases being 2.9 times more prevalent than borderline RHD (1.4% vs 0.5%, respectively) [10]. Subclinical RHD was reported 7 to 8 times more commonly than symptomatic RHD in at-risk populations (21.1 per 1000 individuals vs 2.7 per 1000 individuals, respectively) [11].

Furthermore, the reported prevalence of RHD among students in Ethiopia varies widely across studies (ranging from 3.2 to 56.7 per 1000 individuals), and most of these reports are over a decade old. For instance, echocardiography-based studies have reported a prevalence rate of 30.5 per 1000 individuals in a study including 2000 children [12], 56.7 per 1000 individuals in another study of 987 participants [13], 19 per 1000 individuals in 3238 participants [10], and 3.2 per 1000 individuals in 1874 students [14]. Socioeconomic and environmental factors such as overcrowding, income, and proximity to health centers have been associated with an increased risk of RHD [15]. These factors pose challenges to accurately estimating the current health burden of RHD and hinder the development of prophylactic interventions aimed at preventing recurrent ARF, which are critical to reduce the progression to subclinical RHD.

Subclinical RHD is characterized by the presence of RHD identified via echocardiography in the absence of detectable heart murmurs on auscultation and without accompanying clinical symptoms [16]. The mitral valve (MV) is the most involved valve in patients with RHD with subsequent regurgitation, stenosis, or combined lesion [1,2,17]. In the acute phase, valvulitis may present as mitral regurgitation (MR) due to annular dilation and chordal elongation. Chronic RHD often leads to mitral stenosis (MS) resulting from leaflet thickening, commissural fusion, and chordal shortening [2,17]. Most patients with chronic MR, particularly in the pediatric population, remain asymptomatic for many years [18]. However, over time, the condition can lead to left ventricular dysfunction, and patients typically present with clinical signs in later years of their life. Notably, physiological valvular regurgitations may occur in healthy children as well [19].

While echocardiography remains the gold standard for RHD detection, offering superior sensitivity and specificity compared with auscultation or electrocardiogram (ECG) screening [20], its implementation in resource-limited settings is often constrained by a shortage of skilled personnel and appropriate equipment [21,22]. Nevertheless, structural and functional hemodynamic abnormalities of rheumatic cardiac valves are often subtle, particularly during the early or subclinical stages of the disease. These abnormalities are undetectable through auscultation or ECG alone, resulting in poor sensitivity for identifying asymptomatic RHD. Furthermore, the cardiac hemodynamics of asymptomatic patients with RHD are frequently within normal limits [23]. ECG patterns are also inconsistent in RHD. The most common are prolonged PR intervals and QTc intervals [24-26]. Handheld ultrasound devices, on the other hand, demonstrate high diagnostic performance, with sensitivities reported to be between 92% and 96% when used by expert sonographers [20,27]. Although evidence on the diagnostic accuracy of phonocardiogram (PCG) and ECG remains limited, they can be regarded as potential prescreening tools to identify high-risk individuals who would benefit the most from confirmatory echocardiographic evaluation. Moreover, advances in machine learning provide a promising strategy to enhance their diagnostic utility, potentially improving automated screening sensitivity. Assessment of such scalable and cost-effective RHD screening strategies requires further validation in endemic populations.

Therefore, the aim of this study was to determine the current prevalence of RHD among at-risk, asymptomatic students using the 2012 World Heart Federation (WHF) echocardiographic criteria [2]. We also performed PCG and ECG assessments in students with echocardiography-confirmed RHD to estimate

XSL•FO
RenderX

the proportion of cases that would be missed in routine clinical screening. The PR, QTc, and QRS interval duration was measured for ECG analysis, whereas PCG recordings were assessed for the presence of any pathological systolic or diastolic murmurs. This highlights gaps in early detection for population-level surveillance.

# Methods

## Study Setting

This study was conducted on students recruited from 4 public schools in rural areas of southern Ethiopia (Multimedia Appendix 1). The schools were selected using a systematic random sampling method based on previous demographic surveys conducted at a nearby hospital. In this sample, participants were randomly selected from each grade level, ensuring an even distribution of age and sex. Data were collected by a team of 4 local health care workers, 2 cardiologists and 2 general practitioners.

## Selection of Participants and Randomization

This study used a cross-sectional observational design to assess the prevalence of early RHD among asymptomatic underserved students at schools in rural Ethiopia. The students who met all the inclusion criteria, shown in Multimedia Appendix 1, were included in the study. The inclusion criteria ensured that only medically stable participants without interfering clinical conditions such as severe anemia, chronic lung or renal disease, and malnutrition were enrolled in the study. Children and adolescents outside the 10- to 20-year age range; who had any history of cardiac surgery, replaced cardiac valve, or implanted devices; and who were taking cardiac medications were excluded from screening. Subsequently, the registry of this target population was encoded and anonymized. A systematic random sampling method was used to select participants from each classroom in the study period (March 2023 to September 2023). First, the students in the classrooms were stratified by age groups of 14 years or below and above 14 years. Each student in the classroom was assigned a unique alphanumeric code, and approximately 30% of the numbered list was selected at random. The selected students and, in case of being minors, their parents were then informed about the research protocol via a participant information sheet.

## Sample Size Determination

We based our assumptions on a literature review indicating a disease prevalence of at least 2.7% among students at schools [28]. To estimate such a prevalence with a precision of up to 2% at a 95% confidence level, we determined that a minimum sample size of 504 was necessary. Considering a potential dropout rate of 10%, we aimed to enroll 560 students. The sample size was divided proportionally among the participating schools.

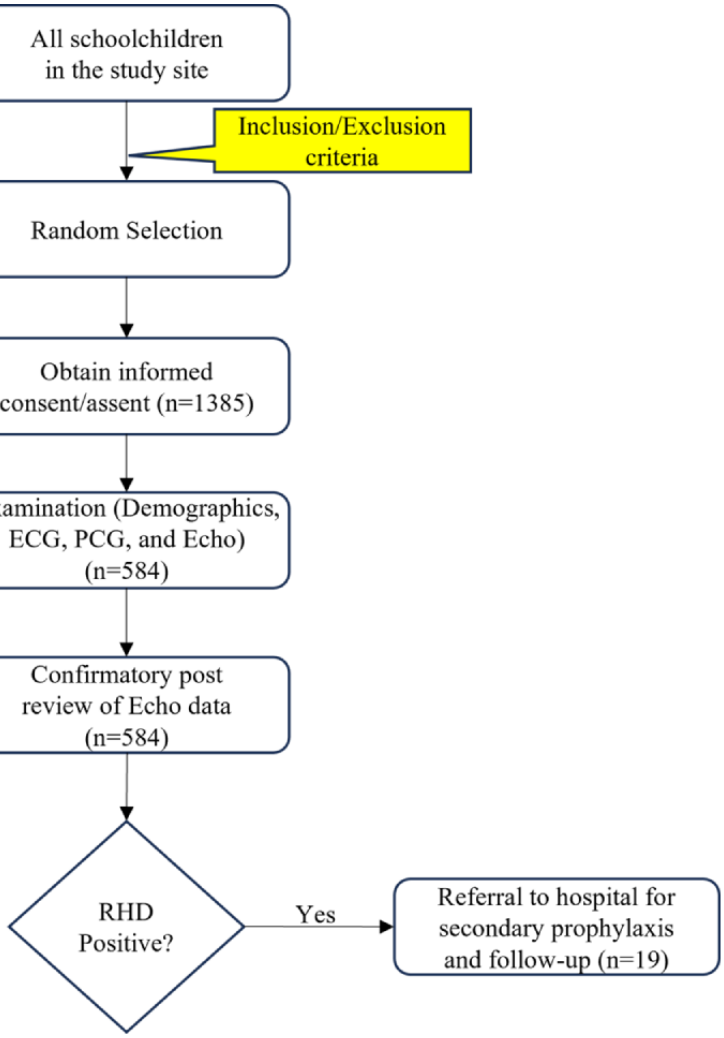
## Ethical Considerations

This study was approved by the ethics committees of University Hospitals Leuven (B3222022001075) and Soddo Christian Hospital (SCH1941015). The study protocol conformed to the ethical guidelines of the 1975 Declaration of Helsinki as reflected in a prior approval from the institutions' human research ethics committees. Written informed consent was obtained from all participants or their guardians. Data were anonymized to protect participant confidentiality. No compensation or tokens of appreciation were provided for participation in the study. To maintain confidentiality, unique identification codes were assigned to the study participants. The principal investigators securely stored and controlled access to the data, limiting it to authorized personnel only.

## Statistical Analysis

Statistical analyses were conducted using the R software (version 4.1.0; R Foundation for Statistical Computing). Continuous variables were summarized as means and SDs for normally distributed data and medians for nonnormally distributed data. Normality was assessed using the Shapiro-Wilk test. For comparison of continuous variables between 2 groups, the Welch *t* test was used for normally distributed data, and the Mann-Whitney *U* test was used for nonnormally distributed data. Categorical variables were presented as counts and percentages, and comparisons were made using the chi-square test. *P* values of less than .05 were considered statistically significant. The prevalence of RHD was estimated per 1000 population. We calculated the sum of RHD-positive cases from the total number of participants examined and extrapolated the result to an estimate per 1000 population.

## Data Collection Procedures



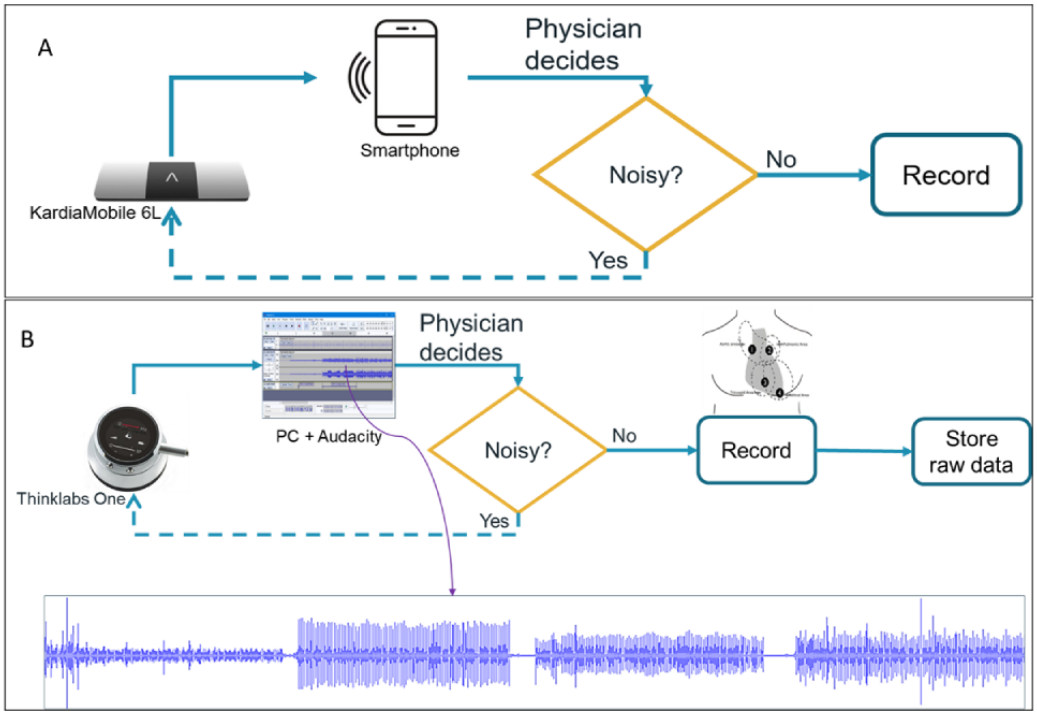
### *Overview*

Study participants underwent a screening examination procedure, as shown in Figure 1. From each study participant, demographic data and ECG, PCG, and echocardiographic data were collected according to International Council for Harmonisation of Technical Requirements for Pharmaceuticals for Human Use good clinical practice. This is a widely adopted internationally agreed upon standard for designing, conducting, recording, and reporting clinical trials involving human participants. No clinical evaluation, including blood tests or swab samples related to ARF, were performed. A total of 1385 participants gave consent participants, of whom only 584 (42.2%) completed the ECG, PCG, and echocardiographic screening procedures, whereas the remainder missed one or more of the examinations mainly due to conflicting schedules, anxiety about echocardiographic screening, peer pressure, or unspecified personal reasons.

XSL•FO
RenderX

**Figure 1.** Screening examination flow diagram outlining participant inclusion and recruitment; the sequence of electrocardiogram (ECG), phonocardiogram (PCG), and echocardiographic (Echo) examinations; and the final diagnostic decision. RHD: rheumatic heart disease.

### *ECG Data*

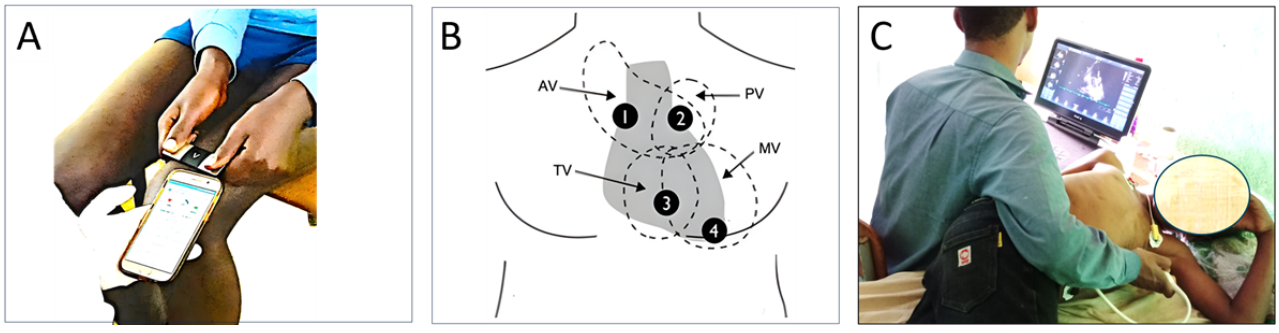


ECG data were recorded using a commercial CE-marked device, KardiaMobile 6L (AliveCore, Inc). KardiaMobile is small pocket device that is connected via Bluetooth to a compatible smartphone that has the Kardia app from AliveCor, Inc, installed, shown in Figure 2A. The device has 3 electrodes with a sampling frequency of 300 Hz. For obtaining an ECG recording, participants must touch 3 electrodes on the device, 1 on the back with their left leg and 2 on the front with the fingers of the left and right hand. ECG recordings were obtained at least twice, both from the knee or ankle positions, and repeated if deemed necessary (Figure 3C-D). Each recording had a duration of 30 seconds.

The temporal evaluations on ECG waveforms were performed manually by 2 physicians. After performing a 50-Hz powerline interference and Butterworth zero-phase band-pass filter from 1 to 100 Hz, an averaged ECG was computed by aligning and averaging the cardiac cycles in the lead II waveform using the R wave as a reference point. Three ECG intervals, PR, QRSd, and QTc, were then evaluated for RHD-positive participants from an averaged ECG. Prolonged changes in these intervals have been reported in patients with RHD [24-26]. The intervals were normalized using the heart rate (HR) and calculated considering a threshold margin of –10 to +10 ms for the QRSd interval and –15 to +15 ms for the PR and QTc intervals. HR-adjusted PR intervals [29] were used to determine PR prolongation. QTc values for each heartbeat were calculated using the formula by Bazett [30]. The QRS morphology was classified as normal if it was within the range of less than 105 ms considering the age of the cohort [31].

XSL•FO
RenderX

**Figure 2.** Connectivity block diagrams of the devices used during screening for rheumatic heart disease: (A) KardiaMobile device (AliveCor, Inc) and smartphone to record electrocardiogram signals and (B) Thinklabs One stethoscope with a computer to record phonocardiogram signals. In cases of noisy recordings, the physician performed a repeat acquisition to ensure signal quality.



### *PCG Data*

PCG data were recorded using a Thinklabs One stethoscope, a CE-marked medical device for auscultation. The stethoscope was connected to a PC, and input cardiac sounds were recorded using the Audacity open-source software (version 3.7.2; Muse Group) [32], as illustrated in Figure 2B. A wideband (20-2000 Hz) device mode audio filtering was set to acquire the heart sounds sampled at 44.1 kHz. The recording was taken from 4 positions: aortic, pulmonic, tricuspid, and mitral areas, as shown in Figure 3B.

The PCG recordings of mild regurgitations from participants with a BMI above 24 kg/m$^2$ were not audible, so different positioning strategies, such as left lateral decubitus, sit-up-lean-forward, and supine, were used to obtain a better signal. A total of 60 seconds of cardiac sound data were recorded from the aortic, pulmonic, tricuspid, and mitral areas. The recorded auscultations were played back and listened to by 2 physicians. Any pathological murmur during systole over the apex was considered an MR. Diastolic murmurs were labeled as aortic regurgitation (AR) or MS based on the intensity and duration of the murmur. Any other murmur was labeled as "other."

**Figure 3.** Data acquisition from the participants screened for rheumatic heart disease: (A) electrocardiogram data acquisition from the knee position, (B) 4 locations from where phonocardiogram data acquisition was performed (1=aortic area, 2=pulmonic area, 3=tricuspid area, and 4=mitral area), and (C) transthoracic echocardiography acquisition. AV: aortic valve; MV: mitral valve; PV: pulmonic valve; TV: tricuspid valve.

### *Echocardiography*

A comprehensive transthoracic echocardiogram was performed by trained cardiologists using a portable Vivid iq (GE Vingmed Ultrasound) equipped with an M5Sc 2.2-MHz transducer (Figure 3C). Image acquisition was performed with the patient in a left decubitus position. Cardiac size and function, as well as the site and severity of the valvular lesion, were assessed using B-mode, spectral Doppler, and color Doppler imaging. We recorded clips with 3 to 5 cardiac cycles or 10 cycles in the case of atrial fibrillation. Afterward, the recorded images were independently reviewed by 2 cardiologists, and decisions were made using the WHF 2012 criteria.

XSL•FO
RenderX

The WHF 2012 criteria [2] (Multimedia Appendix 1) detail the diagnosis for definite RHD, borderline RHD, and normal echocardiographic findings in A, B, C, and D evidence groupings. Definite RHD requires either pathological regurgitation (MR or AR) combined with at least 2 morphological features of RHD in the affected valve, MS with a mean gradient of 4 mm Hg or higher, or concurrent borderline features in both the MV and aortic valve (AV). Borderline RHD is characterized by isolated morphological valve abnormalities or isolated pathological MR or AR without meeting the full criteria for definite RHD. Borderline RHD diagnosis cannot be based on a single abnormality; it requires either mild pathological regurgitation accompanied by at least one morphological feature or multiple morphological features of valvular involvement. Normal findings may include physiological regurgitation and isolated morphological changes without associated pathological stenosis or regurgitation. Participants with other nonrheumatic findings or comorbidities were excluded from the final analysis. Participants and/or their legal representatives were notified about findings indicative of RHD. Furthermore, all RHD-positive patients were referred to a nearby hospital for further guideline-recommended clinical management.

## Results

### Prevalence of RHD

A total of 584 study participants (n=340, 58.2% female and n=244, 41.8% male) were included in the study, of whom 8 (1.4%) were found to have nonrheumatic findings and excluded. Thus, 576 participants (n=334, 58% female and n=242, 42% male) were analyzed, as shown in Table 1. The nonrheumatic cases were observed mostly in female individuals (n=6) than in male individuals (n=2); 4 participants (n=3 female and n=1 male) had a first-degree MV prolapse with no rheumatic etiology, and 1 male participant had aortic sclerosis, whereas a female participant had atrial septal defect. Two additional participants exhibited physiological regurgitations associated with congenital AV anomalies: a bicuspid valve with right-left coronary cusp fusion (female individual) and a quadricuspid valve with a smaller accessory cusp (male individual).

Study participant characteristics are shown in Table 2, and the distribution of confirmatory results among the cohort overall and among RHD-positive participants is shown in Figure 4 and Figure 5, respectively. The overall mean age was 16.1 (SD 2.4; 95% CI 15.9-16.3) years. Participants younger than 13 years accounted for only 15.5% (89/576) of the total cohort due to challenges encountered in obtaining consent from legal guardians. A total of 5.2% (30/576) had a BMI above 24 kg/m$^2$, and 86.7% (26/30) of these participants were female. By applying the WHF 2012 guidelines mentioned in the Echocardiography section, we identified 19 cases of RHD (n=10, 52.6% borderline RHD and n=9, 47.4% definite RHD). Extrapolating from our data, the suggested prevalence of RHD in the age group of 10 to 20 years was 32.5 per 1000 persons (95% CI 18.1-46.9; SE 7.4). The mean age of the RHD-positive participants was 17.0 (SD 2.2) years, with the earliest incidence of RHD being at 13 years. The RHD-positive participants were predominantly female (13/19, 68.4% vs 6/19, 31.6% male), although the difference was not statistically significant (odds ratio 1.59, 95% CI 0.60-4.25; *P*=.35). Overall, 3.9% (13/334) of the female participants were RHD positive compared to 2.5% (6/242) of the male participants. There was no statistically significant correlation between RHD and household size (*P*=.49; *t*=0.705), age (*P*=.09; *t*=1.771), or sex (N=576, $\chi^2_1$=0.8; *P*=.36).

## Echocardiographic Findings

We analyzed the involvement of the valves and their structures according to the WHF 2012 A, B, C, and D groupings discussed in the Echocardiography section and Multimedia Appendix 1. Illustrative echocardiographic images from an RHD-positive participant are shown in Figure 6 [3]. We observed that thickening of the MV leaflets and restricted leaflet motions were dominant features. Specifically, 73.7% (14/19; 9/14, 64.3% female; and 5/14, 35.7% male) of RHD-positive participants exhibited restricted MV leaflet motion. Excessive anterior leaflet motion during systole was observed in 47.4% (9/19; n=7 female and n=2 male) of the participants, whereas posterior leaflet annulus thickening occurred in 21.1% (4/19; all female). Additionally, irregular or focal thickening of the AV was noted in 31.6% (6/19; n=4 female and n=2 male) of the participants. While pathological MR and AR were the most common findings, observed in 84.2% (16/19; 10/16, 62.5% female and 6/16, 37.5% male) of the participants, MS was observed in 10.5% (2/19; all female) of the participants, and isolated AR was observed in only 5.3% (1/19) of the participants. MS coexisted with MR in both cases (Multimedia Appendix 1).

**Figure 6.** Pathological findings based on World Heart Federation 2012 criteria [3] for a patient with rheumatic heart disease: (A) parasternal long axis (PLAX) view showing doming of anterior mitral leaflet and restricted posterior mitral leaflet, (B) mitral regurgitation via color Doppler imaging in PLAX view, and (C) aortic regurgitation in continuous-wave Doppler imaging. The mitral valve is shown using an arrow.

## ECG Findings

The average HR values showed a monotonically decreasing trend as age increased. We observed a nonsignificant tendency toward higher HR in female individuals than in male individuals across all ages (mean 86, SD 9 beats per minute vs mean 67, SD 10 beats per minute in RHD-positive participants and mean 81, SD 12 beats per minute vs mean 71, SD 12 beats per minute in RHD-negative participants, respectively; both not significant with the corresponding *P*=.08 and *P*=.79. Abnormal rhythm irregularities were not observed in the RHD-positive participants. In total, 10.5% (2/19) of the RHD-positive participants (both female) had prolonged QTc above the normal range of 450 ms. A QRS duration above 100 ms was observed in 10.5% (2/19) of the RHD-positive participants (both female). A prolonged PR interval was also observed in 10.5% (2/19; n=1 female and n=1 male) of the RHD-positive participants.

## PCG Findings

PCG evaluation results of the RHD-positive participants are shown in Table 3. The findings showed MR in 52.6% (10/19) of the participants and MS in 10.5% (2/19) of the participants. The murmur was faint in 15.8% (3/19) of the participants, whereas it was determined as “other” in 21.1% (4/19) of the participants. Systolic murmurs were mostly isolated MRs without MS. In students with a BMI above 24 kg/m$^2$, S1 was often muffled due to an increased amount of tissue that affects the resonance of sound waves. However, there were no findings of pleural effusion or pericardial effusion that may have attenuated the heart sounds in these participants.

Such a muffled S1 heart sound with an audible S4 gallop was observed in 5.3% (1/19) of the RHD-positive participants. Moreover, a split S1 sound, suggestive of delayed left ventricular conduction, was observed in 10.5% (2/19) of the participants. For the first participant in the latter case, a 2D echocardiograph image and M-mode ultrasound showed asynchronous myocardial wall motion where contraction of the left ventricular septal wall succeeded the right ventricular contraction. Early closure of the MV preceding tricuspid valve closure, combined with thickened anterior mitral leaflets and excessive leaflet tip motion, contributed to low-velocity regurgitant flow into the left atria during systole. In the second participant, synchronous conduction with progressively prolonged contraction intervals were observed.

**Table 3.** Phonocardiogram evaluation results on confirmed rheumatic heart disease–positive participants (n=19).

| Sex | MR[a], n (%) | MS[b], n (%) | Other, n (%) | Normal, n (%) |
|---|---|---|---|---|
| Female | 8 (42.1) | 1 (5.3) | 2 (10.5) | 1 (5.3) |
| Male | 2 (10.5) | 1 (5.3) | 2 (10.5) | 2 (10.5) |

[a]MR: mitral regurgitation.

[b]MS: mitral stenosis.

# Discussion

## Principal Findings

### Overview

This study investigated the current prevalence of asymptomatic RHD among students aged 10 to 20 years in underserved areas in Ethiopia. The potential use of affordable clinical examination for periodic surveillance via PCG and ECG was assessed on echocardiography-confirmed cases. Our findings showed that there is a persistent high prevalence of RHD in at-risk communities, with female predominance. Echocardiography revealed MV involvement as the most common manifestation of RHD, typically presenting with leaflet thickening and restricted tip motion. Definite participants exhibited characteristic murmurs, whereas borderline or asymptomatic participants often showed nonspecific auscultatory findings. Low-cost ECG and PCG were insufficient for early detection as PR interval prolongation did not reliably indicate early-stage disease, although this prolongation was more prominent in advanced chronic participants [24-26]. These results underscore the importance of echocardiography-based screening for timely identification and management of subclinical RHD.

### Prevalence

RHD is highly prevalent among students in endemic regions, affecting female individuals more often [1,2]. This study also found an asymptomatic RHD prevalence rate of 32.5 per 1000 population among students, which is consistent with reports from Ethiopia (Multimedia Appendix 1). However, our figures are slightly higher than the pooled prevalence figures from other similar studies in LMICs [10,12]. The findings provide further evidence of a nondecreasing trend in RHD burden in high-risk areas, with persistent transmission of group A *Streptococcus* infections and gaps in primary prevention.

### Distribution of RHD

As can be observed in Table 2, the RHD burden was 60% higher in female than in male individuals. Most of the RHD-positive participants (16/19, 84.2%) were older than 15 years, which aligns with trends observed in previous studies [10]. Overall, the asymptomatic presence of early-stage RHD in school-aged children and adolescents was not strongly correlated with household size, age, or sex in this cohort. While elevated prevalence in female individuals has historically been linked to childbearing age susceptibility [21], our data suggest elevated rates among even younger school-aged girls, which prompts further investigation into the potential role of biological, environmental, or sociocultural risk factors. Disease severity also correlated with advancing age, likely reflecting cumulative valvular damage from untreated ARF recurrences, as described in longitudinal cohorts [11]. However, the pathophysiological basis for sex disparities remains unclear. Importantly, while overcrowding was reported to have a positive and strong association with the prevalence of ARF and subsequently RHD, no strong associations were found for socioeconomic factors such as household income, parental occupation, or literacy levels [15]. This reinforces the necessity of population-wide screening irrespective of demographic proxies in disease-prone regions for early diagnosis and timely treatment of group A *Streptococcus* infections.

### Valvular Involvement

Valvular involvement patterns in our cohort align with global epidemiological profiles, where the MV is most frequently affected, followed by the AV, consistent with reports from Australia, New Zealand, and Uganda [19,20]. This sequence of valve involvement is likely attributed to the MV's hemodynamic vulnerability during ARF, where inflammatory insults preferentially target valve leaflets and chordae [17]. Leaflet thickening and restricted motion dominated MV pathology, confirming the revised 2023 WHF RHD diagnostic criteria. As reported in the study by Webb et al [19], isolated MR was more prevalent than MS in asymptomatic participants, thereby supporting the paradigm of early-stage rheumatic damage characterized by inflammatory retraction and chordal elongation rather than fibrotic fusion. However, combined MR and AR occurred in 84.2% (16/19) of the participants in this study, which is consistent with previously reported findings [11]. Conversely, isolated AR was uncommon in this study cohort, with a single case reported. This is inconsistent with the results reported in the study by Rothenbühler et al [11], who found AR prevalence to be 21%. This discrepancy may reflect regional variations in ARF severity, delayed diagnosis, or genetic susceptibility to multivalvular involvement [4-6].

When these patterns of structural and functional involvement are interpreted within the framework of echocardiographic staging of rheumatic valvular disease in the 2012 WHF criteria [2], early inflammatory valvular changes can be distinguished from chronic advanced RHD. Borderline RHD is suggested by isolated rheumatic morphological abnormalities without pathological regurgitation, such as mitral leaflet thickening, posterior mitral annular thickening, restricted leaflet motion, or irregular or focal thickening of the AV. Definite RHD is suggested when these characteristic morphological changes are accompanied by pathological MR and/or AR, indicating established RHD with functional hemodynamic consequences. However, prolonged PR intervals were only observed in participants with borderline RHD (2/19, 10.5%), not in those with definite RHD.

### Contribution of Screening Modalities

It is noteworthy that PCG screening detected pathogenic audible murmurs in approximately two-thirds of the participants (12/19, 63.2%), which surpassed the levels previously reported in auscultation-based studies [28]. This supports the hypothesis that subclinical RHD generates subtle murmurs associated with early valvular changes without a clinically pathological murmur [2]. However, in endemic regions, clinically silent RHD is 7 to 8 times more prevalent than symptomatic RHD [11]. This highlights the limitations of murmur-dependent screening and underscores the need for multimodal data evaluation and echocardiography as the gold standard.

The ECG findings revealed QRSd and QTc interval prolongation in RHD-positive participants, consistent with conduction abnormalities attributed to myocardial fibrosis or inflammatory blockages [24-26]. These changes exhibited a correlation with

XSL•FO
RenderX

the timing of ARF and disease severity. However, these results differed from those of studies that emphasized arrhythmias due to atrial ectopy and heart block in advanced RHD [24,26]. Atrial ectopy increases the risk of atrial fibrillation, whereas heart block typically produces bradyarrhythmia due to impaired electrical conduction. This is because rhythmic disturbances were minimal in our early-stage cohort. This observation suggests that arrhythmic manifestations may emerge at a later stage in the disease progression, although longitudinal data are necessary to substantiate this claim.

In summary, our findings advocate for integrated, technology-enhanced screening frameworks to combat RHD in resource-limited settings. Recent advancements in wearable ultrasounds for cardiac imaging have demonstrated potential to make imaging more cost-effective while maintaining comparable performance to that of standard portable echocardiography devices [33]. Hu et al [33] proposed an automated approach that uses deep learning algorithms to estimate the volume of the left ventricle and interpret B-mode ultrasound images with an intersection over union score above 85%, thereby facilitating more precise and efficient analysis.

Furthermore, the evaluation of MR jet length as a single criterion to detect RHD has shown sensitivity between 73% and 78.9% and specificity of 82.4% to 87.3% [4]. The application of such wearable devices with simplified criteria in combination with low-cost PCG or ECG sensors could improve diagnosis and reduce global RHD-associated burden. The development of such a cost-effective and scalable approach relies on the availability of large, diverse, and multimodal datasets capable of capturing the complex and heterogeneous features of RHD to support accurate and timely diagnosis. Future studies should explore using predictive modeling of multimodal ECG, PCG, and echocardiogram data to stratify the risk of RHD progression and evaluate cost-effective interventions in real-world settings.

### Limitations

The study had limitations. First, a high dropout rate was observed, with 57.8% (801/1385) of enrolled students not completing all the screening examinations, introducing a skewed age distribution toward older students. Consequently, the generalizability of the findings to the broader pediatric population, particularly those under 13 years of age, is limited, and the statistical power to detect significant effects was reduced. Second, the results indicate a high RHD burden among students in a rural, disease-endemic area. The study sample's demographic profile reflects a low socioeconomic status in crowded living conditions; the prevalence among urban, relatively healthier students is unclear. Third, although recurrent ARF is a major precipitating factor for RHD, structured clinical data on ARF episodes were unavailable for analysis. Future studies should include students from diverse socioeconomic backgrounds to provide a more comprehensive understanding of RHD prevalence and risk factors.

### Conclusions

The findings of this study indicate a persistently high prevalence of early RHD, predominantly involving the MV, among asymptomatic students (32.5 per 1000 population). The RHD incidence was higher in female individuals, but the difference between the sexes did not reach statistical significance. In resource-limited settings where echocardiographic facilities are unavailable, clinical screening based on persistent mitral or aortic regurgitant murmurs remains an important approach for large-scale case identification. However, clinical assessment of ECG and PCG alone is insufficient for holistic detection of RHD as a substantial proportion of cases may remain clinically silent. Therefore, persistent screening programs, particularly in school-based settings, are essential to facilitate timely identification and a prompt initiation of secondary prophylaxis. Nevertheless, the use of ECG and PCG assisted with artificial intelligence as a prescreening tool is worth further exploration as it may enable rapid, scalable community screening for early detection of RHD.

## Acknowledgments

The authors are grateful to all the participants and study team members, the collaborating hospitals (University Hospitals Leuven, Tikur Anbessa Specialized Hospital, and Soddo Christian Hospital), and Flanders AI Research Program for their unwavering support. The authors also acknowledge the use of the generative artificial intelligence tool ChatGPT from OpenAI for improving the readability of the manuscript.

## Funding

This research was funded by KU Leuven with reference number B/22/032 and the 5 E – Group T Fund with reference number REF23123123 under Leuven Centre for Affordable Health Technology. RW is supported as a fundamental clinical researcher by the Research Foundation – Flanders. The researchers received no financial compensation from the device manufacturers (Thinklabs; AliveCor, Inc; or GE Vingmed Ultrasound) to conduct this study. None of the companies were involved in the planning of the study, data analysis, or reporting of the data.

## Data Availability

The Rheumatic Heart Disease database analyzed in this study is not currently available publicly due to the GDPR (General Data Protection Regulation) policies. However, it can be shared from the corresponding author on reasonable request.

## Authors' Contributions

ATC conceptualized the study, performed computer programming, collected the dataset, carried out the experiments, and prepared the first draft of the manuscript. JUV, MHA, DMK, CV, RW, and MY designed dataset acquisition, analyzed the experiments and results, and reviewed the manuscript. APS and YAB collected the dataset, analyzed the results, and reviewed the manuscript draft. CW reviewed the experiments and the manuscript. BV conceptualized the study, designed the methodology, analyzed the experiments and results, and reviewed the manuscript.

## Conflicts of Interest

None declared.

Multimedia Appendix 1
The echocardiographic diagnosis criteria used for diagnosis is given in A1. The map of the study site and inclusion exclusion criteria used for recruiting the participants is provided in A2 and A3, respectively. The overall echocardiograph-based prevalence of rheumatic heart disease among students in Ethiopia from previous studies is given in A4 and echocardiograph measurements of the rheumatic heart disease cases of this study cohort is given in A5.

## Abstract

**Background:** Accurate small-area estimates of vaccination rates and disease burden can inform public health interventions.

**Objective:** This study aimed to compare population denominators derived from census data and electronic health record (EHR) data from a statewide collaboration in Minnesota and examine concordance between Centers for Disease Control and Prevention and EHR-based estimates of diabetes and hypertension prevalence at the census tract level.

**Methods:** A retrospective study was conducted using EHR data from 2018 to 2022 from the Minnesota EHR Consortium (MNEHRC), population estimates from the 2020 census, and disease prevalence estimates among adults from the Centers for Disease Control and Prevention Population Level Analysis and Community Estimates (PLACES) project. Patients were included if they had a Minnesota address and a clinic visit in the last 3 years. Patients with hypertension and diabetes were identified based on the presence of at least 1 diagnosis code in the Observational Medical Outcomes Partnership condition occurrence table in the last 5 years or an elevated outpatient blood pressure (systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg) on 2 or more days in the last 3 years for hypertension or at least 1 hemoglobin $A_{1c}$ value of ≥6.5 in the last 3 years for diabetes.

**Results:** The 2020 census estimate for the population of Minnesota was 5,707,254. A total of 5,271,191 (92.4% of the census estimate) unique individuals visited 1 of the 11 MNEHRC health care systems in 3 years (2018-2020). The ratio of MNEHRC patients to the Minnesota statewide 2020 census estimate was higher for female individuals (0.97) than for male individuals (0.88)

XSL•FO
RenderX

and higher for older age groups (individuals aged 65 years and older: 1.05) than for younger age groups (individuals aged 0-17 years: 0.83). The MNEHRC patient-to-census ratio also differed by race—the ratio was the highest for Black Minnesotans (1.17) and the lowest for American Indian and Alaska Native Minnesotans (0.68). According to MNEHRC data, the percentage of adults in Minnesota with diabetes in 2022 was 9.5% (415,914/4,376,805), and the percentage of adults in Minnesota with hypertension in 2021 was 32.2% (1,365,413/4,234,000). Estimates from PLACES for diabetes were 9.9% (435,481/4,389,028) and for hypertension were 29.9% (1,311,459/4,389,028). The percentage of census tracts where the MNEHRC estimate was within 10% of the PLACES estimate was 40.3% (605/1500) for diabetes and 42.3% (635/1500) for hypertension; 77.9% (1168/1500) of census tracts for diabetes and 79.7% (1195/1500) for hypertension were within 25% agreement.

**Conclusions:** Our analysis suggests that there are both similarities and important differences between small-area estimates derived from EHR and survey data. Such differences suggest that further research is needed to determine the optimal collection method for local estimates of health conditions.

## Introduction

Accurate population-level denominators are essential for providing reliable estimates of disease burden and evaluating public health interventions [1]. Many governmental and academic entities rely on census-derived population estimates to determine the rate of procedures and prevalence of chronic diseases [2,3]. These estimates of condition prevalence can guide intervention efforts to improve health at the neighborhood, state, and national levels [4-6]. However, inaccuracies in census data and discrepancies between census data and health data measures—particularly among underrepresented populations—have at times led to anomalies in reporting [7]. For example, during the COVID-19 pandemic, vaccination rates exceeding 100% were reported in some groups in both California and Massachusetts [8,9]. In Minnesota, we developed a statewide distributed data network that captures electronic health record (EHR) data for more than 90% of the population, offering an alternative source for deriving population-level denominators for public health data [10-13].

In addition to syndromic surveillance, population estimates play a critical role in allocating public health resources and designing interventions to address inequities [14]. The Centers for Disease Control and Prevention (CDC), through the Behavioral Risk Factor Surveillance System (BRFSS) and its Population Level Analysis and Community Estimates (PLACES) project, reports estimates of chronic disease prevalence for adults aged 18 years and older at the census tract level using small-area modeling that incorporates survey and census data [15]. While these modeled estimates guide federal and state funding to address health disparities, their accuracy may be limited by sparse sampling at the neighborhood level. On average, BRFSS includes only approximately 5 individuals per census tract per year [16]. By contrast, our EHR-based system enables direct observation of diagnosed chronic disease prevalence in nearly every census tract across Minnesota, offering an opportunity to compare EHR-based and model-based small-area estimates [10].

In this study, we compared population denominators derived from census data and Minnesota-based EHRs and examined concordance between CDC and EHR-based estimates of hypertension and diabetes prevalence at the census tract level in the adult population. We assessed concordance between CDC-modeled and EHR-derived prevalence estimates across Minnesota and explored the area-level sociodemographic factors associated with prevalence estimates from EHR data and CDC PLACES. These findings have implications for improving the accuracy of population health surveillance and ensuring equitable distribution of public health resources.

## Methods

### Minnesota EHR Consortium

The Minnesota EHR Consortium (MNEHRC) is a collaboration among individuals from the 11 largest health care systems in Minnesota, the Minnesota Department of Health, local public health departments, the University of Minnesota, and Minnesota Community Measurement. Each of the 11 health care systems has mapped its EHR data to the Observational Medical Outcomes Partnership (OMOP) common data model [17]. Patient addresses have been geocoded to census tracts to facilitate area-level analyses. Individuals who have sought care at multiple health systems are deduplicated using a secure, privacy-preserving record linkage process with hashed identifiers from each health care system [18,19]. An algorithm based on frequency of care in the last 3 years assigns individuals to 1 health care system for reporting purposes.

Data are from the Health Trends Across Communities (HTAC) in Minnesota project, which includes EHR-derived prevalence estimates for several chronic conditions at the census tract level. Patients are eligible for inclusion for a given year if they are alive and aged 18 years or older on December 31 of that year and have had an encounter in their assigned health care system in the past 3 years. Therefore, the EHR data represent a health care–seeking population. Patients with hypertension were identified based on the presence of at least 1 hypertension diagnosis code in the OMOP condition occurrence table in the last 5 years or an elevated outpatient blood pressure (systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg) on 2 or more days in the last 3 years. Patients with diabetes were identified based on the presence of at least 1 diabetes diagnosis code in the last 5 years or at least 1

XSL•FO
RenderX

hemoglobin $A_{1c}$ value of ≥6.5 in the last 3 years. To compare with census data, we used 2020 counts for population estimates (individuals alive on December 31, 2020, with an encounter in 2018-2020). To evaluate concordance with the most recent data available from CDC, 2022 data were used for counts of diabetes, and 2021 data were used for counts of hypertension.

### Census and CDC PLACES Estimates

Census data at the county level were obtained from the 2020 Census Demographic and Housing Characteristics Person and Housing tables [20]. Race and ethnicity data were grouped to be consistent with mutually exclusive categories in the EHR data: Hispanic and then non-Hispanic American Indian; Asian or Native Hawaiian or Other Pacific Islander; Black; White; and other (more than 1 race or other).

Census tract estimates of diabetes and hypertension prevalence among adults were obtained from the CDC PLACES data portal [21]. These estimates were based on results from BRFSS questions that ask whether individuals have ever been told by a physician or a health professional that they have diabetes or high blood pressure [22]. PLACES generates estimates at the census tract level using multilevel regression and poststratification that incorporates BRFSS results and the US Census Bureau's American Community Survey data [23].

### Census Tract–Level Variables

Patient addresses were geocoded to a census tract at each of the MNEHRC health care systems. Census tracts for addresses that did not successfully geocode were assigned based on population ratios using a zip code to a census tract crosswalk from the US Department of Housing and Urban Development [24]. Census tract–level sociodemographic variables were obtained from multiple sources. Social Vulnerability Index (SVI), a measure "designed to identify and quantify communities experiencing social vulnerability," was obtained from the CDC [25]. For analytic purposes, the continuous SVI was categorized based on quartiles, with SVI 1 referring to those in the lowest quartile of vulnerability. Rurality was assigned based on the US Department of Agriculture's Economic Research Service rural-urban commuting area codes and the percentage of individuals living in rural areas from the US Census American Community Survey [19]. Census data were used to determine the age, race distribution, and the percentage of the population with a high school degree or General Educational Development [20].

### Analyses

Statewide population counts for various demographic subgroups were tabulated from MNEHRC's 2020 HTAC data and compared with corresponding estimates from the 2020 census. County population counts from HTAC data were also compared with 2020 Census counts to assess coverage at the county level.

MNEHRC estimates of census tract hypertension and diabetes prevalence were calculated using 2021 and 2022 HTAC data, respectively. The obtained estimates were compared with CDC PLACES prevalence estimates, both of which were scaled 0 to 100. To assess agreement, the relative difference between the MNEHRC and PLACES estimates was computed. Bland-Altman plots were created to visualize agreement and systematic bias across all prevalence values.

Associations between tract demographic and socioeconomic characteristics and the prevalence of diabetes and hypertension were estimated separately for the 2 sources using linear regression. Predictors measured as proportions (eg, age >65 years, race, and poverty level) were modeled as a percentage of census tract population with a range from 0 to 100. Analyses were conducted using R (version 4.4.2; R Foundation for Statistical Computing).

### Ethical Considerations

HTAC is a public health surveillance project conducted in partnership with the Minnesota Department of Health and local public health agencies and, therefore, was not considered research per 45 CFR 46.102(l)(2). Therefore, it was not subject to institutional review board approval [26].

## Results

The 2020 census estimate for the population of Minnesota was 5,707,254. A total of 5,271,191 (92.4% of the census estimate) unique individuals visited 1 of the 11 MNEHRC health care systems in 3 years (2018-2020; Table 1). The ratio of MNEHRC patients to the Minnesota statewide census estimate was higher for female individuals (0.97) than for male individuals (0.88) and higher for the older age groups (65 years and older: 1.05) than for the younger age groups (0-17 years: 0.83). The MNEHRC patient-to-census ratio also differed by race—the ratio was highest for Black Minnesotans (1.17) and lowest for American Indian and Alaska Native Minnesotans (0.68). The MNEHRC data also had a greater number of individuals with missing, other, or unknown race (MNEHRC-to-census ratio 1.31). Coverage by county was generally consistent across the state, with a median MNEHRC patient-to-census estimate ratio of 0.89 (IQR 0.73-0.96; Figure 1).

[a]MNEHRC: Minnesota electronic health record consortium.

[b]Population estimates from the Minnesota statewide 2020 census.

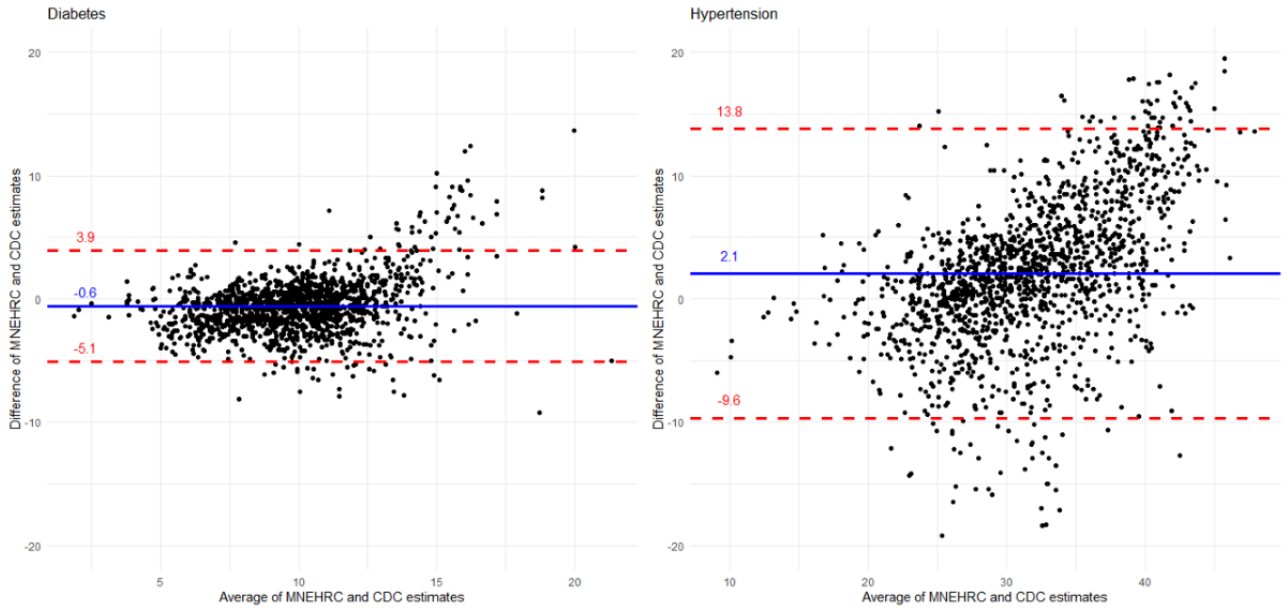
[c]The values in all the columns indicate MNEHRC patients, Minnesota statewide 2020 census estimate, and the ratio of MNEHRC patients to the Minnesota statewide census estimate.

**Figure 1.** Ratio of 2020 Minnesota Electronic Health Record Consortium patient count to census population estimate, by county. EHR: electronic health record.

XSL•FO
RenderX

According to the MNEHRC data, the percentage of adults in Minnesota with diabetes in 2022 was 9.5% (415,914/4,376,805), and the percentage with hypertension in 2021 was 32.2% (1,365,413/4,243,000). Crude prevalence estimates from PLACES data for diabetes were 9.9% (435,481/4,389,028) and for hypertension were 29.9% (1,311,459/4,389,028). There was a moderate level of concordance between the prevalence of diabetes and hypertension at the census tract level among adults comparing MNEHRC and PLACES estimates (Figure 2). Relative to the PLACES estimates, MNEHRC estimates tended to be higher in high-prevalence census tracts. This was particularly true for hypertension. The percentage of census tracts where the MNEHRC estimate was within 10% of the PLACES estimate was 40.3% (605/1500) for diabetes and 42.3% (635/1500) for hypertension. The percentage of census tracts where the MNEHRC estimate was within 25% of the PLACES estimate was 77.9% (1168/1500) for diabetes and 79.7% (1195/1500) for hypertension (Figure 3).

**Figure 2.** Bland-Altman plots comparing diabetes and hypertension prevalence estimates from the Centers for Disease Control and Prevention (CDC) Population Level Analysis and Community Estimates and cross-sectional electronic health record data from the Minnesota Electronic Health Record Consortium (MNEHRC) using census tract–level data.



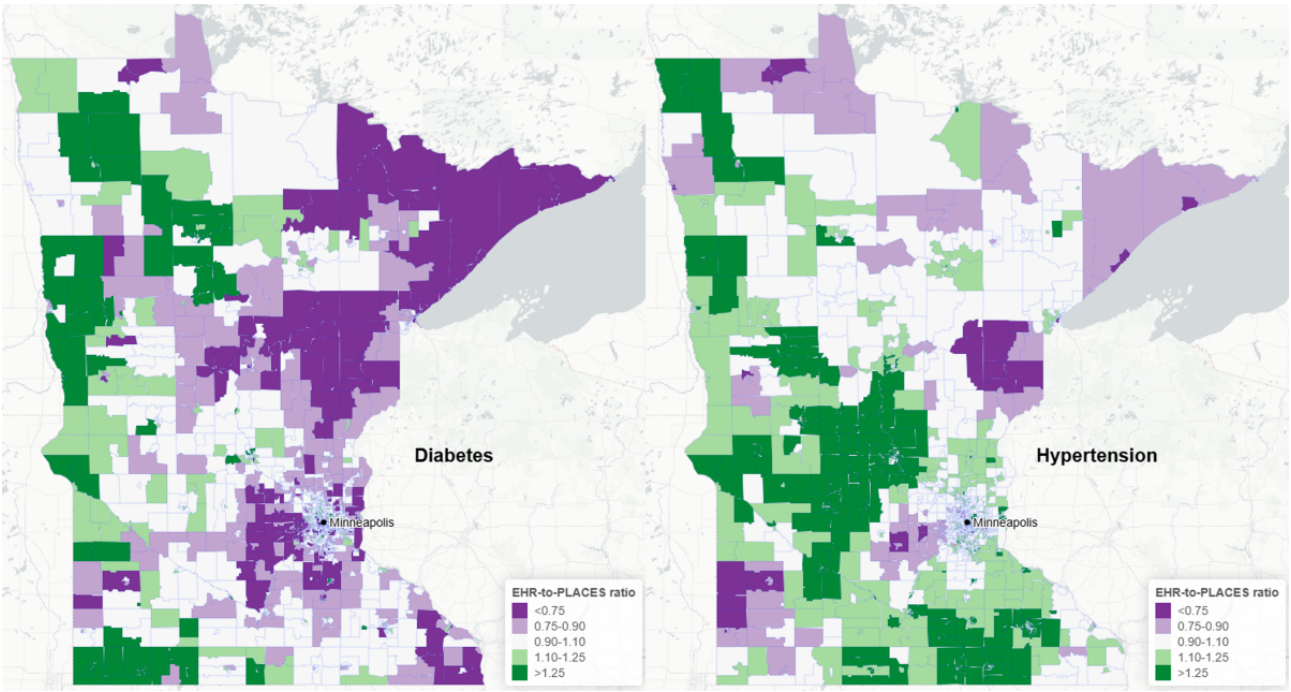


**Figure 3.** Ratio of Minnesota Electronic Health Record Consortium (MNEHRC) to Centers for Disease Control and Prevention Population Level Analysis and Community Estimates (PLACES) prevalence estimates for diabetes and hypertension at the census tract level. Blue represents census tracts where the MNEHRC estimate is lower than the PLACES estimate. Green represents census tracts where the MNEHRC estimate is higher than the PLACES estimate. White represents census tracts where the 2 estimates are within 10% of each other. EHR: electronic health record.

XSL•FO
RenderX

Area-level factors associated with diabetes and hypertension prevalence were generally similar in linear regression models for MNEHRC and PLACES (Table 2). Factors associated with higher prevalence in all models included a higher proportion of persons aged 65 years and older, a higher SVI, nonurban census tracts, and a lower proportion of individuals with at least a high school degree or General Educational Development. A higher proportion of Black individuals in a census tract was associated with lower hypertension prevalence in MNEHRC models but higher diabetes and hypertension prevalence in PLACES models. SVI was a stronger predictor of diabetes and hypertension in MNEHRC models compared with PLACES models. Model $R^2$ for diabetes was 0.46 in the MNEHRC model and 0.75 in the PLACES model; for hypertension, model $R^2$ was 0.52 in the MNEHRC model and 0.81 in the PLACES model.

**Table 2.** Census tract factors associated with hypertension and diabetes prevalence estimates from the Centers for Disease Control and Prevention Population Level Analysis and Community Estimates (PLACES) and a cross-sectional study using electronic health record data from the Minnesota Electronic Health Record Consortium (MNEHRC).

## Discussion

In this analysis comparing Minnesota statewide EHR data with census and CDC PLACES data, we demonstrated that population estimates from EHR data and the census are generally similar, though there are important differences by age, sex, and race. This finding has important implications for public health data; when possible, it is preferable to obtain numerators and denominators from the same source to avoid overestimating or underestimating prevalence or uptake of services. We also demonstrated moderate concordance between small-area prevalence estimates from EHR data and CDC PLACES. However, we did observe a greater than 25% relative difference in estimates for 22% of census tracts for diabetes and 20% of census tracts for hypertension. These results indicate the need for multiple data sources to accurately estimate small-area prevalence for chronic conditions.

Our results add to the literature evaluating the accuracy of BRFSS-based estimates. In the Boston validation study, BRFSS estimates were compared with estimates from a survey of 7340 individuals in 15 neighborhoods [27]. The BRFSS model estimates of diabetes prevalence were within the 95% CIs of the Boston survey for 80% of the neighborhoods. In the Missouri County-Level Study, 50,690 adults were surveyed across 115 counties [28]. The correlation between the BRFSS estimate for diabetes prevalence at the county level and the Missouri County-Level Study estimate was only 0.51. These prior studies were limited in that they compared estimates between 2 surveys. The results of this study allow a comparison between BRFSS and an estimate from a different data source, namely, EHR data.

Differences in population estimates between MNEHRC and the census may be due to multiple factors. Census undercounting may lead to a lower estimate of the number of Black Minnesotans. American Indian and Alaska Native Minnesotans may receive care at facilities that are not included in the MNEHRC, such as Indian Health Service clinics. The causes of differences in disease prevalence estimates between MNEHRC and PLACES are less apparent. PLACES may be inaccurate in certain census tracts due to their low survey rate, which necessitates modeling-based prevalence estimates. This may have led to some inaccuracies in prevalence estimates, which may be more apparent for the high-prevalence census tracts, as we observed with hypertension. Notably, the relationship between census tract characteristics and disease prevalence differed between MNEHRC and PLACES. A higher proportion of Black and American Indian or Alaska Native residents was associated with lower hypertension prevalence in MNEHRC data but higher hypertension prevalence in PLACES. This could represent differential access to care, lower rates of diagnoses, or PLACES model assumptions—such as age distribution—that are inaccurate in Minnesota. SVI was more strongly associated with hypertension and diabetes prevalence in MNEHRC models than in PLACES models, which may be due to a stronger association between SVI and prevalence in Minnesota compared with national estimates. The higher overall $R^2$ in the PLACES model is expected as those estimates are inherently model based using census tract characteristics.

Estimating small-area prevalence using EHR data has several potential advantages. First, EHR data can capture nearly the entire population. In our MNEHRC data, more than 90% of the census-estimated population had an encounter at a participating health care system within a 3-year period. Comparatively, surveys collect data from a small number of individuals within each census tract, and most census tracts are not represented in the National Health and Nutrition Examination Survey at all. This study included the availability of statewide data from a large, multi–health care system distributed EHR network that is scalable in other states. The number of adults in the EHR data for most census tracts is >75% of the census estimate for that population, which makes the EHR-based estimates robust. This allowed for, what we believe is, the first comparison of CDC PLACES– and EHR-based small-area estimates of diabetes and hypertension prevalence. Second, established data collection methods reduce the need for expensive and time-consuming survey collection and field work. Third, EHR data can be produced in near real time. While our analysis cannot comment on which approach (EHR based vs survey) is more accurate, it appears that using EHR data to assess area-level trends would provide similar information to survey-based data and reduce the risk of errors related to discrepancies between numerator and denominator sources. Both EHR data and survey data are prone to some misclassification. While inaccuracies in EHR data may be a particular concern for people who have infrequent health care use, a common concern with survey data is recall bias. Factors that would favor use of EHR data include (1) high percentage of population included in EHR data sources, (2) ability to use objective data to identify conditions (eg, blood pressure for hypertension and hemoglobin $A_{1c}$ values for diabetes), (3) conditions where EHR data have a high sensitivity, (4) conditions with low prevalence that would require surveying thousands of individuals, (5) conditions that patients may be unlikely to report on surveys either due to stigma or because they are unaware they have the disease, (6) when disease prevalence estimates for key subpopulations would be informative, and (7) when assessing local temporal trends in disease prevalence.

Our study has important limitations. First, the EHR patient count may overestimate the population due to incomplete deduplication, though this is likely to be small. Second, EHR data are unable to account for out-migration, which might represent 1% to 2% of the effect on the population in any given year [29]. By contrast, the EHR patient count may underestimate the population due to individuals being seen by health care providers not included in MNEHRC and individuals who have not been seen by a health care provider in the last 3 years. Third, patients who never seek care may vary in important ways from health care–seeking patients, resulting in EHR-based population and prevalence estimates that do not reflect the entire population. By contrast, the census and PLACES data represent individuals who respond to surveys. Relatedly, both EHR estimates and survey estimates likely underestimate disease prevalence due to undiagnosed disease and lack of disease awareness, but EHR estimates may underestimate disease prevalence less than self-report. Fourth, our study does not allow us to identify a threshold of EHR data coverage above which it becomes more

XSL•FO
RenderX

appropriate to use EHR data rather than survey data for public health decision-making. The results of this study are relevant to distributed data networks with robust geographic coverage, particularly those that use OMOP. Finally, our models were estimated via ordinary least squares regression, which assumes independence across census tracts. Because tracts are spatially correlated, uncertainty surrounding coefficient estimates is likely understated, although the estimates themselves are unbiased.

In conclusion, we identified important differences between EHR and census data by age, sex, and race. These differences should be considered in public health reporting when 2 different data sources are used for the numerator and denominator, as was frequently done during the COVID-19 pandemic, where vaccination rates were estimated using census denominators. The prevalence of diabetes and hypertension at the census tract level was generally concordant between MNEHRC and PLACES, but differences suggest that EHR data may help inform targeting of public health interventions to reduce prevalence and adverse outcomes from chronic conditions. Our analysis suggests that there are both similarities and important differences between small-area estimates derived from EHR and survey data. Such differences suggest that further research with validation against an assessment of all individuals using clinical gold standards is needed to determine the optimal collection method for local estimates of health conditions.

## Data Availability

The datasets generated or analyzed during this study are not publicly available as they include patient data from multiple health systems. Only aggregate results were shared centrally.

## Funding

The study was funded by the Minnesota Department of Health as part of the Health Trends Across Communities project. Individuals from the Minnesota Department of Health and local public health agencies participated in the design of the study and interpretation of the results.

## Authors' Contributions

## Abstract

**Background:** Tick-borne diseases (TBDs) in the United States are increasing due to ecological and climate changes. However, national surveillance data are principally available only at aggregate state and federal levels, limiting granular analysis and constraining TBD diagnosis, prevention, and public health communication. From a One Health perspective, recognizing the shared environments of people and animals and integrating canine serological data with human surveillance can improve geographic risk assessment and reduce reporting bias. Oklahoma offers a useful case in point: several TBDs are endemic, the state contains significant vulnerable populations, and public health records date to 1928, providing a longitudinal record examinable at the county level.

**Objective:** With Oklahoma as a use case, we (1) identify geographic patterns and disparities in county-level human TBD reporting, (2) compare human TBD distribution with canine disease data to assess underreporting and geographic risk gaps, and (3) examine long-term disease trends and data inconsistencies across reporting periods.

**Methods:** A descriptive analytical ecological study using a One Health triangulation approach was conducted in which the units of analysis were counties (n=77) in the US state of Oklahoma. Data were summarized using 1990-forward human reporting histories, human county tables (2004-2007), and Companion Animal Parasite Council (CAPC) canine testing summaries (2012-2026). National Oceanic and Atmospheric Administration (NOAA) 1991-2020 Climate Normals were used to derive a Tick Season Risk Index summarizing county-level climatic suitability for tick activity. Primary outcomes included reported human cases, county-level human disease incidence rates (per 100,000 population), and canine positive tests, total tests, and percent-positive values.

**Results:** Trend, county burden, TBD incidence rate, and regional graphs illuminate variations that are not apparent in more aggregate state-level analyses. Central metro counties account for the largest number of tests performed and of reported human cases, while eastern, northeastern, and southeastern counties show stronger disproportionate burden signals. Several low-reporting western counties fall within a moderate Tick Season Risk Index range. This index is an exploratory 2-variable climatic screen, not a validated habitat suitability model; it cannot establish tick presence, habitat suitability, or the reasons for sparse case reporting, and no conclusion about surveillance gaps is drawn.

**Conclusions:** This study triangulates human, canine, and climatic data at the county level within a One Health framework, reporting a standardized index. Unlike prior studies, it addresses ehrlichiosis, spotted fever group rickettsiosis (SFR), and tularemia across nearly a century of public records, offering a replicable workflow that reveals discordance between human and canine surveillance. These findings support standardized reporting at the county level, integration of animal health data into human surveillance, and clinician awareness of TBD risks. Interpretation is limited by geolocation by residence rather than exposure and by canine serology that cannot distinguish *Ehrlichia* species pathogenic to humans.

## Introduction

### Background

Tick-borne diseases (TBDs) are among the fastest-growing vector-borne public health threats in countries worldwide, driven by ecological disruption, land-use change, wildlife population shifts, and an increasingly warming climate. In the United States, ticks account for more than 75% of all vector-borne disease cases, and annual reports of tick-borne bacterial and protozoan diseases more than doubled between 2004 and 2016, surpassing 48,000 reported cases by the end of that period [1]. Despite this trajectory, the true burden is likely substantially underestimated. For example, the US Centers for Disease Control and Prevention (CDC) estimates that approximately 476,000 people are diagnosed and treated for Lyme disease (LD) each year in the United States, a figure that far exceeds the case counts captured by national surveillance, and similar reporting gaps affect other TBDs, including ehrlichiosis, Rocky Mountain spotted fever (RMSF), tularemia, and anaplasmosis [2,3]. Indeed, underreporting and misdiagnosis remain central and unresolved challenges in the surveillance system, attributable in part to the nonspecific symptom profiles of most TBDs and limited clinician familiarity outside established endemic regions [4].

The geographic range of vector tick species is actively expanding. The lone star tick (*Amblyomma americanum*) is the primary vector of ehrlichiosis, tularemia, Southern tick-associated rash illness (STARI), and Heartland virus infection and is associated with alpha-gal syndrome (AGS) in the United States. It has demonstrated ongoing northward and westward range expansion, a trend projected to accelerate under current and high-emissions climate scenarios [5-7]. Eisen and Eisen [8] documented substantial shifts in the geographic distribution of *Ixodes scapularis* over 5 decades, underscoring the need for continuously updated surveillance as vector ranges move beyond historically recognized endemic boundaries. In 2024, lone star ticks were found displacing blacklegged ticks in previously uninvaded northeastern habitats, with concurrent emergence of new human ehrlichiosis cases in those communities [9]. These dynamics underscore a core challenge: existing surveillance systems were largely designed for geographically stable, historically understood disease distributions and are poorly equipped to track pathogens in real time as vectors expand into new territory, underscoring the need for adaptive surveillance frameworks capable of tracking emerging tick-borne zoonoses as vector ranges shift [10].

Active surveillance in the United States relies on the CDC's National Notifiable Diseases Surveillance System (NNDSS), which gathers case reports submitted by health care providers and state health departments. However, except for LD and a limited number of years for selected other TBDs, the CDC provides access to case surveillance data only at the aggregate state and federal levels [11]. This restriction is a significant impediment to localized public health action. County-level TBD data, when made available at all by individual states, are provided inconsistently, with formats shifting from handwritten mortality logs to narrative reports to standardized electronic tables over the decades, making longitudinal or comparative analysis highly labor-intensive. Moreover, fragmented and often outdated national maps represent foundational barriers to effective risk communication, especially since national maps of tick distributions and associated pathogen prevalence are "often incomplete, outdated, or lacking entirely" [12]. The US Department of Health and Human Services (HHS) Tick-Borne Disease Working Group similarly confirms that data integration across surveillance systems and the lack of standardized county-level reporting remain among the highest-priority unmet needs in TBD surveillance and research [13].

The consequences of these kinds of surveillance gaps extend directly to public health communication and clinical practice. When localized data are unavailable, residents, clinicians, and public health agencies cannot accurately characterize disease risk in their communities. This is especially consequential in areas where TBD awareness is lower (eg, nonnortheastern US regions), and, for example, clinicians may not consider TBD diagnoses in the differential for febrile illness [4]. Triangulation of human-reported cases, canine serological data, and CDC records could significantly improve county-level surveillance resolution beyond what any single source provides, and research has called for broader consistency and application of integrated data approaches in TBD surveillance [6].

A One Health perspective, which recognizes the interdependence of human, animal, and environmental health across local, regional, and global scales [14], offers a substantively powerful lens through which to view these surveillance gaps. Canines (*Canis familiaris*) are well-established sentinels for human TBD risk: They share outdoor environments with humans, are exposed to the same tick vectors, and are tested for tick-borne infections at rates substantially exceeding those of humans [15]. Accordingly, expanded canine sentinel surveillance can be useful in the application of a range of zoonotic pathogens, including *Rickettsia* spp. and *Ehrlichia* spp. [16]. Moreover, canines are among the most commonly kept companion animals in US households, yielding a large, geographically distributed sentinel population for tick-borne pathogen exposure [17].

Oklahoma presents a particularly compelling use case for this approach. Several TBDs are endemic to the state, including tularemia, ehrlichiosis, RMSF, and Heartland virus infection, although not LD [18]. Tularemia cases in particular in Oklahoma, Arkansas, Kansas, and Missouri collectively account for approximately 50% of all nationally reported cases, with national tularemia incidence rising 56% from 2011 to 2022, with four-fifths of cases classified as probable, raising questions about diagnostic and reporting accuracy [19,20]. Note also that such issues are especially critical among various already vulnerable populations in the United States. For example, tularemia incidence among Indigenous American Indian or Alaska Native persons was approximately 5 times that of White persons nationwide, a disparity of acute relevance in Oklahoma,

XSL•FO
RenderX

where almost half of the state land area comprises tribal territories and where poverty rates among native residents reach 19%-20%, well above the national average [19,21,22]. These populations face compounded vulnerability from both higher environmental exposure to tick vectors and reduced access to quality health care and timely diagnosis. In addition to elevated tick exposure, these native communities tend to have limited prior TBD knowledge, as is often the case among vulnerable populations, and tend to be underrepresented in TBD epidemiological observations and reporting [23].

A lack of standardization in TBD diagnostics and insufficient clinician education regarding regional endemic patterns are key drivers of both misdiagnosis and underreporting [4]. Clinically, ehrlichiosis and RMSF frequently present with overlapping flu-like symptoms, including fever, headache, myalgia, and thrombocytopenia, making differential diagnosis challenging without geographic context and a high index of suspicion [4,18,24]. Furthermore, some emerging conditions transmitted by the lone star tick, such as STARI, have no commercially available diagnostic tests, meaning patients may present with TBD-compatible symptoms, test negative for all notifiable diseases, and remain undiagnosed and untreated [25,26]. In states such as Oklahoma, where TBD prevention relies primarily on personal protective measures, the quality of public health communication directly determines whether residents and clinicians can take appropriate preventive and diagnostic action [27].

### Objectives

The research objectives were to (1) identify geographic patterns and disparities in county-level human TBD reporting, (2) compare human and canine surveillance measures to characterize geographic concordance and discordance, and (3) describe long-term trends and inconsistencies across reporting periods.

## Methods

### Overview

#### *Study Design and Setting*

To address the identified intersecting gaps in surveillance resolution, data standardization, One Health data integration, and targeted public health communication, this study presents the US state of Oklahoma as a use case, using a descriptive analytical ecological design and a triangulation approach combining archival human TBD records with canine sentinel data at the county level [6]. That is, the unit of analysis was the county (n=77) in the US state of Oklahoma. Note that, other than LD, availability of TBD data is extremely limited at the county level, typically preventing exact year-to-year matches across reporting periods. The approach used here, reflecting a multimodal surveillance framework and the sentinel surveillance model [6,16], is designed to reveal geographic patterns in TBD burden that can remain invisible in standard aggregate national and state-level human surveillance and to identify specific gaps in public health communication that, if addressed, could meaningfully improve disease prevention, clinical diagnosis, and disease outcomes for all residents of the state. In STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) terms, this is a descriptive, retrospective ecological study: the unit of observation is the county rather than the individual, all data are secondary and aggregated, and no individual-level exposures or outcomes were analyzed. No hypothesis test was specified, and no inferential statistics were computed; findings are descriptive throughout.

#### *Study Units, Variables, Data Sources, and Measurement*

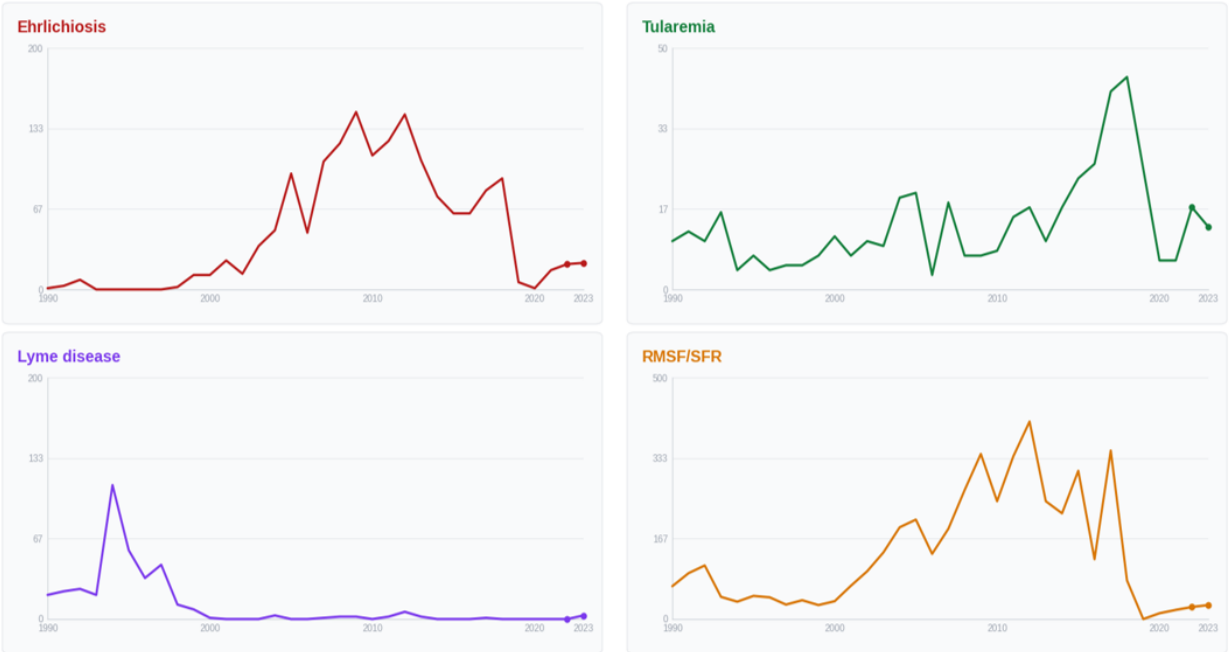
All 77 Oklahoma counties were included; there was no individual recruitment, sampling, matching, eligibility screening, or power calculation because the study used complete, publicly available aggregate county and state series for the periods described below. Primary variables were reported human cases, published human county incidence rates, canine positive and total tests, canine percent-positive values, and county climate normals.

The triangulation design integrated 4 complementary data streams: human TBD surveillance, CDC NNDSS county-level case counts together with Oklahoma State Department of Health (current and archival reports), canine serological data from the Companion Animal Parasite Council (CAPC), an environmental climate layer derived from the National Oceanic and Atmospheric Administration (NOAA), and historical archival records spanning 1928 onward. For the environmental layer, NOAA 1991-2020 30-year US Climate Normals were obtained for all 77 Oklahoma counties, and annual average temperature and annual average precipitation were extracted for each county. Each variable was rescaled to a 0-100 range, and the 2 were combined into a composite Tick Season Risk Index, weighting temperature at 55% and precipitation at 45%, to summarize each county's relative climatic suitability for *A americanum* questing activity [28,29].

While recognizing that other environmental factors are also important in determining tick habitat suitability, climatic effects based principally on temperature and precipitation are used here as conventional exploratory indicators. The climate layer was used only to order counties by 2 county-average climate normals. It cannot establish tick presence or distinguish ecological absence from surveillance limitations. The selection of temperature and precipitation as the 2 input variables follows published species distribution modeling for *A americanum*, in which thermal and moisture variables are consistently identified as the dominant climatic correlates of the species' range. Ensemble modeling across the continental United States. identified temperature- and humidity-related variables, particularly average July vapor pressure, as the strongest determinants of climatically suitable habitat [30]; correlative ecological niche modeling retained annual precipitation, precipitation seasonality, mean diurnal temperature range, and maximum temperature of the warmest month as the most informative predictors of current and projected distribution [5]; and process-based modeling identifies accumulated degree-days as the limiting condition for population establishment at the northern range margin [31].

The 55%/45% weighting applied here, however, was not derived from a fitted species distribution model or from any published parameterization. It is a pragmatic, author-assigned approximation intended to give modest precedence to thermal

XSL•FO
RenderX



conditions, consistent with the emphasis placed on temperature-related constraints in that literature [5,30,31], and it should be regarded as a transparent analytic convention rather than an empirically optimized weighting. Accordingly, the Tick Season Risk Index is used here solely as a coarse, relative screening layer for ordering counties along a climatic gradient. It is not a validated habitat suitability model; it was not calibrated or ground-truthed against active field sampling of host-seeking ticks, and no index value is proposed or implied as a threshold for *A americanum* establishment. Land cover, land use, host community composition, forest canopy and leaf-litter structure, and microclimate are likewise important determinants of local tick presence and abundance, and none were incorporated into the index [5,30,32,33]; counties classified here as climatically moderate may therefore still be unsuitable for *A americanum* for reasons the index cannot detect.

## Variables and Methods

The descriptive analytic triangulation approach integrates county-level and statewide data streams to review TBD risk and surveillance gaps across the 77 Oklahoma counties. County-level results were displayed on standard Oklahoma county base maps [34], with county population taken into account when interpreting reported case incidence rates and low-population areas [35]. Canine serological data are available at the county level for multiple years from CAPC, constituting an important analytical resource for extending the geographic resolution of human TBD surveillance, especially in low-population and rural areas where human case counts are insufficient to signal endemic disease. Statewide TBD case counts were graphed from 1990 to 2023, parsed human incidence rates by county were summarized for 2004-2007, and CAPC canine testing summaries were summarized for 2012-2026; 2026 CAPC values should be interpreted as year-to-date. Tularemia is a secondary reportable TBD in Oklahoma and is attributable to both the lone star tick and the American dog tick (*Dermacentor variabilis*) [36]; it is therefore summarized alongside ehrlichiosis and RMSF/spotted fever group rickettsiosis (SFR), these being the 3 diseases available in the parsed 2004-2007 county tables. The county incidence rates were transcribed as printed in the 2004-2007 Oklahoma State Department of Health annual-summary county tables; the authors did not recalculate them. The source-table footnotes define each rate as reported cases divided by the relevant US Census Bureau county population and multiplied by 100,000. The 2004, 2005, and 2006 tables use the 2000 Census county population; the 2007 tables use the 2007 Census Bureau county population estimate [37-40].

For the comparative index (Figure 1 [41]), the human component was the mean of the 12 printed county incidence-rate values for 3 diseases—ehrlichiosis, RMSF/SFR, and tularemia—across 4 years (2004-2007). All 12 values were available for each county, and printed zeros were retained. The canine component was pooled positive tests divided by pooled total tests, multiplied by 100, across canine LD, anaplasmosis, and ehrlichiosis observations from 2012 to 2026; 2026 values were year-to-date. The comparative index was calculated for counties with a positive pooled canine testing denominator (n=59). The remaining 18 counties were classified as having no canine data and were not assigned a value. Within the 59 eligible counties, each component was converted to an average-rank percentile score, and the 2 scores were averaged with equal weight. Map classes were defined by empirical quintiles of the resulting index.

**Figure 1.** Statewide annual reported human tick-borne disease cases in Oklahoma, 1990-2023. Small multiples show ehrlichiosis, tularemia, Lyme disease, and RMSF/SFR. Values are the annual OSDH history-table counts used in the analysis. Source: Oklahoma State Department of Health, Number of Reported Cases of Communicable Diseases, Oklahoma, 1990-2024. RenderX

Regarding the human component, we have the following equation:

For the canine component, we have the following equation:

For percentile transformation, we have the following equation:

Regarding the comparative index, we have the following equation:

Here, DH and YH denote the sets of diseases and years included in the human component, and DC and YC denote the sets of diseases and years included in the canine component, where DH = {ehrlichiosis, RMSF/SFR, tularemia}, YH = {2004, 2005, 2006, 2007}, DC = {LD, anaplasmosis, ehrlichiosis}, and YC = {2012, …, 2026}. IRc,d,y is the printed human incidence rate per 100,000 population for county c, disease d, and year y. Posc,k,t and Totc,k,t are the canine-positive and total tests for county c, disease k, and year t. Rj,c is the average rank of component j among the 59 eligible counties, with tied values assigned the mean of their ranks. Pj,c is the percentile score, and Ic is the equally weighted comparative index.

Descriptive annual means, sample SDs, and ranges were calculated from 34 statewide annual observations per disease (1990-2023). No inferential tests were performed.

### Bias and Missing Data

Potential biases include passive case ascertainment, changing case definitions and reporting formats, veterinary access and testing practices, noncontemporaneous human and canine periods, geolocation by residence or testing location rather than exposure, and canine assays that do not distinguish *Ehrlichia* species. Suppressed or unavailable human values were treated as missing rather than 0; no missing value was imputed. Counties with no CAPC canine records or 0 total canine tests were excluded from the comparative index rather than assigned 0% positivity, and pooled canine percent-positive values based on small test denominators are less stable than those from counties with larger testing volumes.

Variation in Oklahoma's public health TBD reporting formats across decades (also exemplifying national inconsistencies) is shown in Textbox 1. This research required manual extraction of data from heterogeneous archival formats spanning nearly a century. The table shows the variability in reporting format, geographic resolution, and case definition across all primary data sources used in this study.

**Textbox 1.** Evolution of public health tick-borne disease (TBD) data reporting formats, Oklahoma State Department of Health, and US Centers for Disease Control and Prevention (CDC), selected periods 1928-2022. Missing data in any period does not indicate 0 cases.

- 1928: handwritten archival mortality report; first recorded tularemia death. Data manually extracted.
- 1940s-1960s: printed narrative reports with mortality counts embedded in paragraph text; no standardized format.
- 1970s: shift from mortality to case reporting. Reports begin including county-level breakdowns in some years; formats vary by year.
- 1980s-1990s: periodic graph and table formats are introduced; demographic breakdowns (ie, age and sex) appear in some but not all reports. Case counts for Rocky Mountain spotted fever (RMSF), ehrlichiosis, and tularemia appear at endemic levels.
- 2000s-2010s: annual state-level case reports only; county-level data rarely provided. Format shifts between narrative, tabular, and mapped presentations. Some files are in nonreadable formats requiring manual data entry.
- 2016-2022: CDC provides aggregate 4-year county-level datasets for selected TBDs (ehrlichiosis 2016-2019 and 2019-2022; tularemia 2016-2019 and 2019-2022). No county-level data for individual years. The Companion Animal Parasite Council (CAPC) provides annual county-level canine data.

### Ethical Considerations

This study is exempt in accordance with HHS' Revised Common Rule, 45 CFR 46.102(e)(1), and uses only publicly available, aggregate data with no identifiable private information [42,43]. Informed consent is excluded and defined as not applicable under 45 CFR 46.102(l)(2). No individual was recruited, contacted, enrolled, or identified, and no compensation was provided. We confirm that the materials contain no images of identifiable individuals.

## Results

### Outcome Data and Main Results

All 77 counties were represented in county-level displays; the comparative index (Figure 1) was computable for 59 counties, and the 18 counties without a usable canine denominator are shown as "no canine data." Availability varied by source and period (Textbox 1). Across the 2 aggregated CDC reporting periods, reported human case totals fell for every disease examined: ehrlichiosis from 243 (2016-2019) to 44 (2019-2022), RMSF/SFR from 553 to 56, tularemia from 136 to 55, anaplasmosis from 10 to 2, and LD from 1 to 0 (Table 1). Statewide annual counts show ehrlichiosis and RMSF/SFR peaking in the 2000s and early 2010s and declining sharply after 2019, while tularemia fluctuates without a sustained trend (Figure 2). Across 1990-2023 (34 annual observations per disease), mean annual reported counts were 47.2 for ehrlichiosis (SD 48.6; range 0-147), 13.5 for tularemia (SD 9.6; range 3-44), 11.1 for LD (SD 22.6; range 0-111), and 135.7 for RMSF/SFR (SD 117.2; range 0-409). Canine testing over 2012-2026 returned a far larger number of positive results than the human

XSL•FO
RenderX

system recorded cases over any comparable period, with 5189 canine ehrlichiosis positives, 253 anaplasmosis positives, and 114 LD positives in 2019 alone (Table 1). Counties in the eastern, northeastern, and southeastern regions of the state (including Latimer, Pittsburg, Haskell, Adair, Cherokee, Sequoyah, Mayes, and McIntosh) reflect elevated human county average incidence rates for ehrlichiosis, RMSF/SFR, and tularemia (2004-2007; Figure 1) coinciding with high CAPC canine percent-positivity for LD, anaplasmosis, and ehrlichiosis (2012-2026; Multimedia Appendix 1). Ranked by number of reported human cases, the leading counties are concentrated in the central metropolitan area, whereas ranking the same counties by incidence rate shifts the leaders to the sparsely populated east and southeast (Multimedia Appendices 2 and 3), a regional contrast that persists when counties are aggregated to a region (Figure 3A). The canine data show the same divergence between count and proportion: positive-test totals are highest in the most populous counties, while percent-positive values are highest in eastern and southeastern counties (Figure 3B; Multimedia Appendices 1 and 4).

County-aggregated Tick Season Risk Index values derived from NOAA 1991-2020 Climate Normals were highest in the southeastern and northeastern regions (index approximately 67-77/100), intermediate in the central region (approximately 60/100), and lowest in the western (southwestern and northwestern) regions, where values nonetheless remained within a moderate range (approximately 45-53/100). While not verified against field collection of host-seeking ticks, these values represent relative climatic ordering among Oklahoma counties rather than absolute or validated measures of habitat suitability (Multimedia Appendix 5).

**Table 1.** Reported human cases and canine positive tests for selected tick-borne diseases by disease and reporting period, Oklahoma, United States. Human case data from CDC[a] NNDSS[b] county-level datasets (4-year aggregated periods); canine positive-test data from CAPC[c] serological testing records (single-year counts, 2019). Human data are aggregated across 2 four-year periods (2016-2019 and 2019-2022), which overlap in 2019; canine values are single-year positive-test counts for 2019[d].

| Disease | Principal vector | Pathogen | Reported surveillance values | | |
|---|---|---|---|---|---|
| | | | Human, 2016-2019 | Human, 2019-2022 | Canine, 2019 |
| Lyme disease | Blacklegged tick (*Ixodes scapularis*) | *Borrelia burgdorferi* | 1 | 0 | 114 |
| RMSF[e] | American dog tick (*Dermacentor variabilis*)[f] | *Rickettsia rickettsii* | 553 | 56 | —[g] |
| Anaplasmosis | Blacklegged tick (*I scapularis*) | *Anaplasma phagocytophilum* | 10 | 2 | 253 |
| Ehrlichiosis | Lone star tick (*Amblyomma americanum*) | *Ehrlichia chaffeensis* [h] | 243 | 44 | 5189 |
| Tularemia | Lone star tick (*A americanum*) and American dog tick (*D variabilis*) | *Francisella tularensis* | 136 | 55 | — |

[a]CDC: US Centers for Disease Control and Prevention.

[b]NNDSS: National Notifiable Diseases Surveillance System.

[c]CAPC: Companion Animal Parasite Council.

[d]This table lists the principal vector and pathogen for each disease as commonly reported in surveillance and is not exhaustive. Reported human anaplasmosis counts are small and are presented as reported; *Anaplasma phagocytophilum* is transmitted by *Ixodes scapularis*, which is not established across most of Oklahoma [8,18], and no published epidemiologic investigation has established that reported Oklahoma human anaplasmosis cases were locally acquired. These counts are therefore not interpreted here as evidence of local human transmission.

[e]RMSF: Rocky Mountain spotted fever.

[f]For Rocky Mountain spotted fever, in addition to the American dog tick (*D variabilis*), the brown dog tick (*Rhipicephalus sanguineus*) transmits *R rickettsii* in parts of the southern and southwestern United States and along the US-Mexico border [44,45].

[g]An em dash (—) indicates no available canine data for that disease (Companion Animal Parasite Council canine serology covers Lyme disease, anaplasmosis, and ehrlichiosis).

hEhrlichiosis in humans and canines is caused by several Ehrlichia species beyond E chaffeensis, including Ehrlichia ewingii and Ehrlichia muris eauclairensis in humans, and Ehrlichia canis (transmitted by Rhipicephalus sanguineus and D variabilis) and E ewingii in canines [46,47]. The CDC's NNDSS human ehrlichiosis category combines E chaffeensis, E ewingii, and undetermined ehrlichiosis or anaplasmosis, as used in this study.

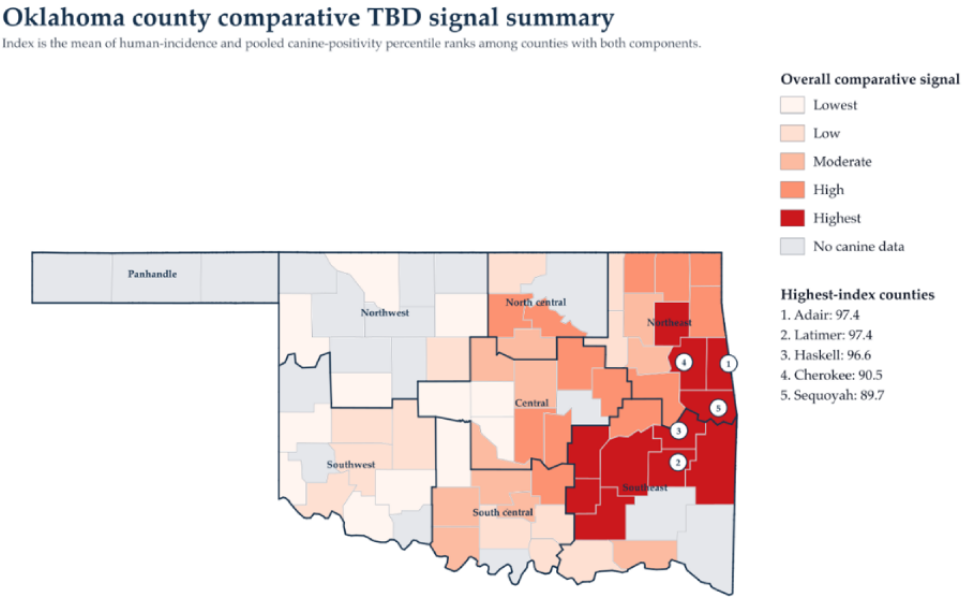
**Figure 2.** Oklahoma county comparative tick-borne disease surveillance signal. For each county, the human component is the mean of 12 printed incidence-rate values (3 diseases × 4 years, 2004-2007); the canine component is pooled positive tests divided by pooled total tests across 3 diseases and 2012-2026. Each component was converted to an average-rank percentile across the 59 counties with canine testing data, and the 2 percentile ranks were averaged with equal weight; the 18 counties without a usable canine denominator are shown as "no canine data" and were excluded from ranking and quintile classification. Classes are quintiles; numbers identify the 5 highest-index counties; heavy boundaries and labels show analytical regions; 2026 is year-to-date. Darker shading denotes a stronger combined surveillance signal, not a higher number of cases or tests. Sources: Oklahoma State Department of Health annual-summary county tables (2004-2007) and Companion Animal Parasite Council canine testing summaries (2012-2026).



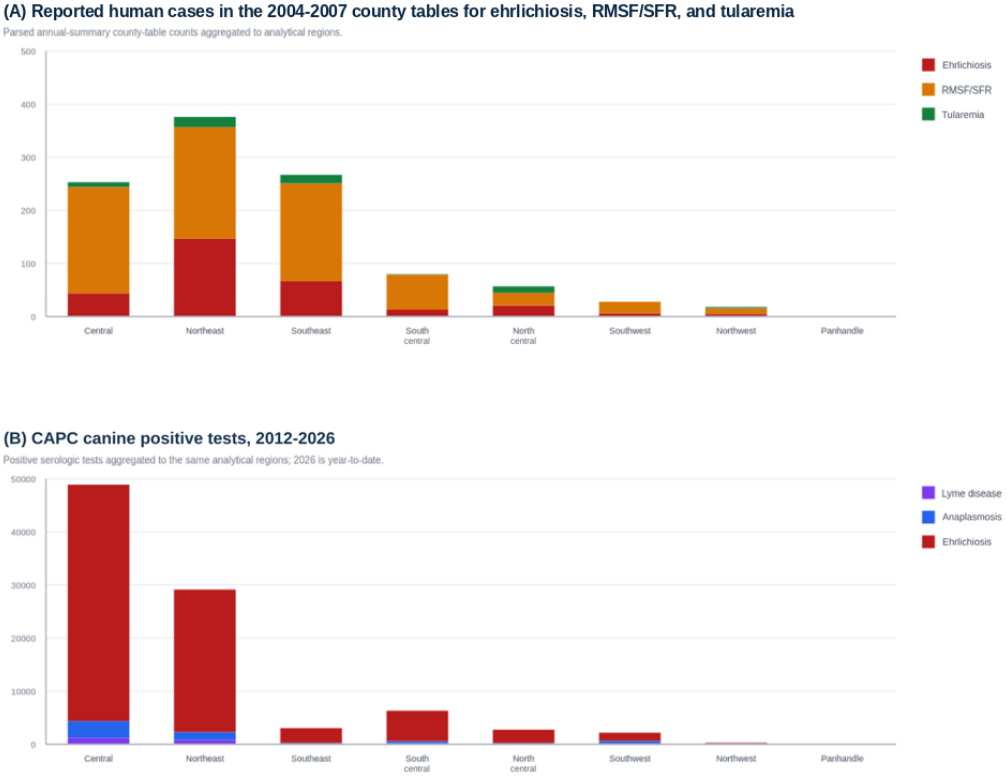


**Figure 3.** Human and canine surveillance results by Oklahoma analytical region. (A) Reported human cases in the 2004-2007 county tables for ehrlichiosis, RMSF/SFR, and tularemia. (B) Canine positive tests from CAPC for LD, anaplasmosis, and ehrlichiosis, 2012-2026; 2026 values are year-to-date. Panels use different scales and periods and are shown together for geographic comparison, not direct numerical equivalence. Human case counts and canine positive-test counts are complementary surveillance signals and are not directly comparable incidence estimates. CAPC: Companion Animal Parasite Council; LD: Lyme disease; RMSF: Rocky Mountain spotted fever; SFR: spotted fever group rickettsiosis.

### Human and Canine Case Comparisons

Table 1 presents a summary reference of selected TBDs in Oklahoma. The statewide findings show the largest reported human ehrlichiosis values in the 2000s-2010s and lower reported values after 2019. County-level results identify Tulsa, Oklahoma, Pittsburgh, LeFlore, and Pottawatomie counties as the counties with the highest number of reported human cases in the parsed 2004-2007 tables, while CAPC canine ehrlichiosis percent-positive is highest in Haskell, Cherokee, Sequoyah, Mayes, and McIntosh among counties with at least 500 total tests. The county graphs show the highest number of canine positive tests in Oklahoma, Tulsa, Cleveland, Rogers, and Washington counties, while canine percent-positive values were highest in eastern, northeastern, and southeastern counties. Average human county incidence rates for the 3 diseases available in the parsed 2004-2007 county tables (ehrlichiosis, RMSF/SFR, and tularemia) were highest in Latimer, Pushmataha, Pittsburg, Haskell, and Adair counties.

## Discussion

### Principal Findings

Viewed through a One Health lens, this study used a descriptive analytic triangulation approach to examine county-level human and canine TBD data in Oklahoma across nearly a century of archival public health records, with three stated objectives: (1) to identify geographic patterns and disparities in human TBD reporting at the county level, (2) to compare human TBD distribution with canine disease data to assess potential underreporting and geographic risk gaps, and (3) to present historical TBD data to illustrate long-term disease trends and data inconsistencies. Across all 3 objectives, findings were consistent and mutually reinforcing. Geographic patterns in human ehrlichiosis and tularemia were highly localized, concentrated primarily in central and northeastern counties, and differed substantially from the broader spatial distribution suggested by canine ehrlichiosis data, which extended into low-density southwestern counties where 0 human cases were recorded. Historical tularemia data revealed dramatic and largely unexplained variation in case counts across decades, illustrating the instability and inconsistency that characterize passive TBD surveillance. Taken together, the findings identify geographic discordance between the human and canine surveillance systems that warrants targeted epidemiologic and entomological follow-up [6,16].

The marked geographic discordance between human and canine ehrlichiosis distributions in this study is consistent with the national literature on TBD underreporting and the limitations of passive surveillance. Passive surveillance systems such as the CDC NNDSS are known to substantially undercount true TBD incidence, as case reports depend on patients seeking care, clinicians ordering appropriate tests, and laboratories reporting confirmed results, a chain of events that is less likely to occur in rural, low-density areas with limited health care access [1,4]. Even in areas with well-established ehrlichiosis burden, the use of confirmatory molecular testing (polymerase chain reaction [PCR]) has been minimal, with fewer than 1% of tested samples undergoing PCR-based confirmation, underscoring how testing gaps perpetuate surveillance blind spots [48].

Nationwide, *Ehrlichia ewingii* ehrlichiosis, one of the species included in this study's combined ehrlichiosis counts, was found to be expanding geographically between 2013 and 2021, with clinician education identified as a critical unmet need for improving diagnosis [49]. In Oklahoma, the absence of human cases in western counties stands in stark contrast to robust canine positivity in those same areas, a pattern that aligns with the well-established role of canines as early sentinels for tick-borne pathogen exposure in communities where human testing rates are insufficient [16,44]. This interpretation must nonetheless be tempered by the recognition that both human and canine cases are assigned to county of residence rather than county of exposure, so some of the discordance between human and canine distributions may reflect where people and canines live rather than where they encountered infected ticks.

Canine CAPC records provide a signal that is complementary to, rather than equivalent to, human surveillance, in that they capture the number of canine tests performed and the percentage positive rather than confirmed human cases. Two features of these data constrain how far that signal can be carried. First, neither the human nor the canine datasets record travel or exposure history, and both are geolocated by residence or testing location rather than by site of exposure. Second, canine ehrlichiosis serology does not distinguish among *Ehrlichia* species, so an unknown share of canine positivity may represent *Ehrlichia canis*, which is not a recognized human pathogen and is transmitted by dog ticks that do not vector the human-pathogenic species. Canine positivity is therefore best read as evidence of tick exposure and *Ehrlichia* circulation in the canine population, and only indirectly as a marker of human ehrlichiosis risk. Multimodal spatial analysis has demonstrated that canine serological data substantially improved county-level TBD risk assessment beyond what human case reports alone could provide, directly supporting the approach taken here [6].

The integration of county-level climate data as a fourth layer supplies only coarse context: a moderate score means that county-average temperature and precipitation fall near the middle of the Oklahoma distribution. It does not establish *A americanum* presence, habitat suitability, or the reason for sparse human reports. Land use, land cover, host availability, microclimate, and range-expansion timing were not measured [5,30,32,33].

Because the comparative index standardizes a human incidence-rate summary and a canine percent-positive summary, it identifies counties where the 2 surveillance measures rank relatively high. It does not estimate disease burden, individual risk, or local exposure, and a high number of cases or tests need not correspond to a high standardized signal.

Several low-population western counties register weak combined signals, but these data cannot distinguish low transmission from limited ascertainment. The human (2004-2007) and canine (2012-2026) periods are noncontemporaneous, so range expansion between periods could also contribute to discordance. Targeted entomological sampling and exposure-based

XSL•FO
RenderX

epidemiologic investigation are required before attributing the pattern to ecology or surveillance.

The sharp decline in human ehrlichiosis case counts between the 2 CDC reporting periods observed in this study may reflect changes in case definition [49], testing practices, the COVID-19 pandemic's disruption of routine health care visits, or some combination thereof, rather than a true reduction in disease burden, a distinction with significant implications for how these trends are communicated to clinicians and the public. Several factors have been identified as plausible explanations for the observed decline in reported ehrlichiosis and tularemia cases between the 2016-2019 and 2019-2022 periods. Most prominently, the later reporting period encompasses the COVID-19 pandemic (2020-2021), which had well-documented effects on both health care–seeking behavior and disease surveillance nationwide. Emergency department visits for tick bites decreased substantially in 2020 relative to 2017-2019, and the number of LD tests performed fell by approximately 25%, concluding that TBD case reporting in 2020 was likely artificially reduced by pandemic-associated changes in health care–seeking behavior despite ongoing or even increased tick exposure [50].

Critically, the CDC's own national surveillance analysis of *E ewingii* ehrlichiosis explicitly noted that, although cases increased overall across 2013-2021, the number of reported cases decreased in 2020 and 2021 compared with previous years, an effect attributed to the COVID-19 pandemic and observed across other TBDs as well [49]. Pandemic-related delays in the diagnosis and treatment of SFR and ehrlichiosis in the southeastern United States also affected not only whether cases were reported but also how promptly they were diagnosed [51]. Given that the 2019-2022 CDC dataset used in this study includes 2 full pandemic years, the steep declines observed for both ehrlichiosis and tularemia in Oklahoma are likely attributable in substantial part to pandemic-related surveillance artifacts rather than to a true reduction in disease transmission.

Another possibility raised is whether improved public health messaging may have positively influenced the use of TBD prevention measures among Oklahoma residents, thereby contributing to fewer infections. The evidence on this point is suggestive but inconclusive. Personal protective measures (including use of US Environmental Protection Agency [EPA]–registered repellents, permethrin-treated clothing, and postexposure tick checks) are effective at reducing tick bites when used consistently, and community survey research indicates that individuals who have previously seen TBD information from their health department report higher use of repellents and tick checks than those who have not [52,53]. However, owing to cross-sectional study designs, it cannot be determined whether educational efforts are driving protective behaviors or whether individuals with higher perceived risk are simply more likely to seek out such information [53].

No Oklahoma-specific data are available to confirm that prevention messaging measurably reduced TBD incidence, and the magnitude and abruptness of the observed declines, concentrated in the pandemic years, are more consistent with surveillance disruption than with gradual behavioral shifts. While enhanced prevention messaging remains a worthwhile public health goal and may contribute to long-term risk reduction, the available evidence does not support attributing the observed case declines primarily to improved prevention behavior. This ambiguity reinforces a central argument of this study: without consistent, granular surveillance data, it is not possible to distinguish a genuine reduction in disease from an artifact of reporting, which in turn limits the ability to evaluate the effect of public health interventions.

Historical tularemia data in Oklahoma reveal a pattern of substantial unexplained variation in case counts across decades. National tularemia surveillance reporting covering 2011-2022 indicates an increase of 56% over that period, although four-fifths of cases were classified as probable rather than confirmed, raising important questions about the accuracy of diagnostic classification and testing practices [19]. While national tularemia surveillance data have confirmed Oklahoma's status as a high-burden state [54], reliance on probable case classifications introduces significant uncertainty into surveillance trends and may partly explain the wide variation in Oklahoma's historical case counts. Changes in surveillance case definition criteria over the time frame examined represent another plausible, and largely unquantifiable, source of this variation. Case definitions for nationwide notifiable TBDs have been revised repeatedly; for tularemia, the disease was removed from the national notifiable list in 1994 and reinstated in 2000 with a revised case definition that introduced a probable case category, and the ehrlichiosis and spotted fever rickettsiosis definitions have likewise been restructured on several occasions to reflect changes in laboratory methods and recognized etiologic agents [11,19,49]. Because the historical Oklahoma records analyzed here span decades before standardized national case definitions existed, and because each revision alters which illnesses are counted, some of the apparent decade-to-decade variation in tularemia case counts may reflect changes in what constituted a reportable case rather than true changes in disease occurrence.

Still, enhanced surveillance and recognition of localized ecological factors, including tick density and land use, as key drivers of case clustering suggest that Oklahoma's tularemia variation may reflect shifting environmental conditions as much as changes in surveillance capacity [55]. The observation that single-year tularemia mortality counts in earlier decades approached the total case counts seen across recent 4-year surveillance periods is particularly striking and likely reflects some combination of higher historical case fatality rates before modern antibiotic availability, changes in case ascertainment over time, and reduced environmental exposure or improved clinical management in more recent years [19]. More research using longitudinal ecological and entomological data is needed to disentangle these competing explanations.

However, the interpretation of tularemia case variation requires caution. Tularemia is unique among the TBDs examined in this study in having multiple nontick transmission routes. *Francisella tularensis* can infect humans not only through the bite of infected ticks (in Oklahoma, principally the American dog tick, *D variabilis*, and the lone star tick, *A americanum*) and deer flies, but also through ingestion of contaminated food or water,

XSL•FO
RenderX

inhalation of infectious aerosols, and direct contact with infected animal tissues, for example, through cuts sustained while butchering an infected rabbit or other lagomorph [19,36,56]. Aerosol transmission has also been documented during agricultural and landscaping activities when machinery such as a tractor or lawnmower passes over an infected animal carcass [36,57]. Consequently, the geographic and temporal pattern of reported tularemia cases cannot be assumed to reflect tick vector distribution or density alone; variation may equally be influenced by hunting and trapping activity, rabbit and rodent population dynamics, agricultural practices, drinking water sources, and the relative frequency of each exposure route in a given county and year [19,56].

This multiplicity of transmission pathways is an important consideration for the inferential strength of the canine-sentinel triangulation approach for tularemia. Whereas canine ehrlichiosis positivity is a relatively direct proxy for shared tick exposure, canine data are a weaker proxy for human tularemia risk, since human tularemia infections also may arise from nontick routes to which canines are not comparably exposed. Therefore, tularemia findings should be interpreted relative to reported case patterns rather than as a direct index of tick-borne transmission risk.

The diagnostic complexity surrounding TBDs in Oklahoma is compounded by the presence of STARI, an emerging lone star tick-transmitted condition that presents with an expanding erythema migrans (EM)–like rash clinically indistinguishable from early LD, accompanied by fatigue, headache, and myalgia [25,26]. The EM-like rash of STARI itself may lead to a LD misdiagnosis for some patients, as the presence of provider-diagnosed EM rash alone meets national surveillance case definition criteria for a diagnosis of LD without any additional confirmatory laboratory testing. Because the etiologic agent of STARI has not been definitively identified, no nationwide notifiable case definition exists, no commercial laboratory test is available, and STARI is not included in NNDSS reporting [25,26]. Patients with STARI who seek care for a LD-like presentation will test negative for *Borrelia burgdorferi* and may be dismissed without treatment, despite the documented clinical benefit of doxycycline in most reported cases [26]. This diagnostic gap emphasizes the urgent need for standardized TBD diagnostic protocols and improved clinician education regarding regional endemic patterns [4].

The overlap in symptom profiles among ehrlichiosis, RMSF/SFR, tularemia, and STARI (conditions that occur in Oklahoma but involve different vectors or transmission routes) means that a provider unfamiliar with local TBD epidemiology may not order appropriate tests, particularly in western counties where surveillance data have historically suggested low disease burden despite canine sentinel data pointing to the contrary. The variation in Oklahoma's public health TBD data formats over nearly a century (Textbox 1) illustrates how data inconsistency compounds this problem. Without reliable historical baseline data, clinicians and public health officials cannot accurately communicate risk levels to communities, and opportunities for early case detection are lost [4,13].

The One Health triangulation approach used in this study builds on an established and growing evidence base for canine sentinel surveillance as a complement to human TBD reporting [58-61]. Along with the present findings from Oklahoma, there appears to be a systemic expansion of canine sentinel data integration into state and federal TBD surveillance frameworks. However, this study also demonstrates that CAPC canine data already in the public domain can be better and more regularly used for this purpose. The NOAA layer supplies a coarse climatic comparison only; because it omits land cover, hosts, microclimate, and field validation, it cannot distinguish surveillance failure from ecological unsuitability [28,29]. The TBD surveillance gap is therefore not solely a data availability problem as such; it is also a data integration and communication issue that could be addressed within the existing public health infrastructure.

The heterogeneity of Oklahoma's historical TBD data, spanning handwritten mortality logs, printed narrative reports, tabular presentations, and modern electronic formats across nearly a century, illustrates a challenge that is common to TBD public health surveillance [12,13]. Addressing this challenge systematically would require substantial investment in data standardization and digitization. Emerging AI tools offer promising approaches for assisting in and accelerating this process, with implications for public health surveillance and integrating heterogeneous data sources, including historical records, electronic health records, and social media streams, and for reducing delays in outbreak detection [62,63], although there are also problems associated with their use, such as privacy violation concerns and other ethical challenges. In any case, applied to the archival TBD data challenges, AI assistance and tools appear to hold promise for data collection and engagement in relation to public health data and records, enabling more rigorous longitudinal analyses than are currently feasible.

## Limitations

Noted here are particular limitations that should be considered when interpreting the findings.

First, some limitations may be associated with passive disease reporting, including differential case ascertainment, testing variability, and reporting completeness across counties and time periods [1,4]. It is also critically important to note that reported cases of both human and canine TBD often lack travel or exposure history and, in the datasets used here, are mapped exclusively by county of residence (for canines, the county of the testing veterinary clinic) rather than by county of exposure. Because ticks may be acquired during travel, recreation, or work outside the home county, and because canines frequently accompany their owners on such activities, county-level counts and percent-positive values may attribute infections to counties where exposure did not occur, which limits geographic interpretation of both the human and canine surveillance patterns presented here. This constraint bears directly on the small number of human anaplasmosis cases reported in Oklahoma, which cannot be assumed to have been locally acquired: *Anaplasma phagocytophilum* is transmitted by *I scapularis*, a vector not established across most of the state [8,18], and we identified no published case report establishing local acquisition through epidemiologic investigation. Human anaplasmosis is

XSL•FO
RenderX

accordingly reported here as a surveillance count only and is not characterized as an endemic human TBD in Oklahoma.

Second, the use of aggregated multiyear CDC county-level data, available only in 4-year blocks for most TBDs studied, prevents analysis of year-to-year trends and may mask meaningful within-period variation, including, for example, the impact of the COVID-19 pandemic on health care usage and TBD testing [49]. The later study period (2019-2022) also coincides with the COVID-19 pandemic, which is known to have artificially depressed TBD reporting nationwide [49-51], such that observed declines in case counts cannot be interpreted as true reductions in disease burden.

Third, county-level case counts suppressed by the CDC for privacy (fewer than 5 cases per county per period) were treated as missing, which is the methodologically appropriate approach but means that an estimated 40%-50% of counties in the ehrlichiosis analysis had no usable human case data, limiting the geographic completeness of the human surveillance picture.

Fourth, CAPC canine data are derived from canines presenting to veterinary clinics and reflect testing practices and veterinary access patterns, not a random sample of the canine population; counties with fewer veterinary testing resources may have lower reported canine positivity independent of true disease burden [15,16]. An important related limitation is that canine ehrlichiosis serology has the potential to greatly overestimate human ehrlichiosis risk. Commercial canine assays detect antibodies to several *Ehrlichia* species without distinguishing among them, and where the majority of canine infections are caused by *E canis*, an agent that is not a recognized human pathogen, canine seropositivity has little bearing on human risk. *E canis* is transmitted by the brown dog tick (*Rhipicephalus sanguineus*) and the American dog tick (*D variabilis*), both of which are present in Oklahoma [46,47]. Although American dog ticks frequently bite people and brown dog ticks occasionally feed on humans, neither species transmits the human-pathogenic *Ehrlichia* species (*E chaffeensis* and *E ewingii*), which are vectored primarily by the lone star tick (*A americanum*) [44,46,47]. Consequently, canine ehrlichiosis resulting from *E canis* infection transmitted by either species of dog tick would not be an indicator of human ehrlichiosis risk. Because the CAPC canine data used here do not identify the infecting *Ehrlichia* species, the geographic extent of canine positivity, particularly in western counties with no reported human cases, should be interpreted as evidence of *Ehrlichia* exposure in the canine population rather than as a direct measure of human ehrlichiosis risk, and may in part reflect *E canis* transmission by dog ticks.

Fifth, the historical tularemia data (1928-1980) were manually extracted from archival records of heterogeneous quality and format, introducing the possibility of transcription error and limiting comparability across time periods. In addition, case definition criteria for human TBD surveillance changed at multiple points during the time frame examined, and pre-1990 archival counts were compiled without a standardized national case definition; such changes could account for a substantial portion of the dramatic variation in case counts across decades and cannot be separated from true changes in incidence using the available data [11,19].

Sixth, for tularemia specifically, the canine-sentinel triangulation approach is inherently limited because *F tularensis* is transmitted through multiple nontick routes (including ingestion, inhalation, and direct animal contact) to which canines are not comparably exposed, weakening canine data as a proxy for human tularemia risk [19,36,56].

Seventh, this study is geographically limited to Oklahoma as a use case and the ecological conditions, tick species distribution, and health care infrastructure specific to that state; findings may not be generalizable to other states without replication using locally appropriate data [18,64].

Eighth, no longitudinal county-level tick density data exist for Oklahoma across the study period, preventing direct assessment of whether changes in vector abundance contributed to observed case variation [33].

Ninth, regarding vector tick density specifically, the current county-level *A americanum* presence data from the CDC, while useful for establishing broad vector distribution, do not adequately contextualize the historical tularemia and ehrlichiosis surveillance information presented here. To our knowledge, no systematic, longitudinal, county-level dataset of *A americanum* or *D variabilis* density exists for Oklahoma across the full period represented in the graph set. The figures therefore do not treat climate or tick-distribution maps as direct evidence of tick density; instead, they summarize observed human and canine surveillance patterns through statewide, county, and regional graphs. This point underscores the need for dedicated, ongoing entomological surveillance to complement disease-based human and canine data streams [32,33]. Relatedly, the Tick Season Risk Index used as the environmental layer in this study is a simple two-variable construct based on county annual mean temperature and annual precipitation, with weights assigned by the authors rather than estimated from data. Although temperature and moisture variables are well established in the modeling literature as principal climatic correlates of *A americanum* distribution [5,30,31], the specific variables, weights, and 0-100 scaling used here have no published precedent, were not fitted to tick occurrence records, and were not ground-truthed against active surveillance for host-seeking ticks in Oklahoma counties. The index therefore cannot identify a threshold for tick establishment, and counties falling in its moderate range should not be assumed to support *A americanum* populations: land use, land cover, host community composition, and microclimate may render such counties unsuitable irrespective of county-average climate. The index should be interpreted only as a coarse, exploratory screen indicating that county-average climate does not obviously preclude tick activity, and validating it will require paired field collection of host-seeking ticks across the climatic gradient described here.

Finally, future research also should address demographic factors within the human case data, such as age, sex, occupation, or race or ethnicity, which are known to be associated with differentiating socioeconomic health determinants affecting both TBD exposure risk and access to diagnosis and care [19,21,23].

### Generalizability

Oklahoma is presented as a use case. The workflow can be replicated where comparable human and animal surveillance data exist, but the observed rankings and discordance should not be generalized to other states without local data, harmonized periods, and locally appropriate vector and ecological information. While dependent on data availability, the method itself is broadly transferable. As noted, CAPC canine test summaries are published at the county level nationwide [15], NOAA Climate Normals are available for all US counties [28], and most state health departments maintain current and archival notifiable disease records. The specific findings, however, are conditioned on Oklahoma's setting, including the dominance of *A americanum* and the endemic status of ehrlichiosis, RMSF/SFR, and tularemia rather than LD [18], a large rural population with uneven access to medical and veterinary care, extensive tribal lands [22], and the particular years and formats in which county data were released. States where LD predominates, and *I scapularis* is the principal vector, or where county data are released on different schedules, would be expected to show different patterns of human and canine concordance. The approach is likely most directly transferable to neighboring states with similar tick ecology and tularemia burden, such as Arkansas, Missouri, and Kansas [19], and to states into which *A americanum* is expanding [5,9], where canine positivity may become detectable before human cases are recognized [16].

### Conclusions

Oklahoma is one of the highest-burden states for several non-Lyme TBDs, consistently ranked among the states contributing the greatest share of national case counts for spotted fever group rickettsioses (including RMSF), ehrlichiosis, and tularemia [3,11,19]. More than 75% of spotted fever rickettsiosis cases nationally occur in just 7 states, with Oklahoma standing alongside Arkansas, Missouri, North Carolina, Virginia, Alabama, and Tennessee [11]. Oklahoma, along with Arkansas, Missouri, and Kansas, collectively accounts for approximately 50% of all nationally reported tularemia cases [19]. The lone star tick (*A americanum*) is the primary driver of this burden; it is the most abundant tick infesting both animals and humans across the southern United States. [32]. In Oklahoma, its peak activity has historically concentrated in late spring and early summer, though recent entomological data from north-central Oklahoma indicate a shift in adult peak activity approximately 1 month earlier than historical norms, likely reflecting ongoing climatic changes [32].

Beyond the notifiable diseases tracked in this study, *A americanum* in Oklahoma is also the implicated vector for Heartland virus infection, Bourbon virus disease, AGS, and STARI. These conditions are not nationally notifiable, have little-known or no commercially available diagnostic tests, and are essentially invisible in standard surveillance systems [25,26,65,66]. AGS alone has seen a documented spike from approximately 12 confirmed US cases in 2009 to more than 34,000 by 2019, with Oklahoma among the states with the highest per-capita positive antibody rates [66]. While not establishing the magnitude or location of unobserved human disease burden, the findings (that human TBD case counts in Oklahoma are geographically concentrated) show geographic discordance among available surveillance measures. They support evaluating ascertainment and exposure attribution, especially in low-density counties.

This study has implications that extend well beyond Oklahoma. The NNDSS continues to make most TBD data publicly available only at the aggregate state level, a structural constraint that hinders the localized risk assessments necessary for effective clinical decision-making, public health communication, and targeted prevention [11-13]. This limitation is particularly consequential in high-burden states such as Oklahoma, where the full scope of TBD risk, including nonnotifiable conditions such as STARI and AGS, substantially exceeds what passive surveillance records indicate. Noting the lack of a systematic, standardized mechanism for collecting, reporting, and integrating TBD data within and across states at the county-level and below, the identified interpretive challenges illustrate the practical cost of surveillance gaps. For example, the marked declines in reported ehrlichiosis and tularemia cases between the 2 study periods cannot be confidently attributed to any single cause, because the available data cannot disentangle a true reduction in transmission from the well-documented effects of the COVID-19 pandemic on health care–seeking and reporting [49-51], from possible improvements in prevention behavior [52,53], or, in the case of tularemia, from shifts in the relative frequency of the disease's multiple nontick transmission routes [19,36,56]. The inability to distinguish among such explanations, each plausible and each supported by the published literature, is itself a key finding, demonstrating that current surveillance infrastructure is inadequate for evaluating whether disease burden or public health interventions are genuinely changing over time. As lone star tick ranges expand northward and westward under ongoing climate and ecological change [5,9], states not yet considered endemic for ehrlichiosis, tularemia, or STARI will face the same surveillance blind spots experienced in Oklahoma.

The triangulation approach demonstrated here, integrating archival human surveillance data with publicly available canine serological data and environmental climate data from a One Health perspective, offers a scalable, low-cost model for improving geographic TBD risk assessment using data already in the public domain [6,16,58,60]. A principal contribution of this study lies in the reporting of case counts, incidence rates, and percent positivity separately and combining them in a standardized comparative index at the county level. It differs from existing studies, which have relied largely on aggregate reporting at the state level or on canine sentinel data for LD, by applying the approach to ehrlichiosis, RMSF/SFR, and tularemia across nearly a century of archival records. For clinicians practicing in or near known *A americanum* habitats, including most of Oklahoma, the implication is clear: aggregate state-level TBD data cannot resolve county-level heterogeneity. At this point, canine positivity data can provide a more geographically sensitive signal for TBD exposure in the community, provided such data are interpreted with attention to their limitations, including geolocation by residence rather than exposure, the absence of travel history, and the inability of canine serology

XSL•FO
RenderX

to distinguish *Ehrlichia* species pathogenic to humans from those that are not [6,16,46,58]. Additionally, treatment arguably should not be withheld pending confirmatory testing in suspected rickettsial or ehrlichial illness, given that outcomes worsen significantly with delayed treatment and that the overlap between these conditions and STARI, RMSF, and tularemia makes differential diagnosis on clinical grounds alone unreliable [4,65]. For public health practitioners and policymakers, this study reinforces the case for federal investment in standardized county-level (and below) TBD reporting and the formal integration of relevant animal health data into human disease surveillance frameworks [13]. Moreover, a One Health perspective, in which human, animal, and environmental health data are routinely integrated, is an operational necessity for understanding and managing the full, and largely undercounted, array and burden of TBD in the United States [14,16,62].

## Funding

The authors declared that no financial support was received for this work.

## Generative AI Use

The authors declare the use of generative AI in the research and writing process. Generative AI was not used to generate the original manuscript. After submission, the tools assisted with reviewer-response drafting, manuscript language editing, abstract condensation, terminology and citation formatting, figure-code revision, and source-data spot checks. The authors reviewed and verified the AI-assisted output and take responsibility for the accuracy and integrity of the final paper. According to the GAIDeT (Generative AI Delegation Taxonomy; 2025), the following tasks were delegated to generative AI tools under full human supervision: literature search and systematization; code generation; process automation; creation of algorithms for data analysis; validation; data analysis; visualization; reproducibility testing; text generation; proofreading and editing; summarizing text; reformatting; quality assessment; identification of limitations; recommendations; and publication support. The tools used were Claude (Anthropic; Fable 5) and ChatGPT Codex (OpenAI). Responsibility for the final paper lies entirely with the authors.

In "Awareness of Sexual Partner's HIV Status Among Men Who Have Sex With Men in China: Cross-Sectional Survey Study" [1], the authors made one correction.

Affiliation 1 has been changed from the following:

> *Department of Rheumatology Immunology & Allergy, Zhejiang University School of Medicine, Hangzhou, China*

The affiliation now reads:

> *Department of Rheumatology Immunology & Allergy, The Children's Hospital, Zhejiang University School of Medicine, National Clinical Research Center for Child Health, Hangzhou, China*

The correction will appear in the online version of the paper on the JMIR Publications website together with the publication of this correction notice. Because this was made after submission to PubMed, PubMed Central, and other full-text repositories, the corrected article has also been resubmitted to those repositories.

In "Diagnostic Testing Preferences in Rural and Vulnerable Populations During a Pandemic: Discrete Choice Experiment" [1], the authors noted one error.

The Ethical Considerations section has been changed from the following:

> *This study (STUDY00002116) has been reviewed by the Institutional Review Board of the University of Vermont and the Institutional Official has authorized the publication of the research data.. Focus group protocols were reviewed by the IRB using the exempt procedures set forth under 45 CFR 46.104, specifically, under Exemption Category: (2)(ii) tests, surveys, interviews, or observation (low risk), with waiver of documentation of consent under 46.117(c)(1). The Discrete Choice Experiment (DCE) was originally deemed not human subjects research by the IRB's assessment tool; a quality review later determined that the study should have been reviewed and would likely have been approved with a waiver of written consent. In the DCE, survey data were collected without identifiers. Respondents received $5 compensation for their time from the survey company Centiment. Additionally, no identification of individual participants in any images of the manuscript or supplementary material is possible.*

This section now reads:

> *Focus group protocols were reviewed by the IRB using the exempt procedures set forth under 45 CFR 46.104, specifically, under Exemption Category: (2)(ii) tests, surveys, interviews, or observation (low risk), with waiver of documentation of consent under 46.117(c)(1). The Discrete Choice Experiment (DCE) was originally deemed not human subjects research by the IRB's assessment tool; a quality review later determined that the study should have been reviewed and would likely have been approved with a waiver of written consent. In the DCE, survey data were collected without identifiers. Respondents received $5 compensation for their time from the survey company Centiment. Additionally, no identification of individual participants in any images of the manuscript or supplementary material is possible. The IRB director at UVM gave permission to publish this manuscript.*

The correction will appear in the online version of the paper on the JMIR Publications website, together with the publication

# Beyond Longitudinal Sampling: Translating Sexually Transmissible Enteric Infection Research Into Gastrointestinal Diagnostic Pathways

***(JMIR Public Health Surveill 2026;12:e102167)*** doi:10.2196/102167

**KEYWORDS**

sexually transmitted disease; sexually transmitted enteric infection; gay; bisexual; men who have sex with men; longitudinal sampling; acceptability; feasibility

We read with interest the study by Fountain et al [1] assessing the acceptability and feasibility of longitudinal sampling for sexually transmissible enteric infections (STEIs) among gay, bisexual, and other men who have sex with men (GBMSM) [1]. The study highlights important gaps in our understanding of STEI carriage, persistence, and transmission dynamics.

The conventional divide between “sexually transmitted” and “enteric” pathogens is less clear-cut than has historically been presumed. Enteric pathogens were traditionally conceptualized as foodborne or fecal-orally transmitted organisms, yet sexual transmission within GBMSM networks is increasingly recognized. While organisms such as *Shigella* and *Campylobacter* are now well described in this setting [2], other pathogens, including *Salmonella* spp and *Entamoeba histolytica*, may also be encountered in association with sexual exposure and anorectal inflammatory syndromes [3,4].

The authors appropriately emphasize the public health importance of this issue, including antimicrobial resistance, asymptomatic carriage, and the need for better longitudinal epidemiological data. However, these observations also carry important implications for day-to-day gastrointestinal clinical practice. Patients with STEIs may present not only to sexual health services but also to emergency departments, primary care, and gastroenterology clinics. In such settings, the possibility of sexually transmissible enteric infection may not be immediately considered, particularly when symptoms resemble inflammatory bowel disease.

This overlap is clinically important. Sexually transmitted colorectal infections may mimic inflammatory bowel disease, potentially resulting in diagnostic delay, unnecessary colonoscopy, inappropriate corticosteroid or biologics exposure, and missed opportunities for transmission control [5]. This is particularly relevant in patients presenting with proctitis or proctocolitis, where standard clinical, endoscopic, and radiological features may not reliably distinguish inflammatory bowel disease from infectious causes.

Building on the work of Fountain et al [1], we suggest that future clinical pathways should translate STEI research into a more structured diagnostic approach for GBMSM presenting with proctocolitis. Such an approach could follow 3 steps. First, perform initial rectal sexually transmissible infection testing after careful, nonjudgemental sexual history taking, including testing for classical anorectal sexually transmitted pathogens where clinically indicated. Second, perform expanded enteric testing if symptoms persist or initial sexually transmissible infection testing is negative, using fecal multiplex gastrointestinal molecular panels that include bacterial and parasitic pathogens. Third, perform colonoscopy, although this should be reserved for selected cases, particularly when microbiological investigations are negative, symptoms persist, inflammatory markers remain elevated, or there is ongoing concern regarding inflammatory bowel disease, malignancy, or another noninfectious pathology.

This is not intended to suggest indiscriminate testing in all patients. Rather, it reflects a risk-adapted and behavior-informed diagnostic model. In this sense, careful sexual history taking becomes part of precision medicine, allowing clinicians to tailor microbiological investigations and treatment decisions according to individual exposure patterns, epidemiological context, and clinical phenotype.

Earlier recognition of STEIs in gastrointestinal clinical settings may improve case detection, facilitate appropriate partner

XSL•FO
RenderX

notification, support antimicrobial resistance surveillance, and help interrupt transmission within sexual networks. As the spectrum of sexually transmissible infections continues to evolve, diagnostic pathways must similarly adapt to recognize the growing overlap between sexual health, enteric infection, and gastrointestinal inflammation.

## Acknowledgments

## Abstract

Public health data dashboards have substantial potential to improve transparency, understanding, and decision-making at multiple levels, from individuals to public health practitioners and policymakers. However, creating effective dashboards presents many challenges. In this case-based tutorial on public health dashboard development, we share lessons learned from our experience developing data dashboards for the HEALing Communities Study (HCS), a National Institutes of Health (NIH)–funded, community-engaged intervention to deploy evidence-based practices to reduce opioid overdose deaths in 67 communities across 4 states. We present key decision points dashboard teams must address, along with the major considerations and trade-offs that shaped our approach. First, we describe core considerations of the who, what, why, where, when, and how of data dashboard development. Second, we outline steps in data curation, including the identification of key metrics and potential data sources and developing processes to acquire the data. Third, we discuss practical aspects of developing data visualizations that can effectively communicate key messages to the end users of interest. Fourth, we describe the infrastructure considerations to host and publish data dashboards. And finally, we discuss maintenance and sustainability of the dashboard. While the material can be read sequentially as a step-by-step guide, we refer to this resource as a “playbook” because readers may engage with specific domains in a random-access fashion, that is, based on their specific needs and/or starting point rather than a fixed sequence. The information, supplemental materials, and resources will assist individuals and organizations seeking to build data dashboards by fostering context-sensitive evaluation of design and implementation choices to realize the promise of data-driven decision-making.

**KEYWORDS**

dashboard systems; data visualization; public health; opioid epidemic; drug overdose

## Introduction

Automobile instrument panels are perhaps the most familiar type of dashboard. They combine analog and digital visualizations—for example, gauges, counters, and icons—to help drivers monitor key aspects of their vehicle, including fuel levels, speed, engine temperature, and mileage. Warning indicators alert drivers to critical issues like low oil, low tire pressure, or an unfastened seatbelt. Designed for instant readability, these dashboards prioritize essential information, with standardized warning lights and speedometers placed centrally to capture the driver’s immediate attention.

Public health data dashboards function much like automobile dashboards; both use data visualizations to communicate critical information and support decision-making. By consolidating valid and useful epidemiological metrics and other public health data, these dashboards enhance awareness, facilitate monitoring, and drive informed action. Their value has been especially evident during public health crises, such as the COVID-19 pandemic and the opioid overdose epidemic, where real-time data have played a crucial role in response efforts [1-3].

Despite an influx of public health data, challenges and barriers have emerged with regard to the effective and efficient communication of these data to a broad range of individuals. Issues critical to the uptake and use of public health data

XSL•FO
RenderX

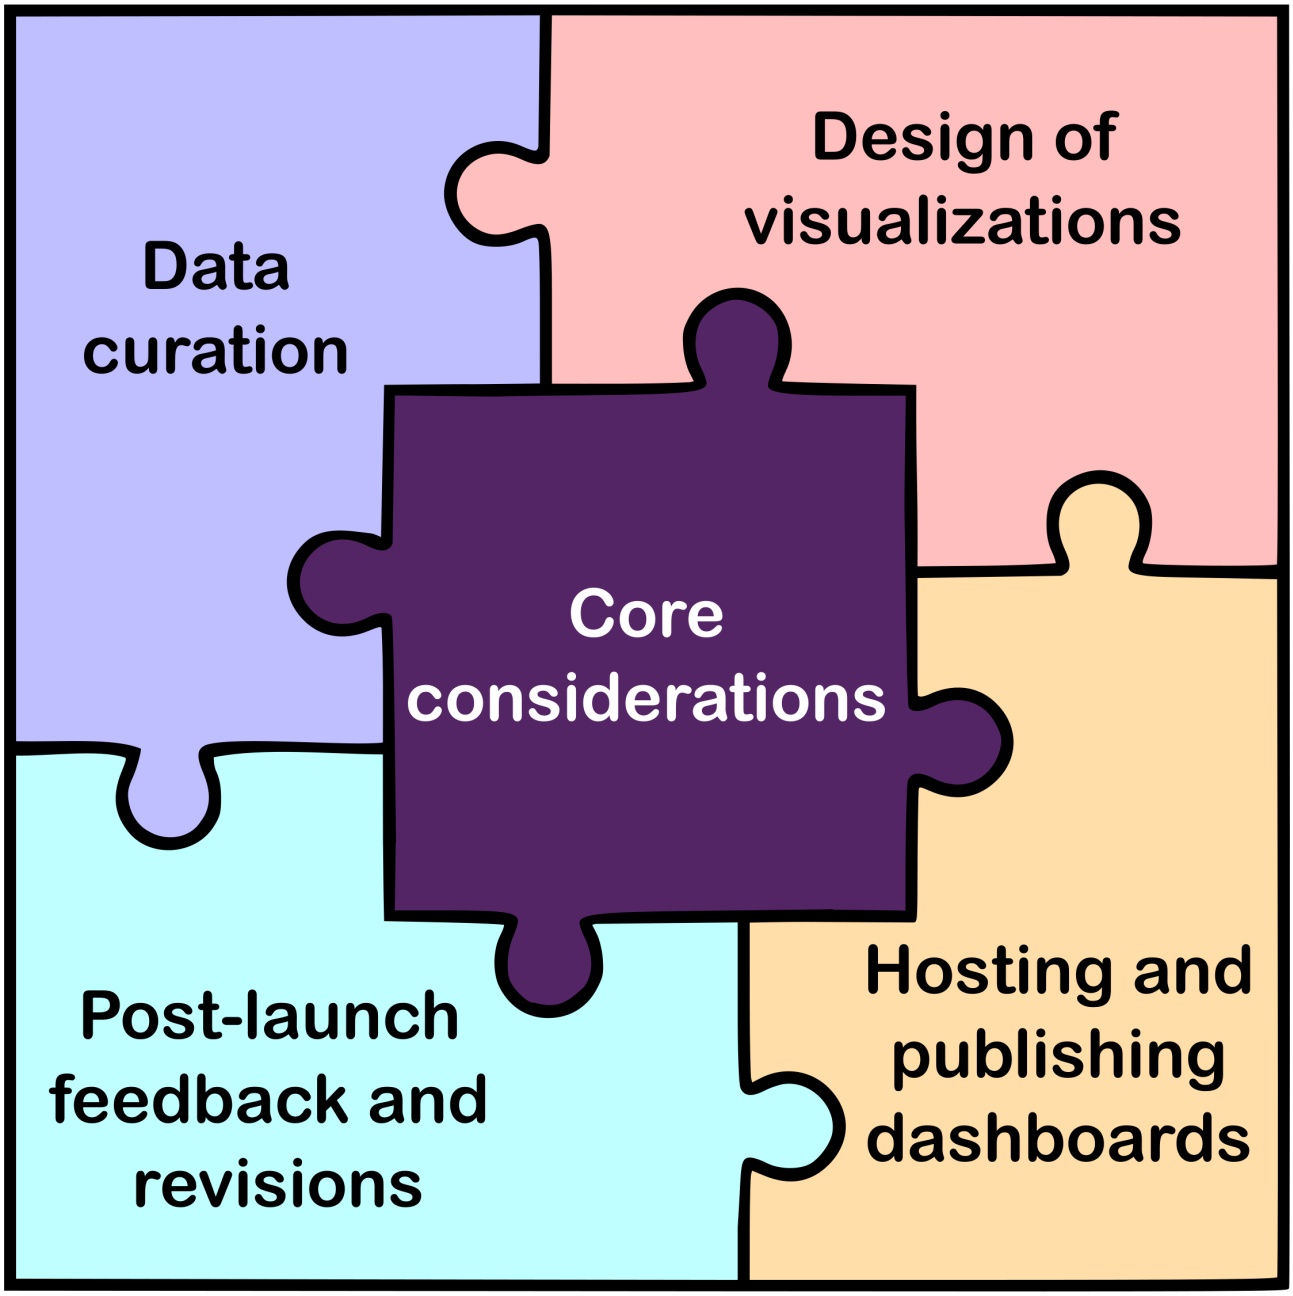
dashboards include a design that contains the most useful data, usability, cognitive load, implementation and evaluation, and sustainability [4]. Studies on data visualizations and dashboards have discussed notable challenges that pertain to these issues, including lack of rigorous scientific methodology, superficial or incorrect application of design principles, data literacy of end users, and limited scope in the representation of end user input [5-7].

Within this context, our research team engaged in the development of data-driven dashboards for a large, multisite cluster-randomized pragmatic trial. The HEALing Communities Study (HCS) was a community-based cluster-randomized trial aimed at addressing the opioid crisis in communities with high opioid overdose death rates. The National Institute on Drug Abuse (NIDA), in partnership with the Substance Abuse and Mental Health Services Administration (SAMSHA), funded the study in April 2019 to test the immediate impact of the implementation of an integrated set of evidence-based practices across health care, behavioral health, justice, and other community-based settings to prevent opioid overdose deaths and treat opioid use disorder [8]. Among the 4 states ("study sites") involved in the HCS, communities (n=67) were randomized to receive the intervention first or be in the wait-list control group. In each community, a community coalition was established to provide local leadership and data-driven decision-making for the intervention [9]. Data dashboards—to support data-driven decision-making [10]—were co-created with coalition members to provide visualizations of key metrics on opioid overdoses and treatment for opioid use disorder within a community [3]. The coalition stakeholders (1) used data to define their local opioid situation, including prevention and treatment gaps and resources; (2) developed a data-driven action plan for implementing evidence-based practices linked to local needs; and (3) after deploying the action plan, they used data dashboards to monitor progress and adjust as needed.

Eighteen months after deployment, we conducted a usability evaluation of the HCS dashboards using a mixed methods approach that involved quantitative feedback from the System Usability Survey (SUS) [11] and qualitative interviews guided by the Technology Adoption Framework [12]. The SUS scores indicated the end users found HCS dashboards to be acceptable for usability; for example, the overall grand mean SUS score from 62 users of the HCS dashboards (39% response rate) was 73 (SD 4.6), which falls between the 70th and 80th percentile of SUS responses and is comparable to scores reported for widely used tools such as Microsoft Word and PowerPoint (Microsoft Corp) [13]. The interview results indicated positive feedback around dashboard usability and intention to use from the end users sampled.

The considerations described in this case-based tutorial playbook are grounded in our prior work in the development and evaluation of HCS data dashboards. Although some aspects of HCS dashboard development reflected consensus decisions or externally imposed requirements (eg, minimum required metrics and National Institutes of Health [NIH] funding conditions), the purpose of this tutorial playbook is not to present consensus guidance or a prescriptive methodology. Rather, we focus on identifying key decision points that arise during public health dashboard development and the attendant major considerations and trade-offs that shape how those decisions are approached. By emphasizing decision points rather than prescriptive solutions, this tutorial playbook supports adaptation across different public health settings. The manuscript is organized along a typical dashboard development lifecycle, from conceptual considerations through postlaunch revision. While this can be used as a step-by-step guide, dashboard development is often nonlinear; thus, we refer to this document as a "playbook" to indicate that readers can refer to specific sections as dictated by their context, starting point, and immediate needs at a given time.

## Public Health Dashboards: Key Tasks



Based on lessons learned from the HCS, we provide this playbook for creating public health data dashboards. While HCS dashboards focused exclusively on opioid use disorder and overdose-related metrics for each community, the information and considerations provided here can be applied to myriad public health issues. Consistent with the case-based foundation of this manuscript, the core considerations and domains are presented as guiding questions and decision points rather than as required artifacts (ie, tools or steps that are applicable across all contexts, such as accessibility review checklists, compliance sign-off documentation, and articulated user personas), success criteria, or approval gates that are likely to vary substantially both qualitatively and quantitatively across contexts.

Each section is a conceptual domain of questions that help guide dashboard developers as they design and deploy a dashboard. For purposes of this tutorial playbook, we organize these along a prototypical dashboard lifecycle, starting with (1) core considerations and then progressing through (2) data curation, (3) design of visualizations, (4) hosting and publishing dashboards, and (5) postlaunch feedback and revision. However, as depicted in Figure 1, the process is neither linear nor discrete. Each section in the playbook is equally important, and the interrelationships and/or interplay among domains require developers to revisit decisions across domains over time.

XSL•FO
RenderX

**Figure 1.** Overview of the playbook.

### Core Considerations

A useful framework for guiding dashboard development at every stage is based on the classic journalistic "Five Ws and One H" approach: who, what, why, where, when, and how. These questions help ensure a structured and comprehensive approach to designing, deploying, and maintaining public health data dashboards (Textbox 1). By addressing these key decision-making topics, dashboard developers can ensure a holistic approach to planning, designing, and deploying effective dashboards. The core decision-making topics manifest throughout the key domains involved in dashboard development and publishing that are described in the ensuing sections of this playbook.

XSL•FO
RenderX

**Textbox 1.** Core considerations.

The "Five Ws and One H" approach:

- Who is the target audience (ie, end users)?
- What do the end users want to be able to learn or infer from the data?
- Why are dashboards a useful or the optimal tool to meet the need?
- Where will the dashboard be published and/or made available?
- When do the dashboards need to be published, updated, etc?
- How will we actually build and publish the dashboards?

### *Who: Understanding the End Users*

Identifying the target audience—or end users—is essential. Dashboard developers must assess and tailor to their users' technical expertise, data literacy, professional roles, and specific needs. Workflows also shape dashboard requirements; for instance, some users may need real-time monitoring, while others might only check a dashboard weekly, monthly, or quarterly.

### *What: Defining the Dashboard's Purpose*

Dashboards should be designed to answer key questions for end users efficiently. Developers must determine, "What information do users need? How can the data be presented to support decision-making?" Ideally, visualizations should allow users to grasp insights quickly with minimal cognitive effort, delivering essential information "at a glance."

### *Why: Establishing the Dashboard's Core Objectives*

This question prompts developers to define the overarching goals of the dashboard. What key messages or insights should be communicated? What operational or policy decisions should the dashboard support? Design choices—such as whether to use graphical summaries or textual explanations—should align with these objectives to maximize clarity and usability.

### *When: Considering the Timeline for Development and Updates*

Developers must plan for the time required to acquire and integrate data, design and test the dashboard, and manage its lifecycle post launch. This includes establishing a schedule for updates, revisions, and long-term sustainability.

### *Where: Ensuring Availability and Visibility*

The dashboard's availability is a critical consideration. Developers must decide whether it should be hosted on a public website or restricted to an internal platform. If public, should it be optimized for search engines, or should access be controlled? Additionally, dashboards should be designed to function seamlessly across different devices—desktops, laptops, tablets, and smartphones—each of which has unique constraints related to screen size, processing power, and internet connectivity. In some cases, a dedicated app or embedded dashboards within an existing platform may enhance usability.

### *How: Assessing Resources and Infrastructure*

Successful dashboards require technological and human resources. Developers must evaluate factors such as cybersecurity, data storage, processing capabilities, and integration with external data sources. Managing these elements effectively ensures the dashboard remains functional, secure, and scalable over time.

In addition, governance is an important consideration, as decisions about data access, processing, and publication are often shaped by legal, contractual, and institutional constraints. In practice, dashboard teams need to address how data use agreements (DUAs), applicable privacy regulations (eg, the Health Insurance Portability and Accountability Act [HIPAA]), and data suppression rules affect what data can be ingested, how it can or needs to be transformed and displayed, and with whom it can be shared. These constraints often extend beyond technical implementation to influence workflows, timelines, and responsibilities across the data lifecycle, from data acquisition and quality assurance through publication, revision, and eventual retirement.

An information architecture diagram can help document how data move through a system, from source data through transformation and storage to visualization, access control, and monitoring. Such diagrams may be useful for identifying or clarifying the human and technical resources involved, how those resources are organized, key dependencies, and where governance and security considerations arise, as well as for supporting communication among technical and nontechnical stakeholders involved in dashboard development.

## Data Curation

Data curation involves identifying desired metrics, sourcing available data, and establishing procedures to acquire or "ingest" the data (Textbox 2). This process is foundational to building a reliable and actionable public health dashboard. Desired metrics—shaped primarily by the who, what, and why—typically are the primary outcome and key epidemiological characteristics and/or targets of prevention and intervention efforts (eg, incidence or prevalence of a disease or phenomenon of interest). Other data that are often desired include secondary outcomes, key drivers of the outcomes of interest, and data that allow for subgroup characterization (eg, age, sex, race, ethnicity, geography).

XSL•FO
RenderX

**Textbox 2.** Decision points for data curation.

The following questions outline key decision points to consider when planning and implementing data curation processes for dashboards and other data-driven systems:

- What are the desired metrics and visualizations?
- What data are available?
- What are the acquisition requirements (eg, data use agreements and security needs) and associated costs for infrastructure and staffing?
- What are ways to address data quality and refresh discipline?
- How do these requirements match available or planned resources and funding?
- Based on all of the above, what are the relative priorities of potential metrics and visualizations?

Many metrics require calculations that integrate multiple data points. For example, prevalence is derived from case counts relative to a denominator—typically population size—which may also need stratification by demographic variables. Similarly, spatial visualizations require both temporal and geographic details for each case. Thus, desired metrics may involve multidimensional databases or combining and calculating across different data sources. Regardless of the exact metric, the most effective dashboards ensure that such data are not only accurate but also actionable (eg, lag between data collection and reporting does not undermine relevance for decision-making).

In identifying available data, several potential sources should be considered. Administrative data may be collected and made available from government agencies and initiatives (eg, vital statistics, Medicaid, or prescription drug monitoring programs) as well as service providers (eg, health care providers and social service agencies). Data may be collected and made available from research studies, program evaluations, population-level surveys (eg, the National Survey on Drug Use and Health and the Behavioral Risk Factor Surveillance System), and contracted third parties (eg, HCS used data from IQVIA and Millenium Health). Many data repositories also make data available (eg, Centers for Disease Control and Prevention [CDC] WONDER and the National Notifiable Diseases Surveillance System). Existing dashboards and other surveillance or monitoring systems may provide data directly or, when permitted, be incorporated into planned dashboards via embed codes that display existing visualizations without transferring the underlying data, or through scraping data from existing visualizations in accordance with applicable terms of use for local processing into a new visualization.

Constraints often govern the use and visualization of data, shaping how dashboards can present and share information. Data providers may impose restrictions on who can access specific datasets, limiting or prohibiting certain audiences from viewing them. These conditions are typically outlined in a DUA, which defines the expectations, requirements, and responsibilities between data providers and those developing and publishing the dashboard. A DUA specifies what data are being shared, the procedures for data transmission, storage, and publication, and any restrictions on visualization. These may include requirements for attribution, contextual definitions, or limitations on further distribution. Additionally, government regulations and institutional policies often impose further constraints, such as suppression rules designed to protect privacy and confidentiality. These rules dictate how data can be displayed, ensuring that sensitive or identifiable information remains secure while maintaining the integrity and utility of the dashboard. Other privacy-preserving computation approaches (eg, secure multiparty computation and federated approaches) may also be relevant, particularly for analyses that span data across multiple organizations or jurisdictions, although such approaches can involve greater technical complexity and coordination.

Within these constraints, data quality and data refresh are ongoing considerations in data curation. HCS teams regularly examined and tracked data quality dimensions such as completeness, timeliness and lag, internal consistency, and stability over time [14]. Dashboard designers may want to display refresh schedules or lag indicators, and the use of tools such as data quality scorecards (eg, to assess whether data meet thresholds indicating sufficient quality or warrant caution) may be useful for standardization, monitoring, and quality assurance. We note, however, that appropriate thresholds and related decisions depend heavily on context, including data source characteristics, suppression requirements, the potential clinical or policy impact of over- or misinterpretation, and intended dashboard use. Those are some of the aspects that allow for tailoring of data quality and refresh discipline (ie, the exact metrics, thresholds, or automation approaches for detecting problems stemming from lower quality or lag in data).

Data ingestion refers to the process of transferring data from its source to the recipient responsible for building the dashboard. This transfer can occur through various methods, including pushing, where the data provider actively transmits the data; pulling, where the recipient requests and retrieves the data; and scraping, where data are electronically extracted from existing documents or publications when permitted and in accordance with publishers' terms of use. In many cases, ingestion also involves preliminary data processing to ensure compatibility with dashboard visualization and storage. This preprocessing follows an extract, transform, and load workflow, which may include data cleaning (such as removing disallowed values or correcting inconsistencies), transforming variables (such as calculating rates from raw counts or aggregating data across time periods), and restructuring datasets to align with the platform used for visualization. The efficiency and reliability of data ingestion improve with greater automation. For example, some data sources provide an application programming interface, a standardized set of protocols that allow software to

XSL•FO
RenderX

directly request and retrieve data from the source, subject to authorization and applicable restrictions on use, storage, or display. However, implementing automation requires investment in human resources for design, programming, and ongoing maintenance as data systems evolve or become obsolete. Before establishing a data ingestion plan, it is essential to assess the capabilities of the existing cyberinfrastructure. If these resources are inadequate, the costs—whether in terms of personnel, hardware, or development time—must be factored into planning. When budgets and timelines are constrained, trade-offs may become necessary, potentially limiting the scope of data sources or the complexity of visualizations that can be supported.

Selection of data to be ingested for visualizations often cycles back and forth among desired versus available data, utility of data, and resources needed to transform the data into visualizations as well as maintain the cyberinfrastructure that hosts and publishes the dashboards. Desired metrics usually drive a targeted search for the relevant data needed to calculate and display the metric. Conversely, an examination of available data may prompt the desire for additional data (eg, disaggregated into subgroups such as race or ethnicity or age group, subtypes of substances, or variants of infectious agents; greater specificity with respect to time or geography). Given that resources do not allow for every possible visualization—nor is it advisable from a health communications perspective to provide vast quantities of information all at once—the full menu of potential visualizations should be prioritized for creation and inclusion in the dashboards. This decision-making process is about the appropriate or, ideally, optimal balance among data quality, utility of the metric, and costs or resources available to curate the data and publish the dashboards.

In public health, researchers, policymakers, and practitioners play a central role in determining key metrics and are typically considered the primary end users of data dashboards. The HCS operated under the principle that community members bring invaluable perspectives on the relevance, utility, and limitations of different data and metrics. Toward this end, HCS researchers developed the Community-Engaged Data Science model to assist data scientists working with communities in identifying and integrating relevant data for making informed decisions [15]. For data dashboard development, this ethos translated into a co-creation approach that sought to ensure that those affected by public health decisions, whether or not they hold formal decision-making roles, were actively involved in identifying and prioritizing the metrics and visualizations that would shape the dashboard. Engaging community members from the outset of the project fostered greater relevance, usability, and impact, making the dashboard a more effective tool for addressing the overdose crisis and other real-world public health challenges.

## Design of Visualizations

Ideally, the team-building dashboards include experts in human-centered design and graphical design who can work with the consumers of the displays (Textbox 3). A starting point is understanding the wants and needs of the end users. Interviews of end users can capture both what they want to know at a glance and what inferences and conclusions they would like to support (eg, trends in the data over time). During the initial development, focus groups and public meetings allow design teams to identify the types of people that will be using the dashboard. Understanding their data literacy—the ability to read and understand data and data visualizations—is paramount. For example, knowing that a dashboard will be used by public health practitioners would suggest that terms like “incidence” and “prevalence” can be used unabashedly, but if the same dashboard will be used by people without any background in statistics or epidemiology, avoiding jargon and using plain language is preferred to avoid confusing and alienating the audience. In the context of designing public health dashboards, it is critical to identify all end user groups and then develop an outreach plan to make sure that all constituents are assessed, rather than just the vocal and/or immediately available audience who may first provide information.

**Textbox 3.** Decision points for the design of visualizations.

The following questions highlight key considerations for designing effective visualizations that support user understanding and informed decision-making:

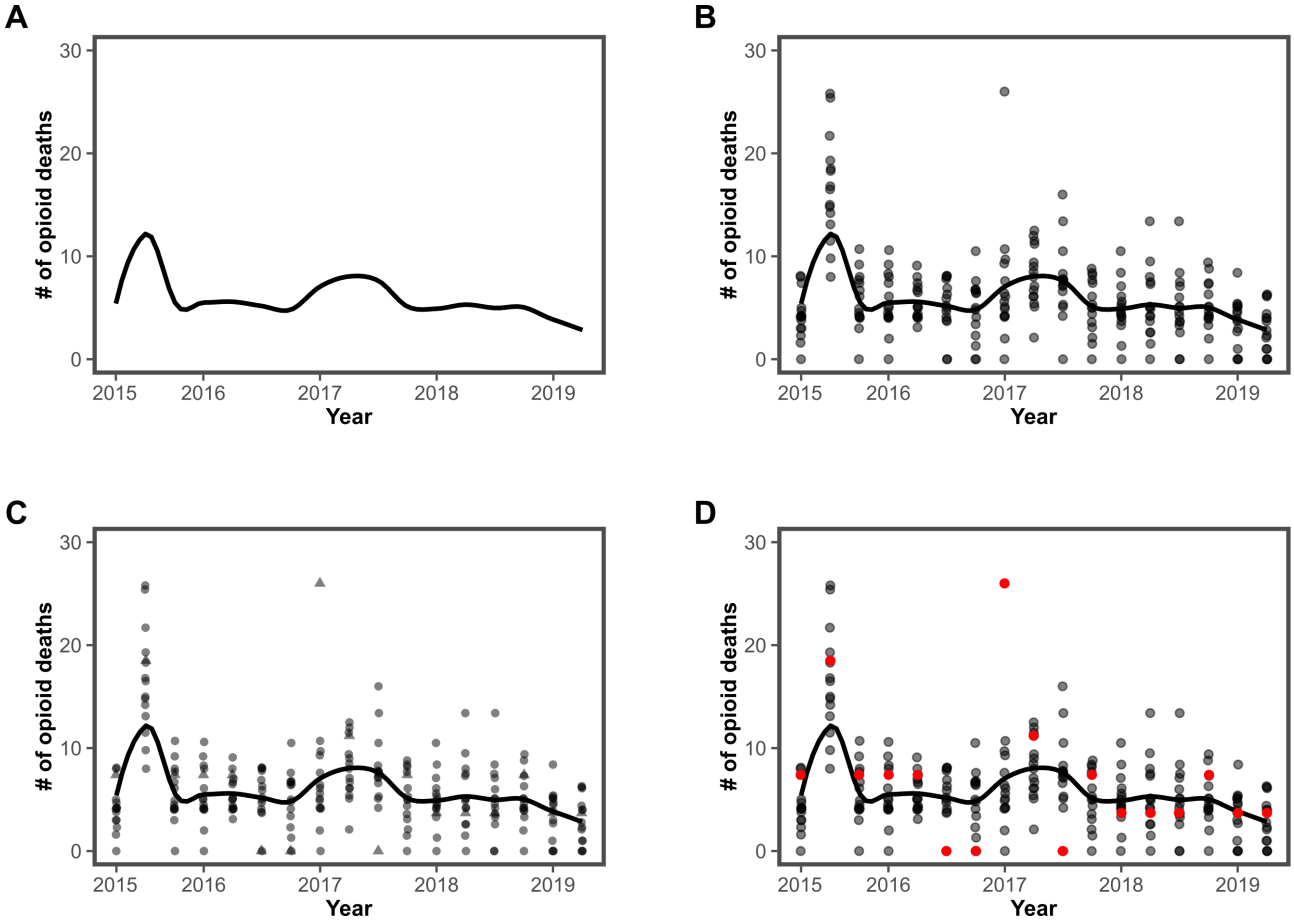
- How can we engage and elicit feedback from all end users?
- How can the data be transformed and/or presented so the end users can grasp the desired point at a glance?
- What additional visual elements will aid in comprehension or reduce misinterpretation?
- How can specific design elements be tweaked or refined to take advantage of how humans process information?
- What ancillary information is needed or helpful to the user?
- How can the dashboard interface allow the user to access such information without distracting from the main visualization?

A well-designed dashboard allows end users to quickly extract key insights and draw meaningful inferences. Within the design community, a widely used approach is to identify and/or envision different user “personas”—distinct groups of individuals who will interact with the data—and tailor the visualization to meet their specific needs [16]. Effective visual design prioritizes clarity and accessibility. High-level, at-a-glance insights can be embedded in intuitive graphics that communicate key trends immediately, while more detailed or supporting information can be provided separately in text or tables that would take additional time to process [17]. Well-crafted data visualizations enable users to perceive both central tendencies and variability immediately. For instance, a straight trend line clearly indicates whether a pattern is increasing or decreasing over time. However, as illustrated with synthetic data in Figure 2A, a flexible line—such as a curve generated by mathematical smoothing techniques like beta splines or locally estimated scatterplot smoothing—can reveal

XSL•FO
RenderX

nuanced departures from linear trends [18-20]. These features are particularly important for data that could have seasonal trends (eg, drug overdose patterns that vary by time of year) or identifying sudden shocks in data, such as unexpected spikes in mortality.

Combining multiple visualization elements enhances interpretability. As shown in Figure 2B, overlaying individual data points on a trend curve allows users to assess both the overall pattern and the underlying variability. This approach is especially valuable for identifying extreme events, such as a sudden surge in mortality due to drug supply contamination. At the same time, it helps distinguish genuine outliers from data anomalies that may stem from reporting errors rather than true shifts in the trend. When relevant, tagging outliers with contextual metadata can prevent misinterpretation (eg, a change in data reporting rather than a change in the underlying trend) and ensure that decision-making is based on accurate, reliable insights. By applying these visualization principles, dashboards can effectively support data-driven decision-making, enabling users to quickly grasp patterns, detect anomalies, and respond to public health challenges with confidence.

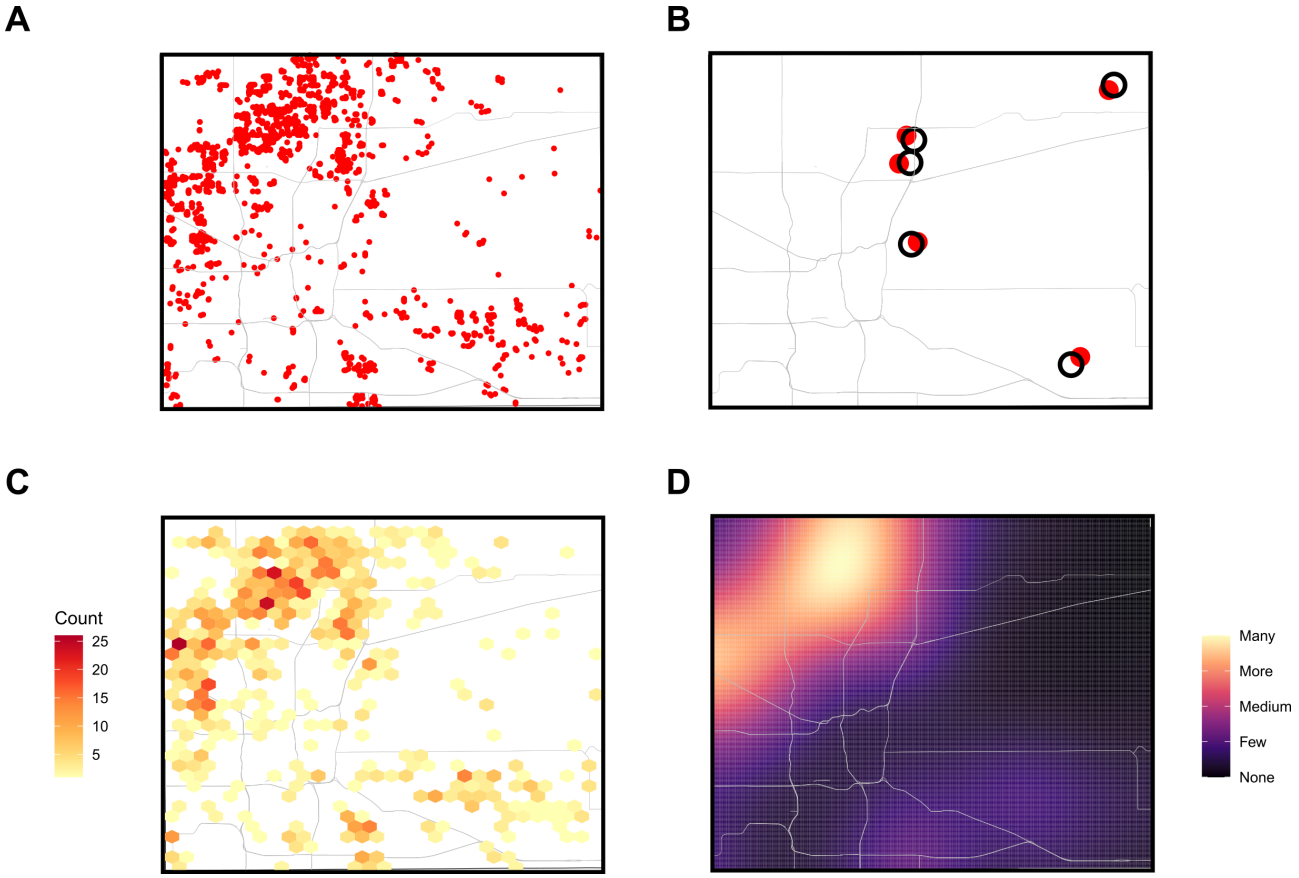


Some visualizations are static, meaning they function as fixed images where the information displayed remains unchanged. These are essentially bitmaps; what the user sees is exactly what they get. However, digital dashboards presented in a web browser or app can incorporate interactivity, allowing visualizations to change based on user actions. Interactive features enhance user engagement and data exploration. For example, users can zoom in or out on a graph by clicking buttons, dragging a slider, or pinching on a touchscreen. Filtering options, such as checkboxes, allow users to display or hide specific subgroups based on characteristics like race, age, or sex. Another valuable feature is the hover-over function, which reveals additional details when a user places the cursor over a data element, providing deeper insights without cluttering the initial visualization. While interactivity can significantly improve a dashboard's functionality by allowing users to focus on information most relevant to them, it comes with trade-offs. Implementing interactive features requires additional human and computational resources, both for development and ongoing maintenance. Design challenges also emerge, as excessive interactivity can be distracting or even counterproductive. Too many visual elements, animations, or overly complex interactions may overwhelm the user, while poorly optimized interactivity can slow down rendering, diminishing the user experience. Thoughtful design ensures that interactivity enhances rather than hinders the dashboard's effectiveness, striking a balance between flexibility and usability.

To ensure clarity and prevent misinterpretation, dashboard visualizations must be tested with multiple, diverse audiences. This is especially critical in public health, where data suppression is often necessary to protect anonymity or account for incomplete reporting. Misrepresentation can be particularly problematic when tracking rare events, such as overdoses. In small communities, just a few deaths can cause sharp fluctuations in rates, while in large urban areas, high death counts may appear less pronounced due to the sheer size of the population. In the HCS data dashboards, population-based rates were used to account for these disparate but real-world scenarios. However, even these metrics required careful handling. Overdose death rates, for example, were based on highly sensitive data that had to be suppressed in locations with low case counts to protect individual privacy. Simply omitting data points to comply with suppression rules could create misleading gaps in trend lines, making it difficult for policymakers to assess emerging patterns. Instead, smoothing techniques, such as locally estimated scatterplot smoothing curves (as shown in Figure 2A), allowed users to view approximate trends without revealing suppressed values, preserving both privacy and interpretability.

XSL•FO
RenderX

**Figure 2.** Scatterplot variations of the same synthetic data of opioid deaths versus time. (A) Panel A shows the general trend in opioid-related overdose deaths for all counties in an illustrative state. (B) Panel B adds markers for each county. (C) Panel C distinguishes a county of interest using a different shape. (D) Panel D distinguishes the same county of interest using color.



Similar challenges arise when incorporating maps into dashboards. Policymakers rely on geospatial data to allocate resources—such as overdose reversal kits—to the areas most in need. However, to protect individual privacy, maps cannot display the precise locations of overdoses. Various methods can address this issue, each with trade-offs in accuracy and usability. One approach, illustrated with maps of synthetic data in Figure 3B, involves randomly shifting (“jittering”) [21], overdose locations to nearby points on the map; this preserves the overall count information but could foster misinterpretation for users who do not read the legend carefully. Alternative methods include overlaying a grid and shading areas based on case density or using mathematical density functions to blur exact locations. While these approaches help preserve anonymity, they can reduce granularity and make interpretation more challenging. Additionally, choices on the distance to offset or the amount of blur (Figure 3C and 3Ds) are complex [22,23]. A higher number of events in very densely populated areas (eg, urban areas) can safely allow for smaller offsets or blur, but a lower number of events in sparsely populated regions (eg, rural areas) requires larger jitter parameters to hide the exact locations of events.

XSL•FO
RenderX

**Figure 3.** Map variations of the same geographical data. (A) Panel A shows an illustrative county with its primary roads along with simulated locations of overdoses, which are shown as red dots. (B) Panel B shows the same county with only 5 simulated overdose events displayed as large red dots along with slightly shifted (mean =1.25 km) locations as black circles. (C) Panel C shows the counts as colored hex shapes (hexagon area =1.4 $km^2$) with deeper red colors indicating many events. (D) Panel D shows a density plot from kernel smoothing (40×40 km, max-min normalization) [21], with brighter and lighter colors indicating more overdoses.

Ultimately, the most effective visualization strategies depend on the needs of the end users. Engaging with stakeholders throughout the design process ensures that visualizations balance privacy, accuracy, and usability, making them both ethically responsible and practically useful for decision-making. Consistent with the community co-creation ethos described earlier, the HCS used the community-engaged data science model [15] as an approach to community co-creation key considerations, such as differences in data familiarity, interpretation, accessibility needs, and perceived relevance across roles, geographies, and communities. Community co-creation inputs informed visualization design decisions, including choices related to language and reading level, use of plain-language labels or multilingual resources, level of detail, and use of interactivity. Community engagement also informed decisions related to data equity (eg, when suppression risked obscuring inequities and how data gaps were annotated) and how uncertainty or data limitations were communicated. In addition, stakeholder input highlighted practical access considerations, such as the need to account for low-bandwidth environments, mobile access, and alternative formats for resource-limited settings. We note that approaches to community engagement are likely to vary across communities and over time, reflecting differences in local context, resources, intended dashboard use, and public health topics.

Consulting with graphic designers when building dashboards can greatly enhance the clarity and usability of data visualizations. Experts in visual design understand how to optimize information processing, making it easier and faster for end users to extract key insights [24,25]. Principles such as the Gestalt laws leverage the human tendency to group related elements based on similarity and proximity, allowing users to quickly interpret patterns and relationships within the data. The ideal visualization enables users to grasp critical information at a glance.

Reducing cognitive load is a core principle of good design. Directly labeling elements within a visualization, rather than relying on a separate key, prevents users from having to remember reference points while analyzing the graphic. Other mnemonic techniques, such as using meaningful symbols (eg, hollow dots to indicate missing or suppressed data), can further streamline comprehension. However, such symbols must be clearly defined to avoid confusion. Effective visual design requires continuous feedback from end users to ensure that all details are easily understood across diverse audiences.

Certain chart types are inherently more effective than others. Research has shown that bar charts and dot plots allow for faster and more accurate comparisons than pie charts, which can be more difficult to interpret [26-28]. In addition to choosing the right type of visualization, graphic designers use visual signals—such as color, shape, and size—to draw attention to

XSL•FO
RenderX

key data points [17,29]. For instance, Figures 2C and 2D compare 2 methods for highlighting a county of interest, one using shape and the other using color. Determining which method is more effective depends on factors such as the overall size of the visualization, the density of the data, and the distribution of key elements. Direct engagement with end users can help refine these choices, ensuring that the most intuitive and efficient design is selected.

The design process should begin with an initial sketch or storyboard of the layout, progress through choices and prototypes, and culminate in a final, refined display. Dashboards are often accessed across devices with different screen sizes and bandwidth constraints (eg, desktop use in a networked office vs use on a personal mobile device with cellular bandwidth). Design decisions related to responsive layouts, content prioritization, and simplification of visual elements may therefore be needed to support use on smaller screens or in lower-bandwidth settings. These decisions may include determining which metrics or visualizations need to be retained across screen sizes and connection types, which elements can be condensed or hidden without loss of meaning, and how interactions are adjusted when space or network capacity is limited. Throughout this process, accessibility must remain a priority. Removing unnecessary clutter helps users focus on essential insights without distraction [30]. Additionally, dashboards should comply with applicable accessibility standards, such as the Americans with Disabilities Act (ADA), to support inclusive use. In practice, this may involve attention to issues such as color contrast and color blindness, keyboard navigation and focus states, the use of alternative text for non-text elements, and accessible labeling or markup to support screen readers. Addressing these considerations can help ensure that dashboards remain usable for individuals with a range of visual, motor, and cognitive needs. Accessibility checklists may be useful tools, including those informed by the Web Content Accessibility Guidelines (WCAG), for reviewing common accessibility considerations. Thoughtful, user-centered design ultimately ensures that dashboards are both functional and accessible, allowing all audiences to interact with data effectively.

In addition to the design decisions for the visualizations themselves, dashboards need to be constructed to allow users to expand their knowledge beyond what is on the page through proper attribution to the data. Data attribution refers to listing the data source for the underlying data used in the visualization. Specifically, the design team needs to decide if those details will always be visible, which increases visual clutter, or available on demand when users interact with the display, increasing the risk of users not identifying the sources of the data. For example, a visualization of drug overdose deaths may include a note that the data originate from the December 2022 mortality report from the state department of health. For the HCS displays, where we had a great deal of information to put on the dashboard, we typically opted to display additional information when the end user hovered over data or clicked on buttons to learn more. Feedback gathered from the community suggested that they were able to easily glean the details for the sources of the data.

## Hosting and Publishing Dashboards

Hosting and publishing dashboards are shaped by governance considerations that affect data access, release, and ongoing maintenance (Textbox 4). Rather than prescribing a specific governance model, this playbook emphasizes key governance-related decision points that arise as dashboards are hosted and published, such as who has authority to approve data use and release; how DUAs and privacy requirements (eg, 42 CFR Part 2 obligations) are monitored over time; how suppression rules are implemented within analytic and visualization workflows; how changes to data sources, metrics, or visualizations are reviewed and communicated; and how equity and inclusion goals are incorporated into these processes.

**Textbox 4.** Decision points for hosting and publishing dashboards.

The following questions highlight key considerations when planning the infrastructure, resources, and processes required to host and publish dashboards:

- What are the cyberinfrastructure requirements for data storage, creation of visualizations, publishing the dashboards, hosting the platform, and access permissions?
- What are the human resource requirements (eg, key roles, levels of expertise needed, and amount of effort)?
- Does this infrastructure meet requirements and regulatory rules for data storage and security?
- What are the existing institutional capacities with regard to servers, data visualization tools, and content management systems?
- What is the schedule for testing and quality assurance that will achieve a smooth publication of the official release version of the dashboard?

Implementing dashboards requires technical resources for both hosting the dashboard software and the data engineering processes necessary to convert raw source data into standardized measures [14]. Infrastructure requires resources to host or purchase commercial web hosting services. Personnel are needed for multiple roles and tasks, back-end database management staff, analytical staff to generate clean, standardized results, embedded testing staff for quality assurance, visual designers to implement effective visualizations, front-end engineers to produce dashboards and visualizations for end users, and a manager to coordinate internally and communicate externally to engage key stakeholders and the dashboard's target audiences. Real-world resource constraints may dictate that more than one role and task be assumed by one individual. By some combination of skills and experience, technical expertise at every level of the process—as well as allocating sufficient effort and time—is just as integral to success as the infrastructure itself.

In addition to staffing and infrastructure needs, hosting and publishing dashboards involve ongoing resource and cost

XSL•FO
RenderX

considerations beyond initial development. These can include the scale and complexity of data pipelines and hosting environments, recurring effort related to system administration, security reviews, software updates, and dependency maintenance, and the level of effort needed to support different refresh cadences or degrees of automation. As in the HCS, decisions about hosting and publishing often require balancing available staffing, technical capacity, desired functionality, and timeline considerations. Hosting and publishing dashboards also involve a range of operational tasks across build-out, launch, and maintenance. In practice, this may include clarifying staff roles and responsibilities for tasks, such as data engineer for extract, transform, and load processes; software engineer for visualization coding; designer for website design; and administration and support staff for hosting and administration, user support, and coordination across technical and programmatic staff. Operational considerations may also include determining appropriate data refresh patterns for different metrics and ensuring that routine maintenance activities—such as monitoring data pipelines, updating dependencies, and addressing security issues—are incorporated into ongoing workflows. Consistent with the case-based nature of this manuscript, these issues are treated as considerations rather than as a prescriptive costing or operational blueprint, with feasible approaches varying by organizational size, mission, context, and the maturity of available technologies.

The data infrastructure supporting raw data, analytical results, and dashboards must meet or exceed the security and protection requirements specified in the associated DUA and, when applicable, comply with broader regulatory frameworks, such as the HIPAA. For instance, storing and processing unsuppressed data may necessitate a secure network server with robust cybersecurity measures before the data are processed and prepared for publication.

Access control is another critical consideration. Depending on the sensitivity of the data, it may be necessary to restrict access to entire dashboards or specific features. Managing user access requires dedicated human resources for tasks such as account creation, access approval, validation, and ongoing monitoring. Access models can range from fully open dashboards, where no account management is needed, to tightly controlled environments in which each user must be individually verified and assigned an account. Intermediate approaches include self-managed accounts, where users can opt-in or sign up for access, balancing security with convenience. Integration with external authentication systems can further influence infrastructure requirements. For example, allowing Open Authorization—which enables users to log in with existing credentials from work accounts, Gmail (Google LLC), or other third-party services—can simplify access management but requires additional technical and security considerations. Ensuring that the cyberinfrastructure can support these access control mechanisms while maintaining compliance with security and privacy regulations is essential for safeguarding sensitive data while maintaining usability.

There is a wide variety of software for dashboarding, database management, analysis, and content management with varying degrees of cost and technical skill needed for implementation. Important considerations for dashboard development teams during evaluation, comparison, and selection of platforms and services include costs for licenses and feature sets; required technical expertise; scalability (eg, based on data volume, types of visualizations, user base size and heterogeneity, and accessibility); and the maintenance burden. Additional considerations include if and how dashboards can be embedded into other web content—for example, by providing application programming interfaces along with attendant restrictions on reproduction and further use—and how well tools integrate with existing infrastructure and workflows. In the HCS, different sites selected tools based on local expertise, resources, and institutional constraints. Open-source solutions, such as Shiny (Posit PBC) or D3, minimized licensing costs and allowed for greater customization but often required more advanced programming skills to implement and maintain. Commercial platforms, such as Tableau (Salesforce) and Microsoft Power BI, provided graphical user interfaces that supported rapid development of common visualization types but were less flexible for customization. In addition, academic and government organizations may already have enterprise licenses for commercial dashboard software, which can strongly influence platform selection.

Prior to publication and dashboard launch, the project implementation team should outline a plan for end user testing and review of all data visualizations, including feedback on navigation, design style, functionality, and processing speeds. Staging or test sites are common and widely available across different hosting platforms and should allow for different user access and permissions during this prelaunch review phase. Unforeseen obstacles are common and should be included in any work plan and accounted for in project launch timelines, as one programming solution will usually lead to a new and separate issue to solve. Often overlooked, testers need to also test for acceptability and performance on different device and browser types for any web-based application during a review phase. Once a thorough and transparent feedback and review process has been completed and final dashboard versions are ready for launch, it is recommended to use a “soft launch” to allow for time to address any bugs not detected on test site development. While every system and dashboard build varies and presents different challenges from development to publication, maintaining flexibility and the ability to adapt to new inputs or requirements is critical.

## Postlaunch Feedback and Revision

After the initial launch, live dashboards require routine maintenance and resolution of bugs to maintain trust and prevent burdensome obstacles to stakeholder engagement (Textbox 5). This requires a transparent mechanism in place for users to report bugs, submit feedback, and request new data or visualization formats. This mechanism should be easily accessible to end users either using an embedded form or a contact email address solely used for reporting issues or general feedback. Whichever method is implemented, site administrators would optimally receive automatic alerts to facilitate responsiveness. The dashboard team should also maintain a tracking tool to keep detailed records of each case to respond quicker and prevent similar issues in the future.

XSL•FO
RenderX

**Textbox 5.** Decision points for postlaunch feedback and revisions of dashboards.

The following questions highlight important considerations for monitoring dashboard performance after launch, collecting user feedback, and implementing revisions to improve functionality and usability over time.

- What is the plan for identifying bugs and issues and then implementing resolutions on an ongoing basis?
- What types and levels of end user feedback are integral to dashboard optimization, revision, and/or sunsetting?
- What are available methods for collecting end user feedback?
- What processes are in place for revising and enhancing dashboard components?
- How are postlaunch changes to metrics and visualizations documented and communicated to users?

Ongoing long-term feedback and revision of the dashboard system are equally necessary processes for assessing and evaluating whether dashboard aims are being met. These processes can iterate over the course of a project timeline but should be given consideration and built into initial scopes of work in early stages. Specific dashboard aims will differ depending on the project criteria; however, a central question in all public health dashboards should center on whether key metrics reach the intended audience and meet their needs. Are end users receiving useful information quick enough to inform decisions, understandable, and easy to apply in their own work or research? The answer to this question can determine whether information or insights gleaned from a data dashboard is in fact actionable in real-world settings (eg, setting program targets and monitoring implementation outcomes).

There are various methods to assess end-user experience. Well-documented and applied methods to collect feedback include usability testing (ie, direct observation of a participant performing a task), user surveys, focus groups, interviews, and website analytics tools that collect real-time site traffic data [31,32]. Each of these methods varies in resources required to implement and the types of data and insights they elicit. Balancing these factors and identifying one or a combination of methods throughout the course of the project can help ensure dashboard sustainability, as this feedback should be a key factor in the dashboard implementation team's decisions on potential revisions and enhancements to the initial platform content and design.

Website analytics tools (eg, Google Analytics) require few resources to set up and provide useful real-time and trend data on user sessions, most visited pages, average time spent on a page, and pathways of navigation. A simple metric, such as which pages are most visited, should not be overlooked, as this can inform how to prioritize certain visualization enhancements and modifications over others. Website analytics also provide data on end user characteristics (eg, where users are located, device type, and language), which are important inputs when prioritizing revisions and new feature development.

User surveys are a common method for gathering website feedback and vary in resource allocation from automated pop-up surveys that require little maintenance to more comprehensive questionnaires that may incorporate validated usability and user satisfaction scales, such as the SUS or its modified version, the Standard User Experience Percentile Rank Questionnaire (SUPR-Q) [33]; these validated questionnaires include prompts that address end users' attitudes about data credibility, appearance, ease of navigation, and willingness to return to the website and recommend to others. Despite the benefits of using these validated questionnaires, they alone will not provide the level of specificity needed to make targeted revisions for any single dashboard audience. While requiring more time in survey design, recruitment, and analysis, a more comprehensive survey that combines targeted prompts based on existing dashboard visualizations could prove to be a valuable source of end user feedback.

Focus groups, live webinars, and in-depth interviews are a more direct method of collecting end user feedback. While resource-intensive, these ensure direct community input and an opportunity to collect more nuanced real-time feedback from key stakeholders. In our prior usability study with the HCS, one important lesson we identified was the need to use an interdisciplinary approach to understand and improve engagement with data visualizations, which involves use of innovative technologies such as eye-tracking and audit log files and use of plan-do-study-act cycles to ensure fidelity with the co-creation process [12]. Such approaches generate multiperspective feedback that can support better design of a data dashboard.

Measuring a dashboard's usefulness and ability to facilitate an action or decision is often a challenge for any dashboard evaluation. While the various feedback collection methods mentioned, combined with website analytics, may provide insight into end-user satisfaction and dashboard traffic, they will not sufficiently capture the breadth of how end users are applying information from the dashboard and insights learned in real-world settings. A routine process of soliciting these examples from key dashboard stakeholders may involve pop-up prompts, requests via email listserv, and invitations to participate in follow-up surveys, webinars, focus groups, or user story-telling events. The process of gathering examples of real-world applications of dashboard content should repeat over the lifetime of a dashboard, and sustained documentation of these occurrences is integral to a comprehensive evaluation at the end of a project cycle.

Evaluation of public health dashboards can occur at multiple levels, ranging from usability and user experience to patterns of use and, in some cases, downstream decision-making. As noted earlier, evaluation in the HCS focused primarily on usability and perceived usefulness, using the SUS and qualitative interviews informed by the Technology Adoption Model [12]. Beyond usability, teams may also benefit from examining how dashboards are used over time (eg, views, click-through rates,

XSL•FO
RenderX

and dashboard item interactions) and how insights from dashboards inform decision-making processes. However, appropriate evaluation metrics, thresholds, and study designs (eg, AB testing) depend heavily on context, including dashboard purpose, data availability, organizational capacity, and intended use.

Once mechanisms for collecting evaluation data and feedback are in place, consistent and organized documentation of evaluation findings, end user feedback, ongoing maintenance issues, and new data and features requests is essential to informing prioritization. A collaborative process between dashboard implementers, key project stakeholders, and end users must weigh factors ranging from feasibility and required resources to potential impact when deciding which dashboard components to revise and enhance [34]. Across the HCS dashboards, feedback from different sources and endeavors informed multiple variations and versions of dashboard content and design. For example, qualitative feedback interviews indicated a need for support in data interpretation; this led to the team revising the dashboards to include "story" panels that contained brief textual summaries of temporal trends in the data. In another instance, community members raised questions during coalition planning meetings about the reach of online antistigma campaigns, which prompted the team to update the dashboard website to include visualizations of page views and click-through rates by campaign. These examples illustrate how user feedback informed dashboard development decisions without relying on a single, standardized feedback-to-change workflow.

As dashboards evolve post launch, changes to data sources, metrics, calculations, or visualizations should be tracked and documented (eg, changelog) in a systematic fashion. This includes situations in which metrics are modified, replaced, deprecated, or no longer supported due to changes or updates in data availability, definitions, reporting, or analytic approaches. Clear documentation of these changes can help maintain transparency, support interpretation of trends, and reduce confusion among end users, particularly when historical values are revised or when metrics are removed. While specific approaches to versioning, changelogs, or handling deprecated metrics will vary by platform and organizational context, the key task is considering how changes are documented and communicated.

# Discussion

## Summary

Well-designed dashboards serve as powerful tools for communicating public health data to key stakeholders and communities. Just as a carefully crafted automobile instrument panel can ensure a driver can reach their destination safely, an effective public health dashboard empowers community stakeholders to make informed, data-driven decisions. This is particularly crucial when epidemiological trends are rapidly changing or evolving across different locations and time periods. Unlike static data displays, interactive dashboards with real-time data provide a means of tracking and responding to public health challenges as they unfold. This playbook for developing data dashboards outlined steps and key considerations in data curation, design of visualizations, dashboard hosting and publishing, and feedback and revision.

## Limitations

While we expect this playbook to be valuable for a wide range of public health applications, our experience with the HCS may not always be generalizable. HCS focused specifically on opioid overdose and opioid use disorder, shaping the selection of dashboard metrics and data to reflect epidemiological trends and modifiable factors related to overdose prevention and treatment, such as safer prescribing practices and naloxone availability. The unique challenges encountered—such as suppression rules for sensitive data—may not directly apply to other public health issues, particularly those with different temporal, geographical, or population-level dynamics that influence the usability of visualizations and dashboard features. The intervention being tested in HCS was highly community-engaged; thus, opportunities for community co-creation and feedback for dashboards may have been more readily available. We also recognized that the underlying basis for this material is a series of case studies rather than a systematic, empirical investigation of dashboard development and deployment. The coordinated, multisite structure of the HCS allowed individual dashboard teams to benefit from cross-site discussion, problem-solving, and deliberation around key considerations. While the lessons presented here reflect consensus developed across multiple teams, similar opportunities for coordination and shared learning may not be available in other dashboard development efforts. Finally, as part of a grant-funded study, HCS dashboards were not required to include formal or coordinated sustainability planning. As a result, issues shaping sustainability (eg, funding, technical debt, knowledge transfer, and ongoing stakeholder engagement) were not systematically addressed. We posit that these considerations remain important for future dashboard sustainability efforts but are also highly context- and resource-dependent, thus prohibiting us from recommending universal sustainability templates, diagrams, or checklists. Altogether, while this case-based tutorial playbook offers practical considerations, further research and evaluation are needed to refine effective and practical practices for designing and implementing public health data dashboards across diverse contexts.

## Resources

The HCS dissemination efforts include a brief video entitled "How to Build Opioid Data Dashboards for Community Decision-Making: Best Practices from the HCS" [35]. This is a preview for a more in-depth, 5-session webinar for organizations interested in building public health data dashboards; webinar recordings and downloadable resources can be retrieved from the Data Dashboard Learning Collaborative Portal [36] (access provided upon request). The HCS also created a publicly accessible GitHub repository [37] with materials from a workshop organized along the following topics: (1) data acquisition and quality; (2) co-designing dashboards; (3) implementing and using dashboards in the community; (4) best practices for dashboard use; and (5) supporting the dashboard enterprise. The repository also includes

XSL•FO
RenderX

a DUA template, synthetic data, and sample code to construct metrics (eg, apply suppression rules), and workbooks to visualize data from our HCS dashboards.

### Next Steps

Although the examples presented in this playbook are drawn from HCS dashboards developed for opioid overdose surveillance, we aimed to identify and describe decision points and considerations with potential portability to other public health issues. By emphasizing decision points rather than specific or prescriptive solutions, the tutorial playbook is intended to support adaptation across settings where data sources, governance structures, regulatory constraints, and available technologies may differ. We have provided Multimedia Appendix 1 to provide illustrative information and examples of using the playbook for building a dashboard for maternal mortality. However, public health encompasses a vast array of topics, and unforeseen challenges may arise when applying these principles to different issues beyond the scope of this work.

The scientific principles guiding the co-design of public health dashboards are still emerging and most likely will be subject to continual evolution, with many concepts remaining open to interpretation. This playbook provides a structured approach to addressing the challenges of designing rigorous, stakeholder-informed dashboards, offering key insights into the who, what, why, where, when, and how of dashboard development within the context of opioid use disorder and the overdose epidemic. This playbook's design is a representation of first-hand experience and lessons learned while co-creating dashboards to communicate important public health information to community stakeholders, not a representation of scientific research such as an empirical review. While sustainability was mentioned, it remains an area that warrants further exploration; readers and developers are encouraged to seek successful models from government-funded endeavors, public-private collaborations, or community efforts. Additionally, some notable technological advances—such as machine learning (ML) and generative artificial intelligence (AI)—emerged during the period in which these dashboards were developed but were not implemented at the time (hence, outside the scope of this case-based tutorial playbook). Future public health dashboards may explore the value of such technologies for dashboarding, including forecasting trends, identifying emerging patterns, or supporting scenario-based planning [38]. Beyond analytic applications, AI tools have also been described as potential "design collaborators" that may augment the utility, effectiveness, and appeal of visualizations [39]. At the same time, ML and AI raise important challenges, including data privacy and governance considerations, the need for specialized technical expertise, and the risk of misinterpretation or overreliance on model outputs (eg, with spurious findings or hallucinations). Taking such care, ML and AI in public health dashboards remain potentially exciting and valuable areas for further investigation. Altogether, as the allied fields and technologies continue to evolve, dashboard development paradigms should be refined and evolve with allied fields—such as data science, graphic design, psychophysics, and cognitive sciences—to maximize the public health impact that dashboards can bring to the field.

## Abstract

The demand for high-quality population health data at the local level calls for expanded tools for those working to enhance the health of communities across the country to easily calculate small area estimates. Statistical models that generate small area estimates often use Bayesian estimation techniques, which are computationally complex and not readily accessible to most public health professionals. We developed 2 tools to facilitate small area estimation. For ArcGIS Pro users, we developed the Rate Stabilizing Toolbox ArcGIS plugin (RSTbx), and for R users, we developed the Rate Stabilizing Tool R package (RSTr). In this tutorial, we demonstrate how to use these tools to calculate small area estimates and evaluate their reliability. We also demonstrate 3 key benefits from using either of these tools: (1) decreased number of geographic units with suppressed estimates, (2) flexibility to set the threshold for statistical reliability, and (3) credible intervals that can be used to identify statistically significant differences between geographic units. Additionally, both tools offer built-in age-standardization capabilities. We created census tract–level maps from North Carolina mortality data and Rhode Island hospitalization data to showcase the benefits of generating small area estimates with these tools. Rate Stabilizing Toolbox and Rate Stabilizing Tool for R are powerful tools that can be used to meet the demand for high-quality local-level data to inform public health programs and tailor health promotion activities to the needs of communities across the country.

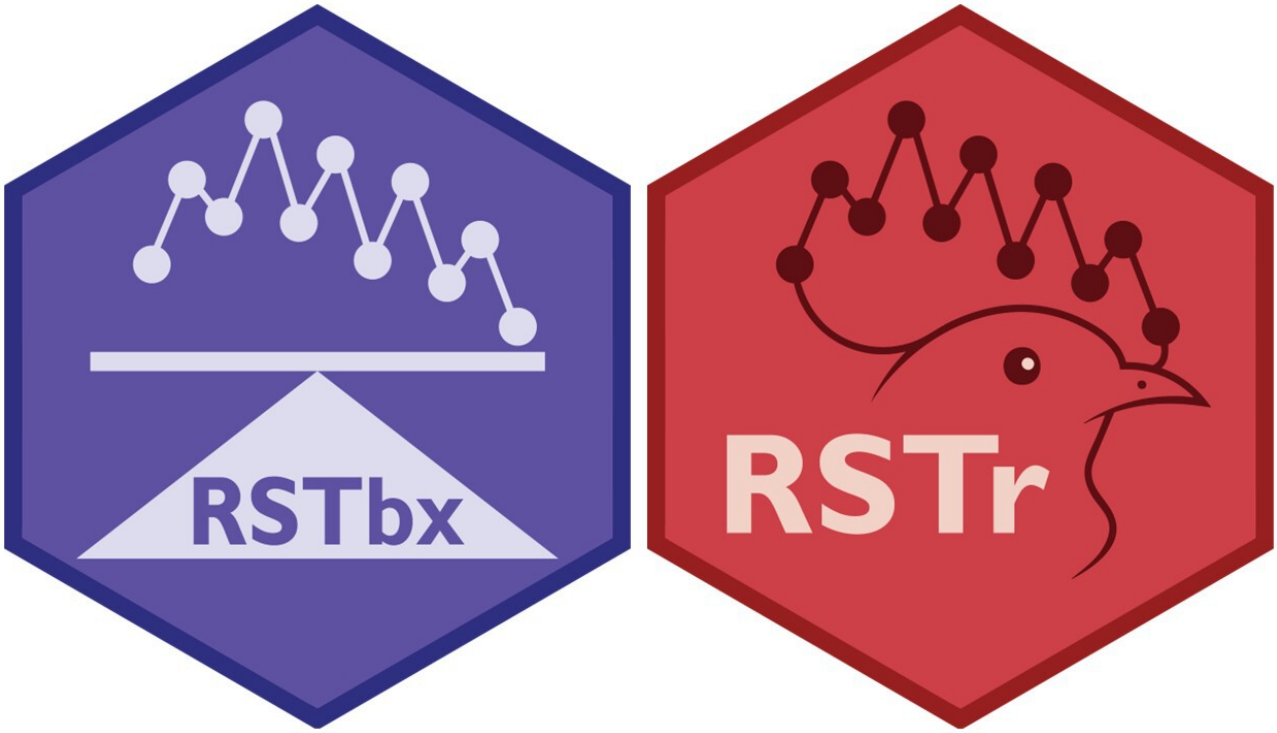
small area estimates; spatial analysis; software; geographic information system; GIS; spatiotemporal models; R; Bayesian statistics



## Introduction

The demand for high-quality population health data at the local level calls for expanded tools that public health professionals and others can use to easily calculate robust small area estimates [1-3]. A key challenge for calculating robust small area estimates occurs in regions with small population sizes or few numbers of events; these small numbers introduce statistical uncertainty, leading to challenges in the meaningful interpretation of results [4]. Statistical methods that appropriately address these challenges are often computationally complex and may not be readily accessible to those working to enhance the health of communities across the country. In response to this need, we implemented established statistical models into 2 distinct tools: an ArcGIS toolbox (the Rate Stabilizing Toolbox [RSTbx]) and an R package (the Rate Stabilizing Tool for R [RSTr]) (Figure 1). These tools enable users to input local-level data and calculate robust small area estimates. This tutorial provides step-by-step instructions for how to use each tool along with a demonstration of the benefits derived from using these tools.

XSL•FO
RenderX

**Figure 1.** Icons for Rate Stabilizing Toolbox (RSTbx; left) and Rate Stabilizing Tool for R (RSTr; right).

Based on Tobler's First Law of Geography [5], which asserts that closer places are more alike than further places, spatial statistical models improve estimate precision by leveraging the data's underlying spatial structure (ie, spatial smoothing). Among these existing models, RSTbx and RSTr are based on the conditional autoregressive (CAR) model developed by Besag, York, and Mollié (BYM) [6], which is used extensively in spatial epidemiology and disease mapping [7]. Outcomes as varied as excess cardiovascular disease death rates in the United States during the COVID-19 pandemic [8], tuberculosis relative risk in Indonesia [9], and under-nutrition among under-five children in Ethiopia [10] have recently been investigated with methodology based on the BYM model. The popularity of the BYM model is further enhanced due to its extensions into spatiotemporal and multivariate settings through the MCAR of Gelfand and Vounatsou [11] and the MSTCAR of Quick et al [12]. Recent developments in BYM models involve strategies to quantify model informativeness and avoid oversmoothing [13,14] and outlining of standards for estimate reliability [15].

The RSTbx and RSTr both offer key benefits for calculating and mapping small area estimates of population health. First, by leveraging spatial and other dependencies in the data, the estimates produced by the RSTbx and RSTr are more precise than those based solely on the observed data. As such, the estimates produced by these tools will be more reliable, resulting in fewer estimates being suppressed, thereby permitting the documentation of geographic patterns with a more comprehensive geographic coverage. Second, both tools allow users to relax the threshold for reliability based on measures of uncertainty (eg, basing thresholds for reliability on the 80% credible intervals [CIs] rather than the standard 95% CIs). Third, these measures of uncertainty can be used to assess statistically significant differences between estimates for geographic units and other domains.

We have divided this tutorial into 3 sections. We begin with an overview of each tool, including how to use the tool, the input and output datasets, and their modeling capabilities. Then, we demonstrate the benefits of using the tools by mapping small area estimates of mortality using RSTbx and hospitalization rates using RSTr. Finally, we review the tools' strengths and limitations and provide a table comparing their major features.

## RSTbx: An ArcGIS Toolbox

### Overview

RSTbx is a Python-based set of tools designed for Environmental Systems Research Institute's ArcGIS Pro software [16]. Users can input their own local-level data and calculate local-level estimates using Bayesian spatial smoothing methods. RSTbx uses a BYM model framework that smooths across space using data from adjacent geographic units [6]. RSTbx also includes options for data processing, age-standardization, and the generation of CIs. RSTbx, with detailed instructions, is available for download on GitHub [16].

RSTbx is an upgrade to the original Rate Stabilizing Tool (RST) that was created in 2019 [17]. Enhancements include the following:

- A CAR model implementation based on the BYM model to replace the Poisson-gamma empirical Bayes method used in the original RST [7,8].
- The user interface has been revamped for greater ease of use.
- Users can import custom features; they are no longer limited to 2010 US Census geographies.
- Users can import their own population tables, whereas the original RST allowed only population data from the 2010 Census of the Population.

XSL•FO
RenderX

- Age-standardization to 10-year age groups is now possible using either the 2000 US Standard Population or the 2010 US Standard population [18].
- Population tables from the decennial US Census and American Community Survey (ACS; by census tract or county) can now be downloaded directly into an ArcGIS Pro project along with US Census TIGER and cartographic geographic boundaries [19].

RSTbx includes 3 tools: the Census Data Retriever (CDR), the Individual Data Processor (IDP), and the RST. The CDR generates population tables at the county or census tract level using data from the US Census' Decennial Census or the ACS. It can also be used to download TIGER or cartographic boundaries. The IDP aggregates individual-level event data by calculating the number of events within each geographic unit and joining the aggregate counts to the provided population table. The IDP can aggregate individual-level event data by age group to produce aggregate data for each geographic unit. The IDP also performs several data validation checks (eg, the IDP will check for null data, incorrect datatypes, or duplicate geographic units within population data). Finally, the RST runs a BYM model and generates small area estimates.

## Installing RSTbx

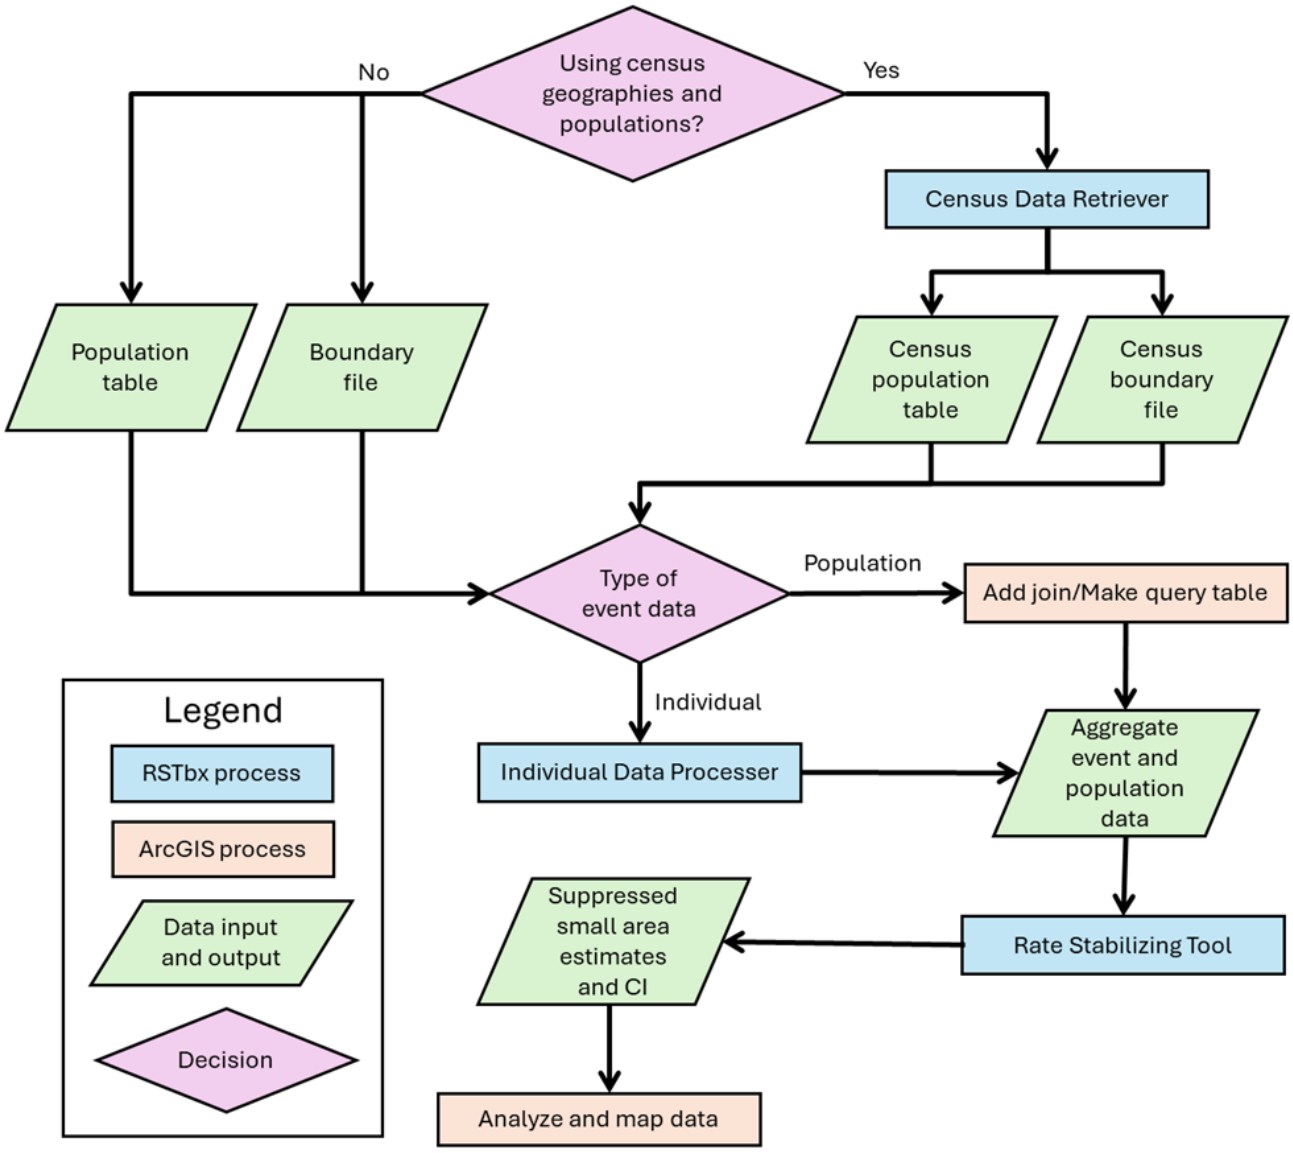
To install RSTbx, users first download the latest release from the GitHub repository as a zip file [16]. After unzipping this file, users should open an ArcGIS Project, navigate to the Catalog Pane, right-click on Toolboxes, click on Add Toolbox, and find the rate_stabilizing_toolbox.pyt file within the unzipped RSTbx folder. After completing these steps, RSTbx is ready to use.

## Input Data Requirements

RSTbx requires a minimum of 3 sets of data: event data, population data, and a boundary file. First, users enter event data for the health outcome of interest. RSTbx is designed to accommodate event data at either the individual or group level. For individual-level event data, RSTbx requires a unique identifier for each geographic unit (eg, GEOID). The age of each individual is also required to calculate age-standardized rates. For group-level event data, RSTbx requires a unique identifier for each geographic unit, the number of events in each geographic unit (ie, the numerator for the health outcome of interest), and the age group. The age group is optional and only required if users want to generate age-standardized rates. If the age group is included, the groups are restricted to: "0-4," "5-14," "15-24," "25-34," "35-44," "45-54," "55-64," "65-74," "75-84," "85up." For both the event and population data, the typical use case is single-year data, but data can be analyzed along any temporal aggregation.

Second, users must provide a table with the population data for each geographic unit or geographic unit–age group combination. Users can either supply their own population-level data or access the CDR within RSTbx to retrieve population data for census geographies. Users with noncensus geographies must provide their own population-level data. Importantly, RSTbx assumes that data for each geographic unit are a census (ie, data represent the entire population).

Finally, users enter a boundary file for the geographic area of interest. RSTbx supports most major file types through ArcGIS Pro, including but not limited to Geodatabase features, GeoPackage features, GeoParquets, and shapefiles. Each geographic unit must have at least 1 neighbor. If users are not using their own geographic boundary files, the CDR can be used to download TIGER or cartographic boundaries from the US Census Bureau.



## Generating Small Area Estimates With RSTbx

Figure 2 outlines the steps involved in using RSTbx to calculate local-level measures of population health. The first steps include determining the geographic unit of analysis and obtaining population data and a boundary file for the chosen geographic unit. If the event data (eg, health data) are at the individual level, they must be aggregated to the geographic unit and joined to the population table with the IDP; population-level event data may be directly joined to the population table. The next step entails choosing the desired threshold for reliability. Finally, if conducting age-standardization, it is necessary to choose the age groups and a standard population year to be used in the age-standardization process. Detailed directions are provided within RSTbx and within the GitHub repository [16].

XSL•FO
RenderX

**Figure 2.** Flowchart for generating small area estimates using the Rate Stabilizing Toolbox (RSTbx).

### Output

After running the models, RSTbx generates samples from the posterior distribution for each geographic unit, from which an output table is created. The table includes spatially smoothed estimates (ie, the posterior medians), lower and upper bounds of the user-defined CIs, and the level of reliability (eg, 95%, 90%, 75%) for each geographic unit. If age-standardization is requested, results will be produced for the age-standardized age range and all composite age groups within the data.

## *RSTr R Package*

### Overview

RSTr is an R package using Rcpp and RcppArmadillo [20-23] that generates small area estimates of health outcomes using CAR models [24]. Users may choose from one of many BYM-based models to generate small area estimates, including the univariate CAR, multivariate CAR (MCAR), and multivariate spatiotemporal CAR (MSTCAR). RSTr's CAR model smooths across space using data from neighboring geographic units [6,13]. The MCAR expands upon the CAR model by smoothing across both geographic units and domains (eg, sociodemographic groups) [11]. The MSTCAR further expands the MCAR model by smoothing across geographic units, domains, and time [12]. Statistical and technical details of these models are available in the package documentation [24].

### Package Setup

RSTr uses the R statistical software [25] and can be installed from the Comprehensive R Archive Network (CRAN) [24].

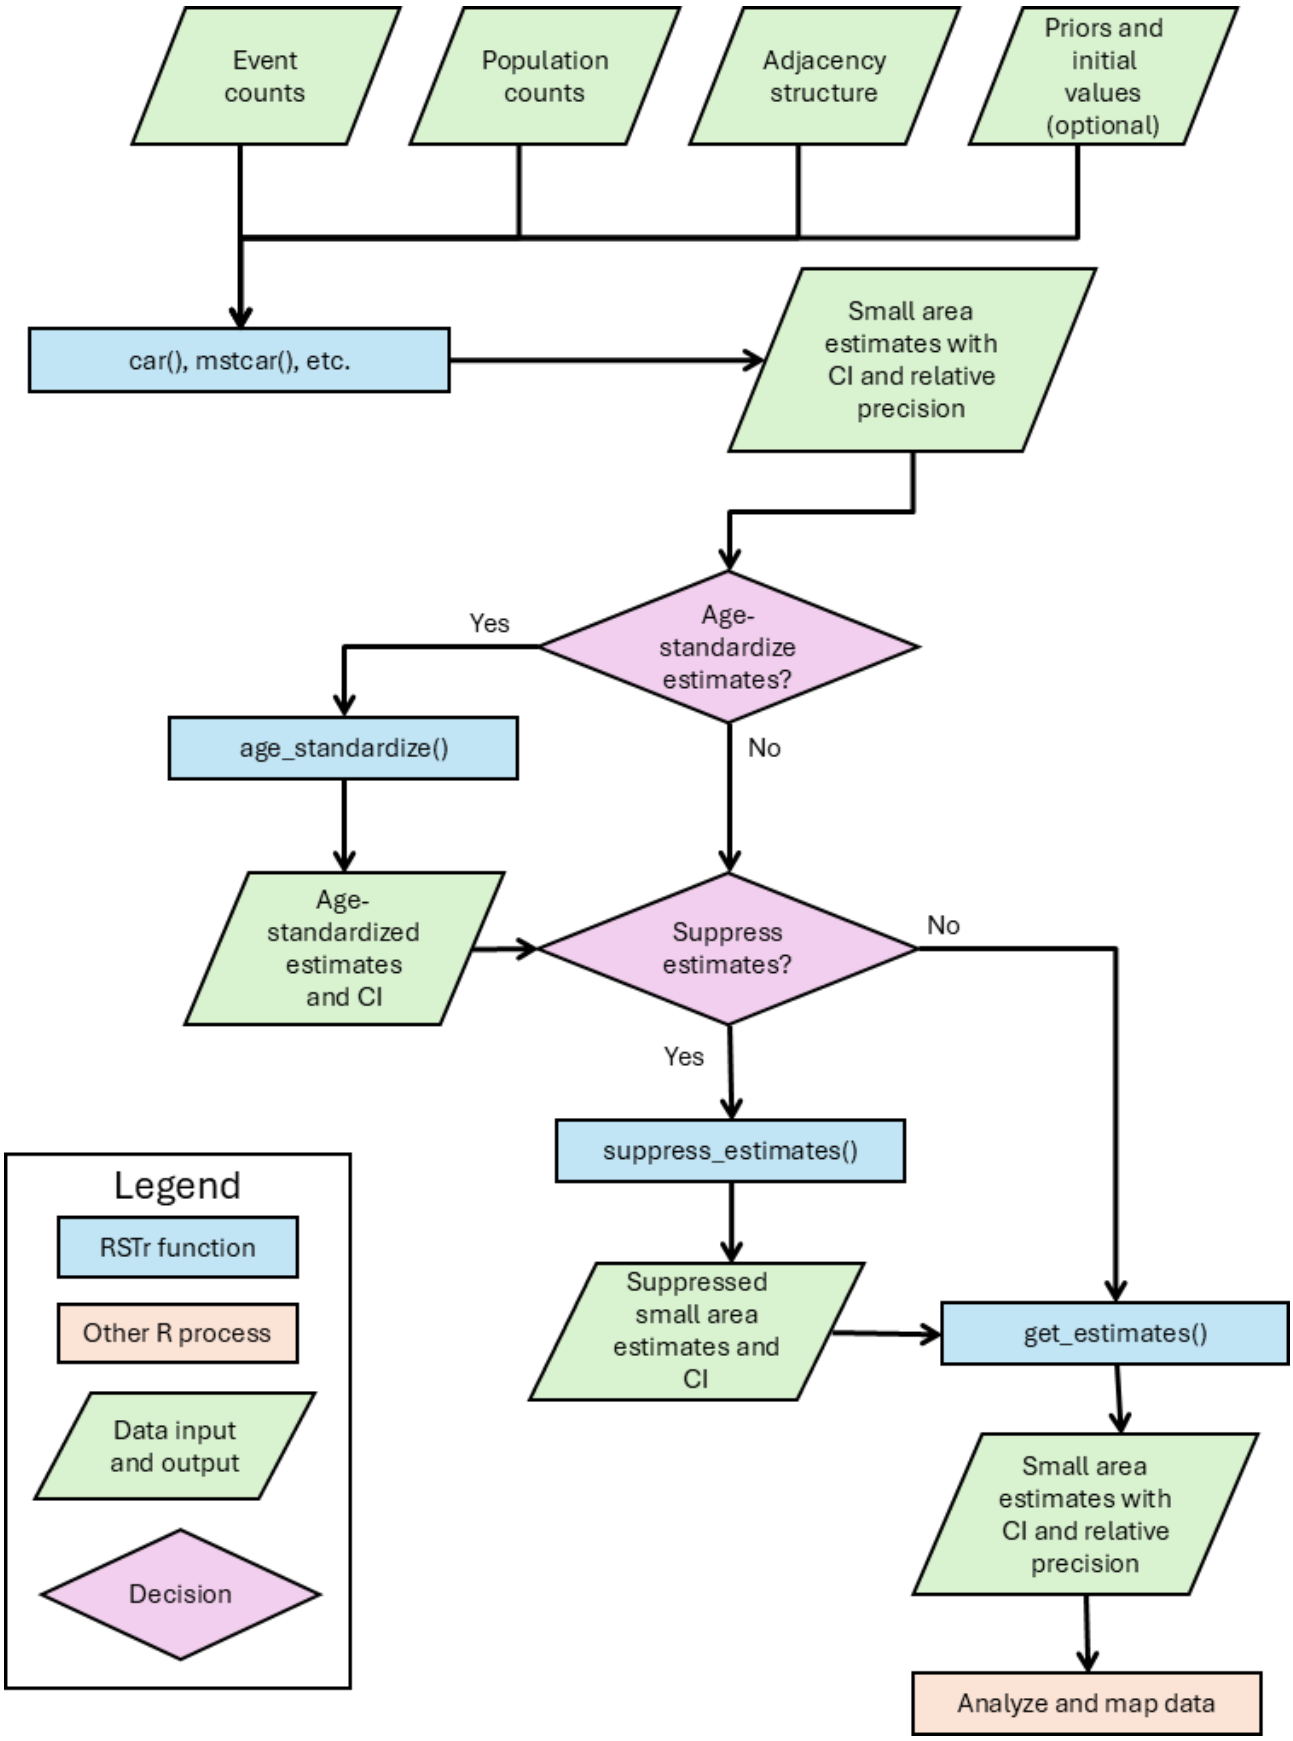
### Input Data Requirements

RSTr requires 3 pieces of input data: event counts, population data, and the adjacency structure of the geographic units. RSTr uses aggregate, rather than individual-level, data. Requirements for the structure of these inputs are described in detail in the package documentation [24]. Briefly, datasets for the event and population data for each geographic unit should be combined into an R list object. Requirements for the data structure differ based on the selected model. For example, the CAR model uses vectors, the MCAR model uses matrices, and the MSTCAR model uses 3-dimensional arrays. Importantly, RSTr assumes

XSL•FO
RenderX

that data for each geographic unit represent a census (ie, data represent the entire population). For both event and population data, the typical use case is single-year data, but data can be analyzed along any temporal aggregation. For the MSTCAR model, any temporal aggregation can be used, but all time periods must be an equal distance apart. Users must supply their own population count data, but can easily acquire data through the use of the tidycensus package for downloading 1-year and 5-year ACS estimates, along with 10-year decennial census data [26]. Finally, RSTr's models will impute data for estimates censored due to privacy reasons. For additional information about the data setup process, refer to the vignette titled "01: Understanding and Preparing Your Event Data."

Adjacency information tells RSTr the neighbors of each geographic unit. Each geographic unit must have at least 1 neighbor. These adjacency data should be formatted in a structure the same as that generated by the poly2nb() function from the spdep package [27,28]. RSTr supports any filetype supported by GDAL through the use of the sf package [29,30], which has drivers for nearly every geospatial format.



## Generating Small Area Estimates With RSTr

Figure 3 provides an outline of how to run models with RSTr. When running the model, users specify, at a minimum, the event data, population data, and adjacency structure. However, users may also specify the distribution of the event data (either Poisson or binomial as appropriate), initial values, priors, and other parameters to tune the model. Historically, birth and death data have been assumed to arise from Poisson processes [31], thus prompting the use of Poisson distributions to model birth [14,15] and death data [32,33]. However, because the Poisson distribution can be used to approximate the binomial distribution—and because a binomial might be more appropriate for other types of data—RSTr defaults to using a binomial distribution.

XSL•FO
RenderX

**Figure 3.** Flowchart for generating small area estimates using the Rate Stabilizing Tool for R (RSTr).

The decision of which model to select depends on the nature of the underlying data. In particular, the UCAR model is appropriate for a single year of data and a single demographic group, while the MCAR model is appropriate for a single year and multiple demographic groups (ie, multiple age groups to generate age-standardized estimates) and the MSTCAR model

XSL•FO
RenderX

is appropriate for data with both multiple years of data and multiple groups.

### Output

Typical of Bayesian models, the RSTr models generate output in the form of samples. These samples are then used to generate small area estimates and CIs. Samples are included as a standalone output; estimates based on those samples, along with their corresponding CIs and relative precisions, are included as part of a larger model object from which these elements can be extracted.

Estimates are defined as the median of these samples and are extracted using the get_estimates() function on the RSTr model object. The output of get_estimates() is by default a long table containing medians (ie, estimates) for each region, group, and time period included in the model. The get_estimates() function also returns the credible interval, event and population counts, and relative precision, defined by Quick et al [13] as the ratio of the posterior median and the width of the user-specified CI, for each estimate. Relative precisions greater than 1 correspond to "reliable" estimates, per the framework of Quick et al [13].

Users may specify thresholds for reliability from 0 to 1 to define the CI used for relative precision calculations. At the default level of 0.95, the CI is defined as the 2.5 and 97.5 percentiles of the samples. This function may be especially beneficial when data are limited and few, if any, estimates would be deemed reliable at the traditional 0.95 level. For example, presenting maps of the estimates that are reliable at the 0.80 level will allow more estimates to be displayed while also acknowledging that a relaxed standard of reliability is being used. This functionality is demonstrated below.

## Benefits of Mapping Small Area Estimates Generated by RSTbx and RSTr

### Overview

There are many benefits to mapping small area estimates of population health generated by the RSTbx and RSTr. In this section, we demonstrate 3 key benefits: (1) decreased number of geographic units with suppressed estimates, (2) flexibility to set a threshold for reliability, and (3) CIs that can be used to identify statistically significant differences between geographic units.

### Datasets Used to Demonstrate the Benefits of RSTbx and RSTr

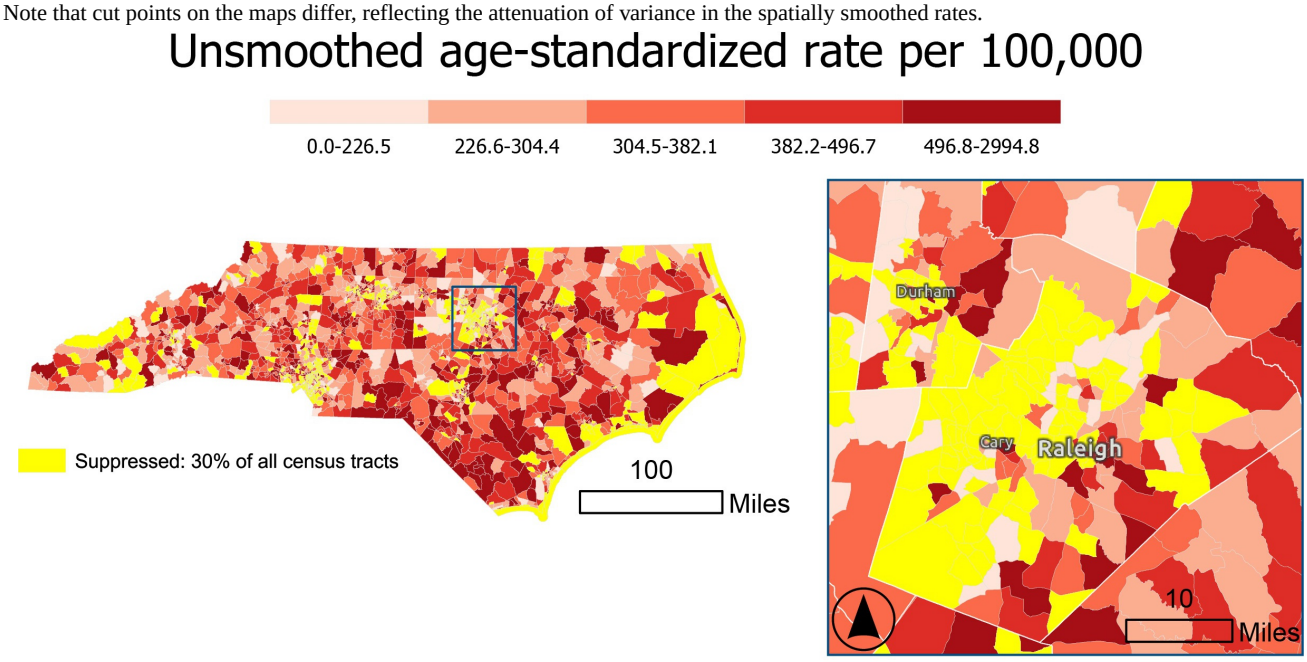
#### *RSTbx: North Carolina Mortality Data*

To demonstrate the benefits of the RSTbx, we used North Carolina mortality data at the census tract level. Specifically, we examined heart disease deaths among adults aged 35 to 64 years in North Carolina census tracts for the years 2017 to 2019. Heart disease deaths were defined as deaths with International Classification of Disease, 10th revision (*ICD-10*) I00–I09, I11, I13, I20–I51 listed as the underlying cause. Results were age-standardized in 10-year age bands to the 2010 US Standard Population. Underlying data were made available through an agreement with the North Carolina Department of Health and Human Services, Division of Public Health.

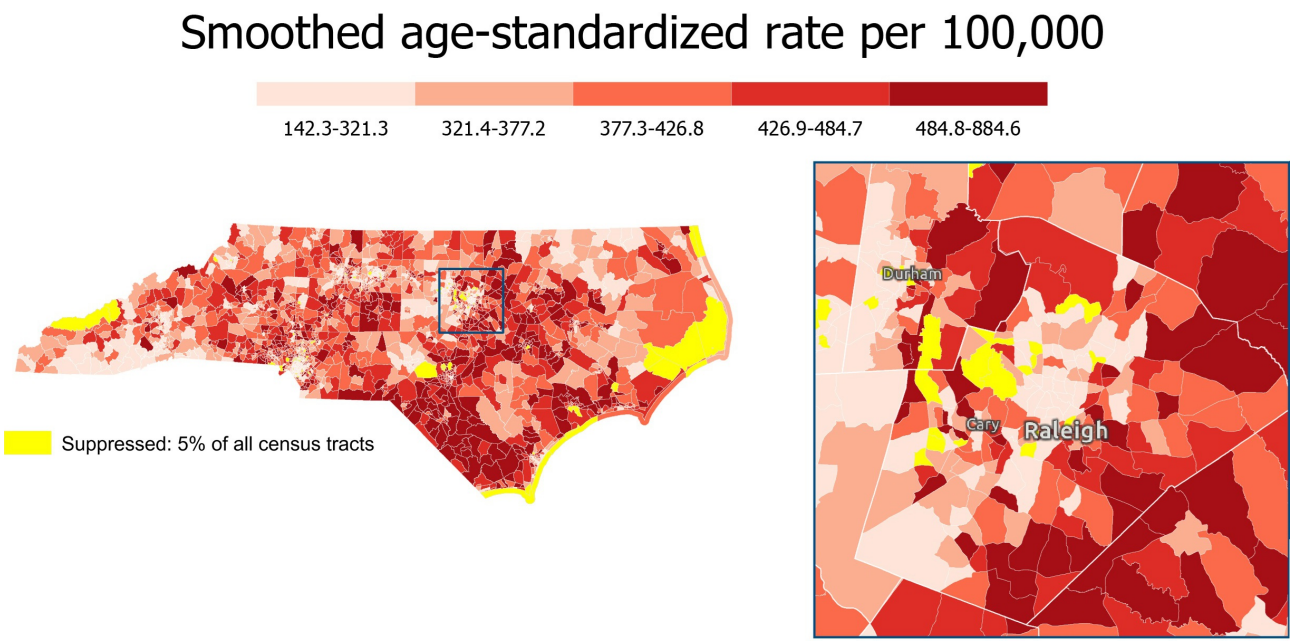
#### *RSTr: Rhode Island Hospitalization Data*

To demonstrate the RSTr, we use Rhode Island hospitalization data from the Rhode Island Department of Health Hospital Discharge Data Program [34]. Specifically, we examine myocardial infarction and stroke-related inpatient hospitalizations in acute care hospitals among adults aged 20 to 69 years for Rhode Island census tracts in 2021 to 2023. Myocardial infarction and stroke hospitalizations were defined as hospitalizations with *ICD-10* I21-22, I60-63, I65-66 as the primary diagnosis. We ran an MSTCAR model for the years 2021 to 2023 by sex and 10-year age group and used the 2000 US Standard Population in 10-year age bands for age-standardization [18]. We then aggregated across sex and age-standardized across age groups. Underlying data were made available through an agreement with the Rhode Island Department of Health Hospital Discharge Data Program and are not publicly available.

### Benefit 1: Decreased Number of Geographic Units With Suppressed Data



#### *Overview*



An important advantage of the underlying Bayesian statistical models in RSTbx and RSTr is their ability to increase the precision of estimates, thereby offering the potential to produce reliable estimates even when the event counts and/or population sizes are small. Compared to crude, unmodeled estimates, RSTbx and RSTr generate reliable estimates for a greater number of geographic units and therefore display fewer suppressed geographic units on maps (Figures 4 and 5). In these figures, estimates are deemed reliable based on their 95% CI. Additionally, the models used by these tools attenuate outliers and therefore narrow the range of estimates after spatial smoothing. This change reflects the improved precision and reliability of estimates that are otherwise sporadically high or low.

XSL•FO
RenderX

**Figure 4.** Rate Stabilizing Toolbox (RSTbx)-generated heart disease death rates by North Carolina census tract, adults aged 35 years and older, 2017 - 2019. The rates displayed in the top map are unsmoothed and suppressed according to United States Cancer Statistics suppression criteria; the rates displayed in the bottom map are spatially smoothed and use suppression criteria based on relative precision using a 95% CI. Comparison of the smoothed and unsmoothed rates shows the decreased percentage of census tracts that have suppressed rates when using RSTbx, demonstrating Benefit 1. Note that cut points on the maps differ, reflecting the attenuation of variance in the spatially smoothed rates.

XSL•FO
RenderX

**Figure 5.** Rate Stabilizing Tool for R (RSTr)-generated myocardial infarction and stroke inpatient hospitalization rates by Rhode Island census tract, adults aged 20 - 69 years, 2021 - 2023. The top map displays unsmoothed hospitalization rates suppressed according to the Rhode Island Department of Health Small Numbers Policy suppression criteria; the bottom map shows spatially smoothed hospitalization rates and use suppression criteria based on relative precision using 95% CIs and an overall census tract population threshold of 100. Comparison of the smoothed and unsmoothed rates shows the decreased percentage of census tracts that have suppressed rates when using RSTr (50% and 7%, respectively), demonstrating Benefit 1. Note that cut points on the maps differ, reflecting the attenuation of variance in the spatially smoothed estimates.

XSL•FO
RenderX

### *Benefit 1: RSTbx Demonstration*

Figure 4 displays age-standardized heart disease death rates for adults aged 35 - 64 years by census tract in North Carolina for the years 2017 - 2019. In the top map of unsmoothed death rates, census tracts with fewer than 16 deaths are suppressed according to United States Cancer Statistics guidelines [35]. Using these guidelines, 30% (n=656) of census tracts were suppressed. The suppressed census tracts were distributed across the state, particularly in coastal regions and urban areas. The bottom map of Figure 4 displays death rates that were spatially smoothed using RSTbx. Here, applying the default threshold for reliability (which is based on the 95% CI) resulted in 5% (n=105) of census tracts being suppressed.

### *Benefit 1: RSTr Demonstration*

Figure 5 displays age-standardized myocardial infarction and stroke inpatient hospitalization rates for adults aged 20 to 69 years by census tract in Rhode Island for the years 2021 to 2023. In the top map, estimates are suppressed according to the Rhode Island Department of Health Small Numbers Reporting Policy [36]; the bottom map is spatially smoothed and suppressed based on precision and population. The Rhode Island Department of Health Small Numbers Policy features data suppression recommendations for a wide variety of data types and data reporting scenarios. In the case of the hospitalization data, several layers of consideration about the data are needed to determine whether or not to suppress rates. In brief, the rates suppressed in the unsmoothed map take into consideration small numerators (number of hospitalizations) paired with large denominators, leading to unreliable or unstable rates. The suppression criteria result in 50% (n=122) of census tracts being suppressed. The suppressed census tracts were primarily located in small Rhode Island towns and villages, especially small coastal towns and villages.

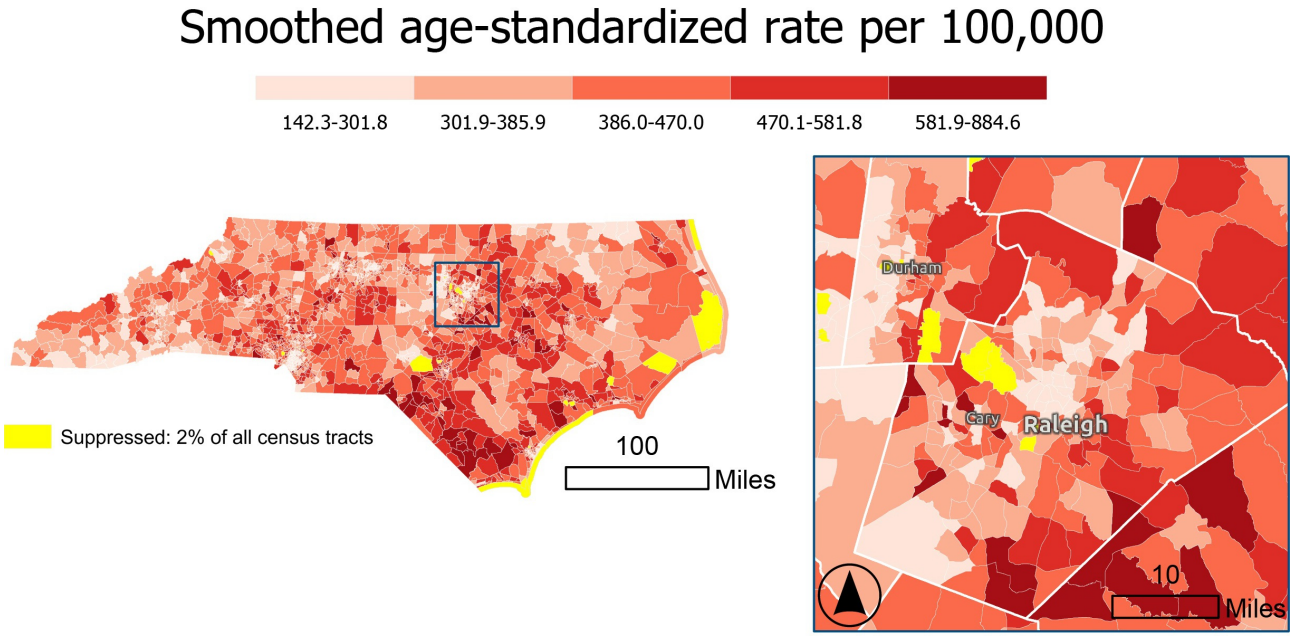
For the spatially smoothed map, relative precision was calculated using a 95% CI and resulted in 7% (n=17) of census tracts being suppressed with an overall census tract population threshold of 100. Additionally, the smoothed map demonstrates an extension of the spatial patterns in the unsmoothed map. The inner census tracts of Providence have more tracts in the higher categories than in the unsmoothed data, and many less dense areas have low hospitalization rates. In this example, the increase in the number of reliable estimates using the smoothed estimates tells a clearer version of the story presented by the unsmoothed data.

## Benefit 2: Flexibility to Set the Threshold for Reliability for Small Area Estimates

### *Overview*

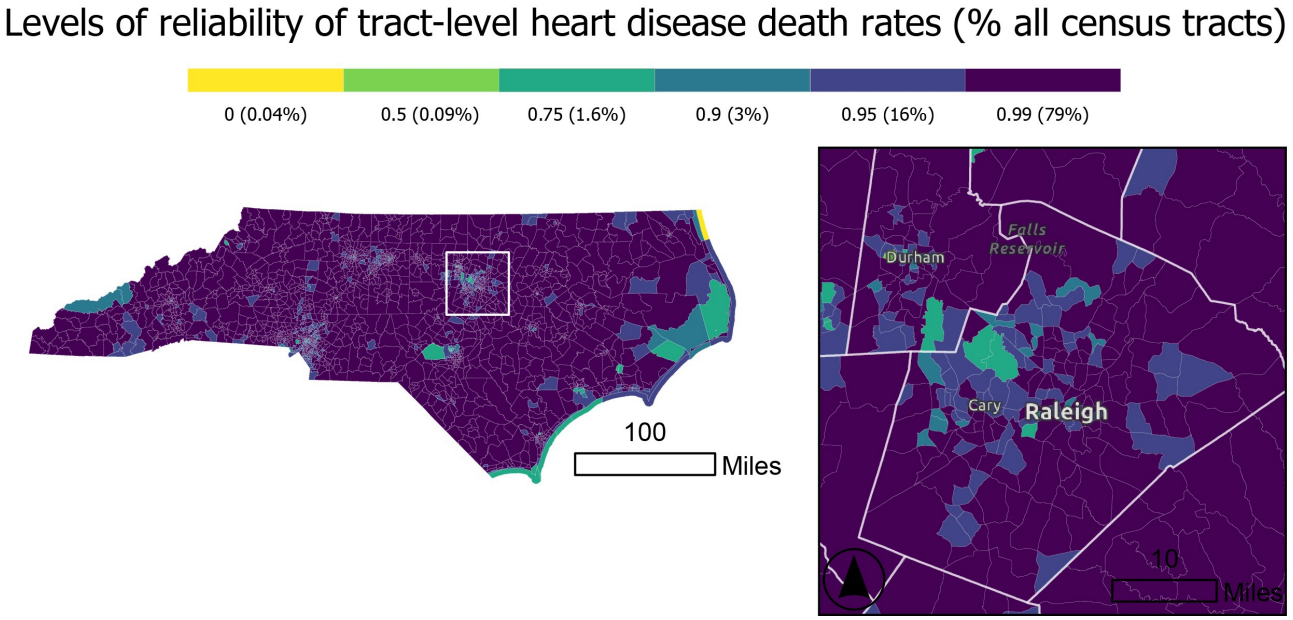
The default threshold for reliability for both RSTbx and RSTr is set at the commonly used 95%. However, RSTbx and RSTr both allow users to relax that threshold to less than 95%. Both tools use the definition in Quick and Song [13] to deem an estimate “reliable” if its relative precision (ie, the ratio of the posterior median and the width of the CI) is greater than 1. RSTbx output includes the maximum CI for which each estimate is deemed reliable, known as its level of reliability. RSTr allows users to relax the threshold for reliability by calculating the relative precision using narrower CIs (eg, 90% or 80%).

This feature allows users to more completely visualize geographic patterns due to less suppression at lower levels of reliability. This advantage, however, comes with a caveat: at some point, with a low enough threshold for reliability (eg, 70%), all geographic units would be considered to have “reliable” estimates. However, estimates with low levels of reliability may be based on very small numbers, leading to potential privacy concerns. Therefore, relaxing the reliability level may need to be accompanied by additional suppression criteria based upon population size.



### *Benefit 2: RSTbx Demonstration*

Figure 6 displays North Carolina heart disease mortality rates for census tracts that meet the threshold for reliability using the 90% CIs. Relaxing the threshold for reliability from 95% in Figure 4 to 90% decreases the percent of census tracts that are suppressed from 5% to 2%.

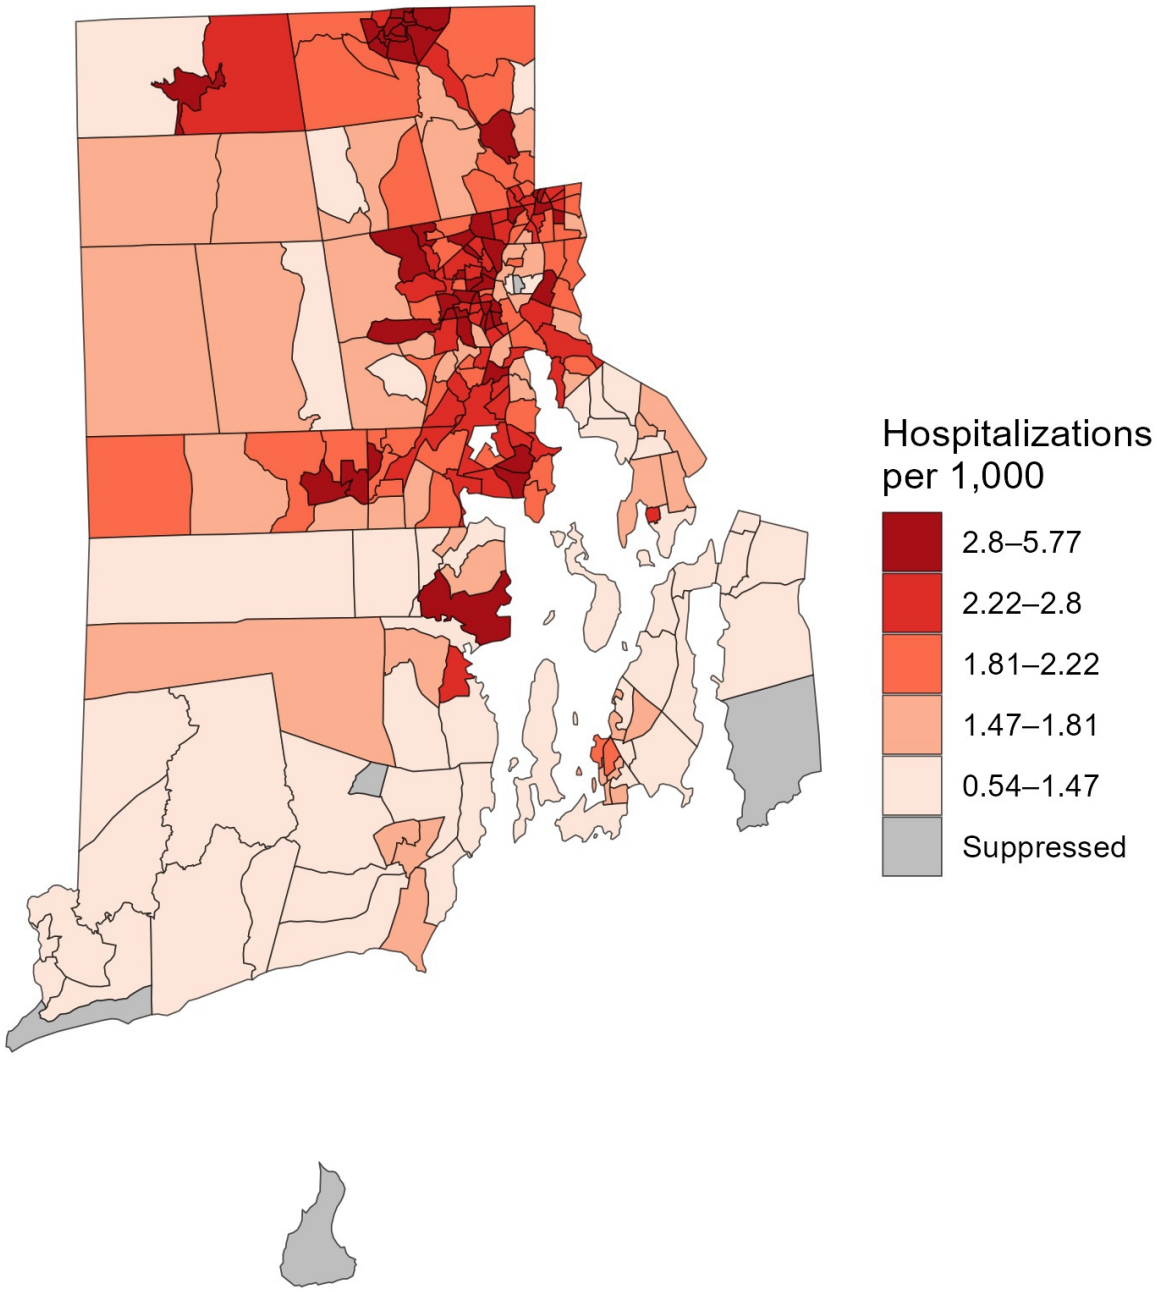


XSL•FO
RenderX

**Figure 6.** Rate Stabilizing Toolbox (RSTbx)-generated heart disease death rates by North Carolina census tract, adults aged 35 years and older, 2017 - 2019. The map displays spatially smoothed rates, and reliability is defined by relative precision using 90% CIs. Comparison of this figure with Figure 4 shows the decrease in the percentage of census tracts with suppressed rates when using a relaxed precision level, demonstrating Benefit 2.

RSTbx also permits users to map geographic units by their level of reliability since those are included in the RSTbx output. Figure 7 displays the level at which the estimate for each census tract is reliable. Estimates for much of the state are reliable at or above 95%. From this map, users can easily see geographic patterns in the reliability of the estimates and the range of reliability across estimates. As demonstrated in Quick and Song, these maps can be viewed as mapping a measure of uncertainty, as they highlight the geographic variation in the amount of information contributed by each geographic unit [15].

**Figure 7.** Levels of reliability of Rate Stabilizing Toolbox (RSTbx)-generated age-standardized heart disease death rates by North Carolina census tract, adults aged 35 years and older, 2017 - 2019. This map shows the maximum credible interval level at which stable and reliable smoothed estimates can be produced, illustrating the spatial variation in the quality of RSTbx-derived estimates and demonstrating Benefit 2. Wider credible intervals reflect greater uncertainty, which tends to occur in tracts with smaller total population estimates and lower case counts.



### *Benefit 2: RSTr Demonstration*

Figure 8 displays Rhode Island myocardial infarction and stroke in-patient hospitalization rates for census tracts that meet the reliability criteria using a 90% CI. Relaxing the CI for the reliability criteria from 95% in Figure 5 to 90% further decreases the percent of census tracts that are suppressed (from 7% to 2%), but includes less precise estimates.

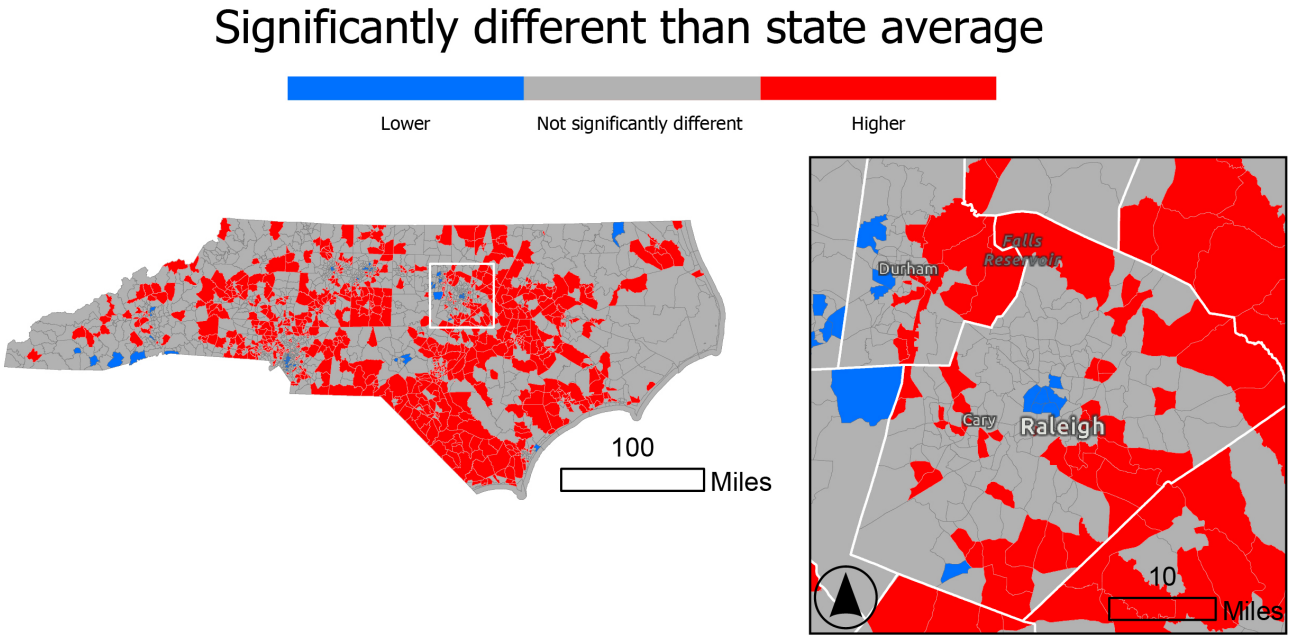
XSL•FO
RenderX

**Figure 8.** Rate Stabilizing Tool for R (RSTr)-generated myocardial infarction and stroke hospitalization rates by Rhode Island census tract, adults aged 20 - 69 years, 2021 - 2023. The map displays spatially smoothed rates. Reliability is defined by relative precision using a 90% CI. Comparison of this figure with Figure 5 shows the decrease in the number of census tracts with suppressed rates using a relaxed precision level, demonstrating Benefit 2. A total of 5 (2%) of census tracts are suppressed.

Geographic patterns in the levels of reliability (ie, the maximum CI whose width is less than the posterior median) will closely align with the population sizes of the geographic units. However, unlike maps of population sizes—where a given population size may be sufficient to produce reliable estimates for a common outcome and be insufficient to produce reliable estimates for a rare outcome—maps of the reliability levels will be standardized across outcomes. That is, estimates from analyses of different outcomes in different datasets with the same level of reliability can be viewed as being equally precise on a relative basis.

## Benefit 3: Using Credible Intervals to Identify Statistically Significant Differences Between Places

### *Overview*



Another benefit of RSTbx and RSTr is the ability to compare estimates for geographic units to another value. This other value may be a single value (eg, a state rate) or another estimate (eg, the census tract with the lowest estimate). This comparison is made by using the CI at a specified level (eg, 95%). Estimates with a CI that excludes a value or that does not overlap with another CI are determined to be statistically different. Importantly, estimates that are unreliable can still be statistically significantly different from a comparison rate. As demonstrated in Figures 9 and 10, this approach can be used to highlight

XSL•FO
RenderX

geographic units (eg, census tracts) that are statistically higher or lower than the state rate.

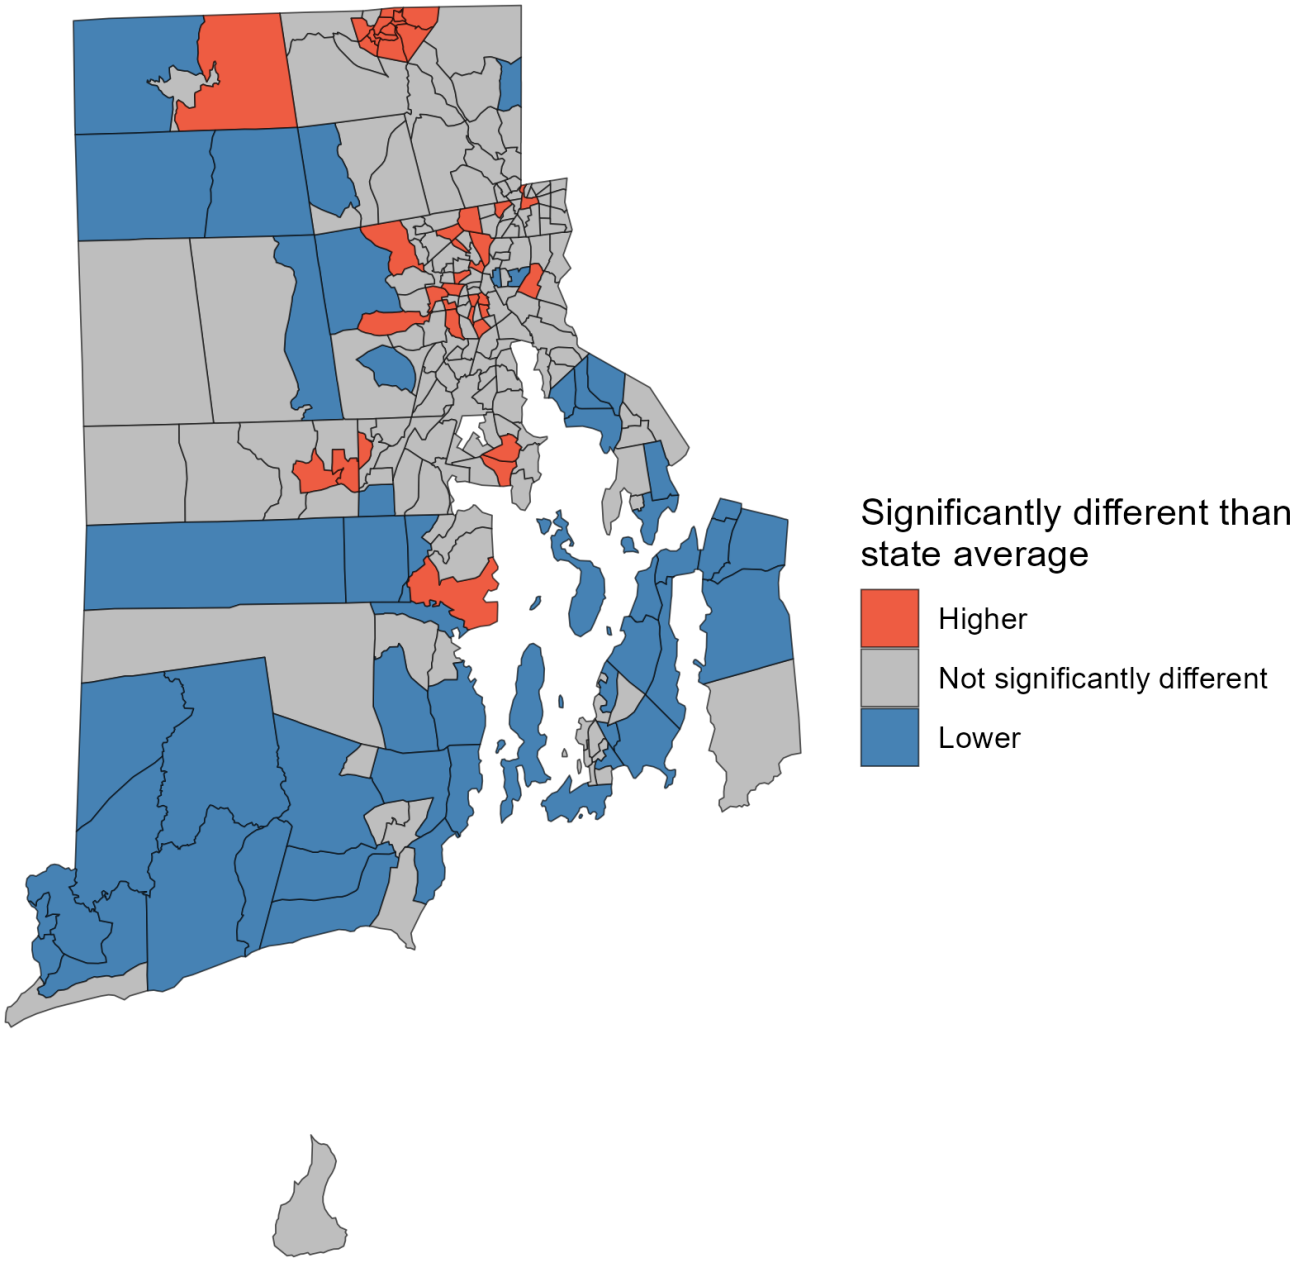


**Figure 9.** Comparison of Rate Stabilizing Toolbox (RSTbx)-generated census tract level heart disease death rates to the state rates, ages ≥35 years, 2017 - 2019, North Carolina. By using 95% CIs that are generated for each census tract, this map shows census tracts with heart disease death rates that are statistically significantly higher or lower than the North Carolina heart disease death rate, demonstrating Benefit 3.

XSL•FO
RenderX

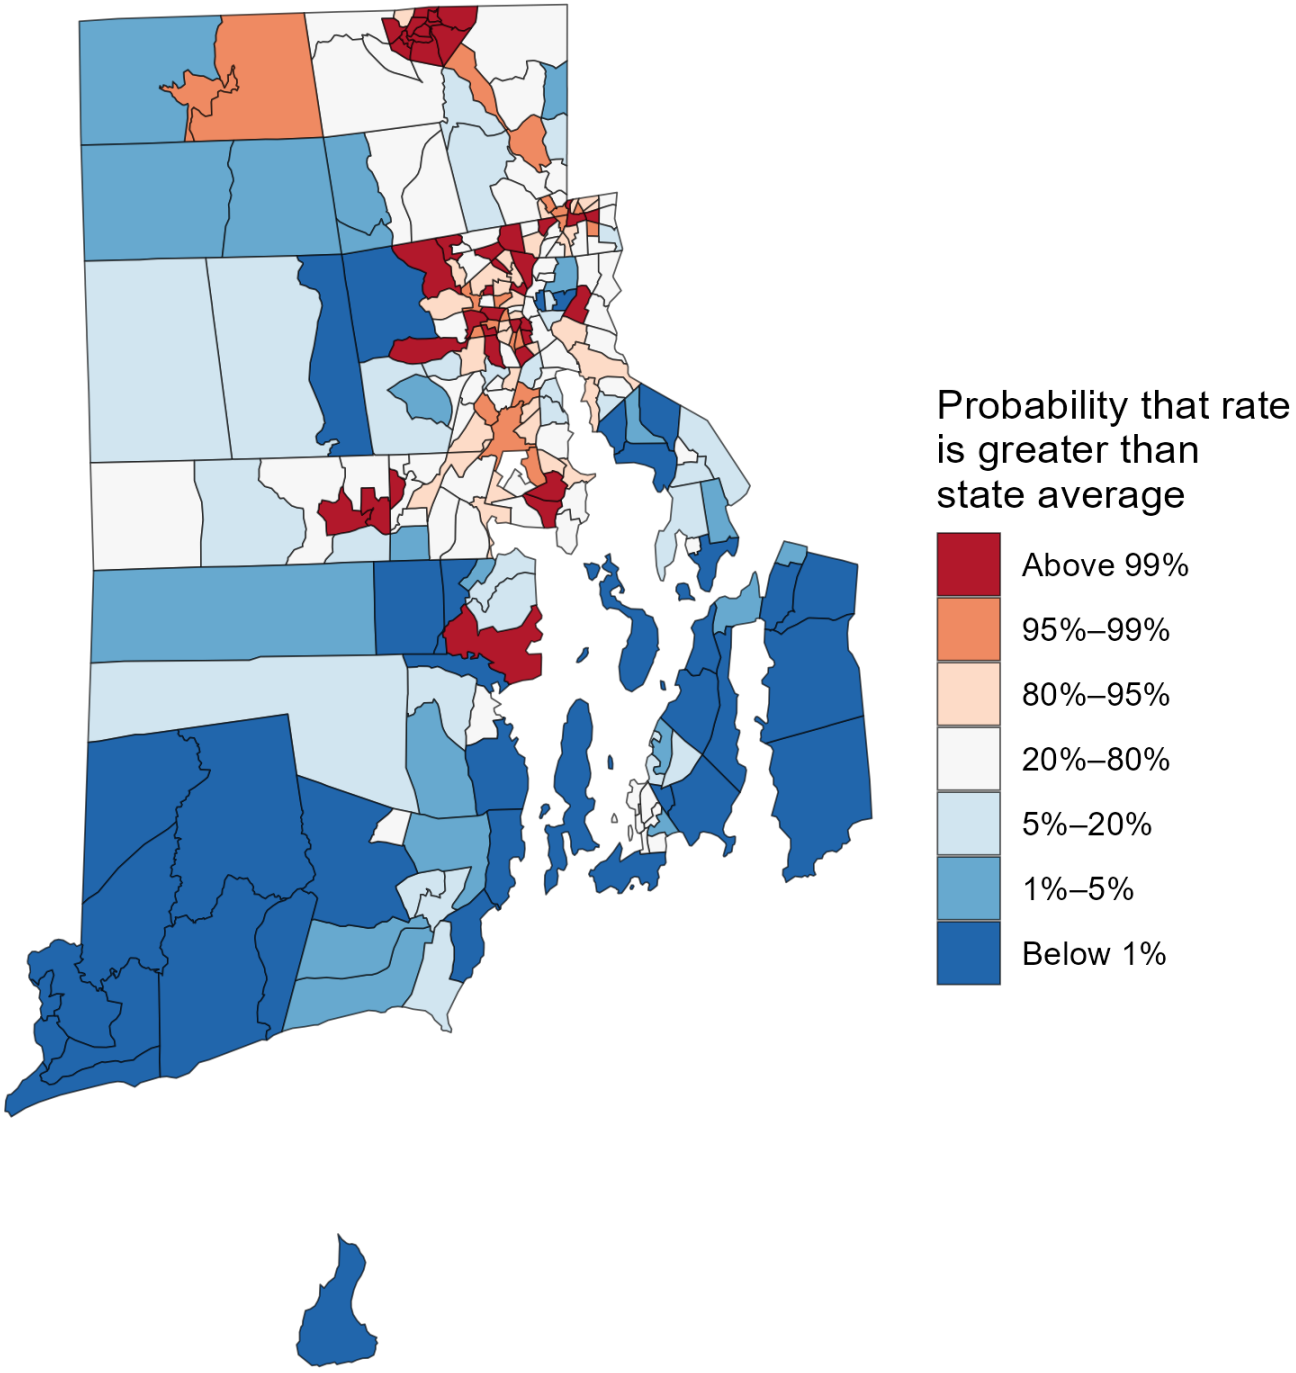
**Figure 10.** Comparison of Rate Stabilizing Tool for R (RSTr)-generated census tract level myocardial infarction and stroke hospitalization rates to the state rates aged 20 - 69 years, 2021 - 2023, Rhode Island. By using 95% CIs, this map shows census tracts with hospitalization rates that are statistically significantly higher or lower than the Rhode Island hospitalization rate, demonstrating Benefit 3.

### *Benefit 3: RSTbx Demonstration*

Figure 9 displays census tracts in North Carolina for which the age-standardized, spatially smoothed heart disease death rates are statistically higher (red) or lower (blue) than the state level. Statistical significance is determined when the 95% CI for the tract level death rates do not include the state level value. Census tracts with rates that are statistically different from the state rate are found across the state. Notably, statistically higher rates are concentrated in the state's urban areas.

### *Benefit 3: RSTr Demonstration*

Figure 10 displays census tracts in Rhode Island for which the age-standardized, spatially smoothed myocardial infarction and stroke in-patient hospitalization rates are statistically higher (red) or lower (blue) than the state rate. Statistical significance is determined when the 95% CI for the tract level death rates do not include the state rate. Census tracts shown in gray have estimates that are not significantly different from the state hospitalization rate.



Additionally, the output from RSTr allows users to calculate the probability that one value is greater than another, frequently referred to as an exceedance probability. In Figure 11, we demonstrate the probability that the tract level hospitalization rates in Rhode Island exceed that of the state level. Unlike the approach in Figure 10, we are not limited to binary differences in probability, revealing a nuanced look at the statistical strength of the estimates. With RSTr's samples, users can calculate the percent of samples for a given region, group, or time that exceed a given value. In this approach, the percent estimate implies its opposite as well: an 80% chance for an estimate to be greater than the state hospitalization rate implies a 20% chance for the estimate to be less than that rate. In Figure 11, most of the

XSL•FO
RenderX

strongest probabilities of an estimate being greater than the rate for Rhode Island are clustered in urban areas, whereas rural areas tend to have the lowest probabilities of being greater than the state's hospitalization rate, indicating that their rates may be significantly lower than the state rate.

**Figure 11.** Probability that Rate Stabilizing Tool for R (RSTr)-generated myocardial infarction and stroke hospitalization rates by census tract are greater than the state value, adults aged 20 - 69 years, 2021 - 2023, Rhode Island. This is an extension of Benefit 3.

## Discussion

### Strengths and Limitations

RSTbx and RSTr have many strengths. First, as we have demonstrated, the outputs of both RSTbx and RSTr can be used to map small area estimates or statistical comparisons, with varying thresholds for reliability. Second, these tools allow users to quickly run complex Bayesian models. Third, users can easily generate age-standardized rates. RSTbx includes integrated standardization to either the 2000 US Standard Population or the 2010 US Standard Population in 10-year age groups. RSTr users may age-standardize to any population and are able to aggregate by domains other than age, such as race, sex, year, or region.

Though software such as JAGS, Stan, and BUGS [37-39] have addressed many of the same issues as RSTr and RSTbx and provide many of the statistical models used by our tools in a more generic framework, our tools come with distinct advantages. First, RSTr features a wider family of CAR models to choose from with more complex specifications available;

XSL•FO
RenderX

Stan and JAGS, for example, provide at best an MCAR model for estimation, and BUGS only provides a BYM CAR model. Additionally, since RSTbx and RSTr are designed specifically to run CAR models, their parameters and initial values are pre-specified based on existing work in the literature. More general software like Stan and BUGS requires a more hands-on approach and can lead to nonideal CAR model specification. Finally, RSTbx and RSTr utilize recent advances in CAR model methodology not seen in other statistical packages. The UCAR model implemented in both tools features enhancements that restrict the strength of the spatial smoothing using models which aim to establish a minimum on the amount of data required to yield a reliable estimate [13,15].

Both RSTbx and RSTr have limitations. First, the input data are assumed to be a census or representative sample of the population being studied. Neither tool is designed to accommodate survey weights or potential disparities in reporting quality (eg, undercounts). Any data quality issues that would cause the crude values (ie, the event counts divided by the population sizes) to be biased would also affect the quality of the estimates. Spatial data in general are prone to many limitations; nuances such as the modifiable areal unit problem, the ecological fallacy, and edge effects should all be considered when interpreting results generated by RSTbx and RSTr. Additionally, RSTbx includes only the UCAR model, meaning that smoothing occurs only over space and not over time or other domains.

Finally, our statistical models have some limitations. In contrast to the UCAR models used in both tools, RSTr's MCAR and MSTCAR models do not feature enhancements to restrict the strength of the spatial smoothing and thus have the potential to yield estimates with relative precisions greater than one when zero events have been observed. As a result, these models may produce estimates that are overly smooth (ie, reduced geographic disparities between adjacent geographic units) and overly precise (ie, inflated levels of reliability). To address this limitation, users can flag estimates generated by RSTr as unreliable when population sizes are not sufficiently large in addition to the use of relative precision. While Quick and Song do not provide guidance regarding requirements for population sizes, others have suggested requiring population sizes be at least 30 or 100 in order to display estimates [12]. Development of restricted MCAR and MSTCAR models is an active area of research, and future updates to RSTr and RSTbx aim to include such models. Additionally, there are future plans to expand RSTbx to use open-source GIS software, such as QGIS. Future versions of RSTbx will also include imputation of censored data and further streamline the data setup process.

## Conclusion

RSTbx and RSTr facilitate the calculation of small area estimates of population health for ArcGIS and R users, respectively. Table 1 summarizes the main features for RSTbx and RSTr. Overall, both tools simplify the implementation of complicated Bayesian spatial and spatiotemporal models. Both tools also take advantage of recent methodological developments for the CAR model and easily age-standardize estimates. Using census tract-level data from North Carolina and Rhode Island, we demonstrated the benefits of using RSTbx and RSTr to generate and map small area estimates, especially when there are small numbers of events or population sizes. We focused on three key benefits of using these tools: (1) decreased number of geographic units with estimates being suppressed based on reliability criteria, (2) flexibility to set the threshold for reliability, and (3) using credible intervals to identify statistically significant differences between geographic units. In summary, RSTbx and RSTr are powerful tools that can be used to meet the demand for high-quality, local-level data to inform public health programs and tailor health promotion activities to the needs of communities across the country.

## Abstract

**Background:** Early detection of health threats is an objective of public health surveillance, and event-based surveillance (EBS) using unstructured information from diverse sources has played an increasingly important role in achieving this objective. However, the evaluation of EBS systems has been hindered by the lack of reference data on outbreak onsets.

**Objective:** We introduce the concept of an "early detection interval" and create a dataset of these intervals across multiple countries for the epidemic caused by the Omicron variant of SARS-CoV-2.

**Methods:** We defined the early detection interval as the time between the date of introduction of an infectious agent to a country and the date at which an increase is detectable in traditional public health surveillance data. To determine the date of the introduction of the Omicron variant, we analyzed phylogenetic studies and genome databases. We estimated the end of the interval by applying Bayesian online change point detection to reported COVID-19 case counts. In addition to the early detection intervals, this dataset also contains variables indicating data quality. To further understand the variation in the lengths of the early detection intervals, stratified analysis and univariate Cox proportional hazards were implemented.

**Results:** This dataset contains early detection intervals for the Omicron variant in 117 countries. The intervals have a median length of 28 (IQR 18-44) days, with a median beginning date of November 27, 2021 (IQR November 17, 2021, to December 12, 2021), and a median ending date of January 2, 2022 (IQR December 19, 2021, to January 9, 2022). Countries with high sequencing availability tend to have earlier start dates with a maximum difference across data sources of only 15 (IQR 7 - 39) days and consequently a prolonged interval length with a median length of 29 (20-47) days. Countries with low incomes were underrepresented in this dataset, with only 12 (29.27%) out of 41 included, and they tended to have shorter intervals with a median duration of 16 (IQR 12 - 23) days. The univariate Cox proportional hazards ratio regression analysis confirmed prolonged interval length in countries with high sequencing availability (hazard ratio 0.59, 95% CI 0.38 - 0.92) and shortened interval length in low-income countries (hazard ratio 2.37, 95% CI 1.29 - 4.36).

**Conclusions:** The dataset of early detection intervals created in this study can serve as reference data and facilitate the evaluation of the timeliness of alerts generated by EBS systems. Systematic and comprehensive evaluation of EBS is important to guide the development of EBS and motivate the integration of EBS into public health practice. Our study also highlights cross-country disparities in data quality, particularly for genomic evidence, and the need for data collection and sharing focused on low-resource settings.

## Introduction

Infectious diseases continue to pose a major threat to global health [1,2]. As a recent example, the COVID-19 pandemic resulted in over 777 million cases and 7 million deaths reported as of May 2025 [3]. Early detection of infectious disease outbreaks is important for initiating timely prevention and mitigation measures to minimize health and social impacts [1,2,4]. To improve the timeliness and sensitivity of outbreak detection, public health agencies conduct surveillance using various information sources, such as online news and social

XSL•FO
RenderX

media (known as event-based surveillance; EBS), as a complement to traditional case- and laboratory-based surveillance data (known as indicator-based surveillance; IBS) [5-7].

Evaluating the performance of EBS is crucial to ensure the objective of early detection is achieved, to understand the value of different surveillance methods, and to identify opportunities for performance improvement, but limited studies have comprehensively assessed EBS performance [4,8-12]. In particular, timeliness is one of the most important attributes for evaluating EBS systems aiming at the early detection of outbreaks [4,6,9,13]. Intrinsic timeliness measures the time from the start of an outbreak to an EBS alert [6,13]. Although the start of an outbreak is usually defined as "the earliest epidemiologically linked symptom onset or death," the intrinsic timeliness of EBS alerts was found in several studies to range from 19 days to 3 months after the first retrospectively identified cases [14,15]. However, retrospective analyses of genomic data have revealed that the transmission of viruses among a population can occur weeks before the index case is retrospectively identified, which may provide a better approximation of the ground truth compared to the index case approach, for evaluating EBS timeliness [6,16-20]. For example, phylogenetic estimation has shown that the earliest transmission of the Omicron variant in South Africa occurred over a month before the reporting of the index case [18,21].

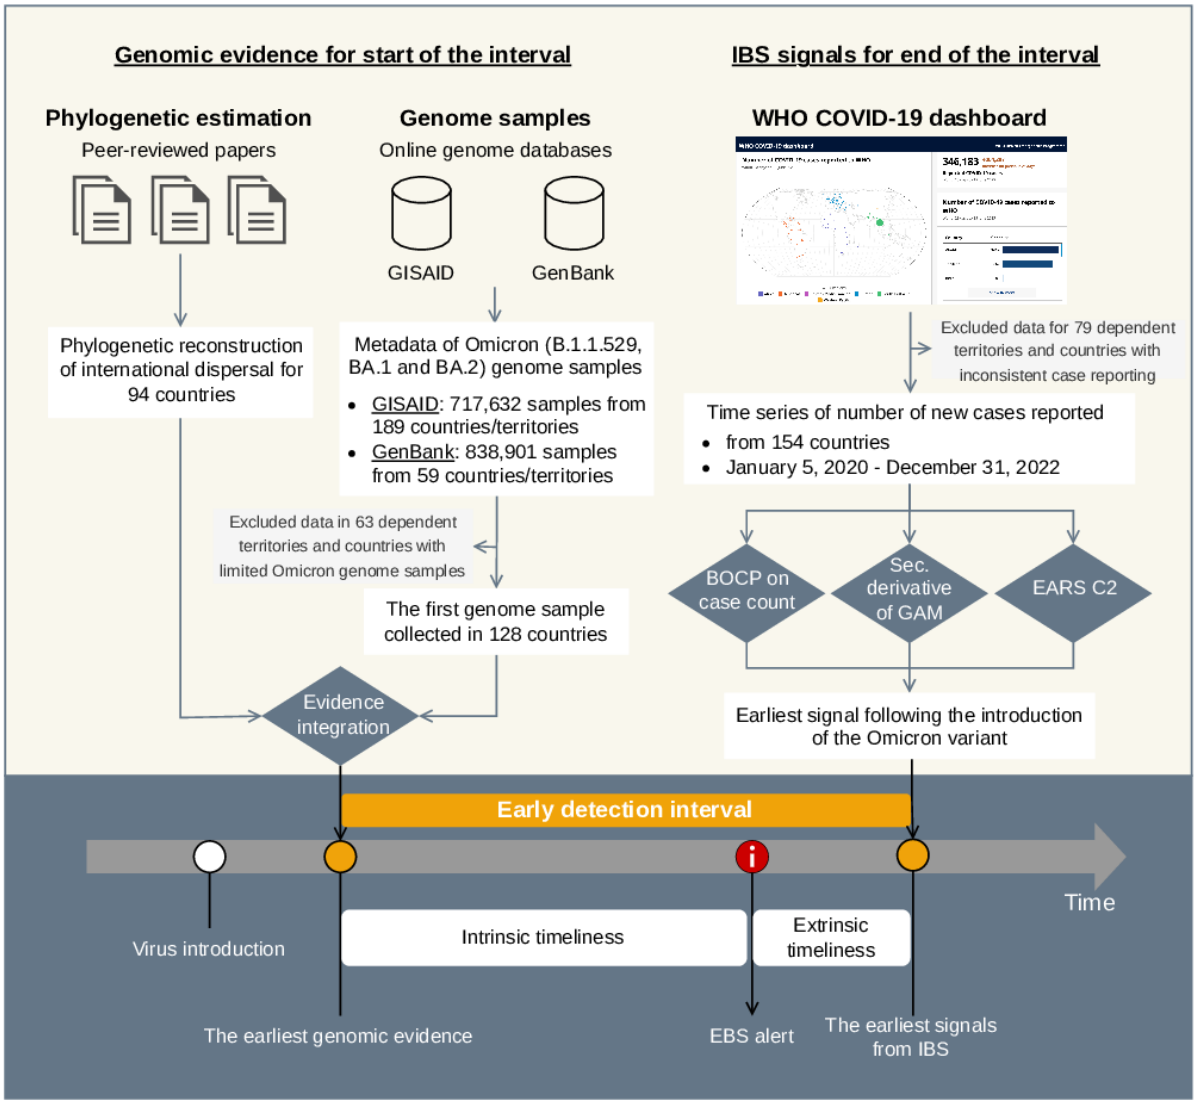
Extrinsic timeliness measures the time interval from EBS alerts to the notification or report of the same event from official sources [6,8,11,12,22-24]. In previous evaluation studies, the timeliness of EBS detection compared to official reporting ranged from −1 (ie, 1 day lagged behind) to 20 days, with results varying by disease, EBS system, and geographic region [8,11,23,24]. Official reports are generally well documented and relatively easy to access but are subject to reporting delays, which may lead to overestimating extrinsic timeliness. Meanwhile, the interpretation of extrinsic timeliness alone can be ambiguous, as alerts occurring much earlier than the official report may not be related to the corresponding outbreak. Additionally, a few studies use a fixed time window to define timely EBS detection. For example, Ganser et al [10] categorized EBS detections as timely if they occurred within a fixed, 4-week time window and found that only 9.2% of seasonal influenza outbreaks were detected in a timely manner by EBS systems. However, such a fixed time is arbitrary, even with some justification based on disease-specific knowledge, and, more importantly, ignores possible different contexts across countries, which may consequently lead to the misclassification of alerts.

In this study, we develop a dataset of intervals based on genomic evidence and IBS data that can serve as a reference framework for evaluating the timeliness of EBS, allowing the assessment of the potential contribution of EBS to early outbreak detection, prior to detection through IBS. We introduce the concept of an early detection interval, which is the time between the earliest evidence of pathogen introduction in a population and the earliest signals from routine analysis of traditional IBS data. Specifically, using the example of the Omicron variant, we build a dataset of early detection intervals that begin with the earliest introduction of the Omicron variant based on genomic evidence and end with the detected increase in reported COVID-19 case counts. We present a descriptive analysis of this dataset to summarize the temporal distribution of the start and end of the early detection intervals and explore the country-level factors associated with the length of the early detection interval using Cox proportional hazards regression models.

## Methods

### Study Design

In this study, we created a dataset of early detection intervals for the earliest subvariants of the Omicron variant of SARS-CoV-2 (ie, BA.1 and BA.2) in countries worldwide from the end of 2021 to the beginning of 2022. The early detection interval was defined as the time from the earliest genetic evidence of the Omicron variant's introduction among the population in a country to the detectable increase in reported COVID-19 incidence cases.



To identify the beginning and end of the early detection interval in different countries, we conducted a retrospective analysis by compiling and linking genomic evidence from published papers and 2 online genome databases and detecting change points from COVID-19 incidence cases reported in different countries, as shown in Figure 1. In addition to the early detection interval, we also created supplementary variables to support users in assessing the data quality and potential biases of the early detection intervals.

We included countries with at least 1 data source for identifying the beginning of the interval and available case data. We excluded dependent territories from our study as our analysis was at the country level. The dependent territories tended to have different transmission patterns and capacities for public health surveillance and reporting compared to their sovereign states, while the available data sources had limited granularity to reflect within-country variation. To ensure the reliability of the interval, we also excluded countries with limited genome surveillance, data accessibility, and unreliable case reporting, as described in the following subsections.

## The Start of the Early Detection Intervals

The early detection interval in a country should begin when a pathogen (ie, the Omicron variant in this study) is first introduced to and begins circulating among the population. Among the multiple subvariants of the Omicron variant, we considered BA.1 and BA.2 only, as they are the earliest subvariants emerging at a similar time. Despite their genetic and epidemiological differences, both BA.1 and BA.2 have high transmissibility contributing to a new wave of COVID-19 cases in different countries. However, this ground truth of virus introduction and the start of transmission among the population is generally not possible to capture exactly, given the limited sample collection and sequencing capacity in most countries. Therefore, our definition of the start of an early detection interval was the earliest date of genomic evidence of the circulation of either the BA.1 or BA.2 Omicron variant in a country.

The primary data source for such genomic evidence is published studies estimating the initial introduction of the Omicron variant in different countries using phylogenetic reconstruction methods (Table S1 in Multimedia Appendix 1) [18,25-30]. One of the main studies we used was conducted by Tegally et al [25], which provides the reconstruction of the international dispersal patterns of variants of concern from Alpha to Omicron inferred from a representative sample of genome sequences using ancestral state reconstruction of discrete spatial locations for each variant of concern. From this study, we obtained global dispersal data, including the origin, destination, and date of international dispersal, estimated by 10 repeated phylogenetic analyses. We identified the earliest introduction of the Omicron variant in a destination country as the median of the 10 earliest international dispersals estimated. There are two countries, Bulgaria and Romania, where the median of the earliest exportation occurred a few days earlier than that of the earliest introduction. In this case, we modified the earliest introduction to the lower quartile

XSL•FO
RenderX

of its estimation to ensure that the introduction occurred before exportation and to avoid confusion.

As many countries are not covered in the published studies identified, we also used the first collection date of Omicron genome samples to define the beginning of the interval. We collected the metadata of genome samples from 2 of the most popular genome databases that host large numbers of genome data on SARS-CoV-2 and have been widely used by researchers worldwide, the Global Initiative on Sharing All Influenza Data (GISAID) and GenBank hosted and maintained by the Federal Ministry of Food and Agriculture in Germany and the National Institutes of Health in the United States, respectively [31-33]. Both databases rely on the voluntary submission of genome data from laboratories worldwide with unknown sampling processes. Consequently, the two databases have different geographic coverage and focus despite a large degree of overlap. We tried to mitigate these biases to some extent by using these databases together so that we could identify the earliest possible collection of Omicron genome samples. Using the filter function of each platform, we selected Omicron genome samples collected after October 1, 2021, and obtained their metadata. Based on the date of sample collection in the metadata, we identified the first Omicron genome sample collected from human or environmental samples (eg, wastewater) in different countries.

For each country, we matched phylogenetic estimates from published studies with the earliest Omicron genome collection dates from GISAID and GenBank and then used the earliest of these as the beginning of early detection intervals. To indicate the quality of the data sources and the reliability of the genome evidence, we documented the number of data sources available for defining the beginning of an interval and computed the minimal and maximum temporal gap of the earliest evidence among these data sources. Meanwhile, for each genome database, countries were marked as having questionable data quality if a limited number of Omicron genome samples (ie, lower than 10% percentile in a database) or all samples were submitted on the same date, which might indicate a lack of sufficient and consistent sequencing and reporting efforts in these countries to provide reliable genome evidence. We excluded countries if they had evidence from only 1 genome database, and their data quality in this genome database was marked as questionable.

### The End of the Early Detection Intervals

The end of the early detection interval was defined as the earliest alert of a potential outbreak captured by traditional IBS. We assumed that alerts from other surveillance systems would add little value to early detection after this date. The number of new cases indexed by time and geolocation is one of the most commonly used indicators for early outbreak detection in IBS, as case counts are a timelier indicator than other metrics, such as the frequency of hospitalizations and deaths. We collected the weekly number of new COVID-19 cases reported from January 5, 2020, to December 31, 2022, from the World Health Organization (WHO) COVID-19 dashboard, which uses the date of reporting (rather than the date of symptom onset) for the WHO definition of a confirmed case of SARS-CoV-2 infection: "(a) a person with a positive Nucleic Acid Amplification Test, regardless of clinical criteria OR epidemiological criteria; (b) a person meeting clinical criteria AND/OR epidemiological criteria with a positive professional-use or self-test SARS-CoV-2 Antigen rapid diagnostic test" [3]. We excluded countries when the first case was reported later than May 31, 2020 (ie, no COVID-19 cases have been reported for nearly 3 months after the announcement of the global pandemic, which is unlikely to reflect transmission dynamics but reporting errors) or when no incident cases were reported in over one-third of the interval, both of which suggest inconsistent or delayed case identification and public health surveillance reporting.

We applied the Bayesian online change point (BOCP) detection model, the second derivative of the generalized additive model (GAM), and the Early Aberration Reporting Systems (EARS) C2 method to the entire time series of the number of new COVID-19 cases reported [34-40]. The change point detection methods have been applied to detect the beginning and end of outbreaks, and both models selected are reported to have good performance in some previous studies [10,35,36,41]. The BOCP algorithm assumed that the differenced case count could be divided into nonoverlapping partitions, and within each partition, it followed a Gaussian distribution. For countries with low case counts reported (ie, a median weekly count lower than 100), a BOCP model assuming a Poisson distribution was used. The differenced case count was used to remove the autocorrelation and stabilize the data. The BOCP analysis was implemented using the R package ocp (version 0.1.1). The change points were selected based on the global maximum of the posterior distribution of all change points. We also detected the change points of the growth rate of the case count using a GAM, assuming a negative binomial distribution with a log link. In the GAM, a single explanatory variable of time in weeks was included and modeled using thin plate splines. We also implemented a simple aberration detection method, that is, the EARS C2 method, as a baseline method for the BOCP and GAM models, using the R package surveillance (version 1.24.1) [38-40]. The EARS C2 method compares the observed case count with the most recent baseline, calculated as the moving average of the case count reported 3 to 5 weeks before the observed case count.

We identified the end of the early detection interval as the earliest change point detected by any of the models that occurred between the 7 days after the introduction of the Omicron variant (ie, the beginning of the interval) and the date of the maximum number of case counts reported within the subsequent 120 days. By doing so, we enforced a minimal interval length of 7 days, which is approximately 2 incubation periods of Omicron. We also recorded (1) the number of change point detection models that agreed on the selected point and (2) the temporal gap from the selected point to the following peak of case counts (Table 1). These measures provide future users with information about the reliability of the estimated interval end.

**Table .** The definitions of variables in the dataset of early detection intervals, including the beginning and end of the early intervals and data quality variables.

| Variable | Working definition |
|---|---|
| Define the interval | |
| Country | Country where the transmission activity of the Omicron variant was taking place. |
| Date when the interval starts | The date when the earliest genomic evidence that indicates the dissemination of the Omicron variant among the population was presented, considering data from phylogenetic estimation and the earliest genome samples collected and submitted to GISAID[a] and GenBank. |
| Date interval end | The date when the earliest increasing change point was detected from the case count time series by the highest number of models during the time between the 7 days after the beginning of the interval and the following peak of incidence case count reported within 120 days. |
| Length of interval | The number of days from the beginning to the end of an early detection interval. |
| Data quality for interval start | |
| Data source for interval start | In a country, the data source, among phylogenetic estimation, GISAID, and GenBank, that provides the earliest genomic evidence. |
| Number of data sources available for identifying the start of interval | In a country, the number of data sources, among the phylogenetic estimation, GISAID, or GenBank, that are available. |
| The minimal temporal gap across different data sources | In a country, if more than 2 data sources are available, the minimum difference in the time when the earliest evidence of transmission of the Omicron variant across data sources. |
| The maximum temporal gap across different data sources | In a country, if more than 2 data sources are available, the maximum difference in the time when the earliest evidence of transmission of the Omicron variant across data sources. |
| Data quality for interval end | |
| Completeness score | In a country, the proportion of weeks with new cases reported in the case count dataset. |
| Number of change point detection models that agree on the selected end point | In a country, the number of the change point detection models, including BOCP[b] on differenced count, second derivative of GAM[c] and EARS[d] C2, detected the selected end point. |
| Temporal gap from the interval end to the following peak of case count | For a country, the number of days from the end of the early detection interval to the following peak of incidence case count reported within 120 days. |

## Statistical Analysis

We computed the median and IQR of the timing of the start and end of the interval and length of the early detection intervals for all included countries and by strata of countries based on the WHO regions and income levels (ie, low-income countries [LICs], lower-middle-income countries, upper-middle-income countries, and high-income countries [HICs]), based on the World Bank's classification of the economies and public availability of genomic sequencing of countries (ie, low, moderate, and high availability based on a previous study) [42]. For levels of sequencing availability, we merged countries with low and moderate availability into 1 group to ensure sufficient observations for stable and reliable estimates. We compared the median of the length of intervals in different strata using the Wilcoxon rank-sum test (for 2-level strata) and the Kruskal-Wallis test (for multilevel strata). We also used univariate Cox proportional hazards regression models to assess factors associated with the hazard of the end of the interval. With the interval length as the outcome, the factors explored included income level (LICs vs non-LICs), sequencing availability, and indicators of data quality for genomic evidence, such as the number of data sources available and the maximum difference in the timing for the earliest genomic evidence across data sources. We verified if the proportional hazards assumption held by testing the correlation of scaled Schoenfeld residuals with time.

### Ethical Considerations

The original data in this study were aggregated and nonidentified, which are publicly accessible from the WHO COVID-19 dashboard [3], GenBank [33], and GISAID [31,32]. Thus, ethical approval and participant consent were not required for this study.

## Results

### Interval Characteristics

In this study, we collected phylogenetic estimates of viral introduction for 94 countries; metadata of 717,632 and 838,901 Omicron variant genome samples collected in 189 and 59 countries and territories from GISAID and GenBank, respectively; and case count data for 233 countries and territories from the WHO COVID-19 dashboard. After applying the inclusion and exclusion criteria, 117 countries were included in our study, with 46 out of 70 (65.71%) HICs and 12 out of 41 (29.27%) LICs included. The early detection intervals began on a median date of November 27, 2021 (IQR November 17, 2021, to December 12, 2021) and ended on a median date of January 2, 2022 (IQR December 19, 2021, to January 9, 2022), with a median length of 28 (IQR 18-44) days (Table 2).

[a]LIC: low-income country.

[b]LMIC: lower-middle-income country.

[c]UMIC: upper-middle-income country.

[d]HIC: high-income country.

When defining the beginning of an interval, 33 out of 117 (28.21%) countries were based on the phylogenetic estimation, whereas 84 out of 117 (71.79%) countries were based on the date of the first collection of the Omicron genome sample, mainly from GISAID. The phylogenetic estimations were, on average, 7 (IQR 4 - 11) days earlier than the first collection in GISAID for 35 countries and 24 (IQR 14 - 39) days earlier than the first collection in GenBank for 20 countries. Among 100 out of 117 (85.47%) countries with more than 1 data source to define the beginning of an interval, the maximum difference across different data sources was a median of 16 (IQR 8 - 41) days, and the minimum value for this difference was a median of 13 (IQR 4 - 32) days. Meanwhile, when defining the end of an interval, the completeness score of the COVID-19 case count data for the included countries had a median of 94.23% (IQR 92.31% - 94.87%). Most countries (101/117, 86.32%) had the end of their interval detected by either the BOCP model or the GAM model, and in only 16 out of 117 (13.68%) countries, the EARS C2 method detected an increase in case counts prior to detection by the BOCP or GAM models. The number of new COVID-19 cases reported peaked after a median of 18 (IQR 14 - 42) days after the end of the interval.

## Factors Associated with the Length of the Early Detection Interval

In a stratified analysis, countries with high sequencing availability had the smallest range in earliest transmission evidence across 3 data sources and a lead of 12 (95% CI 5 - 21) days at the beginning of the interval, compared with countries with moderate or low sequencing availability (Table S2 and Figure S1 in Multimedia Appendices 2 and 3, respectively). Conversely, the intervals began on similar dates across countries with various income levels and ended 7 (95% CI −0.00004 to 21) days earlier in LICs compared to non-LICs, resulting in intervals that were a median of 11 (95% CI 3 - 20) days shorter. However, the case count peaked about 2 weeks after the end of intervals in LICs, which was 14 (95% CI 7 - 21) days shorter than in non-LICs. Meanwhile, in HICs, the case count peaked at a median of 35 (IQR 21 - 54) days after the end of intervals. HICs also had consistent genomic evidence for the introduction of the Omicron variant, with the maximum gap across different sources of 8 (IQR 4 - 26) days, which was 12 (95% CI 5 - 20) days shorter than that of other countries. Across different WHO regions, the earliest signals from case counts occurred first in the African Region on December 19, 2021 (IQR December 10, 2021 to December 27, 2021), which was about 2 weeks before the peak of new COVID-19 cases occurred, while this signal was the latest in the Western Pacific Region, which was 1 month after the same signal in the African Region and 5 weeks before the peak of COVID-19 cases in the Western Pacific Region.

The univariate Cox proportional hazards ratio regression analysis confirmed prolonged interval length in countries with high sequencing availability, with a hazard ratio of 0.59 (95% CI 0.38 - 0.92), and shortened interval length in LICs, with a hazard ratio of 2.37 (95% CI 1.29 - 4.36; Table 3). The other 2 variables, the number of data sources available and the maximum difference across different data sources for defining the beginning of intervals, were significantly associated with prolonged intervals with an estimated hazard ratio below 1, both of which indicated the reliability of the data quality of the beginning of intervals.

| Low to moderate | 27 | Reference | |
| High | 83 | 0.59 (0.38-0.92) | .02 |

[a]LIC: low-income country.

# Discussion

## Principal Findings

In this study, we defined an early detection interval as the time between the date of the earliest genomic evidence of the presence of a pathogen in a country and the date of the first alert from an IBS system, which is conceptually tailored to support evaluating early outbreak alerts with well-defined boundaries. We created a dataset of such intervals for the early detection of the Omicron variant in 117 countries worldwide with a median start date of November 27, 2021 (IQR November 17, 2021, to December 12, 2021) and an end date of January 2, 2022 (IQR December 19, 2021, to January 9, 2022) [43]. We also observed interval lengths ranging from 7 to 66 days across countries, which may reflect the influence of factors such as the capacity for sequencing and data sharing in genomic surveillance, the capacity for case identification and reporting of IBS systems, and the transmission dynamics of the Omicron variant. This dataset can serve as a reference dataset in future evaluation studies to evaluate both intrinsic and extrinsic timeliness of EBS.

The early detection interval begins, in theory, with the initial introduction of the Omicron variant into a population, as only then can the variant cause excess infections and be detected in the population. Yet, the timing of introduction is difficult to measure consistently across countries with existing data, so we approximated this date using the earliest genomic evidence of the presence of the variant, retrospectively identified. Retrospective analysis of genomic data has been widely adopted to understand transmission dynamics and the impact of virus variants, and it can generate evidence uncovering the transmission of specific substrains of viruses such as SARS-CoV-2 among a population, in some cases weeks or even months before other data sources [16-20]. High-quality genomic evidence that closely approximates the introduction of the Omicron variant allows capturing the contribution of early EBS alerts. When used as a reference dataset in evaluation studies, this early detection interval can avoid the underestimation of the intrinsic timeliness of EBS alerts compared to previous studies that have used the first retrospectively identified case to approximate the beginning of an outbreak [14,15].

We found that countries with high sequencing availability and income levels tended to have concordant genomic evidence across data sources (ie, an indicator of the data quality of genomic evidence we compiled) and therefore a relatively earlier start of the intervals than those of other countries. Genomic data may have uneven quality across countries due to differences in sequencing capacities, sampling strategies, and data reporting and sharing, which consequently translate into biases in the measurement of the start of intervals [16,42]. We integrated several data sources to identify the earliest possible genomic evidence for the introduction and transmission of the Omicron variant. We found that integrating multiple sources for genomic evidence may help reduce disparities in early detection, compared to using a single database. For example, the phylogenetic estimations were earlier than the first collection in GISAID in 35 countries, with a median of 7 (IQR 4 - 11) days of lead time. Specifically, South Africa had its retrospectively identified first collection of the Omicron genome sample 28 days before the index case reported [21], yet 11 days after the phylogenetic estimation of the earliest introduction.

The early detection interval ended with the detection of the earliest alerts from IBS data. Using this end of early detection intervals as a reference, we can assess the extrinsic timeliness that highlights the added value of EBS in comparison with the IBS alerts and the potential for accelerated response. Unlike several studies that compared EBS alerts with the first official reporting [6,8,11,44], this measurement also avoids overestimating the contribution of EBS alerts that occurred after the earliest IBS alerts. Using 3 different methods to detect signals from IBS data, we found that the EARS C2 method was likely to generate detections later than BOCP and GAM and missed the gradual and subtle increases, which aligns with findings in previous studies showing EARS methods to be inferior to regression-based methods for aberration detection [45,46]. We also found that the temporal distribution of the end of intervals mainly varied across countries in different geographic regions, aligning with the global dispersal pattern of the Omicron variant [25]. The reported case increase,

XSL•FO
RenderX

however, may lag behind the increase in actual infections due to asymptomatic cases. Such a lag may be more evident in countries that were first impacted by the Omicron variant due to a lack of awareness before official identification [47,48]. A delayed end may cause the overestimation of the interval length and, when combined with a delayed start, shift the early detection interval later in time, both contributing to an overestimation of EBS's extrinsic timeliness.

As for the length of early detection intervals, while it is not a measurement of the timeliness of IBS, the median length of approximately 1 month indicates the potential for improvement in early outbreak detection of a newly emerged variant of SARS-CoV-2. Our findings also demonstrate the substantial variation in the lengths of early detection intervals across countries. Our analysis mainly revealed the association between varying lengths and genomic data quality. Given this variation in data quality, the interval lengths should be interpreted with caution, considering potential biases. For example, shorter interval lengths observed in LICs compared to those in non-LICs in our study may indicate extensive underestimation of the introduction of the Omicron variant due to limited genomic surveillance, rather than a lower value of adopting EBS.

## Limitations

This study is subject to several limitations. First, the countries included in this dataset are not a representative sample. This dataset includes 117 countries, yet is overly represented by HICs, with 46 out of 70 (65.7%) HICs included. Conversely, less than half of the LICs (12/31, 38.7% countries) and countries in the African Region (21/51, 41.2% countries), the Region of the United States (19/54, 35.2% countries), and the Western Pacific Region (12/41, 29.3% countries) were included due to limited data availability. Therefore, although EBS generated timely signals in LIC included in our study, caution is warranted in generalizing our findings to all LICs. There is also a need for additional research to generate the data that would allow this reference dataset to be expanded to a larger and more representative sample of LICs.

Second, as we discussed earlier in this section, our measurements of both the start and end of the intervals are likely to be biased toward later in time, which can further bias the lengths of early detection intervals and the Cox analysis of the interval lengths. To minimize such biases, we designed our inclusion and exclusion criteria and compiled genomic evidence from several data sources. We also included several supporting variables alongside the early detection interval to support potential users in assessing the data quality and corresponding biases. However, the data quality variables may not fully reveal the potential biases, and we could not include additional quality metrics due to the limited metadata available for some sources. For example, the data collection and sampling processes and representativeness of both genomic data from GISAID and GenBank and reported incidence cases are unknown but very likely to be different across countries and be uneven within a country [16,49]. Moreover, although the models selected in our study are reported to have good performance in some previous studies [10,35,36,41], further evaluation using simulation data could help us to understand the performance of these models and identify important factors that could impact the accuracy of the measurement of early detection intervals. Therefore, the timeliness metrics measured using these early detection intervals should be interpreted in the context of each country and carefully considering measured and unmeasured biases.

Third, in terms of generalizability, the concept of the early detection interval can be applied to other infectious diseases for evaluating the timeliness of detection. However, it requires corresponding data of relatively high quality to be available. As the early detection intervals are designed to evaluate the timeliness of EBS, a substantial delay in case identification that is hard to resolve by improving practice within IBS will likely increase the value of EBS for early outbreak detection. Therefore, this early detection interval may also apply to some vector-borne diseases, such as dengue virus disease and Zika virus disease, as well as avian influenza. Early indication of outbreaks of these diseases can be observed from environmental, zoonotic, entomologic, and genomic data, while asymptomatic infections make early detection through IBS challenging. When generalizing this early detection interval to other contexts, the definition and measurement of the interval should be adapted to the study context, which in turn would alter the interpretation of the evaluation results. Conversely, this approach might not work well for diseases such as Ebola because of the small number of cases and the relatively low delay in case identification due to severe and abrupt symptoms.

Finally, while the dataset of early detection intervals can enable the evaluation of the added value of EBS relative to the timeliness of outbreak detection, it would also be informative if timeliness metrics could consider other outbreak milestones, for example, verification of a signal and the initiation of interventions [9,50,51]. In our study, we were unable to include these milestones in our dataset due to limited data available across countries. To allow the extension of evaluation to these milestones, public health agencies should document, store, and publish the data on the verification of EBS and IBS signals and on the initiation of interventions. Routine and systematic capture of these data would provide reference data to expand evaluation to allow a more comprehensive and accurate quantification of the impacts of EBS in accelerating response [9,13,51,52]. It should also be noted that this definition of early detection interval may exclude legitimate early EBS signals (eg, reports of unusual clusters prior to sequencing confirmation), which could underestimate the full potential contribution of EBS. In addition to timeliness, other attributes, such as sensitivity, precision, usefulness, representativeness, and flexibility, are also important for comprehensively evaluating the early outbreak detection capacity of EBS [4,6,9]. For instance, the early detection interval focuses on the temporal adjacency of EBS alerts to the target event yet may not reflect their geographic coverage and representativeness. Further analysis is needed to measure these attributes in parallel using quantitative and qualitative analyses [6,9,11].

## Conclusion

Our study created a dataset of early detection intervals for the Omicron variant in countries worldwide by retrospectively compiling and analyzing data from multiple sources. Using this

XSL•FO
RenderX

dataset of early detection intervals as the reference data enables future evaluation studies to assess both intrinsic and extrinsic timeliness of EBS. Our study also highlights cross-country disparities in data quality, particularly for genomic evidence and the need for data collection and sharing, focusing on low-resource settings. While many EBS systems have been developed and improved over the past few decades, the dearth of systematic and structured evaluation has limited the integration of EBS systems into public health surveillance practice. The early detection interval dataset presented in this study addresses important barriers of the lack of reference data and enables evaluation studies to generate valuable evidence on the added value of EBS compared to traditional IBS and the contribution of EBS systems with different designs. This evidence should guide the development of EBS and motivate acceptance and integration of EBS into public health practice, which is key to achieving the goal of timely outbreak detection and response and building collaborative public health surveillance.

## Acknowledgments

We gratefully acknowledge all data contributors, that is, the authors and their originating laboratories responsible for obtaining the specimens and their submitting laboratories for generating the genetic sequence and metadata and sharing via the Global Initiative on Sharing All Influenza Data Initiative, on which this research is based. The authors confirm that no generative artificial intelligence tools were used in the writing or preparation of this manuscript.

## Funding

This work was supported by Canadian Institutes of Health Research and UK Research and Innovation under project EPI-AI: Automated Understanding and Alerting of Disease Outbreaks from Global News Media (Canadian Institutes of Health Research project code: UAI-169305 and UK Research and Innovation grant number ES/T012277/1). YS is grateful for financial support from the Fonds de recherche du Québec–Santé (FRQS, Doctoral training award 313602). DLB is supported by a Canada Research Chair in Population Health Informatics (950-232679).

## Data Availability

To ensure accessibility and transparency, we have adhered to the Findable, Accessible, Interoperable, and Reusable data principles throughout the creation and curation of the dataset. The data and associated metadata are available via Borealis Dataverse, ensuring that researchers from diverse disciplines can easily access and use the resource [43].

## Abstract

**Background:** The endemic channel is a surveillance method that presents statistical indicators and visual representations of a disease's historical dynamics. Its epidemic curve defines the central tendency of cases and their expected variation, providing 3 levels (ie, "safety," "warning," and "epidemic") to assess the epidemiological status of a region. Parameters include the central tendency used as the epidemiological warning threshold (EWT), the size of the retrospective window, and the handling of previous outbreaks and zero values in data. The absence of clear guidelines for the selection of these parameters may compromise reproducibility and hinder outbreak definitions and responses for endemic diseases such as dengue.

**Objective:** This study aimed to review the parameters of the endemic channel used for the definition and monitoring of dengue outbreaks in Colombia while quantitatively assessing the performance of the method.

**Methods:** We reviewed institutional epidemiological bulletins in Colombia and quantitatively assessed the endemic channel in two main aspects: (1) the impact on the EWT of parameter selection regarding the retrospective data window, previous epidemic years handling, and zero-value handling, using a statistical framework; and (2) the endemic channel's performance based on the windows of opportunity, outbreak detection capacity, and the ratio of warnings that correspond to actual outbreaks.

**Results:** The endemic channel's performance is higher as transmission increases due to more robust data that facilitate a timely detection of outliers, while lower-transmission areas show a sharper rise in cases when outbreaks are missed, indicating limited detection capacity. Reducing the retrospective data window improved metrics across all transmission profiles by 6.34% on average, while extending it decreased performance due to changes in detection capacity. There was no significant difference ($P$ value >.01) in performance when data from epidemic years were included or excluded for municipalities with high or very high transmission levels. Instead of adding an entire unit, shifting the data by 0.001 prevents the estimation of null values for the EWT and thresholds and significantly improves performance across all transmission levels ($P$ value <.01) by 23.07% on average.

**Conclusions:** The endemic channel's performance varies with the outbreak definition and the municipality's transmission level. Encouraging an optimal retrospective window is challenging, as data are computed over the years. Nevertheless, the improved performance with shorter retrospective windows is likely due to reduced overlap in seasonal outbreaks. Shifting data by a limiting-to-zero value, instead of adding a complete unit, improves performance and can be easily integrated into existing surveillance templates. Windows of opportunity should be considered when selecting the parameter combination. Finally, reassessing outbreak definitions and method parameters underpinning surveillance tools is essential to ensure their validity and effectiveness, especially when used to inform early warning systems and public policies.

## Introduction

States and policymakers often use various methods to set dengue epidemic warning thresholds in endemic regions, resulting in different outcomes. One prevalent method is the endemic channel approach, which establishes thresholds based on recent data (often excluding epidemic years) by analyzing variability measures, such as the SD, and central tendency measures, such as the mean to, define an expected upper limit for cases (eg, mean plus 2 SDs) [1]. The endemic channel, introduced in 1999 by Bortman [2], exemplifies a surveillance tool that presents statistical metrics and a visual schematic of a disease's historical dynamics in a specific region. It uses case data to construct an epidemic curve, showing cases over time and establishing the central tendency along with upper and lower limits where cases are expected to fluctuate. This method creates a graph with 3 thresholds, defining "safety," "warning," and "epidemic" zones, which are used to assess the region's epidemiological situation based on current case counts.

The World Health Organization (WHO) reports an 8-fold increase in dengue cases over the last two decades, from approximately 505,000 cases in 2000 to more than 2.4 million in 2010 and 5.2 million in 2019 [3]. More recently, in 2024, the Americas region reported an unprecedented rise in dengue cases, exceeding 13 million notifications [4]. Colombia has been under epidemiological warning due to an increase in cases since the second quarter of 2022, prompting the intensification and strengthening of prevention, comprehensive care, surveillance, and control measures [5]. To support these activities, the endemic channel has been widely adopted in the Americas, including Colombia, the Dominican Republic, and Peru, to assess dengue surveillance and response [6]. The method, along with other outbreak definitions, such as deviation of bar charts and moving averages, has been evaluated by experts from the WHO's Special Program for Research and Training in Tropical Diseases [6]. Their assessment highlights several key advantages of this approach: first, it provides a straightforward workflow for monitoring epidemic thresholds, allowing for the quick detection of outbreaks; second, its standardized outbreak definition promotes more transparent and consistent communication across diverse audiences, making messages easier to understand and compare; third, the endemic channel enables public health authorities to evaluate outbreak severity by examining factors, such as duration and total case numbers, thereby simplifying comparisons across different countries; and ultimately, it serves as a crucial tool for evaluating response effectiveness and informing decisions on whether to intensify or reduce intervention efforts, thereby enhancing outbreak management and control.

It is important to recall that the endemic channels focus on intraannual trends, calculating monthly or seasonal means to create a baseline, which simplifies operations but can lead to significant uncertainty [1]. As a result, the endemic channel can be quite uncertain, with outbreak thresholds being occasionally exceeded. These challenges have led to discussions and efforts to develop evidence-based models for dengue surveillance and outbreak management [6]. Methodologically, the endemic channel encompasses several parameters to be considered in its implementation. First, the central tendency measure used is the epidemiological warning threshold (EWT). Then, the size of the retrospective window (in years) for historical data is considered. Finally, the handling of previous outbreaks and zero values in the data is addressed. Owing to the direct influence of these parameters on algorithmic outcomes, an absence of clear institutional pipelines regarding their selection and underlying assumptions could hinder reproducibility and complicate the interpretation of results. This ambiguity can also foster experience-dependent usage and limit the comparability of sensitivity and specificity analyses across regions (eg, Bowman et al [7] and Schlesinger et al [8]) with differing transmission profiles, such as hypoendemic, endemic, and hyperendemic areas. Analytical pipelines implemented in open-access tools, such as the epiCo R package (R software developed by JDU, JM-T, and JO at Epiverse-TRACE) [9], could provide reproducible endemic channel workflows for other diseases or regions and promote the review of the mathematical assumptions embedded in current surveillance systems.

This paper examined how institutions define dengue outbreaks and evaluate the guidelines used to estimate the endemic channel at both national and departmental levels in Colombia. Specifically, we analyze the endemic channel's outcomes by two main aspects: (1) testing how parameter choices—such as the retrospective data window, handling of previous epidemic years, and zero values affect results; and (2) proposing epidemiological metrics to assess the method's performance based on the resulting windows of opportunity, outbreak detection capability, and epidemiological outcomes following a warning.

## Methods

### Overview

This study was conducted in 2 main stages. First, we performed a documentary analysis to characterize how endemic channels for dengue are constructed and used across Colombia. This involved a review of publicly available epidemiological reports at national and departmental levels. The second stage used previous results to establish an institutional baseline, understood as the set of parameters to use in the endemic channel, to assess experiments on the method using official linelist data.

### Ethical Considerations

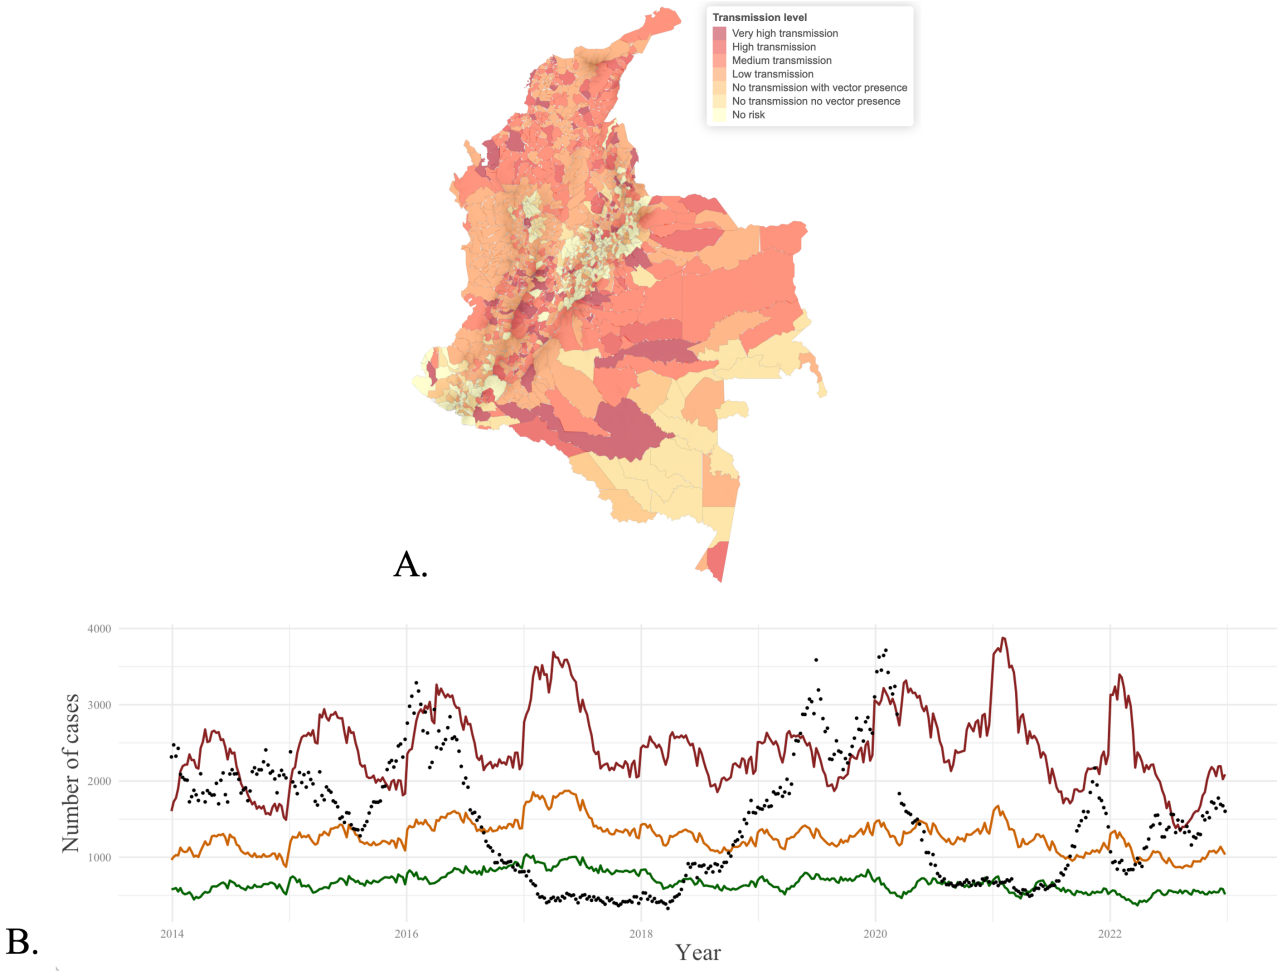
The TRACE-LAC (Tools for Response, Analytics, and Control Enhancing of Epidemics in Latin America and the Caribbean) research project has a no risk classification according to the Ethics Committee of Universidad de los Andes, expresser in the Acta 1632 of 2022 and based on the Colombian resolutions 008430 of 1993 and 2378 of 2008. This work does not involve the manipulation of sensitive data or interaction with vulnerable communities or individuals, nor the performance of any experiment on subjects.

### Exploration of Institutional Reports and Outbreak Definitions

We first developed an analytical baseline to characterize how Colombia constructed and used endemic channels. To support

XSL•FO
RenderX

this analysis, we retrieved the annual dengue reports from 2008 to 2022 from the National Institute of Health (Instituto Nacional de Salud [INS]) [10] and Health Secretariats' websites, covering both the national and department (administrative division one) levels. From these reports, we aimed to identify the type of data and parameters used in constructing endemic channels and assess the consistency and availability of these information methods for constructing endemic channels nationwide. The compiled reports allowed us to establish parameters, such as the method, the retrospective window, zero-value handling, and the previous outbreak handling, which were subsequently used as a reference for the experiments applied to the data described below.



While analyses were outlined for Colombian municipalities with dengue transmission, we replicated the following protocol at departmental resolution to explore how endemic channel outcomes vary when aggregating data from settings with heterogeneous transmission levels. The stratification of transmission at the departmental level was assigned as the level to which most inhabitants within each department are exposed.

## Data Description

### *Epidemiological Data*

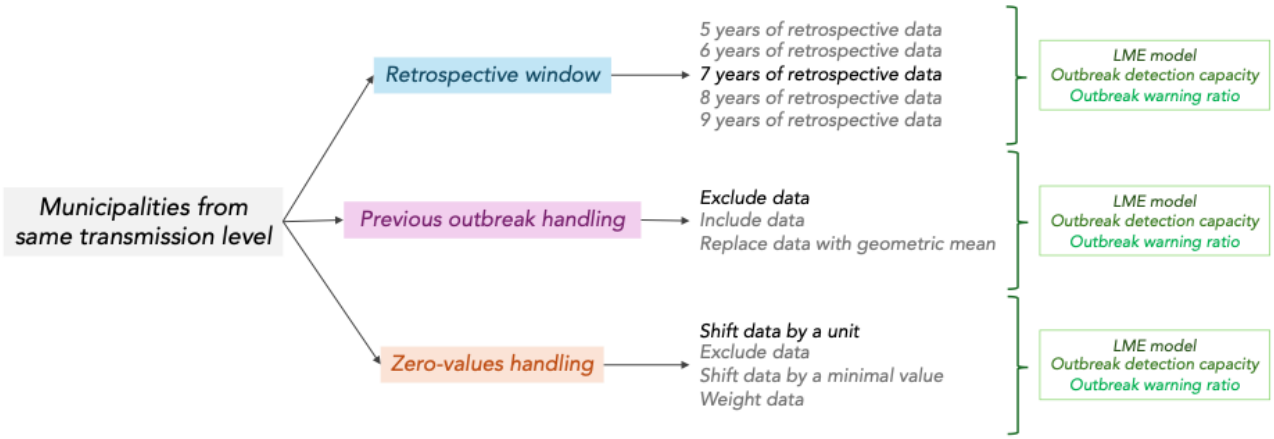
Dengue linelist data between 2007 and 2022 in Colombia were downloaded from the National Surveillance System (SIVIGILA) website using the *sivirep* R package [11]. The dataset comprises anonymized individual case notifications, which were cleaned and harmonized by location codes. Cases were aggregated solely by municipalities or departments of occurrence and grouped by epidemiological weeks according to the symptom onset. Municipalities in Colombia are typically classified into 7 transmission levels by the Ministry of Health and the National Institute of Health [12]; the spatial distribution of the transmission levels and the national weekly incidence are shown in Figure 1A and B, respectively.

**Figure 1.** Epidemiological overview of dengue notification in Colombia. (**A**) Spatial distribution of dengue transmission levels for 2023, (**B**) Continuous endemic channels (from 2014 to 2022) at the national level. Black dots report weekly incidence; green, yellow, and red lines account for "safety," "warning," and "epidemic" levels, respectively.

### *Estimation of the Endemic Channels*

The endemic channels were estimated using the *epiCo* R package [9], which provides statistical analyses and visualizations of vector-borne disease outbreaks in Colombia. *epiCo* is a product of the TRACE-LAC Initiative and implements functions to estimate the expected number of cases as the EWT and the associated CIs used as safety and outbreak thresholds, as proposed by Bortman and explained in detail in Multimedia Appendix 1. We used the case data to calculate the endemic channel in the municipalities of Colombia. Figure 1B

XSL•FO
RenderX



shows the endemic channels from 2014 to 2022 in a continuous graph.

## Endemic Channel Assessment Protocol

### *Overview*

We quantitatively assessed the impact of the endemic channel parameters, focusing on 2 key aspects: their effect on the EWT and their effect on the endemic channel's performance. Figure 2 outlines the implemented protocol. We tested parameter configurations using municipalities grouped by similar transmission levels. Three parameters of the endemic channel method were systematically assessed: the retrospective window, the handling of previous outbreaks, and the handling of zero values. The process was conducted separately for the sake of interpretation, assuming that it is not possible for a region to exhibit exceptional outbreaks and systematic zero cases within its historical records.

**Figure 2.** The quantitative assessment of the endemic channel parameters for dengue surveillance consisted of 3 experiments using the endemic channels of Colombian municipalities with the same transmission level, from 2014 to 2022. The changes in the epidemiological warning threshold of each experiment were evaluated with a linear mixed-effects (LME) model. The outbreak detection capacity and the warning ratio metric assess the effectiveness of the outbreak warning; both metrics contribute to the overall performance evaluation of the endemic channels. In each experiment, parameters shown in bold text represent the resulting baselines used for comparison.

The retrospective window, defined as the number of years of historical data used for threshold estimation, was tested, ranging from 5 to 9 years. To handle previous outbreaks within the retrospective window, three strategies were considered: (1) excluding outbreak periods, (2) including them as-is, or (3) replacing them with the geometric mean of the remaining dataset. To evaluate the effect of zero-value handling strategies, we (1) shifted the number of cases by a unit to avoid zero values as stated by Bortman [1], prior to the EWT calculation, to later be subtracted; (2) excluded data with zero values from the computation; (3) shifted data by a minimal value (0.001 for the purpose of this study) prior to EWT calculation to later be subtracted, as an alternative approach to Bortman; and (4) weighted the estimations by the fraction of zero values present in the data; these last 2 approaches are inspired by de la Cruz and Kreft's [13] and Habib's [14] approaches to estimating the geometric mean of a dataset with zeros. Each parameter combination was then evaluated using a linear mixed-effects (LME) model and a composite performance metric for outbreak detection capacity and warning ratio.

### *LME Model on the EWT*

The following analysis evaluates whether the experiments shown in Figure 2 produce a significant increase or decrease in the EWT. The epidemiological interpretation of the assessment is that changes in the EWT ultimately define the "warning" threshold level, which greatly influences the triggering of the method and subsequent performance evaluations. To ensure a valid evaluation, the analysis recognizes that observations within the same municipality are not independent but influenced by underlying trends over time.

Therefore, we applied an LME model with the EWT as the response variable and each experiment depicted in Figure 2 as a fixed effect. We also incorporated a random effect structure to control for within-group correlations in the observations of the same municipality and date (Equations 3 to 5).

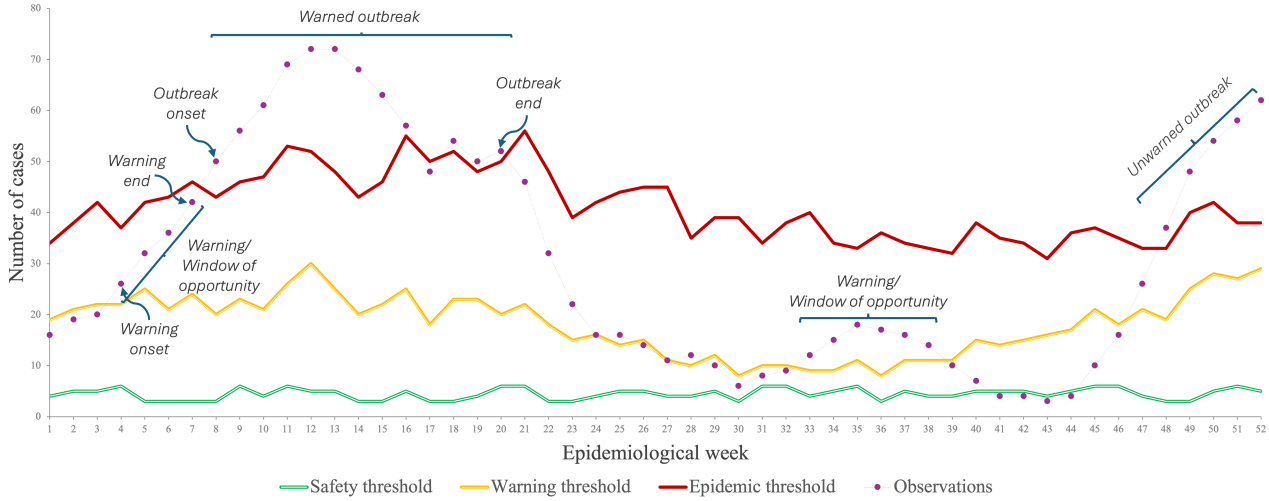
Equation 1EWTij=β0+β1Experimenti+uj(i)+ ij

Equation 2uj(i)~N(0,σu2)

Equation 3 ij~N(0,σ2)

where $u_{j(i)}$ is the random intercept for the group $j(i)$, that is, municipality $j$ with observation at time $i$, $\sigma_u^2$ represents the variance of this intercept, and $t$ describe the variability across the municipalities The model coefficients' analysis focused on whether the EWT was significantly impacted ($P$ value <.01) by each experiment, captured by $\beta_1$, and the percentage of change that this coefficient induces.

### *Epidemic Features and the Endemic Channel Performance*



We developed an algorithm that calculates several epidemic features, such as the outbreak's onset (the first of 3 or more consecutive weeks when cases are above the upper limit after being at least 2 weeks below it), the total number of warnings (the first of 2 or more consecutive weeks when cases are between the EWT and the upper limit), the number of warnings that resulted in an outbreak, the number of outbreaks that occurred without triggering a warning, and the windows of

XSL•FO
RenderX

opportunity. A more detailed definition of these features can be found in Table S1 in Multimedia Appendix 1 and is exemplified in Figure 3.

**Figure 3.** Graphical representation of the epidemic features based on the Joint External Communication [15] from the Ministry of Health and the National Institute of Health. Two warnings at weeks 4 and 33 are shown: the first one resulted in an outbreak with a window of opportunity of 4 weeks, while during the second warning, the increase in cases was controlled in a window of 6 weeks. Cases from weeks 18, 19, and 20 were not classified as a new outbreak because the previous warning did not last 2 or more weeks. Similarly, there was no triggered warning at weeks 25, 28, and 47 because cases were over the epidemiological warning threshold for only 1 week, the last scenario leading to an unwarned outbreak.

On the basis of these epidemic features, we propose 3 metrics to assess the endemic channel methodology: the outbreak detection capacity, the outbreak warning ratio, and the endemic channel performance. Metrics are described in equations 6, 7, and 8. To weigh the impact of outbreak detection capacity and the outbreak warning ratio equally, the parameter is set to 0.5.

$$\text{Outbreak detection capacity} = \frac{\text{Number of warned outbreaks}}{\text{Total number of outbreaks}} \quad (4)$$

$$\text{Outbreak warning ratio} = \frac{\text{Number of warned outbreaks}}{\text{Number of triggered warnings}} \quad (5)$$

$$\text{Endemic channel performance} = \alpha \cdot \text{Outbreak detection capacity} + (1-\alpha) \cdot \text{Outbreak warning ratio} \quad (6)$$

Although we did not assess the endemic channel as a forecasting tool, we aimed to gain insight into the window of opportunity that the method offers in the studied context. The window, then, was defined for all experiments as the delay in weeks between a warning onset (first of 2 or more consecutive weeks when cases are between the EWT and the upper limit) and an outbreak onset (first of 3 or more successive weeks when cases are above the upper limit after being at least 2 weeks below it). Significance in epidemic features was assessed with a mixed-effects ANOVA for a $P$ value <.01.

## Results

### Overview

Our exploration of institutional reports and outbreak definitions did not show a standardized set of parameters; however, the review of national surveillance guidelines and Bortman's original reference informed the selection of the following baseline parameters for evaluating endemic channel outcomes: (1) method: geometric mean; (2) zero-value handling: addition of one unit to the data; (3) outlier year: 2019; (4) outlier handling: exclusion; and (5) retrospective window: 7 years. Table S2 in Multimedia Appendix 1 displays the findings on the method used to estimate the endemic channel for each year, the number of years to consider a retrospective window, and the handling of epidemic years. None of the reports displayed the numerical values of the EWT or the epidemic thresholds.

The same previous baseline was used in the assessment at the departmental level due to the limited number of epidemiological bulletins at this administrative level that reported the used methodology and the heterogeneity in the selection of its parameters when documented. For example, in 2022, from the 28 departments with dengue transmission, only 12 displayed an endemic channel graph, 8 of these documented the used central tendency measure (12.5% used the mean, 12.5% used the geometric mean, 37.5% used the median, and 37.5% reported using more than one method during the year); and, in the same year, the window size was reported only in 16.7% of the departments, varying between 5 and 9 years of data. Tables S3 and S4 in Multimedia Appendix 1 contain the resulting classification of dengue transmission at the departmental level and the corresponding parameters, respectively.

The following subsections detail the results by parameter and by transmission level and describe the behaviors of the windows of opportunity and spatial aggregation when analyzed at the departmental level. As noted in the methodology, only one parameter was varied at a time relative to the baseline, and therefore, parameter combinations were not assessed. Consequently, it cannot be determined whether combining the best-performing settings for each parameter would yield superior overall results.

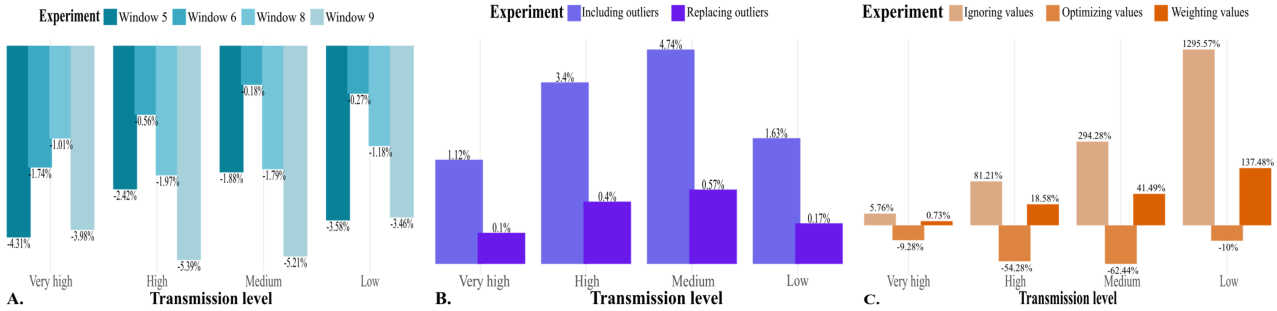
### Assessment of the Retrospective Window

On the basis of the 7-year retrospective data window, the EWT decreased relative to the baseline in all cases. The reduction was particularly pronounced when the extremes of the data window were assessed—specifically, 5 and 9 years of

XSL•FO
RenderX

retrospective data—as illustrated in Table S5 in Multimedia Appendix 1 and Figure 4A. The only exception was the 6-year retrospective data window for municipalities with low and medium transmission levels, which did not significantly change the EWT. Figure 5A depicts the influence of retrospective window size on the performance of the endemic channel. Across all transmission levels, performance declined as the retrospective window increased, primarily due to a reduction in outbreak detection capacity. Notably, municipalities with higher transmission levels demonstrated better endemic channel performance overall. Furthermore, municipalities with low and medium dengue transmission were the most substantially affected by variations in the retrospective data window, highlighting the sensitivity of these settings to the parameters studied.

**Figure 4.** Endemic channel's parameters effect on the epidemiological warning threshold: a linear mixed-effects model analysis. (**A**) Retrospective data windows experiment, (**B**) previous outbreaks handling experiment, (**C**) zero-value handling experiment. Percentages displayed as the logarithm of the value. Detailed data can be accessed in Tables S5, S7, and S9 in Multimedia Appendix 1.



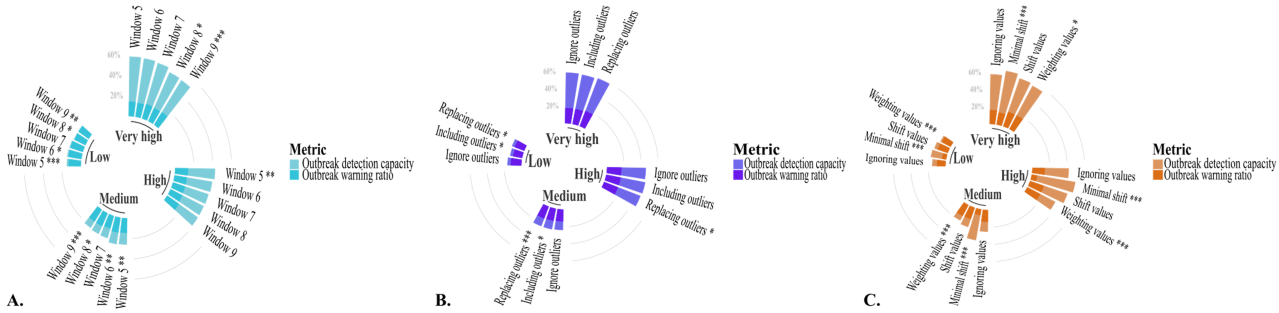


**Figure 5.** Endemic channel's parameters effect on the endemic channel performance: a composite metric including the number of warned outbreaks over the total number of outbreaks (outbreak detection capacity) and the number of warned outbreaks over the total number of triggered warnings (outbreak warning ratio). (**A**) Retrospective windows experiment, (**B**) previous outbreaks handling experiment, (**C**) zero-value handling experiment. Performance is proposed as the contribution of the detection capacity (light colors) and the outbreak warning ratio (dark colors). Detailed data can be accessed in Tables S6, S8, and S10 in Multimedia Appendix 1. Significance levels: **P*<.05, ***P*<.01, ****P*<.001.

## Assessment of How Previous Outbreaks Are Handled

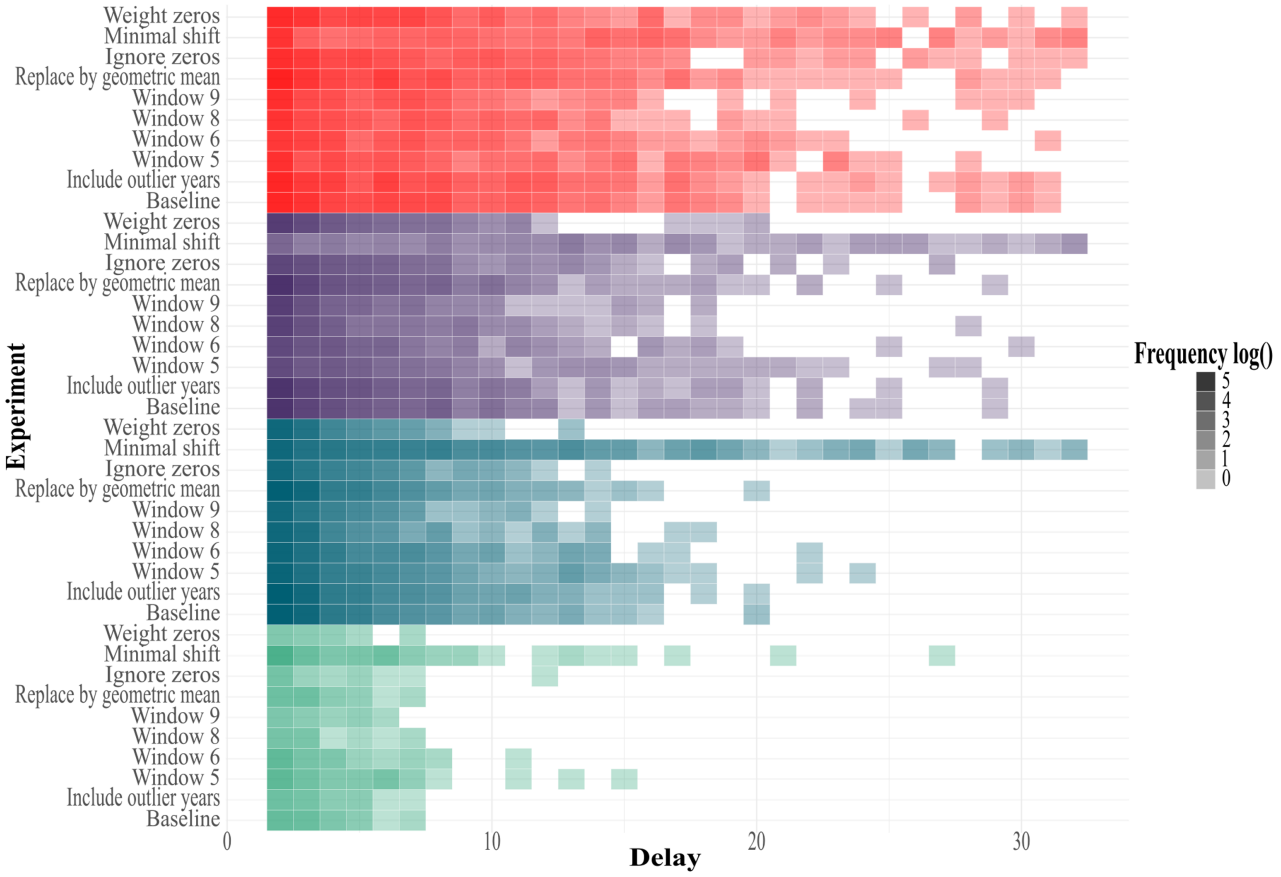
For both treatments, the EWT increased compared to the baseline strategy of ignoring previous outbreaks, with a greater increase observed when data from prior outbreaks were incorporated, as shown in Table S7 in Multimedia Appendix 1 and Figure 4B. The impact of handling previous outbreaks on endemic channel performance is illustrated in Figure 5B. In low-transmission municipalities, the highest performance was achieved when ignoring data from previous outbreak years. In contrast, replacing outbreak data with a geometric mean resulted in better performance for medium and very-high-transmission municipalities. For high transmission municipalities, the best performance was observed when data from previous outbreaks were included. Overall, as transmission levels increase, the performance of the endemic channel improved across different handling methods.

## Effect of Zero-Value Handling

The minimal shift was the only strategy that decreased the EWT compared to the baseline (shifting the data by a unit), as seen in Table S9 in Multimedia Appendix 1 and Figure 4C. The percentage of change was noticeably greater in low- and medium-transmission municipalities, as expected given their higher frequency of zero values.

The impact of zero-value handling strategies on endemic channel performance is depicted in Figure 5C. Metrics for the ignored-value and weighted-value strategies are presented for municipalities where we could estimate these metrics; however, the endemic channel consistently failed when these strategies were applied in cases where retrospective data lacked sufficient nonzero values. Across all transmission levels, performance significantly improved when using the minimal shift strategy. Notably, higher transmission levels corresponded with better endemic channel performance. Moreover, on average, all municipalities, regardless of their dengue transmission levels, were significantly influenced by applying the minimal shift and weighting strategies.

## Windows of Opportunity Behavior



We identified that the 2-week delay is the shortest and most predominant window of opportunity in all transmission levels and experiments, as expected from the definition of the outbreak

XSL•FO
RenderX

onset used in this study. Figure 6 displays the distribution of the windows of opportunity for all experiments across the different transmission levels. Neither the endemic channel nor our predictive assessment considered the magnitude or duration of the outbreak following the warning or the intraannual trend in case numbers.

**Figure 6.** Windows of opportunity distributions across experiments on very high (red), high- (violet), medium- (turquoise), and low-transmission (mint) municipalities. Color intensity is the logarithm of the frequency of observed delays, baselines refer to the institutional protocol, and the figure is shown up to a 32-week delay. Over-a-year outliers were found in municipalities with very high, high, and medium transmission.

In general, at the municipality level, the experiments allowed us to identify 2 settings that consistently improved the performance of endemic channels across all transmission levels: reducing the retrospective window relative to the baseline and applying a minimal shift to data (0.001) instead of adding a complete unit to handle zero values. In contrast, the management of previous outbreaks produced heterogeneous effects across transmission levels. When evaluated at departmental scales, the endemic channel significantly outperformed municipal results in all experiments and all transmission profiles, as seen in Tables S11, S12, and S13 in Multimedia Appendix 1. For instance, the baseline protocol showed a performance approximately 4 times greater for departments with low transmission, 2.3 times greater for those with medium transmission, 1.4 times greater in high transmission settings, and 1.2 times greater for departments with very-high transmission, compared to the performance at the municipality level. In contrast to the experiments at the municipal level, the effect of the retrospective window size, previous outbreak handling, and zero-value handling did not exhibit a statistically significant difference compared to the baseline, leading to similar conclusive insights and recommendations provided in this study.

## Discussion

### Principal Findings

Our assessment of the endemic channel parameters shows that reducing the retrospective data window improved metrics across all transmission profiles by 6.34% on average, while extending it decreased performance due to changes in detection capacity. It also highlights that the additional step of excluding outbreak years, such as 2019, in the estimation of the EWT does not significantly affect the method's performance in municipalities with very high and high transmission but produces significant differences in medium- and low-transmission units, where performance changed by approximately +1.48% and –14.82%, respectively. Experiments on handling zero values demonstrated that adding a small number to observed cases (such as 0.001) not only prevents null estimates of epidemic thresholds but also improves overall performance by an average of 23.07% across all transmission levels. An analysis of the window of opportunity at the baseline showed that its duration varies with transmission intensity; with an average of 8 weeks for very high, 5 weeks for high, 4 weeks for medium, and 3 weeks for low-transmission municipalities, reflecting that the sharpness of windows as transmission decays may make the anticipation of outbreaks difficult.

XSL•FO
RenderX

The use of metrics such as the outbreak detection capacity or the endemic channel performance proposed in this study faces challenges comparable to the definition of an outbreak. For example, Brady et al [16] modeled 5 candidate definitions of an outbreak (recent mean, monthly mean, moving mean, cumulative mean, and fixed incidence threshold) and found that resulting outbreaks varied significantly in terms of frequency, duration, and impact. Additionally, outbreak definitions vary in timing, affecting their suitability for early intervention. Likewise, our results show that the behavior of the endemic channel performance differs according to the selected outbreak definition (tuned by the parameters used in the method and the definitions of the epidemic features) and the transmission context. In addition, implementing performance metrics on outbreak detection methods that exhibit different definitions hinders the comparison of epidemiological scenarios within regions or periods. For example, previous assessments on epidemic thresholds report a limited sensitivity of 40% (accounting for warnings that lead to a significant increase in cases) and a specificity of 90% in Puerto Rico when using 2 SDs as CIs [17]. In contrast, a sensitivity of 66% in Brazil was reported when using 1 SD [18]. These assessments differ from the endemic performance proposed in this study because they do not account for diverse definitions of outbreaks based on other parameters of the surveillance method besides the SD as a threshold size.

To the best of our knowledge, no prior study has examined the effect of retrospective window size, previous outbreak handling, and alternative strategies to handle zero values on the outcomes generated by the endemic channel method. It is challenging to encourage a shorter window, as the selection of retrospective data is defined in year units and hinders the ability to identify an optimal window size. Excluding specific years from the retrospective data could lead to inconsistent usage of the endemic channel, primarily because the selection uses the same criteria once the potential epidemic year has already occurred. In addition, our analyses support the decision to include previous outbreak data with minimal impact on the number of triggered warnings. When evaluating the different experiments to handle the occurrence of zero values in the retrospective data, we identified that the selection is restricted to the shifting strategies in the scenario where all data are zero. Therefore, shifting data with a minimal value is equally feasible to implement in existing surveillance templates in official institutions. It is important to recall that the minimal shift strategy does lead to a significant reduction in the EWT, especially in municipalities with high and medium transmission. This will generate more warnings, and local authorities may review their response protocols to avoid exhaustion of surveillance and control programs. This behavior is better understood when the delay between the warning signal and the outbreak onset is considered, as the following sections in the study do. Given the nature of surveillance data, it is challenging to evaluate if the persistence of the warning is caused by a slow-paced transmission or a mitigated outbreak, for example. Ultimately, for municipalities with very high, high, and medium transmission, the window of opportunity provided more information regarding the amount of time that the system is in a warning status than regarding the timeliness and specificity of the endemic channel to trigger a warning for nonseasonal and significant outbreaks. On the other hand, the low-transmission municipalities display short periods between warnings and outbreaks, reflecting their outbreaks' sharp, intermittent, and difficult-to-anticipate behavior. The temporal criteria in the onset definition, while needed to address that the threshold lines are often surpassed briefly and intermittently [6], condition the analysis of the timeliness of the endemic channel warning, as the minimum delay is policy rather than data driven.

## Study Limitations

The results presented in this study rely on the assumption of a constant guideline for constructing endemic channels, which we subsequently used as baselines regardless of spatial or temporal setting. To enable analyses across all municipalities and years, we did not validate the warnings triggered by these baselines or the experiments against public or private records of health responses. If outbreak definitions were influenced by information beyond reported case data and its expected epidemiological limits, our approach does not capture such adjustments, as it does not account for external variables.

Similarly, the performance metrics used to assess the outcomes of the endemic channel were not compared with other methodologies or with external variables that might better reflect the true epidemiological situation of the regions. Consequently, there is limited certainty that governmental institutions would classify as outbreaks the same events we define as such. Furthermore, our interpretation of the metrics assumes an ideal performance of maximizing the detection of actual outbreaks while minimizing the number of triggered warnings, which may also be biased or constrained from the perspective of a public health officer. This absence of a ground truth dataset, combined with the statistical limitations inherent to the endemic channel, led us to avoid forecasting evaluations or other assessments that may exceed the practical uses of the surveillance method.

Finally, the statistical aggregation of our experiments relies exclusively on the Ministry of Health classification of dengue transmission levels. This stratification was not contrasted with additional approaches and may hinder population and disease dynamics that shape the expected variation of cases and the occurrence of outbreaks. The heterogeneity of our results and their dependency on the transmission level prevent us from recommending a single guideline; instead, they support the need to evaluate the appropriateness of the endemic channel in settings with low disease incidence.

## Conclusions

Our results show that the endemic channel's performance significantly varies according to the outbreak definition and transmission level. The metrics exhibit better performance as the transmission level increases, likely due to (1) more robust retrospective data for high transmission settings, which supports the identification of transmission outliers; and (2) a sharper increase in cases in municipalities with lower transmission when outbreaks occur that are not detected by the endemic channel on time (ie, low outbreak detection capacity in these settings). Therefore, the timeliness of the warnings needs to be considered, especially in departments with a considerable proportion of

XSL•FO
RenderX

low- and medium-transmission municipalities because notification aggregation can obscure the occurrence of incipient outbreaks in these areas.

Concerns about the definition and usage of outbreak thresholds have been previously expressed by the WHO's Special Program for Research and Training in Tropical Diseases [6,19]. In their study, the committee gathered evidence of methods' weaknesses, such as health officers may mislead the outbreak threshold as a "warning sign" rather than an already triggered epidemic; a satisfactory algorithm for recognizing past aberrations has yet to be developed [20]; previous outbreaks may lead to an exaggerated increase in thresholds; seasonal outbreaks may differ in frequency from the fixed retrospective window; and, when geographical units are small, the variation in cases tends to increase, potentially resulting in significant oscillations. This study provides insights into some of these concerns and aims to promote the frequent assessment of methodologies and definitions used in institutional outbreak surveillance, especially in the increasing interest in automated surveillance systems.

Given the relevance of the disease in the region, it is crucial to develop and implement tools to predict possible outbreaks at different geographical scales. In this context, the WHO Global Arbovirus Initiative, for example, has emphasized the importance of innovative tools to promote integration of social and mathematical sciences with public health and include climate and environmental context in early warning and forecasting systems [21]. The initiative also highlights methodological gaps when integrating surveillance systems, field and/or laboratory confirmation, and epidemiological investigations. For example, whereas a predictive system is a deterministic or probabilistic model that uses historical data and identified patterns to infer future values [22], tools such as the endemic channel do not meet this definition, as it is a descriptive statistical method that does not make any inference of future cases. Therefore, to use the endemic channel as a forecasting system, it is necessary to incorporate complementary evidence from other tools, such as stochastic methods [23] or probabilistic models [24]. Additionally, as noted in the various methodologies, it is essential to consider the multiple factors that can affect the presence and biology of the vector, such as climate variability, water storage, population density, and socioeconomic conditions that have been shown to impact the disease behavior [25]. An early literature review of dengue epidemiological surveillance found that, although 46 of the 56 major dengue-endemic countries had dengue surveillance systems in place, only 4 had systems robust enough for epidemic prediction [26,27], and that no plan provided for the use of climate data to predict an outbreak [28]. For this reason, it is advisable not to use the endemic channel as the only source of information for decision-making but to consider other tools that incorporate these factors.

While the endemic channel is a methodology that overlooks the pathogen's transmission dynamics and local contexts, the assessment of parameters for other epidemiological events should be carefully considered. For example, we encountered challenges when defining a consensus of the institutional baselines after reviewing the guidelines and definitions published by official institutions in Colombia. Therefore, caution should be exercised when extrapolating our insights from this study to other contexts and diseases. With this study, we extend an invitation to frequently question and review the mathematical assumptions embedded in current surveillance methods to ensure their correct use and interpretation, especially when their results are used as warning systems in public health response policies.

## Policy Recommendations

Governmental institutions may benefit from public communication of their methodology and parameters when constructing an endemic channel. The usage of the method, as analyzed through the epidemiological bulletins, is heterogeneous across regions and years. Notably, it is often difficult to identify the underlying assumptions and data workflows used in its development, which hinders the ability to replicate results, to establish a baseline, and to compare the epidemiological situation across municipalities or departments.

Including longitudinal (intraannual) analysis in a surveillance methodology, such as the endemic channel, is necessary to strengthen the tool's capacity to account for dengue transmission dynamics and weight notification data according to its recency. Meanwhile, we observed that the superior performance of shorter windows could be explained by the lower overlap of seasonal outbreaks, which occur approximately every 3 years in Colombia. Encouraging an optimal retrospective window is challenging, as data are computed by years, but the endemic channel for dengue surveillance in other regions may improve its performance if its retrospective data window is synchronized with the regional seasonality of the disease.

Alternative analyses to account for seasonal outbreaks should be incorporated when evaluating the epidemiological situation of a region. While removing previous epidemic years from the retrospective data helps mitigate outlier effects on the endemic channel, this practice did not yield a systematic improvement in performance metrics. Despite statistically significant differences in medium- and low-transmission municipalities, we found that this approach compromises the method's reproducibility in higher transmission settings, where its consistency may be more critical.

The addition of a small value to observed cases before the EWT estimation, rather than a complete unit, can be easily implemented for the benefit of the endemic channel's performance metrics. Although this change can increase the number of warnings, additional surveillance activities and tools can enlighten the correct outbreak response in these settings.

## Abstract

**Background:** With the advent of new vaccines, including the COVID-19 vaccines introduced during the recent pandemic, the need for near real-time active surveillance has increased to support timely regulatory decision-making.

**Objective:** This study aimed to assess the feasibility of sequential monitoring for potential adverse events following immunization in Korea, focusing on COVID-19 vaccines.

**Methods:** This population-based study used a linked database that combined the COVID-19 registry with national health insurance claims data. Participants included individuals older than 12 years who received either monovalent or bivalent COVID-19 vaccines in Korea between February 2021 and March 2023. Monthly retrospective sequential testing was performed for 3 prespecified outcomes (acute myocardial infarction, myocarditis, and anaphylaxis) as well as a negative control event (colonic diverticulitis). A Poisson-based maximized sequential probability ratio test was applied to compare postvaccination incidence rates with historical background rates, accounting for multiple testing and claims processing delays. Analyses were stratified by age group, vaccine platform, and dose.

**Results:** This study included over 43 million monovalent and 6.3 million bivalent vaccine recipients. Sequential analyses identified statistical signals for myocarditis following mRNA vaccines in individuals aged 12 to 64 years and protein subunit vaccines in those aged 40 to 64 years. Signals for anaphylaxis were observed following mRNA and nonreplicating viral vector vaccines in individuals older than 18 years. No safety signals were identified for acute myocardial infarction or colonic diverticulitis. Sequential monitoring detected signals for myocarditis and anaphylaxis before regulatory authorities took safety actions, with the earliest signals observed on September 30, 2021, and April 30, 2021, respectively.

**Conclusions:** Near real-time sequential testing detected statistical safety signals for myocarditis and anaphylaxis following COVID-19 vaccination. These signals were recognized by the regulatory authority as being associated with the vaccines, demonstrating the potential of this approach to detect signals requiring further causality assessments, particularly for newly introduced vaccines at an early stage.

## Introduction

Active surveillance for vaccine safety is an ongoing and systematic process designed to comprehensively identify adverse events (AEs) in a population [1,2]. This approach plays a critical role in maintaining trust in vaccines by promptly providing data to evaluate potential associations between vaccinations and AEs, thereby supporting regulatory decision-making [3]. Active surveillance can be broadly classified into two types: (1) near real-time (NRT) sequential monitoring using electronic health

XSL•FO
RenderX

records (EHRs) or claims databases generated during routine health care services, and (2) cohort event monitoring, which collects primary data through individual surveys to assess postvaccination experiences [4]. NRT sequential monitoring is particularly effective for the early detection of vaccine safety signals when a new vaccine is introduced, a vaccine brand is changed, or the recommended target population is expanded [5]. Sequential monitoring has been widely conducted in various countries, including the United States and European nations, to evaluate the safety of various vaccines.

In the United States, NRT sequential monitoring is primarily performed by the Vaccine Safety Datalink (VSD) [1,6] under the Centers for Disease Control and Prevention (CDC) and by the Biologics Effectiveness and Safety (BEST) Initiative [7] under the Food and Drug Administration (FDA). Since the mid-2000s, the VSD has conducted rapid cycle analysis using weekly updated data files [8], and the results have been published for several vaccines, including seasonal influenza [9-11], H1N1 influenza [12], rotavirus [13], human papillomavirus [14,15], pneumococcal conjugate [16], and meningococcal conjugate vaccines [8]. More recently, sequential analyses have been applied to studies on COVID-19 vaccines to rapidly generate safety evidence following vaccine rollout [17-19]. Similarly, the post-licensure rapid immunization safety monitoring system [20], part of the FDA Sentinel Initiative, initially conducted sequential monitoring for influenza vaccines [21]. Subsequently, the BEST Initiative has employed sequential testing methods for active COVID-19 vaccine safety surveillance [22-24].

In Europe, the Accelerated Development of Vaccine Benefit-Risk Collaboration in Europe, a public-private partnership, assessed the feasibility of NRT monitoring for vaccine coverage, benefits, and risks [5]. Building on the methodologies and tools developed by the Accelerated Development of Vaccine Benefit-Risk Collaboration in Europe, the Vaccine Monitoring Collaboration for Europe leveraged EHRs from various European countries to actively monitor the postmarketing safety and effectiveness of COVID-19 vaccines [25]. Additionally, studies have evaluated the feasibility of sequential monitoring using national datasets, such as the Clinical Practice Research Datalink in the United Kingdom [26,27]. These systems facilitate safety monitoring during the early stages of new vaccine introductions and support ongoing monitoring of annual vaccination programs, thereby reinforcing public trust in vaccination.

Early detection of potential safety signals through NRT sequential monitoring enables timely decisions regarding the need for further comprehensive analyses. By using longitudinal observational data, such as EHRs or health insurance claims data, sequential monitoring comprehensively identifies safety signals in real-world populations, including those excluded from clinical trials [28]. In South Korea, studies using nationwide health insurance claims data have demonstrated the potential to detect postmarketing safety signals [29,30]. However, the feasibility of NRT monitoring of vaccine safety using these data has not yet been assessed. Furthermore, prior studies have not used real-world data to investigate whether sequential analysis can accurately identify potential AEs requiring further rigorous epidemiological assessment, or how quickly such events can be detected.

During the COVID-19 pandemic, the importance of early detection of safety signals became even more apparent due to limited preapproval safety evidence on vaccines. NRT sequential monitoring is particularly valuable for identifying risks when new vaccines are introduced, vaccine types or brands are updated, or vaccination eligibility expands. The results of such monitoring can help prioritize new epidemiological studies or inform regulatory actions. Given the ongoing development of various new vaccines, the need for NRT safety monitoring continues to grow. Therefore, this study aims to assess the feasibility of applying sequential testing methods using a nationwide linked database in South Korea. We conducted an exploratory analysis using recently introduced COVID-19 vaccination data. Additionally, the results of this sequential analysis were compared with known safety evidence and the timing of regulatory actions related to COVID-19 vaccine safety in Korea.

## Methods

### Settings and Study Population

This study used a nationwide database combining the COVID-19 registry from the Korea Disease Control and Prevention Agency (KDCA) and the health insurance claims data from the National Health Insurance Service (NHIS). Korea has a universal health insurance system that provides coverage for the entire population. Claims data are generated when health care providers deliver services to patients and subsequently file claims with the NHIS. The NHIS compiles a comprehensive database that includes information on insurance eligibility, premiums, medical services, and health care institutions [31]. This database encompasses records of inpatient, outpatient, and emergency department visits. Since the launch of the national COVID-19 vaccination program on February 26, 2021, the KDCA has managed vaccination records for the entire population [32]. The linked database includes information on COVID-19 vaccinations, laboratory-confirmed SARS-CoV-2 infections, diagnoses, prescribed medications (eg, drug codes, daily dosage, and duration), and health care procedures. It also contains timestamps for data recording, enabling us to track the dates when the data were accrued.

For this study, we used the KDCA COVID-19 registry data from February 26, 2021, to June 30, 2023, and NHIS health insurance claims data from January 1, 2017, to June 30, 2023. The study population consisted of individuals aged 12 years and older who received either monovalent or bivalent COVID-19 vaccines in Korea. Only individuals with Korean nationality who were enrolled in the national health insurance during the study period were included. Individuals participating in clinical trials for COVID-19 vaccines, those vaccinated abroad, or those with erroneous or duplicate vaccination records were excluded.

### Exposure

The exposures of interest included all COVID-19 monovalent vaccines used for primary doses (ie, first and second doses) and

XSL•FO
RenderX

booster doses, as well as bivalent COVID-19 vaccines administered in Korea. Korea introduced 6 types of COVID-19 monovalent vaccines, including those based on mRNA, nonreplicating viral vector, and recombinant protein platforms (Table S1 in Multimedia Appendix 1). Our analysis focused on all primary and booster doses of monovalent COVID-19 vaccines administered from February 26, 2021, to September 30, 2022. During the 2022-2023 winter season, 4 types of mRNA bivalent vaccines were introduced in Korea (Table S2 in Multimedia Appendix 1). As part of the COVID-19 winter booster vaccination program, 1 dose of a bivalent vaccine was recommended regardless of the specific vaccine type. This study included all bivalent COVID-19 vaccines administered from October 11, 2022, to March 31, 2023.

To account for vaccine platforms and recommended dose schedules, we categorized the exposure groups based on the type of vaccines and dose number: mRNA monovalent vaccine (doses 1, 2, and 3), non-replicating viral vector monovalent vaccine (doses 1 and 2), recombinant protein–based monovalent vaccine (doses 1, 2, and 3), and mRNA bivalent vaccine doses. All analyses were stratified by platform and dose number.

## Outcomes

This study selected outcomes of interest by considering both the associations between COVID-19 vaccines and AEs, and the timing of regulatory actions. The selection process involved reviewing the priority lists of adverse events of special interest (AESIs) for COVID-19 vaccines published by the Safety Platform for Emergency Vaccines [33], the VSD [17], and the BEST Initiative [34]. We also considered a list of AEs deemed causally or suspiciously related to COVID-19 vaccines by the KDCA (Table S3 in Multimedia Appendix 1). Through this process, 3 conditions were chosen as the outcomes of interest based on different causal association scenarios: anaphylaxis, myocarditis, and acute myocardial infarction (AMI). Each of these conditions was commonly listed as AESIs by the Safety Platform for Emergency Vaccines, VSD, and BEST Initiative. Anaphylaxis was considered an AESI that was causally associated with COVID-19 vaccines by the KDCA even before vaccine introduction, given that it can potentially be induced by all vaccine types [35]. Subsequent literature further supported this association [36-38]. Myocarditis was included in the AESI lists and, following the vaccine rollout, causal associations were recognized for mRNA and NVX-CoV2373 vaccines [39]. AMI, initially listed as an AESI, has not shown a definitive causal relationship with vaccination in postvaccination epidemiological studies.

In addition, a negative control event was selected—an event for which there is no evidence of a causal association with vaccination and that has not been flagged as a signal [40]. Colonic diverticulitis was chosen as the negative control event, as it was not included in COVID-19 AESI lists and is generally considered unrelated to vaccination. Moreover, this acute condition typically requires immediate treatment, making it unlikely to show significant variations in health care use between the prepandemic and pandemic periods [41].

Table S4 in Multimedia Appendix 1 presents the operational definitions for the selected AESIs and the negative control event. To maintain sensitivity and enable timely analysis for NRT sequential monitoring, operational definitions were based solely on diagnostic codes. The diagnostic codes and the lengths of risk periods were determined by referencing definitions employed by VSD [17] and BEST [34], as well as expert opinions from clinicians in the relevant medical fields.

## Study Design

This study conducted monthly sequential testing to compare the background incidence rates of outcomes of interest with the incidence rates observed during the risk period following COVID-19 vaccination. The study design consisted of three steps: (1) estimation of background incidence rates for the outcomes of interest, (2) analysis of their incidence rates during the postvaccination risk periods, and (3) application of the sequential testing method. Sensitivity analyses were performed when a signal met the statistical threshold.

Sequential testing, which adjusts for multiple comparisons through repeated analyses over time, can rapidly identify potential safety concerns [1,42]. It generates a statistical signal as soon as there is sufficient evidence to reject the null hypothesis of no excess risk, thereby providing timely safety information that can enhance public confidence in vaccines [42]. Sequential testing methods are categorized into continuous sequential methods, which analyze data frequently (eg, weekly or monthly), and group sequential methods, which analyze data at discrete intervals after a specific amount of data has been accumulated [43]. This study adopted a continuous sequential method, known for its superior performance in using data aggregated over short intervals [44]. Among the continuous sequential methods, the maximized sequential probability ratio test (MaxSPRT), developed by VSD for sequential monitoring, is particularly suited for ongoing surveillance as it continues monitoring until the statistical threshold is reached or the maximum sample size is attained [44]. This study used Poisson MaxSPRT (PMaxSPRT) to compare the observed number of cases of AEs with the expected number derived from historical controls, especially for rare events during a large-scale vaccination campaign.

## Statistical Analysis

### *Calculation of Background Rates for AESIs*

Background incidence rates for AESIs, serving as historical controls, were estimated from the 2018 and 2019 incidence data. The prepandemic period was selected to avoid potential pandemic-related changes in health care use during the early phase of COVID-19.

The cohort for calculating background rates was defined as individuals with national health insurance eligibility as of January of each respective year. The cohort entry date was set as the later of either January 1 of the respective year or the date when the individual met the clean period criteria. The clean period was defined as the interval preceding cohort entry during which the AESI must not have occurred, serving as a requirement for inclusion in the study cohort. The specific duration varied depending on each AESI and negative control event. Person-time at risk for each individual was calculated from the cohort entry date to the earliest of the following: the

XSL•FO
RenderX

date of occurrence of the event, December 31 of the same year, or the date of death. If follow-up ended due to an event, individuals could re-enter the cohort if they subsequently met the clean period criteria (Figure S1 in Multimedia Appendix 1).

For each AESI, the annual incidence rates per 100,000 person-years with exact Poisson 95% CIs were calculated by age group. To enhance the sensitivity of the analysis, the lower annual incidence rate between 2018 and 2019 was used as the background rate for each AESI and age group. Monthly incidence rates were also calculated for each year to assess potential seasonality. This approach allowed for sensitivity analysis by using the average monthly background rate for the corresponding months in each sequential test.

### *Analysis of Incidence Rates During the Risk Period*

Although this study retrospectively analyzed data, it was designed under the assumption of conducting sequential analyses starting from the initiation of COVID-19 vaccination. Considering that health care claims from medical care institutions are typically submitted on a weekly or monthly basis, the analysis frequency was set to monthly intervals. Analyses were conducted using data accrued to the database by the end of each month, starting from March 31, 2021. For eligible individuals exposed at each sequential analysis point, the incidence rates of AESIs during the risk period were calculated by age group, vaccine platform, and dose. Follow-up ended upon death or the analysis date, if it occurred before the risk period concluded (Figure S2 in Multimedia Appendix 1).

The follow-up period accounted for delays between the date of medical care and data accrual, which may vary by condition, clinical setting, and institution type. Delays in data accrual during the study period were evaluated using patterns from the prepandemic (January 2019-December 2019) and early pandemic (February 2020-June 2020) periods. For each AESI, monthly accrual rates of claims associated with diagnoses in a given month were calculated, and average delays were derived by analyzing their distribution across subsequent months. The period with higher accrual rates was used to minimize false signal detection. Claims were considered fully accrued once 95% of claims were collected following the month of diagnosis, and the entire follow-up period was used thereafter.

Although vaccination records may also be subject to data delays, they were not considered in this study, as individuals were followed from the recorded exposure date, minimizing the impact on the results. Figure S3 in Multimedia Appendix 1 illustrates the diagram for calculating the follow-up period using historical data on accrual delays.

Sequential analyses incorporated updated data at each testing point. Cases excluded in earlier analyses due to delays in data accrual could be included in subsequent analyses. Similarly, cases initially classified as incident AESIs could be reclassified as having a prior history based on the updated data.

### *Implementation of the Sequential Testing Method*

Sequential analyses were conducted monthly following the initiation of the COVID-19 vaccination program, using the PMaxSPRT method. At each analysis point, the number of observed events during the post-vaccination risk period was compared to the expected number of events calculated based on background rates. The expected number of events for individuals vaccinated between month $t$ and $s$ was calculated by multiplying the number of person-days ($A$) during the risk period (from $w$ d to $T_i$ d for each individual i) by the background rate ($\theta$) and adjusting for data delay by incorporating $P(s,t)$. To account for reporting delays arising from partially accrued data, we introduced an adjustment factor $P(s,t)$, defined as the proportion of AESIs that occurred in study month and were observed by month $s$ [34]. The process used to adjust for data accrual delays is illustrated in Figure S4 in Multimedia Appendix 1.

$$(1)\sum t=1s\sum i=1nt\sum w=0TiAstiw\times\theta\times P(s,t)$$

Sequential analyses began on March 31, 2021, or when at least 1 cumulative case was observed within the follow-up period. Data accumulated by the last day of each month were analyzed. The relative risk (RR) and log-likelihood ratio were calculated to compare the likelihood of the observed RR to the null hypothesis. A statistical signal was declared if the log-likelihood ratio exceeded a prespecified critical value. Surveillance ended when one of the following occurred: (1) the statistical signal threshold was met, (2) observed events equaled expected events under the null hypothesis, or (3) the study period ended [42]. Expected event counts under the null hypothesis were estimated using the expected number of vaccinated individuals in the recommended age group within the resident population.

The null hypothesis ($H_0$: RR≤m) was tested using a one-tailed design with a significance level of 0.05. At least 2 cases were required to declare a signal. Threshold m values were determined based on severity and background incidence of each condition, proposed by Lloyd et al [22] (Table S5 in Multimedia Appendix 1). For colonic diverticulitis, m was set equal to that of anaphylaxis, a severe condition with a comparable background incidence that generally requires hospitalization or emergency department visits. Sensitivity analyses were conducted for all age groups, vaccine platforms, or doses that met the statistical signal threshold, adjusting for time-varying confounders such as seasonality. For outcomes that met the statistical threshold in sequential testing, the timing of the signal was compared with the timing and rationale behind safety measures implemented by the regulatory authority in Korea.

Analyses were performed using SAS Enterprise Guide version 7.1 (SAS Institute, Inc), R version 4.3.1 (R Foundation for Statistical Computing), and the R package *Sequential* version 4.3.3.

## Ethical Considerations

This study was approved by the institutional review board of Ewha Womans University (ewha-202404-0014-01). Informed consent was not required due to the utilization of anonymized patient data.

## Results

### Baseline Characteristics

Table 1 summarizes the sociodemographic and vaccination characteristics of the Korean population who received COVID-19 vaccines during the study period, stratified by vaccine platform and dose number. Over 43 million individuals received monovalent vaccines, with mRNA vaccines being the most frequently administered across all dose levels. Among individuals aged 65 years and older, ChAdOx1 was the vaccine most commonly administered. Since NVV was recommended only for those aged 18 years or older, most individuals aged 12 to 17 years received other vaccine platforms. Recombinant protein–based vaccines, introduced later than other platforms, had fewer recipients. Nonreplicating viral vector vaccines for booster doses were excluded from sequential monitoring as they were not recommended for booster doses.

[a]Not applicable.

Approximately 6.3 million individuals received bivalent vaccines, with the majority being aged 65 years or older, reflecting the prioritization of older adults, immunocompromised individuals, and high-risk groups. BNT162b2 BA.4/5 was the most frequently administered bivalent vaccine. Figures S5 and S6 in Multimedia Appendix 1 illustrate the weekly distribution of vaccinations by vaccine type and dose number for both monovalent and bivalent vaccines.

## Calculation of Background Rates for AESIs

Table 2 presents the annual background rates of AESI derived from data for 2018, 2019, and 2020. For most AESI across all age groups, the background rates in 2020 were either statistically significantly lower or similar to those in the pre-COVID-19 period. This study used the lower incidence rate between 2018 and 2019 as the background rate for each AESI and age group.

XSL•FO

[a]Incidence rate per 100,000 person-years.

[b]The background incidence rate for 2020 was calculated for individuals with eligibility information as of February of that year, considering the observation period from February 2020 to December 2020.

## Incidence Rates During the Risk Period

Figures S6-S9 in Multimedia Appendix 1 present the distribution of delays in data accrual for claims made before the introduction of COVID-19 vaccination. For all AESIs, comparisons revealed that diagnoses from inpatient settings had faster data accrual than those from combined inpatient and outpatient settings (Figures S7-S10 in Multimedia Appendix 1). Consequently, the study used data delay distributions based on inpatient diagnostic claims. During the COVID-19 pandemic, over 95% of claims data were accrued faster compared to the prepandemic period. Thus, this study used data accrual delay distributions from inpatient diagnoses recorded between February 2020 and June 2020 to calculate the contribution of the risk period to sequential testing (Table S6 in Multimedia Appendix 1).

The person-time at risk and the number of events at each sequential testing point were calculated, and the expected number of events within the risk period was estimated using background rates. These calculations were performed separately for each age group, vaccine platform, and dose at each testing.

## Implementation of the Sequential Monitoring Method

For AMI and colonic diverticulitis, none of the analyses stratified by age group, vaccine platform, or dose met the statistical signal threshold (Tables S7 and S8 in Multimedia Appendix 1).

For myocarditis, the statistical signal threshold was met for mRNA vaccines in the 12 - 17 and 18 - 39 age groups across all doses and for the first dose in the 40 - 64 age group. The threshold was also met for recombinant protein vaccines in the 40 - 64 age group for both the first and second doses. Significant results from sequential testing for myocarditis are summarized in Table 3, while the complete results for all age and dose groups are provided in Table S9 in Multimedia Appendix 1.

[a]RR: relative risk.

[b]LLR: log-likelihood ratio.

[c]The log-likelihood ratio is artificially set to 0 when the relative risk is less than 1.

For anaphylaxis, the statistical signal threshold was exceeded for mRNA vaccines in the 18 - 39 age group across all doses and for the first and second doses in individuals aged 40 years and older. For nonreplicating viral vector vaccines, the threshold was met following the first and second doses in the 18 - 39 and 40 - 64 age groups, as well as after the first dose in individuals aged 65 years and older. A summary of significant sequential testing results for anaphylaxis is presented in Table 4, and detailed findings across all age and dose groups are available in Table S10 in Multimedia Appendix 1.

[c]The log-likelihood ratio is artificially set to 0 when the relative risk is less than 1.

Sensitivity analyses were conducted for myocarditis and anaphylaxis to account for temporal trends in monthly incidence rates. For myocarditis, no differences were found between the sensitivity and primary analyses (Table S11 in Multimedia Appendix 1). For anaphylaxis, however, the sensitivity analysis showed that the signal threshold was no longer exceeded for the second dose of non-replicating viral vector vaccines in the 40 - 64 age group or the first dose in individuals aged 65 years and older (Table S12 in Multimedia Appendix 1).

## Comparison of the Timing of Signal Detection and Implementation of Domestic Safety Measures

The timing of statistical signal detection using the sequential monitoring method was compared to the timing of safety measures implemented by the KDCA (Figure S11 in Multimedia Appendix 1).

For myocarditis, the KDCA initially did not recognize an association between COVID-19 vaccines and myocarditis during the early vaccination phase. However, international reports of myocarditis following mRNA COVID-19 vaccination and

XSL•FO
RenderX

reviews by global regulatory agencies prompted further investigation [45,46]. Based on domestic causality assessments, the KDCA announced on March 14, 2022, that myocarditis was causally associated with mRNA COVID-19 vaccination. Subsequently, on December 29, 2022, myocarditis was identified as a potential AE related to recombinant protein–based vaccines [39].

In this study, sequential testing detected statistical signals for myocarditis in different age groups after receiving mRNA vaccines. For the 12 - 17 and 18 - 39 age groups, the signals were detected in January 2022 and September 2021, respectively. In the 40 - 64 age group, signals were detected for mRNA vaccines in December 2021 and for recombinant protein–based vaccines in June 2022. The earliest signal was observed on September 30, 2021, for mRNA vaccines in the 18 - 39 age group.

For anaphylaxis, the KDCA recognized a causal relationship with COVID-19 vaccination from the beginning of the vaccination program. Sequential testing detected signals for nonreplicating viral vector vaccines in the 18 - 39 age group in April 2021 and for mRNA vaccines in June 2021. In the 40 - 64 age group, signals for nonreplicating viral vector vaccines were detected in April 2021, while mRNA vaccines reached the threshold in June 2021, after approximately 80,000 doses. Among individuals aged 65 years and older, signals for both nonreplicating viral vector and mRNA vaccines were detected in July 2021. The earliest signal was observed on April 30, 2021, for the first dose of nonreplicating viral vector vaccines in the 18 - 39 and 40 - 64 age groups.

## Discussion

### Principal Findings

This study conducted an exploratory analysis to evaluate the applicability of NRT surveillance for recently developed COVID-19 vaccines using a sequential testing method. Monthly analyses were performed using PMaxSPRT to compare background rates with postvaccination incidence rates, accounting for data accrual delays. All COVID-19 vaccines introduced in Korea were analyzed by vaccine platform, age group, and dose for 4 outcomes of interest.

The results showed that the statistical signal threshold for myocarditis was met in individuals younger than 64 years after mRNA vaccination and in those aged 40 to 64 years after recombinant protein–based vaccines. For anaphylaxis, the statistical signal threshold was met following mRNA and nonreplicating viral vector vaccines in individuals aged 18 years and older. No statistical signals were detected for AMI or colonic diverticulitis by the end of surveillance.

Comparison with prior studies revealed consistent findings for myocarditis and anaphylaxis. Lloyd et al [22] identified statistical signals for myocarditis, pericarditis, and anaphylaxis following COVID-19 vaccination in the US population aged 12 - 64 years. Similarly, studies analyzing BNT162b2 in adolescents aged 12 years and older also detected signals for myocarditis and pericarditis [23,24]. Wong et al [47], studying US adults aged 65 years and older, reported signals for AMI and other outcomes, but sensitivity analyses accounting for time trends and pandemic background rates showed no signals. These findings align with our study, which detected statistical signals for myocarditis and anaphylaxis but not for AMI.

This study compared the timing of statistical signals with the regulatory actions taken by the KDCA. In Korea, the KDCA delegated COVID-19 vaccine safety monitoring to CoVaSC, which made causality assessments prior to regulatory decisions [32]. Anaphylaxis was recognized as causally associated with COVID-19 vaccination early in the campaign. Sequential testing revealed statistical signals for nonreplicating viral vector vaccines in April 2021 and for mRNA vaccines in June 2021. Subsequent epidemiological studies confirmed the association between COVID-19 vaccines and incident anaphylaxis risk [36,39]. For myocarditis, causality was recognized for mRNA vaccines in March 2022 and for recombinant protein–based vaccines in December 2022 [39]. Sequential testing showed that statistical signals were first detected in September 2021 for mRNA vaccines and in June 2022 for recombinant protein–based vaccines. These findings suggest that NRT sequential testing could have facilitated earlier epidemiological evaluations of high-priority conditions using domestic data.

Sequential monitoring conducted early during the COVID-19 vaccination campaign in countries such as the United States demonstrated the rapid detection of safety signals when applying NRT methods. For instance, sequential testing in the US FDA surveillance program identified statistical signals for AMI, pulmonary embolism, disseminated intravascular coagulation, immune thrombocytopenia, myocarditis, and pericarditis after BNT162b2 vaccination. It also detected a signal for anaphylaxis after mRNA-1273 vaccination [22,47]. In a US pediatric population aged 5 - 17 years, sequential testing detected signals for myocarditis and pericarditis [24]. Initial VSD analyses in the United States did not detect signals for AESIs [17], but extended studies later identified signals for Guillain-Barré syndrome with Ad26.COV2.S and myocarditis or pericarditis in younger adults after mRNA vaccination [48,49].

Countries with established NRT sequential monitoring systems identified safety concerns relatively early in their vaccination campaigns. In contrast, Korea's vaccination campaign began later without a sequential monitoring system in place. As a result, regulatory actions largely relied on international findings, such as safety concerns about myocarditis raised abroad before vaccines were administered to Korean adolescents and young adults. This reliance may have influenced diagnosis coding practices. Cases resembling myocarditis might have been coded as myocarditis, which could have impacted studies based on claims data. Our study, which used a health insurance claims database for sequential analysis, may also have been influenced by these coding practices in analyzing myocarditis, one of our outcomes of interest. Such diagnostic awareness and heightened attention following international safety reports may have increased the likelihood of coding myocarditis, potentially inflating the observed signal strength. If an NRT monitoring system had been established before these issues were raised internationally, or if sequential analysis had been conducted globally at the onset of vaccinations, the time required to detect a myocarditis signal in our study might have been longer. In

XSL•FO
RenderX

that case, a lower relative risk might have been estimated. However, had sequential monitoring been implemented domestically, safety signals might have been detected earlier, as demonstrated by this study.

To implement NRT monitoring effectively within the country, further exploration of data sources capable of supporting NRT monitoring is needed. In this study, we used health insurance claims data and addressed data latency by calculating delay distributions based on recent historical data. One advantage of using domestic health insurance claims data is that they offer medical information for the entire population, allowing for the surveillance of even rare AEs. However, given the nature of claims data, inherent delays may occur during several stages of data processing. These include the provision of medical services, submission of claims by medical institutions, review procedures, and subsequent reimbursement by the NHIS. This process can take approximately 3 months or, in some cases, more than 6 months before the data becomes available. Therefore, to enhance NRT monitoring in the future, collaboration with sample hospitals might be considered to collect data based on EHRs, instead of claims data, which may accelerate the data accrual process. Integrating multiple data sources, such as NRT hospital data and EHRs, would allow timely validation of diagnostic codes and help mitigate potential diagnostic biases and misclassification. Furthermore, to prevent spurious signal detection driven by heightened diagnostic awareness, such as increased hospital visits and changes in coding practices observed for myocarditis, future surveillance systems should incorporate clinical validation processes. These should include case verification using detailed medical record review or laboratory findings. Linking diagnostic data with laboratory results or chart reviews could help distinguish genuine cases from those arising due to increased diagnostic activity.

### Strengths and Limitations

To our knowledge, this is the first study in Korea to apply NRT sequential monitoring based on a nationwide vaccination registry and health care data. We used a data accrual delay adjustment method tailored to claims data. This approach enabled early safety surveillance shortly after vaccine rollout. However, this study has several limitations. First, while analyses were stratified by age group, vaccine platform, and dose—key factors influencing safety and timing of COVID-19 vaccination—the study did not account for sex differences. This was because vaccine recommendations and rollout timing differed across age groups. These factors were expected to have a greater impact on safety signal detection during the signal detection phase. Considering potential biological and behavioral differences between sexes, future studies should incorporate subgroup analyses by sex to identify potential variations. Second, as this study was designed as a feasibility assessment, the scope was intentionally limited to 3 AESIs and 1 negative control outcome. The selected outcomes were mostly diagnosed in Korea after being reported as AEs in countries that began vaccination earlier. Such international reports may have influenced health care–seeking behavior, potentially leading to overdiagnosis of conditions with similar clinical presentations. For instance, myocarditis cases in Korea were diagnosed predominantly after international reports, where heightened awareness may have contributed to an increase in the diagnosis of related conditions. Future research should expand sequential monitoring to a broader range of AESIs, such as Guillain-Barré syndrome or thrombosis with thrombocytopenia, to evaluate its applicability across diverse clinical presentations. Third, the operational definitions of AESIs relied solely on diagnostic codes for timely signal detection, which may limit diagnostic validity. For AESIs that met the statistical signal threshold in sequential testing, follow-up epidemiological studies with refined operational definitions are necessary to improve diagnostic accuracy. Fourth, the average data accrual rate, calculated from historical data, may not fully reflect actual delays or unexpected changes during the study period. However, this study minimized potential inaccuracies by using recent historical data. Further efforts should be made to continuously update and incorporate monthly accrual rates from the most recent data to enhance accuracy. Finally, although the sequential analysis controlled for repeated testing within each analysis stratum, no adjustment was made for multiple testing across all strata. As a result, the possibility of an inflated type I error rate at the overall study level cannot be entirely ruled out, and the findings should be interpreted as hypothesis-generating rather than confirmatory.

### Conclusions

In conclusion, this study demonstrated that sequential monitoring can be effectively applied using Korean data sources in situations that require active surveillance, such as monitoring newly developed vaccines. Comparisons between signal detection timelines and KDCA regulatory actions indicated that NRT sequential monitoring could have enabled earlier recognition of safety concerns, such as anaphylaxis and myocarditis, thereby supporting more timely regulatory decisions. Future studies should explore alternative data sources, such as EHRs, to incorporate a broader range of clinical information and improve monitoring timeliness.

## Acknowledgments

This study was conducted as part of the COVID-19 Vaccine Safety Research Center in the Republic of Korea. The authors sincerely thank the Korea Disease Control and Prevention Agency and the National Health Insurance Service for providing the database used in their study. Special gratitude also goes to Song Vogue Ahn and Minah Park for their insightful comments, which greatly contributed to the development of this manuscript. The authors declare the use of generative artificial intelligence in a limited capacity for language editing during manuscript preparation, under full human supervision.

XSL•FO
RenderX

## Funding

This research was supported by a grant from the Korea Disease Control and Prevention Agency and by a grant from the Ministry of Food and Drug Safety (RS-2024-00332011). The funders played no role in study design, data collection, analysis and interpretation of data, or the writing of this manuscript.

## Data Availability

The study used pseudonymized patient-level data from the Korea Disease Control and Prevention Agency and the National Health Insurance Service, which is protected by strict confidentiality under the Personal Information Protection Act. Access to personal data is granted solely for research purposes by the responsible authority upon submission of a formal application.

## Authors' Contributions

NYJ, HC, and NKC were involved in the conceptualization and design of the study. NYJ conducted the statistical analyses with full access to the data and takes responsibility for ensuring the accuracy of the data analysis. NYJ, HW, SP, JL, HP, and NKC interpreted the data. NYJ and NKC wrote the first draft. All authors critically reviewed the manuscript and approved the final version of the manuscript. All authors had final responsibility for the decision to submit for publication.

## Conflicts of Interest

None declared.

## Abstract

**Background:** Traditional disease surveillance systems often rely on clinical or laboratory-confirmed data, which may delay detection of emerging outbreaks. The National Retail Data Monitor (NRDM), established in 2002, collects anonymized over-the-counter (OTC) health product sales data from more than 28,000 retail outlets across the United States and provides a complementary data source for syndromic surveillance.

**Objective:** This study evaluated the use of NRDM data for detecting and tracking influenza-like illness (ILI), including purchasing patterns suggestive of novel disease outbreaks.

**Methods:** NRDM data from Allegheny County, Pennsylvania, collected between 2016 and 2021, were analyzed using a probabilistic modeling framework to estimate daily ILI activity from OTC purchasing patterns. An expectation-maximization algorithm was applied to data from the training period (June 2016-May 2019) to estimate conditional probabilities of OTC product purchases under ILI and non-ILI conditions. These estimates were then applied to daily sales data from the test period (June 2019-December 2021) to infer daily ILI counts. The framework was further extended into a monitoring system, termed NRDM Tracker, which uses daily log-likelihoods and false discovery rate–adjusted *P* values to detect statistically significant anomalies in purchasing behavior.

**Results:** NRDM-derived ILI estimates were moderately correlated with emergency department (ED)–based ILI counts ($r$=0.66). Compared with other OTC product categories (eg, thermometers and antifever medications), cough and cold medications showed the strongest association with ILI-related purchasing behavior and higher estimated purchase probability under ILI conditions (0.792) than under non-ILI conditions (0.695). During the early phase of the COVID-19 pandemic in March 2020 in Allegheny County, when COVID-19 testing capacity was limited and public awareness and health-seeking behaviors were rapidly evolving, NRDM-based ILI signals increased before corresponding rises in confirmed ED-based COVID-19 counts. Moreover, NRDM Tracker identified significant anomalies in OTC purchasing behavior during major outbreak periods, including a pronounced decline in log-likelihood in March 2020 corresponding to the onset of the COVID-19 pandemic. Multiple product categories exhibited statistically significant deviations in sales during these periods.

**Conclusions:** OTC product sales data, analyzed using probabilistic modeling and anomaly detection methods, can provide timely insights into population-level health activity and may help identify anomalies associated with emerging disease outbreaks. NRDM-based surveillance systems may complement traditional clinical surveillance and strengthen local and national biosurveillance capabilities.

## Introduction

Detection of disease outbreaks is critical to public health surveillance, particularly in the early identification of emerging outbreaks. Traditional surveillance approaches, such as sentinel systems operated by the Centers for Disease Control and Prevention (CDC), rely on confirmed case reports from selected health care systems. While these methods provide accurate clinical insights, they can suffer from reporting delays, limiting their effectiveness for timely response.

To support timely detection, public health surveillance has evolved to incorporate diverse data streams, including electronic health records (EHRs) [1-4], search engine queries [5,6], and social media [7,8], and participatory surveillance systems [9-14] in which individuals directly report symptoms through digital platforms. EHR-based surveillance enables real-time insights from structured health care data but depends on integration with clinical systems. Search engine–based surveillance leverages aggregated query trends, for example, spikes in Google searches for influenza symptoms, to estimate disease activity in near real time. Social media–based surveillance mines user-generated content, such as symptom-related posts, to detect unusual patterns in health behavior. In contrast, participatory surveillance relies on structured, self-reported data rather than passively collected online content. Despite their promise, these approaches—particularly those based on passively collected online data—can be sensitive to shifts in platform algorithms and user behavior, and their spatial resolution may be limited for local outbreak detection, which may reduce their reliability for long-term surveillance.

An additional, underused approach involves analyzing over-the-counter (OTC) product sales, such as thermometer sales, which can reflect self-treatment behaviors [15]. Since these purchases often precede formal medical care, anomalies in OTC sales can signal emerging population-level health events. To support early outbreak detection nationwide, the National Retail Data Monitor (NRDM) [16] was launched in December 2002 as a novel public health surveillance system. Operated by the University of Pittsburgh, the NRDM has collected anonymous sales data on selected OTC health care products, such as antipyretics (fever-reducing medications), cough and cold medications, and thermometers from more than 28,000 participating retail pharmacies, grocery stores, and mass merchandise outlets across the United States. The NRDM was developed to enhance public health capacity for syndromic surveillance, enabling rapid detection of unusual health events through deviations in consumer purchasing behavior. More than 800 public health officials in 49 states, the District of Columbia, and US territories have had access to NRDM through secure online portals [17], supporting them to track anomalies in consumer health behavior in near real time.

Since the launch of the NRDM, studies have been conducted to enhance its functionality from multiple perspectives. Methodological advances include the development of fast spatial and space-time scan algorithms and the integration of user feedback mechanisms [18]. Additionally, application-oriented studies have examined the correlation between OTC sales and health care use, including influenza-like illness (ILI) at urgent care centers [19]. Numerous studies have validated the value of NRDM in complementing traditional surveillance systems for investigations of gastrointestinal illness outbreaks—including those in the San Francisco Bay Area [20], and in New York City in the context of a massive power outage in August 2003 [21]. NRDM data have also been used to help detect spikes in unintentional poisonings [22], support syndromic surveillance during the San Diego wildfires in 2003 [23], and as a component of New York City's syndromic surveillance systems [24].

We previously developed ILI Tracker [25], a Bayesian surveillance method that uses emergency department (ED) data to estimate the daily frequency of multiple ILIs, including potential novel diseases. As an illustrative example, retrospective analysis indicated that applying ILI Tracker to 2014 data would have enabled early detection of an enterovirus D68 outbreak in Allegheny County [25].

Building on this foundation, we sought to determine whether prediagnostic, population-level signals—specifically, OTC product purchases—could support outbreak detection. To this end, we developed and evaluated a similar probabilistic modeling system that uses NRDM data to detect outbreaks of known ILI diseases. The system also seeks to identify unusual purchasing patterns that may indicate the onset of novel diseases by detecting statistically significant deviations in OTC product purchases relative to expected purchases for known disease models. We call this system NRDM Tracker. We evaluated the NRDM Tracker system on five years of real OTC data in Allegheny County.

The objectives of this study were to (1) evaluate whether OTC purchasing patterns can be used to estimate population-level ILI activity, (2) assess the agreement between NRDM-derived ILI estimates and ED-based ILI surveillance measures, and (3) determine whether anomaly detection methods applied to OTC sales data can identify unusual purchasing patterns associated with emerging disease outbreaks. We hypothesized that OTC purchasing patterns contain sufficient information to estimate population-level ILI activity and that model-derived ILI estimates based on OTC sales data would track temporal changes in population-level ILI activity well. We further hypothesized that OTC sales data would be correlated with ED-based ILI activity and that significant deviations from expected purchasing patterns could provide early signals of novel disease outbreaks.

## Methods

### Research Data

We retrieved OTC product sales for Allegheny County, Pennsylvania (270 stores) from the NRDM database, covering the period from June 1, 2016, to December 30, 2021. NRDM product codes were aggregated into 7 analytically defined OTC categories (Table 1). The full time series was partitioned into a training interval (June 1, 2016-May 31, 2019) and a held-out test interval (June 1, 2019-December 30, 2021). The training interval was used exclusively for model parameter estimation (refer to the *Model Development* section), whereas the test interval was reserved for out-of-sample model evaluation and

XSL•FO
RenderX

prospective abnormal event detection (refer to the subsequent sections under *Methods*).

**Table .** Seven over-the-counter (OTC) product categories derived from National Retail Data Monitor (NRDM) sales data collected from 270 retail stores in Allegheny County, Pennsylvania, United States (June 2016–December 2021).

| Category | Description |
|---|---|
| Cough or cold | All cough and cold related medications, including pediatric and adult formulations of liquids and tablets, bronchial remedies, chest rubs, nasal sprays, and throat lozenges. |
| Antifever adult | All products intended for adults that are taken orally for the relief of fever |
| Antifever pediatric | All products intended for children that are taken orally for the relief of fever |
| Baby or child electrolyte | Solutions of primarily electrolytes and glucose used for fluid replacement in children with dehydration; includes products in liquid and freezer pop form |
| Thermometer | All thermometers, designed for both pediatric and adult use, including electronic and "ear" (also known as tympanic membrane) thermometers used for health reasons; also includes nonintrusive fever detectors and replacement sheaths for electronic thermometers |
| Antidiarrheal | Products taken for the relief of diarrhea; all sizes and forms (tablets, liquids, etc); includes bismuth (Pepto Bismol and like products), attapulgite, subsalicylate, and loperamide hydrochloride products |
| Hydrocortisone product | Anti-inflammatory topical corticosteroids used to relieve itching rashes |

To support the method that we used for estimating parameters in the NRDM Tracker model, we derived the daily incidence rate of ILI in the population, which serves as the prior probabilities in the model. To do so, we obtained daily counts of ED encounters associated with ILI-related viruses in the region, including adenovirus, rhinovirus or enterovirus, influenza, human metapneumovirus (HMPV), parainfluenza (PIV), and respiratory syncytial virus (RSV). For each day, we calculated the proportion of encounters related to ILI among all ED encounters. ILI counts were identified based on either positive laboratory test results or relevant *ICD* (*International Classification of Diseases*) diagnosis codes (Multimedia Appendix 1). The participating EDs included (1) University of Pittsburgh Medical Center (UPMC) Presbyterian University Hospital, (2) UPMC Children's Hospital of Pittsburgh, (3) UPMC Shadyside, (4) McKeesport Hospital, and (5) UPMC Mercy Hospital. These 5 sites collectively represent a significant fraction (about 60%) of ED visits in Allegheny County and 30% - 40% of western Pennsylvania. The research data were sourced from the University of Pittsburgh Neptune Research Data Warehouse [26].

The NRDM and ED datasets share strong geographic and population overlap, as both focus on Allegheny County, Pennsylvania. We retrieved OTC sales data from 270 retail stores across the county, while the 5 EDs used for estimating prior disease probabilities also serve this region. The coverage of the NRDM for the Pittsburgh metropolitan statistical area, including Allegheny County, is 73% of all retail stores in the area. Although the datasets are not individually linked, their shared regional focus supports the use of ED-based ILI daily incidence estimates in helping model NRDM purchasing patterns.

## Model Development

Since many OTC products are used to relieve symptoms rather than treat specific diseases, we grouped conditions into two broad categories: (1) ILI diseases and (2) all other diseases, which we label as OTHER. The main abbreviations we used to describe our methods are summarized in Table 2.

XSL•FO
RenderX

**Table .** Mathematical notation used in the NRDM[a] tracker probabilistic surveillance model for estimating influenza-like illness activity from OTC[b] product sales.

| Symbols | Descriptions |
|---|---|
| D | All OTC sales data during the surveillance time period |
| D(p) | A single OTC product bought by a customer with purchase *p*; if a customer buys multiple products in one transaction, each product is treated as a separate purchase.<br>D(p)∈ {cough or cold,antifever for adult,antifever for pediatric,baby or child electrolytes,thermometers,antidiarrheal,hydrocortisones} |
| purd | Total number of OTC purchases on day *d* |
| Pd(D) | Probability of the observed data on day *d* |
| Pd(D(p)) | Probability of an individual purchase p on day d |
| dxi | Disease group *i*; $dx_1$ = influenza-like illness (ILI); $dx_2$ = diseases other than ILI (OTHER) |
| Pd(D(p),dxi) | The joint probability that a customer with a disease in group dxi makes purchase p on day d |
| Pd(D(p)\|dxi) | The conditional probability that a customer makes purchase p on day d, given they have a disease in group dxi |
| Pd(dxi) | Prior probability that an OTC-purchasing customer has a disease in group *i* on day *d* |
| Pd(dxi\|D(p)) | The posterior probability that a customer has a disease in group dxi given that they make purchase p on day d. |

[a]NRDM: National Retail Data Monitor.

[b]OTC: over-the-counter.

As described further in this study, we applied the expectation-maximization (EM) algorithm [27] (refer to Algorithms 1 and 2 in Multimedia Appendix 2) to estimate the conditional probabilities Pd(D(p)|dxi), where Pd(D(p)=productj|dxi=ILI) represents the probability a customer purchases product *j* on day *d* due to ILI either in that customer or in someone they are making the purchase for (eg, a family member). Pd(D(p)=productj|dxi=OTHER) denotes the corresponding probability for patients with conditions other than ILI.

In applying EM to estimate the conditional probabilities above, we made the following assumptions:

1. Time invariance: The conditional probabilities are constant across days, that is, Pd(productj|dxi) is the same for all *d*. This assumes that given a disease-group category (eg, ILI), the likelihood of purchasing a specific product remains stable over time. It is justified by the expectation that symptom-driven consumer behavior remains stable, especially when product availability and public health messaging are consistent. This assumption simplifies modeling by attributing temporal variation to disease-category daily incidence rather than to changes in individual purchasing behavior.
2. Product focusing: We only monitored the purchase of the product categories presented in Table 1.

The EM algorithm iteratively refines probability estimates through two main steps: the expectation step (E-step) and the maximization step (M-step).

In the E-step, the algorithm computes the posterior probabilities Pd(ILI|productj) and Pd(OTHER|productj) for each product *j* on day *d*, using the current estimates of P(productj|ILI) and P(productj|OTHER), along with the prior probabilities of ILI and OTHER on day *d* estimated from ED data (refer to details in the *Research Data* section).

In the M-step, the algorithm updates the conditional probabilities, P(productj|ILI) and P(productj|OTHER) by maximizing the expected likelihood. This is achieved by leveraging the weighted counts of product *j* purchases on day *d*, denoted as, Ndj, using the posterior probabilities obtained from the E-step.

The E-step and M-step are repeated iteratively until convergence is achieved—that is, until the maximum change in estimates of the 2 conditional probabilities falls below a predefined threshold, *tol*.

We used ED data in the Allegheny County region to estimate the priorprobabilities, Pd(dxi), used by the EM algorithm. To smooth the ED time series, we applied a centered 7-day moving average to the daily encounter counts. At the beginning and end of the series, where fewer neighboring values were available, a smaller window size (eg, 4 or 5 days) was used to compute the average. This adaptive window ensures that smoothing can still be applied at the edges without discarding data. Based on the resulting smoothed counts, we calculated daily prior probabilities for ILI and OTHER that were used by the EM algorithm.

### Estimates of Daily Disease Counts Using NRDM Data

After estimating the conditional probabilities P(productj|dxi), we derive the expected number of customers with disease group dxi on day *d*, denoted Ed(dxi), using equation 1. Specifically, Ed(dxi) is calculated as the sum of the posterior probabilities Pd(dxi|D(p)) across all purchases on day *d*. For each individual purchase *p*, the posterior probability is computed via Bayes' rule (equation 2), where the numerator is the joint probability, calculated as the product of the conditional probability of the purchase given the disease (as estimated via the EM algorithm) and the prior probability of the disease. The denominator normalizes this quantity by summing over the 2 disease group categories that we model.

In contrast to the EM training phase, where disease priors were learned from ED data, we fixed the priors at Pd(ILI)=0.05 and Pd(OTHER)=0.95 for each day during the calculation with equation 3 to focus the contribution of NRDM data in estimating daily disease patterns. These values are within the bounds of the probabilities for ILI and OTHER estimated from ED data during the training phase, during which the daily ILI daily incidence ranged from 0 to 0.06 and the daily OTHER daily incidence ranged from 0.94 to 1 (refer to the *Descriptive Statistics* section; Figure 1).

**Figure 1.** Estimated daily influenza-like illness (ILI) incidence rates derived from emergency department encounters at 5 hospitals in Allegheny County, Pennsylvania, United States, from June 2016 to December 2021 and used as disease priors in the NRDM Tracker model.

(1)Ed(dxi)=∑p=1purdPd(dxi|D(p))

(2)Pd(dxi | D(p))=Pd(D(p) | dxi)×Pd(dxi)∑k=12Pd(D(p) | dxk)×Pd(dxk)

### Derivation of the Likelihood of Daily Data

For each day *d*, we used a probabilistic metric, Pd(D), as an indicator of the presence of unusual purchases on that day. This metric represents the probability of the observed data on day *d* (ie, the number and types of OTC purchases on that day). We refer to this probability as the *daily likelihood*. Using equation 3, we estimate this quantity by multiplying the probabilities of all individual purchase events Pd(D(p)), assuming that these purd purchase events are independent. A purchase behavior typically reflects a customer's (or their household member's) illness. However, the specific underlying disease is not recorded in the NRDM database. Therefore, for each purchase behavior, we sum the joint probabilities, Pd(D(p),dxi), across the 2 disease groups that we modeled.

[illegible]

Each joint probability is computed as the product of the prior probability of disease dxi on day *d*, denoted as Pd(dxi), and the conditional probability Pd(D(p)|dxi), which is the probability of observing the purchase behavior given the presence of disease group dxi.

To estimate these conditional probabilities in the model training period, we applied the EM algorithm, as discussed in the *Model Development* section. As mentioned, when training the NRDM Tracker model, we used the daily incidence of diseases in EDs in the same region on day *d* to estimate the prior probability, Pd(dxi). When applying the model to monitor for disease outbreaks, we used a uniform prior for Pd(dxi), Pd(ILI)=0.05 , Pd(OTHER)=0.95, which does not require having access to ED data.

### Derivation of a Normalized Likelihood of Daily Data

We also derive the following normalized likelihood (**Equation 4**), which is the geometric mean of the daily likelihood across all purchases on day *d*:

(4)Gd(D)=Pd(D)purd,

where purd is the total number of the products purchased in the 7 OTC categories on day *d*. Gd(D) reflects the (geometric) average likelihood of individual product purchases. Changes in the unnormalized likelihood, Pd(D), may be due to changes in the relative distribution of the products being sold, the number of products being sold, or both. In contrast, changes in Gd(D) are only due to changes in the relative distribution of the products being sold.

### Detection and Characterization of a Putative Outbreak of a Novel Disease

This section describes the methods that NRDM Tracker applies to monitor a test set of NRDM data for disease outbreaks. It uses the log of the likelihood given by equation 3 to look for low values that may indicate an outbreak. When values are low, it can analyze the data at the product level to look for patterns that may indicate which product categories are being influenced by a putative outbreak; such a characterization may suggest the type of outbreak that is occurring. In the remainder of this section, we discuss how we derive *P* values at the product level.

For each product *j*, we obtain the daily sales count ndj for day *d* and computed a right-sided *P* value based on the empirical distribution of daily sales during a control period from day *d*-38 to day *d*-8, assuming a normal distribution. Approximately 69% (4326/6284) of Shapiro-Wilk normality tests [28] passed the normality check, indicating that most control period count distributions were consistent with a normal distribution.

Since a *P* value is calculated for each day, over many monitored days, we applied the Benjamini-Hochberg procedure [29] to control the false discovery rate (FDR) at a significance level of 0.05. Specifically, we used the multiple tests function from the Python statsmodels.stats.multitest module (statsmodels 0.15.0, 2024) with the method='fdr_bh' option to correct for multiple hypothesis testing. This method adjusts raw *P* values by scaling each value according to its rank and the total number of tests *m*. Refer to equation 5, where *m* is 6284 in our experiment, pj are raw *P* values, and the term *j* is the rank of the *P* value in ascending order. A reverse cumulative minimum is then applied to ensure monotonicity across the adjusted *P* values (equation 6), as described by Dudoit et al [30] and implemented in the *Statsmodels* package. These steps ensure that any day with an adjusted *P* value at or below .05 is considered a statistically significant anomaly, while the expected proportion of false discoveries is controlled. Importantly, the adjusted *P* values, qk, are guaranteed to be nondecreasing with respect to the ordered raw *P* values.

(5)$\tilde{p}_j = \min(m \times p_j / j, 1)$

(6)$q_k = \min(\tilde{p}_j)$ and $j \geq k$

### Ethical Considerations

The research protocol of the study described in this paper was approved by the institutional review board (IRB) of the University of Pittsburgh (study 20030193). As no patients were directly enrolled in this study and no compensation was provided, the IRB granted a waiver of informed consent. The NRDM dataset contains only aggregated purchase counts and does not include any individual-level purchase information. For the ED encounter data, a UPMC-approved honest broker deidentified the records to satisfy the requirements for a limited data set before distribution to our research team.

## Results

### Overview

This section presents the performance and behavior of NRDM Tracker. We begin by summarizing descriptive statistics of daily OTC product sales across 7 symptom-related categories (*Descriptive Statistics* section). Next, we describe the estimation of model parameters using the EM algorithm (*Model Parameters* section). We then evaluate the model's ability to detect population-level anomalies during the COVID-19 pandemic using NRDM data (*Detection of COVID-19* section). Finally, we assess the statistical significance of daily deviations in product sales across individual categories to identify which product categories are influenced by a putative outbreak (refer to the *Detection of COVID-19* section).

### Descriptive Statistics

Table 3 lists descriptive statistics of the daily counts of the 7 categories from 274 stores in Allegheny County, PA from June 1, 2016, to December 30, 2021. The median of the daily OTC sales count over the 7 categories is 4062, with a wide range from 259 to 15,979, indicating substantial daily variation. The cough or cold category has the highest average daily sales (3168), accounting for most of the total OTC purchases recorded in NRDM. Moderate-sale categories include antifever for adult, baby or child electrolytes, and antidiarrheal. Antifever for pediatric, hydrocortisones, and thermometers have relatively low average daily sales. Most categories show right-skewed distributions (mean>median), suggesting occasional sales surges. The large variances (especially in total and cough or cold categories) indicate irregular and potentially seasonal demand.

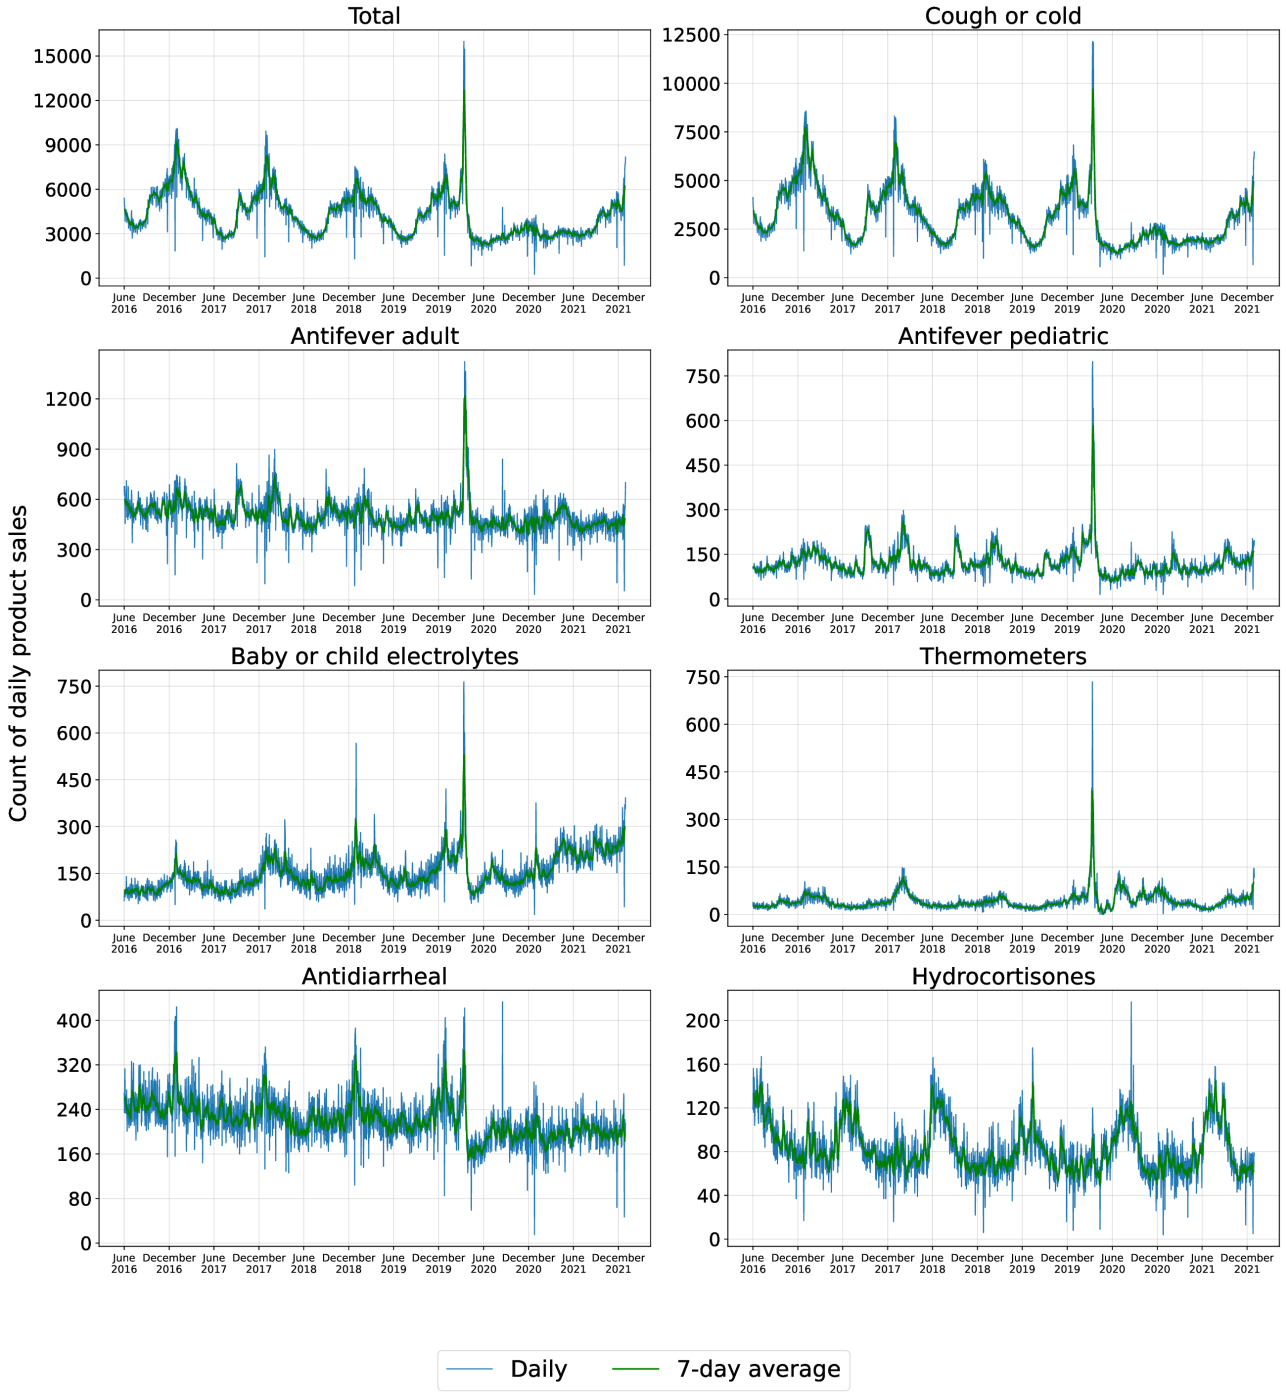
XSL•FO
RenderX

**Table .** Summary statistics of daily over-the-counter (OTC) product sales across seven product categories obtained from the National Retail Data Monitor (NRDM) in Allegheny County, Pennsylvania, USA, from June 1, 2016, to December 30, 2021.

| Category | Mean (SD)[a,b] | % of Total[a] | Median (IQR) | 5% quantile[a] | 95% quantile[a] | Min | Max |
|---|---|---|---|---|---|---|---|
| Cough or cold | 3168 (1408) | 71.8 | 2961 (1983 - 4031) | 1531 | 5652 | 172 | 12,149 |
| Antifever for adult | 503 (100) | 12.7 | 495 (450 - 546) | 385 | 650 | 32 | 1422 |
| Antifever for pediatric | 121 (49) | 2.9 | 112 (93 - 136) | 70 | 198 | 15 | 798 |
| Baby or child electrolyte | 152 (62) | 3.8 | 139 (108 - 187) | 79 | 256 | 18 | 764 |
| Thermometer | 43 (33) | 1 | 36 (26 - 52) | 17 | 88 | 0 | 734 |
| Antidiarrheal | 222 (41) | 5.6 | 218 (195 - 243) | 165 | 291 | 15 | 433 |
| Hydrocortisone product | 83 (24) | 2.2 | 79 (66 - 97) | 52 | 130 | 4 | 217 |
| Total | 4291 | —[c] | — | — | — | — | — |

[a]Percentages represent the proportion of total sales for each product category and are rounded to one decimal place; other values are rounded to integers.

[b]Total of all categories=4291.



[c]Not applicable.

Figure 2 illustrates seasonal patterns in OTC product sales over 5 years. Both total and “cough or cold” categories exhibit strong seasonal patterns, with recurring peaks during the winter months. A prominent spike in early 2020 likely corresponds to the onset of COVID-19, followed by a dip and gradual return to seasonal trends.

XSL•FO
RenderX

**Figure 2.** Temporal trends of daily over-the-counter (OTC) product sales recorded in the National Retail Data Monitor (NRDM) from 270 retail stores in Allegheny County, Pennsylvania, United States, from June 2016 to December 2021.

Sales trends among other product categories reveal varying degrees of seasonality and pandemic impact. Among antifever products, the adult antifever category shows relatively stable daily sales with modest fluctuations until a sharp surge in 2020, a pattern likely explained by the dual role of acetaminophen, ibuprofen, and related medications as both antipyretics and analgesics, which contributes to their steady baseline demand. The pediatric antifever category follows a similar seasonal trend but at a lower scale. Cough or cold products dominate in both volume and seasonality. Baby or child electrolytes show periodic increases with peaks in the winter. Antidiarrheal sales exhibit moderate daily variation with peaks around December. The peaks in hydrocortisone sales are less pronounced but show a consistent seasonal pattern, with increased use in warmer months, plausibly due to higher incidence of skin irritation, insect bites, and sun-related conditions. Thermometer sales remain low at baseline but exhibit dramatic, event-driven spikes—particularly in early 2020—likely due to increased public concern during the onset of the COVID-19 pandemic.

Figure 1 illustrates the temporal evolution of the estimated daily incidence rate of ILI (used as the prior probability in the model), derived from ED case counts for adenovirus, rhinovirus or enterovirus, influenza, HMPV, PIV, and RSV. The series exhibits clear seasonal peaks occurring annually—typically during the winter months (eg, early 2017, early 2018, spring

XSL•FO
RenderX

2019, and early 2020)—consistent with typical seasonal trends of respiratory viruses in this region. A pronounced decline is observed in 2020 and 2021, reflecting reduced ILI-related ED visits during the initial phase of the COVID-19 pandemic in the United States. A modest resurgence is seen in late 2021, coinciding with the return of seasonal respiratory virus activity.

## Model Parameters

Using the EM Algorithm, we estimated the conditional probabilities P(productj|ILI) and P(productj|OTHER). The EM algorithm converged after 36 iterations. Table 4 presents the estimated conditional probabilities, indicating the likelihood that each product category is purchased given an ILI-related or OTHER encounter. These values reflect how specific each product is to ILI activity. Cough or cold medications show a notably higher probability under ILI (0.792) than under OTHER (0.695), suggesting strong relevance to ILI-related symptoms. In contrast, the other products have lower probabilities for ILI than for OTHER, indicating they are more likely to be associated with non-ILI conditions. These conditional probabilities are central to inferring ILI activity from purchase patterns and help distinguish symptom-specific products from those with more general therapeutic use.

**Table .** Conditional probabilities estimated by the EM algorithm.

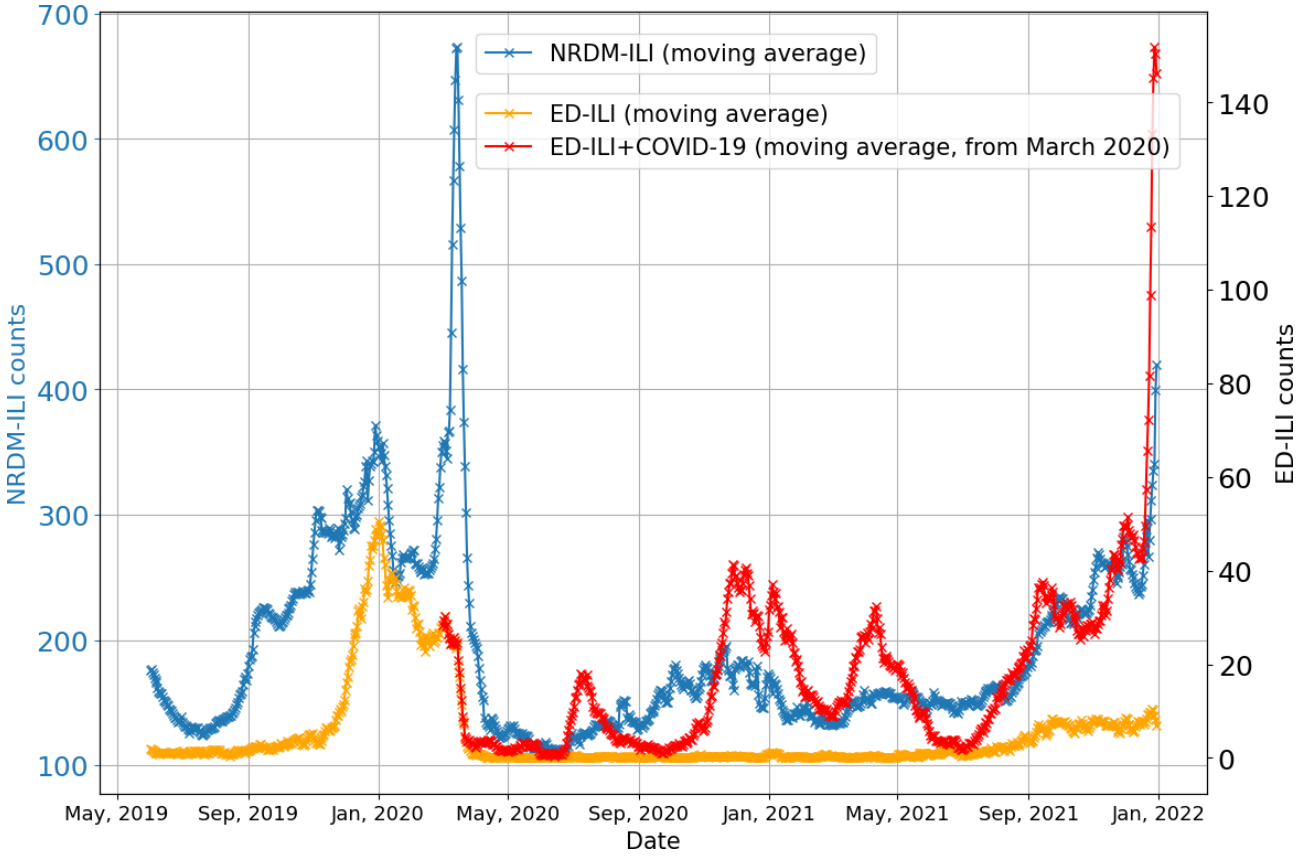
| Category | P(productj\|ILI)[a] | P(productj\|OTHER)[a] |
|---|---|---|
| Cough or cold | 0.792 | 0.695 |
| Antifever for adult | 0.095 | 0.142 |
| Antifever for pediatric | 0.024 | 0.031 |
| Baby or child electrolyte | 0.026 | 0.032 |
| Thermometer | 0.008 | 0.008 |
| Antidiarrheal | 0.043 | 0.064 |
| Hydrocortisone | 0.013 | 0.029 |

[a] Values are rounded to three decimal places.

To assess the robustness of the assumption of time-invariant conditional probabilities, we conducted a sensitivity analysis using time-varying conditional probability tables (CPTs) estimated with a rolling 12-month EM framework and weekly updates (Multimedia Appendix 3). As illustrated in Figure S1 and Table S2 in Multimedia Appendix 3, the estimated CPTs exhibit moderate temporal variation, reflecting changes in product use patterns and disease presentation over time. However, when these dynamic CPTs were incorporated into the NRDM-ILI estimation pipeline, the downstream impact was limited. The resulting NRDM-ILI time series closely matched those obtained using constant CPTs (Figure S2 in Multimedia Appendix 3), with nearly identical correlations with ED-ILI (0.6642 vs 0.6599). These findings suggest that, although conditional probabilities are not constant, the assumption of time-invariant CPTs is reasonably robust in this setting, and the primary conclusions of the model are not very sensitive to this assumption.

Although fever is a defining symptom of ILI, antifever medications show relatively lower conditional probabilities under ILI compared with cough or cold medications. This likely reflects differences in product use behavior rather than inconsistency with clinical definitions. Similar patterns are observed for other product categories, including those associated with ILI symptoms, where medications that are less specific to respiratory illness tend to show weaker associations. For example, thermometers, which are used for general fever monitoring rather than specifically for respiratory illness, show very low probabilities under both ILI and OTHER. These patterns are consistent across both the main analysis and the supplementary sensitivity analysis (Multimedia Appendix 3).

## Detection of COVID-19



Using equations 1 and 2, the NRDM Tracker calculated the expected counts of *ILI* from the NRDM data for the period from June 1, 2019, to December 30, 2021. The NRDM model was trained using data from June 1, 2016, to May 31, 2019, to estimate the CPTs; therefore, this latter period represents out-of-sample model performance.

Figure 3 illustrates the moving averages of those expected ILI counts in blue. The yellow curve shows *ILI* counts derived from the ED cases for the following viruses: adenovirus, rhinovirus or enterovirus, influenza, HMPV, PIV, and RSV, and shows strong temporal alignment with the curve in Figure 1, which depicts daily ILI priors. A disease caused by 1 of these viruses was considered present if a patient had a positive laboratory test result for the virus (eg, a positive PCR [polymerase chain reaction] test for influenza) or an *ICD* code indicative of the infection (listed in Multimedia Appendix 1). These ED-based ILI tests and diagnoses excluded COVID-19 cases, which emulates the situation in which a novel disease may occur before it is explicitly identified and tested for. The Pearson correlation coefficient between 2 time series shown in blue and yellow is 0.66.

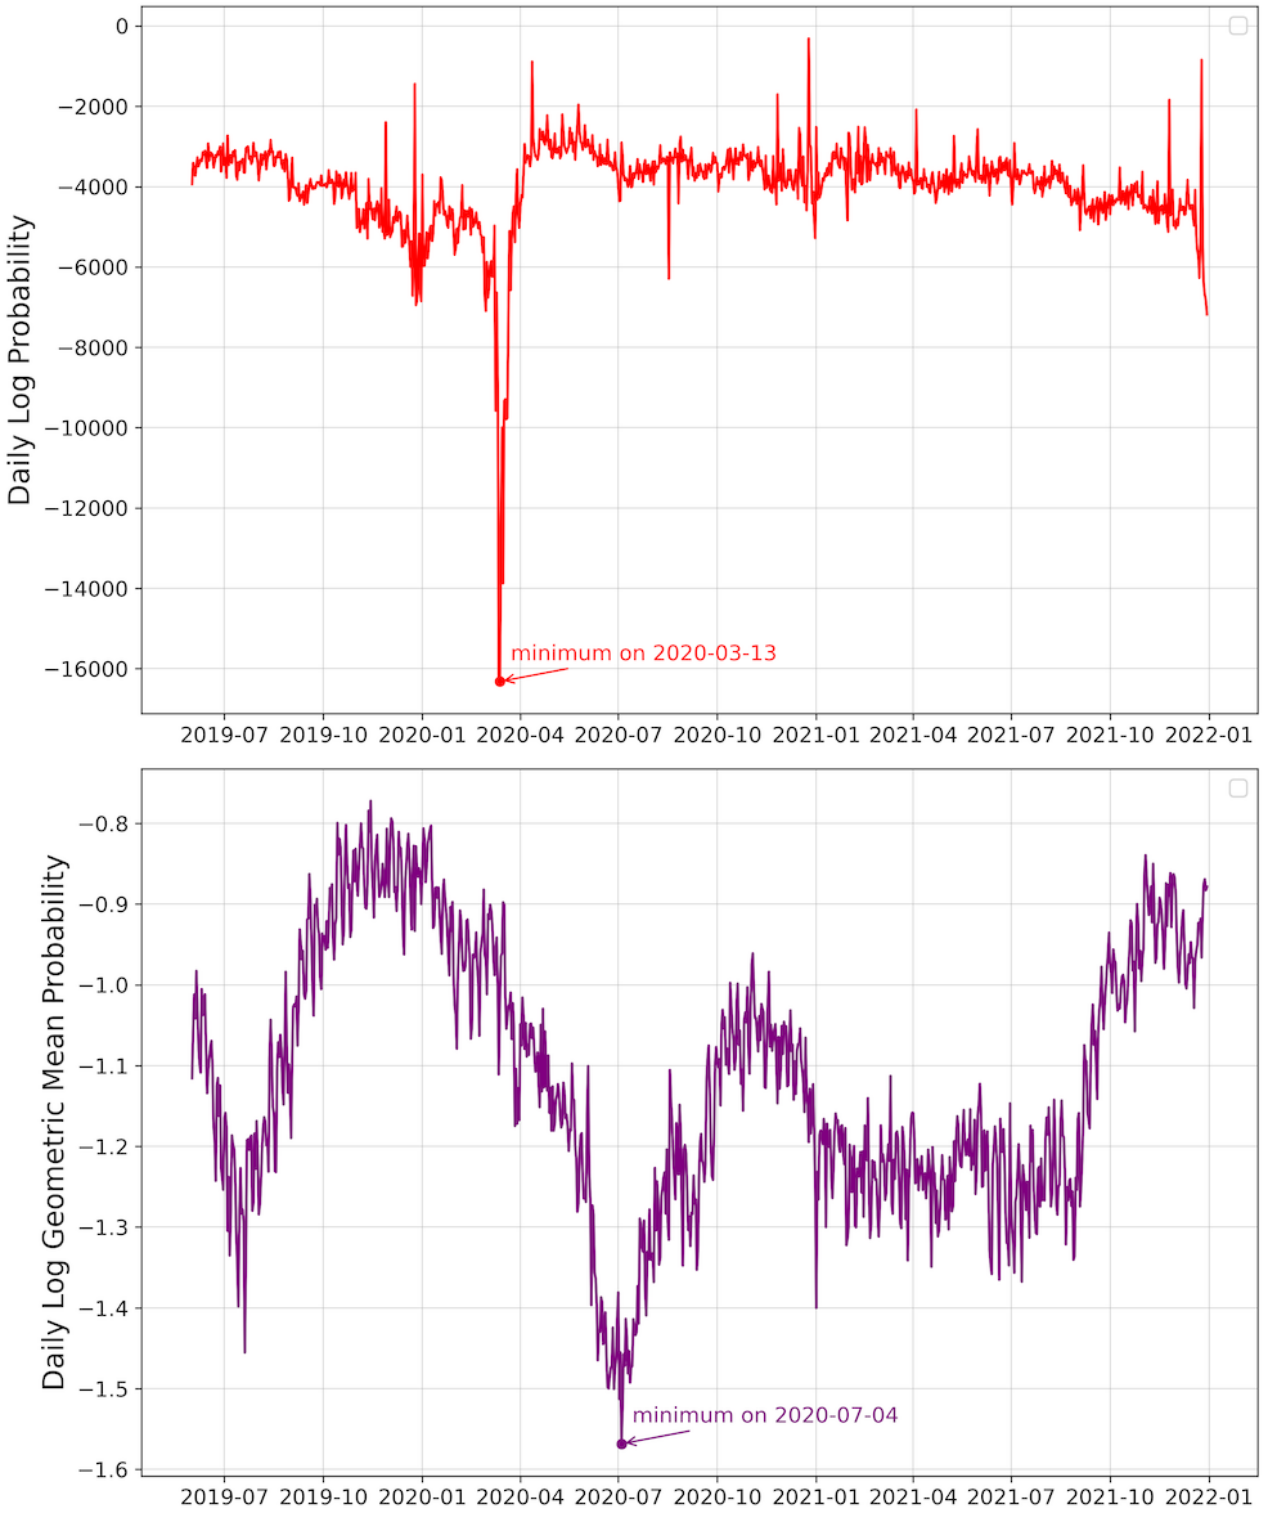
**Figure 3.** NRDM Tracker–estimated influenza-like illness (ILI) counts derived from over-the-counter (OTC) product sales (blue), emergency department (ED)–derived ILI counts based on positive lab*oratory* results and relevant *ICD* (*International Classification of Diseases)* codes for selected respiratory viruses (yellow; see text), and ED-derived counts that include both ILI and COVID-19 cases (red) in Allegheny County, Pennsylvania, United States, during the test period (June 2019-December 2021).

The peak day of the NRDM-estimated ILI counts is March 13, 2020 (based on the underlying data, although not perfectly aligned with the moving average curve in Figure 3), coinciding closely with the clinical onset of the COVID-19 in Allegheny County. Because NRDM-ILI reflects ILI activity inferred from consumer purchasing behavior, the peak on March 13 is likely due to precautionary purchasing triggered by widespread media coverage and growing public concern about COVID-19. The ILI counts from ED data have a peak on January 4, 2020 (not exactly aligned with the moving average curve), which corresponds to increased influenza and RSV activity observed in our ED data in late 2019 and in January and February 2020. A corresponding increase is seen in the NRDM signal during that period as well (Figure 3, blue curve).



In addition, Figure 3 includes a red curve representing ED-derived counts of ILI and COVID-19 beginning in March 2020, corresponding to the initiation of COVID-19 testing in Allegheny County. As COVID-19 subsequently spread throughout the county, it became the dominant respiratory infectious agent, while influenza and RSV cases declined sharply. Consequently, the NRDM-ILI trend (blue curve) began to align more closely with the ED-derived counts that include COVID-19 (red curve), rather than the ED counts that do not (yellow curve).

Figure 4 contains 2 plots displaying the daily log-likelihood of the OTC data computed by NRDM Tracker to monitor for unusual data patterns that may indicate the outbreak of a novel disease. The top panel shows the daily log-likelihood. A prominent drop is visible on March 13, 2020. Interestingly, the top panel also shows sharp declines on other dates, such as July 2020, suggesting potential anomalies in purchasing patterns. The bottom panel depicts the normalized daily log-likelihood, computed as the geometric mean of category-level probabilities. This measure indicates whether there are changes in the relative proportions of product category purchases. The normalized likelihood curve exhibits seasonal patterns and a sustained decline in mid-2020, followed by gradual recovery through 2021. The start of the COVID-19 outbreak does not appear to be associated with a strong change in the relative purchase of product categories, and thus, the prominent drop in the red curve in Figure 4 was driven by spikes or drops in total purchase counts rather than a shift in product mix.

**Figure 4.** Daily log-likelihood of observed over-the-counter (OTC) purchasing patterns (top) and normalized log-likelihood (bottom) estimated by the NRDM tracker surveillance model using OTC product sales from Allegheny County, Pennsylvania, United States, during the test period (June 2019-December 2021). Lower values indicate greater deviation from expected purchasing patterns and may suggest unusual population-level health activity.

Using the Benjamini-Hochberg FDR procedure, we computed the adjusted *P* values for the daily counts of product sales for each of the 7 OTC categories. Figure 5 shows the time series of FDR-adjusted *P* values on a logarithmic scale, with the red dashed line indicating the significance threshold at *P*=.01. Sharp drops in *P* values—particularly around March 2020—are visible across all categories, reflecting significant deviations in product purchasing behavior during the early phase of the COVID-19 pandemic. Several other spikes and dips are also observed in late 2020 and late 2021, some of which may correspond to the resurgence of the COVID-19 pandemic due to evolving variants of SAR-CoV-2.

**Figure 5.** False discovery rate (FDR) adjusted *P* values for daily anomalies in over-the-counter (OTC) product sales across seven monitored product categories in Allegheny County, Pennsylvania, United States, during the test period (June 2019-December 2021). Values below the significance threshold (0.01) indicate statistically significant deviations from expected purchasing patterns detected by the NRDM Tracker system.

## Discussion

### Principal Findings

This paper investigates the potential for NRDM Tracker, using OTC data, as a tool for public health surveillance and early outbreak detection. By leveraging OTC product sales and applying a probabilistic modeling approach, we were able to estimate daily ILI activity and identify abnormal population-level purchasing patterns. The EM-based algorithm estimated conditional probabilities that distinguish ILI-related purchasing behavior from that associated with other health conditions. The resulting *ILI* estimates from NRDM data exhibited moderately strong correlation ($r$=0.66) with ILI-related ED visits, which provides support for the model's alignment with measurable clinical rates of *ILI* disease in the region.

### Interpretation of Findings and Comparison With Previous Work

Our findings indicate that the NRDM-based ILI estimates, derived from OTC purchasing patterns, can capture public behavioral responses to disease outbreaks. These responses likely include purchases of cough and cold medications, antipyretics, and thermometers, even in the absence of corresponding clinical ILI encounters. Such dynamics could explain the divergence between the NRDM and ED curves in late 2019 and very early 2020, when NRDM estimates rose sharply while ED diagnoses for ILI remained comparatively stable. In general, while there is a close correspondence between the NRDM and ED curves in Figure 3, it is apparent that they are at times different, with an NRDM-derived estimate of increased ILI counts sometimes preceding the signal from ED data.

It is important to note that ED-based ILI surveillance, while widely used, may underestimate the true burden of ILI in the population [31], as many individuals with mild symptoms do not seek care in EDs. As a result, ED-derived ILI counts may primarily reflect more severe cases and may lag behind broader community-level disease activity. This limitation may help explain some of the observed differences between NRDM-based estimates and ED-based ILI signals. In particular, OTC purchasing behavior may capture earlier or milder symptom responses in the population, such as self-treatment before seeking professional medical care. A previous study [32] has noted temporal lags between community-level infection trends and subsequent increases in health care use, including ED visits and hospitalizations. In this context, the NRDM-based signals observed in this study may reflect earlier-stage or less severe disease activity, complementing ED-based surveillance. Together, these findings suggest that NRDM-based and ED-based estimates capture complementary aspects of disease activity, and that combining these signals may provide a more comprehensive assessment of population-level ILI than either source alone. Although fever is a defining symptom of ILI, antifever medications show a relatively weaker association with ILI activity compared with cough or cold medications in our analysis. This likely reflects differences in product use behavior rather than inconsistency with clinical definitions. Antifever medications are commonly used across a wide range of conditions and may already be available in households, reducing the need for purchase during illness episodes. In addition, OTC purchasing behavior may capture less severe cases of ILI, where individuals may not require or choose to take antipyretic medications, whereas ED-based surveillance is more likely to reflect more severe cases, potentially with higher fever. Similar patterns are observed for other general-purpose products, which tend to show weaker associations with ILI compared with more symptom-specific medications.

The NRDM Tracker system also derived daily likelihoods (in log form) of observed sales patterns as an overall measure of how well its model fit the OTC data. If the log-likelihood value on a given day is very low, relative to the values on previous days, it suggests the possibility of an outbreak. If so, those product categories with low $P$ values are likely contributing to the low log-likelihood. Our results suggest that likelihood-based signals may provide an early indication of abnormal health-related activity. The sharp drop in log-likelihood observed in March 2020 aligns well with the initial COVID-19 outbreak in the United States. Importantly, our right-tailed $P$ value framework—combined with multiple comparison correction—allowed for detection of statistically significant anomalies across multiple product categories. This analysis provides insights into the product sales that drive the detection of an anomaly.

Compared with previous studies that primarily examined associations between OTC sales and health care use [19,33] or evaluated NRDM for specific outbreak investigations [20,21,23,24], our study extends this body of work by developing a probabilistic surveillance framework capable of both estimating population-level ILI activity and identifying statistically significant anomalies that may indicate emerging or unexpected disease activity. Although previous studies have demonstrated that OTC purchasing data collected through NRDM can provide complementary syndromic signals of infectious disease activity [19,23,24], these studies have primarily focused on evaluating relationships with known clinical outcomes or detecting predefined outbreak events. In contrast, the NRDM Tracker presented in this paper uses probabilistic modeling of product category–specific purchasing patterns to continuously estimate ILI activity and detect statistically significant deviations from expected behavior, providing a framework that may support both seasonal disease monitoring and early identification of abnormal health-related signals potentially associated with emerging infectious disease activity.

### Limitations

There are several limitations of our approach. First, NRDM sales data do not directly record patient diagnoses, making it challenging to validate findings against gold-standard clinical data without assumptions. Second, behavioral factors may influence OTC purchasing patterns independently of underlying disease activity. For example, during the early phase of the COVID-19 pandemic, widespread public concern and media coverage likely contributed to "panic purchasing" of symptom-related products such as fever-reducing medications and thermometers, leading to transient spikes in sales that may

XSL•FO
RenderX

not directly reflect true disease incidence. In addition, changes in supply chains, product availability, and public health advisories—both historically and prospectively—may alter purchasing behavior over time. Public statements or widely disseminated health communications, as for example, those related to the safety of specific medications, may also influence consumer behavior and health care–seeking patterns. These factors may introduce deviations in observed OTC signals that are not directly attributable to disease dynamics, potentially leading to false-positive signals of outbreaks. Finally, our modeling assumes stable conditional probabilities over time, which may not hold true under significant shifts in disease presentation or consumer behavior. This limitation could be attenuated by periodically updating the conditional probabilities.

Taken together, these limitations point to challenges that remain to be addressed in future work. Future research may also enhance the current work by incorporating additional data sources (eg, participatory surveillance systems [9,11,12], social media signals [34,35], and other digital epidemiologic data streams [36]) and by applying adaptive models that account for evolving behaviors and changing disease dynamics [37]. These directions are consistent with recent advances in AI [38] for integrating heterogeneous data sources to improve infectious disease surveillance and epidemic modeling [39].

## Conclusions

In summary, our results provide support that NRDM-based data, when paired with probabilistic modeling and anomaly detection techniques, may provide an effective supplement to traditional disease monitoring systems. In particular, the observed alignment between NRDM-derived ILI estimates and ED-reported ILI cases, along with the detection of known public health events (eg, COVID-19 onset), support the system's potential for early detection of seasonal disease activity and for identifying anomalies that may be associated with novel disease outbreaks. By identifying significant deviations in symptom-related OTC product sales, the system may offer timely public health insights that could support outbreak monitoring and response. Continued refinement and integration with other data sources and modeling frameworks may further strengthen the role of OTC data in the national biosurveillance ecosystem.

## Acknowledgments

The authors declare the use of generative AI (GenAI) in the research and writing process. According to the GAIDeT taxonomy (2025), the following tasks were delegated to GenAI tools under full human supervision: proofreading and editing. The GenAI tool used was ChatGPT (OpenAI). Responsibility for the final manuscript lies entirely with the authors. GenAI tools are not listed as authors and do not bear responsibility for the final outcomes. ## Abstract

**Background:** Drug-induced parkinsonism (DIP) predominantly occurs due to antipsychotic drugs (APDs) blocking dopamine D2 receptors ($D_2$Rs). However, in vitro assays often fail to fully reflect real-world variability in clinical outcomes.

**Objective:** This study aimed to evaluate whether in vitro pharmacological metrics correspond to real-world risk of DIP associated with APD use.

**Methods:** For 8 commonly used APDs, key in vitro parameters—including inhibition constants ($K_i$) of $D_2$Rs and the serotonin 2A receptor, reversal rate ($K_r$) of $D_2$Rs, and blood-brain barrier (BBB) penetration rate—were compiled to construct 6 composite DIP risk metrics. The real-world DIP risk was assessed using the Seoul National University Hospital common data model (2002 - 2021). APD users were matched 1:1 to selective serotonin reuptake inhibitor users using propensity score matching, and Cox proportional hazard regression was performed to estimate the hazard ratios (HRs) for DIP risk. Correlation between each in vitro metric and real-world DIP risk was evaluated using logarithmic regression models.

**Results:** Among 44,664 patients from 8 matched cohorts, haloperidol showed the highest DIP risk (HR=4.56, 95% CI 2.29 - 9.07), whereas aripiprazole exhibited the lowest risk (HR=2.11, 95% CI 1.56 - 2.86). Metric 4 ($pK_r$ × BBB penetration rate) exhibited the strongest correlation with real-world DIP risk ($R^2$=0.95). The correlation decreased when aripiprazole, a partial $D_2$R agonist, was included in the analysis ($R^2$=0.58).

**Conclusions:** Integrating receptor-binding kinetics with BBB penetration may provide an in vitro framework that reflects real-world variation in DIP risk among $D_2$R-antagonizing APDs. These findings support the relevance of combining kinetic and central nervous system exposure parameters for early safety evaluation.

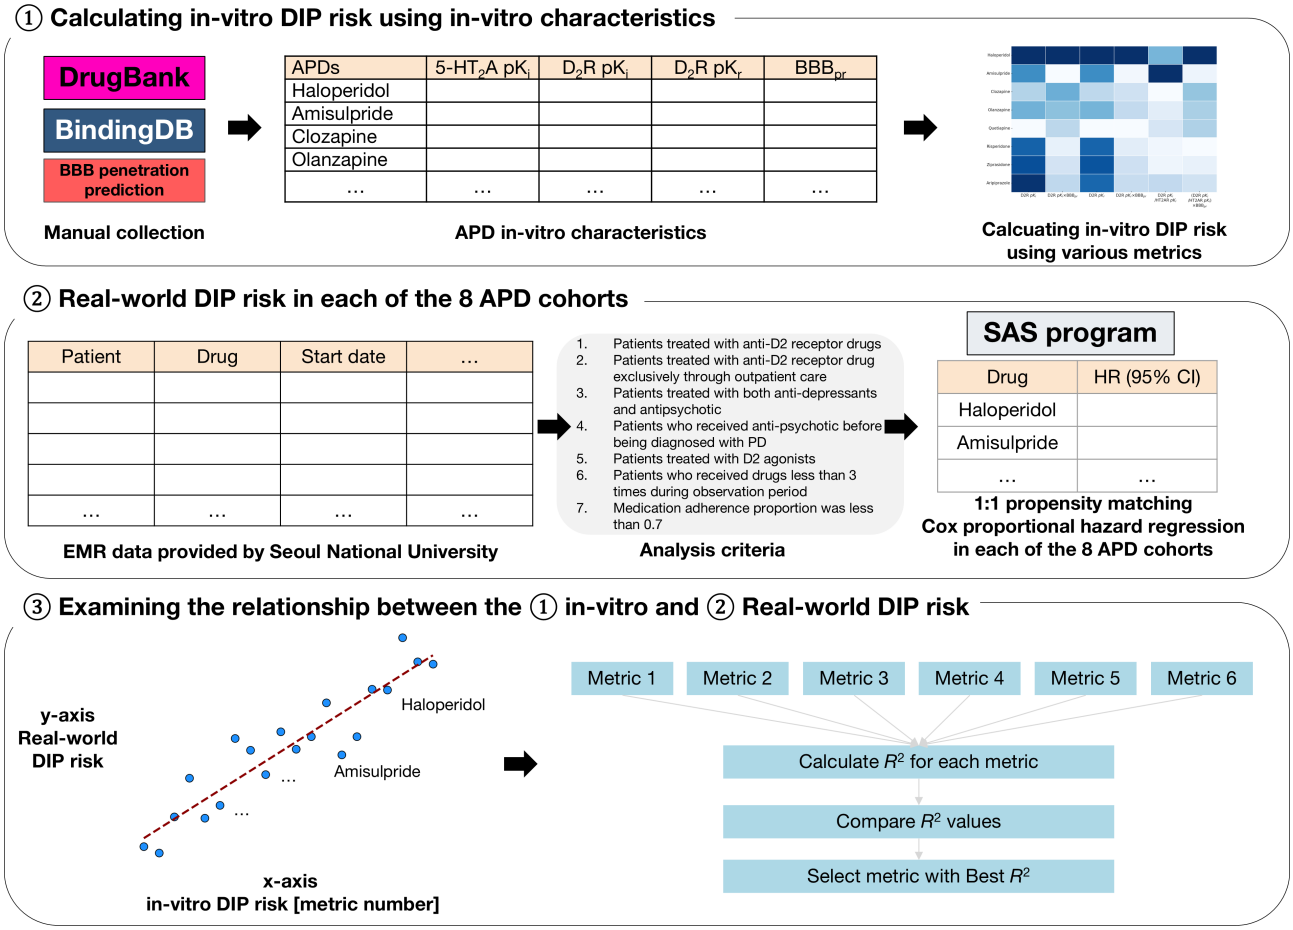
drug-induced parkinsonism; antipsychotic drug; binding affinity; dopamine D2 receptor; blood-brain barrier

## Introduction

The pharmacological action of drugs generally occurs through receptor binding, and side effects are often the consequences of these interactions [1]. To understand how drugs function and anticipate their potential side effects, extensive in vitro experiments on drug-receptor interactions are conducted from the early stages of drug development. However, relying on in vitro analysis, often referred to as “test tube experiments,” makes it difficult to predict how often side effects will occur in real-world patients [2,3]. This translational gap has highlighted the need for mechanistically informed models that integrate

XSL•FO
RenderX



binding kinetics and pharmacokinetic factors to better approximate real-world safety outcomes [3].

Drug-induced parkinsonism (DIP), predominantly caused by antipsychotic drugs (APDs), is one of the most common forms of secondary parkinsonism and remains a clinically significant dose-limiting adverse effect [4]. DIP arises primarily from dopamine D2 receptor ($D_2R$) blockade within the nigrostriatal pathway, leading to symptoms of movement disorders such as muscle stiffness, slow movements, and tremors [5-10]. Because these symptoms can impair quality of life and daily functioning, understanding the pharmacologic determinants that underlie variability in DIP risk across APDs has become an important clinical and research priority [11,12].

In efforts to explain interdrug differences, the inhibition constant ($K_i$) and dissociation constant ($K_d$) have been widely used as a key measure for $D_2R$ blockade; lower values indicate stronger binding to $D_2Rs$ at equivalent drug concentrations [13]. Sykes et al [14] further expanded this framework by demonstrating that receptor-rebinding kinetics—reflecting the probability that a ligand re-engages adjacent receptors after dissociation—can also account for differences in extrapyramidal symptom liability. Other studies have implicated the serotonin 2A receptor ($5\text{-}HT_{2A}R$) in DIP modulation, with newer APDs often exhibiting a higher $5\text{-}HT_{2A}R$–to-$D_2R$ affinity ratio associated with lower DIP risk [15-17]. While binding kinetics contributes to understanding variation in APD-related neurological syndromes, additional pharmacological factors also appear to play important roles. A recent meta-analysis demonstrated that the dose of APDs and $D_2R$ occupancy correlate with extrapyramidal symptom onset, indicating that in vivo exposure should be considered alongside in vitro parameters [18,19]. Furthermore, blood-brain barrier (BBB) permeability, which regulates central nervous system (CNS) drug exposure and can change with certain clinical conditions, may also influence the clinical expression of $D_2R$ blockade [20].

These prior observations collectively suggest that DIP risk reflects an interplay among receptor-binding kinetics, CNS pharmacokinetics, and dose-response. However, despite extensive research on DIP, its precise mechanism and the quantitative translation between in vitro pharmacological parameters and real-world DIP risk remain unclear [6,7,21]. Therefore, this study aimed to evaluate whether specific in vitro pharmacological metrics correspond to variation in real-world DIP risk, with a particular focus on $D_2R$-antagonizing APDs. First, we derived multiple candidate in vitro DIP risk metrics based on receptor-binding and pharmacokinetic parameters of APDs (Figure 1). Second, using longitudinal real-world data (RWD), we estimated the DIP risk associated with commonly used APDs. Finally, we assessed the extent to which each in vitro metric correlated with the observed real-world DIP risk.

## Methods

### Study Design and Overview

This study consisted of two components: (1) an assessment of in vitro pharmacological parameters of APDs related to DIP and (2) a retrospective cohort study evaluating the effect of APDs on the risk of DIP using the common data model (CDM) of Seoul National University Hospital. We subsequently examined the relationship between in vitro metrics and the real-world DIP risk. This study was reported in accordance with the Strengthening the Reporting of Observational Studies in Epidemiology guidelines [22].

### In Vitro DIP Risk Metrics

The key parameters of the APDs used to calculate the in vitro DIP risk were the $pK_r$ values for $D_2$Rs and 5-$HT_{2A}$R collected from DrugBank and BindingDB [23-25]. The receptor reversal rate ($K_r$) values for $D_2$Rs as suggested by Sykes et al [14] were also obtained. Considering that the primary site of action for APDs is within the CNS, the BBB penetration rate of each APD was considered an adjustment factor [26]. The 6 main metrics for the in vitro DIP risk were as follows:

- Metric 1: $pK_i$ for $D_2$Rs
- Metric 2: ($pK_i$ for $D_2$Rs) × BBB penetration rate
- Metric 3: $pK_r$ for $D_2$Rs
- Metric 4: ($pK_r$ for $D_2$Rs) × BBB penetration rate
- Metric 5: ($pK_i$ for $D_2$Rs) / ($pK_i$ for 5-$HT_{2A}$R)
- Metric 6: ($pK_i$ for $D_2$Rs) / ($pK_i$ for 5-$HT_{2A}$R) × BBB penetration rate

All the data were collected through a manual search conducted by the research team. When multiple values were reported, the geometric mean was used as an integrated value.

### RWD Source

The CDM of Seoul National University Hospital included longitudinal data on patient demographics, diagnostic information (such as Parkinson disease and other comorbidities), and prescription details (including prescribed drugs, prescription dates, dosages, and duration of use) from 2002 to 2021. The CDM includes standardized fields for these domains, so conventional item-level missingness is minimal; however, care and prescriptions received outside the hospital are not captured and may result in incomplete ascertainment of medication exposure and clinical events, which was considered when interpreting the results.

### Study Population

Patients were recruited into the study cohort based on prescription records. The experimental group consisted of patients prescribed APDs, including haloperidol, olanzapine, quetiapine, risperidone, amisulpride, aripiprazole, clozapine, and ziprasidone. The active comparator group, which served as the control, consisted of patients treated with selective serotonin reuptake inhibitors (SSRIs), including citalopram and escitalopram, fluoxetine, paroxetine, and sertraline, which are known to have minimal $D_2$R binding affinity ($K_i$ of approximately 10,000 nM) [23-25].

The index date was defined as the date of the first outpatient prescription of an APD or an SSRI during the study period. To maintain methodological consistency, only outpatient prescriptions of the oral formulations of the study drugs were included in the analysis. Patients were excluded based on the following criteria: (1) concurrent prescriptions of APDs and SSRIs; (2) diagnosis of Parkinson disease prior to the index date as the study focused on identifying new-onset DIP attributable to drug exposure; (3) use of $D_2$R agonists within 1 year prior to the index date; (4) fewer than 3 prescriptions of the study drugs after the index date because such limited exposure is unlikely to represent sustained treatment and may not meaningfully influence DIP onset (in our setting, outpatient prescriptions of APDs and SSRIs are usually written for short durations [approximately 2 - 4 weeks], so at least 3 prescriptions typically correspond to 2 to 3 months of continuous therapy and help avoid misclassifying sporadic or trial use as ongoing treatment, consistent with previous register-based studies evaluating psychotropic and antipsychotic medication exposure [27,28]); and (5) poor medication adherence, defined as a proportion of days covered of less than 0.7 as inconsistent medication use could confound assessments of DIP risk [29].

### Outcome Assessment

The onset of DIP was defined by the presence of diagnostic codes for DIP (G21.1, G21.2, G21.8, and G21.9) based on the *International Classification of Diseases, 10th Revision* [30]. To enhance diagnostic specificity, patients were considered to have developed DIP only if they received prescriptions for $D_2$R agonists or anticholinergic agents (standard treatments for DIP) within 60 days of initial diagnosis.

### Covariates

A total of 28 covariates were selected based on the presence of comorbidities or concurrent medication history within 1 year of the start date of medication use. The 11 comorbidities included chronic obstructive pulmonary disease, dementia, diabetes mellitus, dyslipidemia, end-stage renal disease, gout, hypertension, liver disease, osteoarthritis, osteoporosis, and stroke. The list of *International Classification of Diseases, 10th Revision* codes for comorbidities is shown in Table S1 in Multimedia Appendix 1. The 17 concurrent medications included renin-angiotensin-aldosterone system inhibitors, such as angiotensin-converting enzyme inhibitors and angiotensin receptor blockers; alpha-glucosidase inhibitors; anticonvulsants; anxiolytics; beta-blockers; calcium channel blockers; dipeptidyl peptidase-4 inhibitors; erythropoiesis-stimulating agents; glucagonlike peptide-1 receptor agonists; insulin; iron; loop diuretics; meglitinides; metformin; sodium-glucose cotransporter 2 inhibitors; statins; and sulfonylureas. A detailed list of concurrent medications is provided in Table S2 in Multimedia Appendix 1.

### Statistical Analysis

Statistical analyses were performed for the treated population. Patients were followed up on until the earliest events of DIP onset, the last day the patient took their prescribed medication + 30 days, or the end of the 1-year study period. Each APD user was matched 1:1 to an SSRI user, and the distribution of the

XSL•FO
RenderX

propensity score was inspected [31]. The matching variables included age, sex, comorbidities, and concurrent medications. A standardized difference of >0.1 was regarded as a sign of imbalance [32]. The baseline characteristics were summarized using descriptive statistics. Cox proportional hazard regression was used to estimate the hazard ratio (HR) and 95% CI for the risk of DIP associated with APD use. A dose-response analysis was performed by stratifying patients according to their average daily exposure based on the defined daily dose (DDD) [33]. Patients were categorized into 3 groups (<0.5 the DDD, 0.5 - 1.5 the DDD, and ≥1.5 the DDD) to contextualize the in vitro correlation within a clinical dose-response pattern.

### Correlation Analysis

To explore the relationship between the in vitro and real-world DIP risks, we correlated the 6 in vitro metrics with the HR estimated from the real-world cohort. Coefficients of determination ($R^2$) were calculated to quantify the explanatory strength of each association, and an $R^2$ value of 0.7 was used as a descriptive threshold for a strong relationship [34]. The primary analysis focused on APDs with $D_2R$ antagonist properties, whereas aripiprazole—a partial agonist—was examined separately in an exploratory analysis to reflect its distinct pharmacologic profile [35].

For each drug i, the association between the clinical outcome—expressed as an HR—and the corresponding in vitro pharmacological metric (metric 1 - 6) was modeled using a logarithmic regression:

$$HRi=\beta0+\beta1\ln(Xi)+\varepsilon i$$

In this expression, Xi represents the in vitro metric for the ith drug. As each HR estimate was accompanied by a 95% CI, weighted least squares was used to incorporate the varying uncertainty across drugs, allowing the regression to account for the differing precision of each HR estimate. A 95% confidence band for the fitted regression line was constructed based on the SE of the mean predicted HR values:

$$CI95\%(x)=HR\hat{}(x)\pm t0.975,df\cdot SEHR\hat{}(x)$$

In this equation, HR^(x) is the predicted HR at a given in vitro metric value x; t0.975,df is the 2-tailed critical value from the Student t distribution at a 95% confidence level, with df representing the df; and SEHR^(x) is the SE of the estimated mean HR at x, derived from the variance-covariance matrix of the weighted least squares model. The upper and lower confidence limits were visualized as a shaded band around the fitted trend line for each metric. All analyses were performed using SAS (version 9.4; SAS Institute) and Python (version 3.12.12; Python Software Foundation).

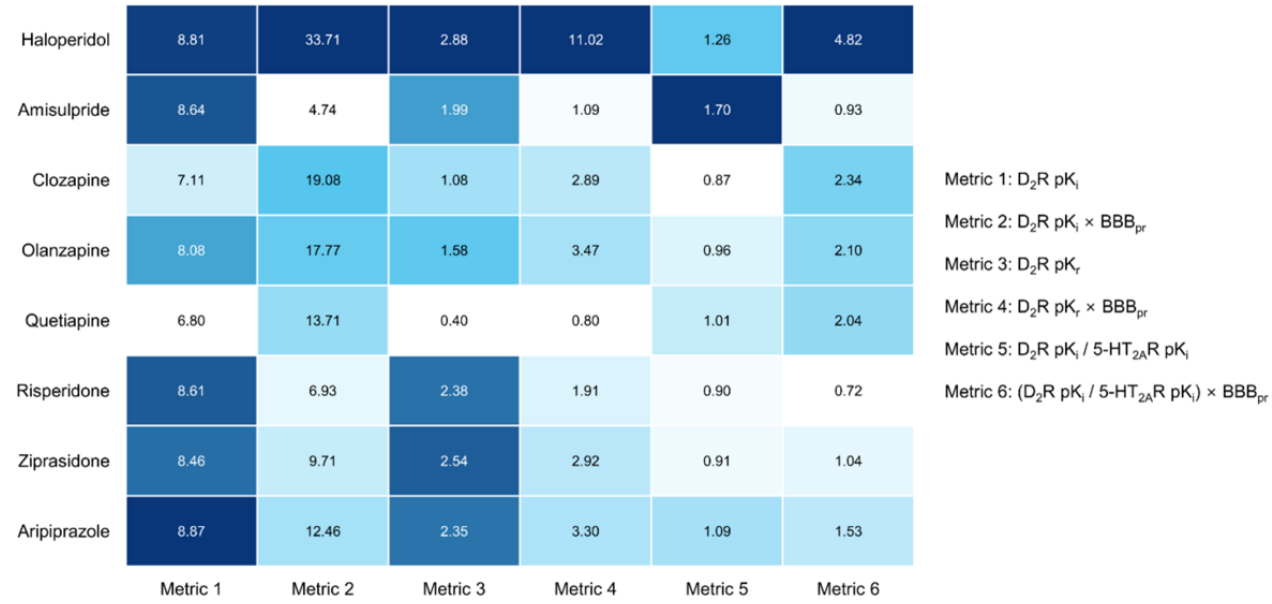
### Sensitivity Analysis

A sensitivity analysis was conducted in which the outcome definition was modified by removing the requirement for anticholinergic prescriptions within 60 days of initial DIP diagnosis, allowing for the assessment of potential misclassification. In a second analysis, we recalculated the in vitro metrics using $pK_i$ values extracted exclusively from the single-source dataset reported by Sykes et al [14]. Because this recalculation affected only the $pK_i$-dependent metrics, the additional evaluation was performed to determine whether the observed in vitro–clinical relationships were robust to variability in $pK_i$ data sources.

### Ethical Considerations

This study was approved by the institutional review boards of Gachon University Gil Hospital (1044396-202312-HR-230-01) and Seoul National University Hospital (E-2409-042-1569). The requirement for informed consent was waived by both review boards because the study involved a retrospective analysis of fully anonymized data, and no identifiable personal information was accessed. All procedures adhered to applicable local and national regulations regarding the protection of personal information, privacy, and confidentiality. As this study involved only secondary analysis of existing anonymized data, no compensation was provided to participants. All personal information was encrypted to ensure that the individuals could not be identified, and access to the dataset was restricted to authorized investigators in accordance with institutional data governance policies.

## Results



### In Vitro DIP Risks

The in vitro pharmacological characteristics of APDs used to derive the 6 in vitro DIP risk metrics are summarized in Table S3 in Multimedia Appendix 1, and corresponding metric values are visualized in Figure 2. Haloperidol showed consistently high values across metrics, ranking first in 4 of the 6 metrics. In contrast, quetiapine exhibited the lowest overall metric values. Amisulpride ranked lower on most measures but held first place in metric 5 ($D_2R$ $pK_i$/5-$HT_{2A}R$ $pK_i$ = 1.70), reflecting its particularly low affinity for 5-$HT_{2A}R$. Clozapine showed a mixed pattern: although it had relatively low $D_2R$ $pK_r$, its BBB penetration rate–adjusted values were higher, placing it second in both metric 2 ($D_2R$ $pK_i$ × BBB penetration rate = 19.08) and metric 6 ($D_2R$ $pK_i$/5-$HT_{2A}R$ $pK_i$ × BBB penetration rate = 2.34). Olanzapine, risperidone, and ziprasidone generally exhibited low to intermediate levels across metrics. Aripiprazole showed high values for several metrics, ranking first in metric 3 ($D_2R$ $pK_i$=8.87) despite its distinct partial agonist mechanism.

RenderX

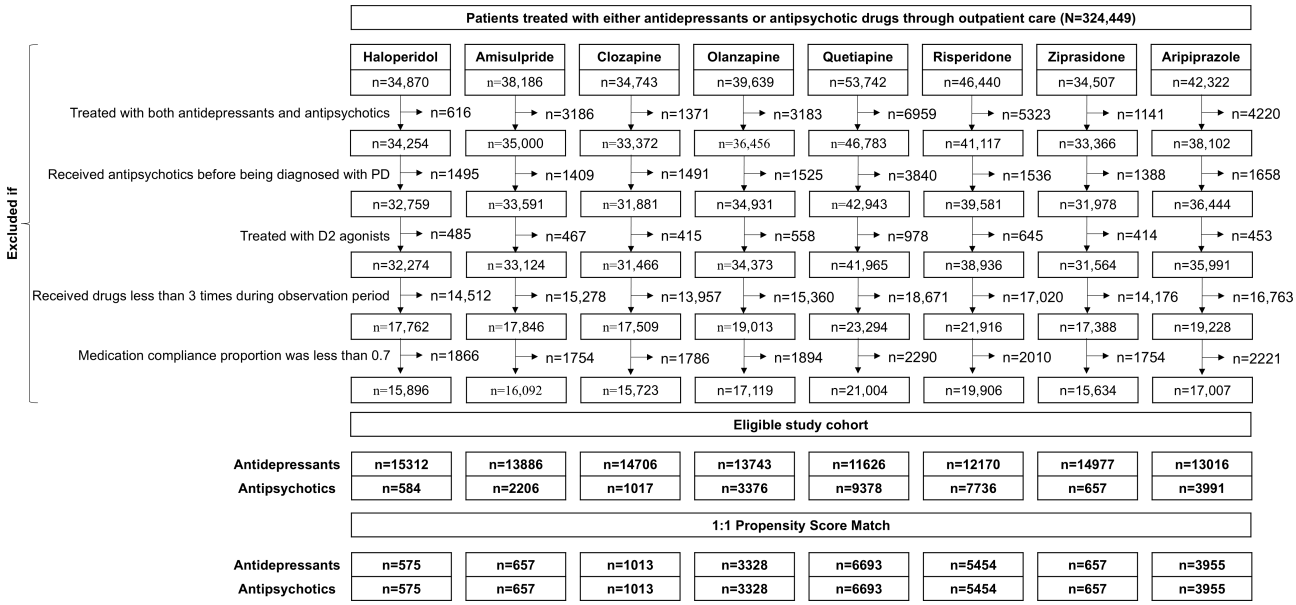

**Figure 2.** Calculated in vitro risk metrics for drug-induced parkinsonism. The intensity of the blue color represents the relative magnitude of the antipsychotic drug's metric within the same in vitro measurement. 5-$HT_{2A}$R: serotonin 2A receptor; $BBB_{pr}$: blood-brain barrier penetration rate; $D_2$R: dopamine D2 receptor.

## Patient Characteristics

A total of 324,449 patients who were exclusively prescribed APDs or SSRIs during outpatient visits were included in the cohort (Figure 3). After eligibility assessment, the final eligible cohort included 109,436 SSRI users and 28,945 APD users. Table 1 presents the baseline characteristics of the haloperidol cohort as a representative example, and those of the remaining cohorts are shown in Tables S4-S10 in Multimedia Appendix 1. Before matching, SSRI users were generally older, whereas APD users showed higher anticonvulsant use. After 1:1 propensity score matching, the final matched cohort included the following numbers for each drug: 575 for haloperidol, 657 for amisulpride, 1013 for clozapine, 3328 for olanzapine, 6693 for quetiapine, 5454 for risperidone, 657 for ziprasidone, and 3955 for aripiprazole. Differences in age and anticonvulsant use, along with other minor discrepancies, were substantially reduced, resulting in well-balanced matched cohorts. Standardized differences for all covariates were below 0.1 across all study cohorts. The median follow-up period was 287 (IQR 142 - 366) days across all participants, with a median of 298 (IQR 159 - 366) days in the SSRI group and 272 (IQR 131 - 364) days in the APD group. The median time to DIP was 71 (IQR 28 - 171) days for the entire dataset, 90 (IQR 39 - 194) days for the SSRI group, and 63 (IQR 23 - 157) days for the APD group.

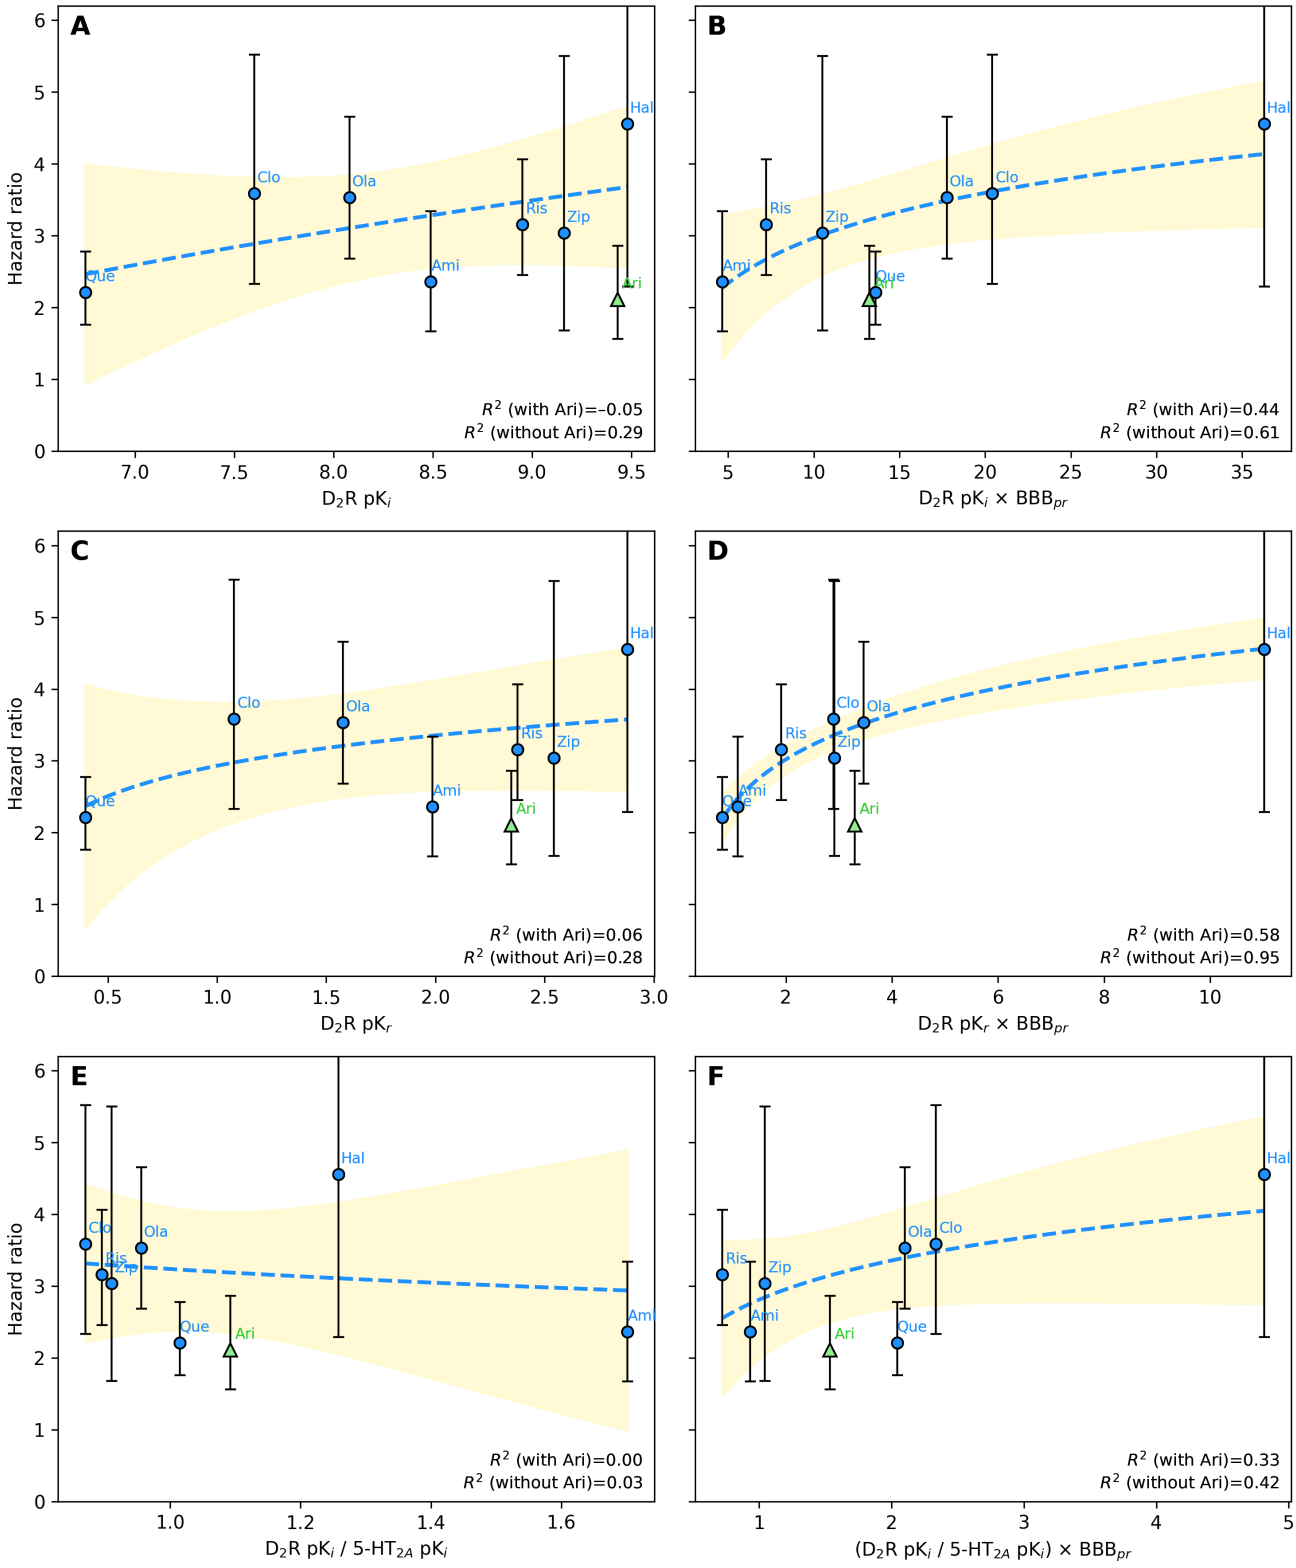
## Real-World DIP Risks

The HRs and 95% CIs for DIP across various medications are summarized in Table 2. The typical APD, haloperidol, had the highest DIP risk (HR=4.56, 95% CI 2.29 - 9.07). Among the atypical APDs, clozapine (HR=3.59, 95% CI 2.33 - 5.52), olanzapine (HR=3.53, 95% CI 2.68 - 4.66), risperidone (HR=3.16, 95% CI 2.45 - 4.06), and ziprasidone (HR=3.04, 95% CI 1.68 - 5.50) showed relatively higher risks. Lower HRs were observed with amisulpride (HR=2.36, 95% CI 1.67 - 3.34), quetiapine (HR=2.21, 95% CI 1.76 - 2.78), and aripiprazole (HR=2.11, 95% CI 1.56 - 2.86). Overall, among the medications analyzed, haloperidol exhibited the highest DIP risk, whereas aripiprazole and quetiapine were associated with the lowest risks.

**Table .** Hazard ratios of drug-induced parkinsonism associated with antipsychotic drugs vs selective serotonin reuptake inhibitors.

| Antipsychotic drug | Hazard ratio (95% CI) |
|---|---|
| Haloperidol | 4.56 (2.29 - 9.07) |
| Amisulpride | 2.36 (1.67 - 3.34) |
| Clozapine | 3.59 (2.33 - 5.52) |
| Olanzapine | 3.53 (2.68 - 4.66) |
| Quetiapine | 2.21 (1.76 - 2.78) |
| Risperidone | 3.16 (2.45 - 4.06) |
| Ziprasidone | 3.04 (1.68 - 5.50) |
| Aripiprazole | 2.11 (1.56 - 2.86) |



## Correlation Between In Vitro and Real-World DIP Risks

Among the 6 in vitro metrics evaluated, metric 4 ($D_2R$ $pK_r$ × BBB penetration rate) demonstrated the strongest correlation with real-world DIP risk ($R^2$=0.95), whereas metric 5 ($D_2R$ $pK_i$/5-$HT_{2A}R$ $pK_i$) showed the weakest correlation ($R^2$=0.03; Figure 4). Incorporating BBB penetration markedly improved the explanatory strength across all metric pairs (metric 1 vs metric 2, metric 3 vs metric 4, and metric 5 vs metric 6). Aripiprazole, a partial $D_2R$ agonist, deviated from the pattern observed among $D_2R$ antagonists. When aripiprazole was included in the analysis for metric 4, the correlation coefficient decreased substantially from 0.95 to 0.58, reflecting its fundamentally different pharmacological mechanism. Across all 6 metrics, stratification by DDD suggested a trend toward higher DIP risk with increasing exposure (Figure 5). For metric 4, the stratified curves showed the clearest parallel pattern across exposure groups, although the explanatory strength declined within strata.

**Figure 5.** Dose-response analysis of in vitro metrics with clinical risk of drug-induced parkinsonism: (A) dopamine D2 receptor ($D_2R$) $pK_i$ (metric 1); (B) $D_2R$ $pK_i$ × blood-brain barrier penetration rate ($BBB_{pr}$; metric 2); (C) $D_2R$ $pK_r$ (metric 3); (D) $D_2R$ $pK_r$ × $BBB_{pr}$ (metric 4); (E) $D_2R$ $pK_i$/serotonin 2A receptor ($5\text{-}HT_{2A}R$) $pK_i$ (metric 5); and (F) $D_2R$ $pK_i$/$5\text{-}HT_{2A}R$ $pK_i$ × $BBB_{pr}$ (metric 6). Each curve represents the fitted logarithmic regression within a dose stratum. Dose 1 (<0.5 the defined daily dose [DDD]), dose 2 (0.5 - 1.5 the DDD), and dose 3 (≥1.5 the DDD) are shown in light, intermediate, and dark red, respectively. The coefficient of determination ($R^2$) is shown for models calculated without aripiprazole.

## Sensitivity Analysis

In the sensitivity analysis using an outcome definition without anticholinergic confirmation, all overall correlation patterns were preserved, and metric 4 continued to show the strongest correlation, with $R^2$=0.83 (Figure S1 in Multimedia Appendix 1). When the in vitro metrics were recalculated using $pK_i$ values derived from a single-study source, the overall correlation

XSL•FO
RenderX

pattern remained similar (Table S11 in Multimedia Appendix 1).

## Discussion

### Principal Findings

In this study, we demonstrated that in vitro–derived DIP risk was closely related to the risk of DIP due to the use of APDs observed in real-world clinical settings. Previous studies have evaluated the inhibitory effects of APDs on $D_2$Rs or 5-$HT_{2A}$R through in vitro experiments [14,36-38]. However, such in vitro receptor affinity measures alone often fail to reliably predict the frequency of clinical adverse events such as DIP [24,25]. Conversely, RWD studies have assessed the impact of APDs on the incidence of DIP. However, most of these studies have often been limited by the evaluation of only a small subset of medications or lack of appropriate active comparator groups [30,39-43]. Consequently, numerous randomized controlled trials comparing the risk of DIP among patients taking APDs have been conducted over time, resulting in significant expenditure of time and resources [44-51]. A notable strength of this study is that it provides a comprehensive comparison of DIP risks associated with 8 commonly used APDs within a single institutional cohort using robust matching techniques to minimize confounding and demonstrating the relationship between in vitro pharmacological metrics and observed clinical outcomes. These findings suggest that integrating in vitro pharmacological data with clinical evidence may help generate hypotheses for future safety evaluation frameworks, particularly in early exploratory stages of drug development.

Consistent with previous literature, APDs significantly increased the risk of DIP compared to SSRIs, which served as active comparators [14,40,52]. Haloperidol, a typical APD, exhibited the highest DIP risks in both the in vitro metrics and the real-world analysis, aligning with its strong $D_2$R antagonist properties. In contrast, atypical APDs showed lower HRs, with aripiprazole exhibiting the lowest DIP risk despite its relatively high receptor affinity and kinetic parameters ($pK_i$, $pK_r$, and $pK_r$ × BBB penetration rate). Sensitivity analyses supported the robustness of the overall associations: using an outcome definition without anticholinergic confirmation yielded correlation patterns that were directionally similar, and recalculating the in vitro metrics with $pK_i$ values derived from a single-study source produced a correlation structure comparable to that of the main analysis. Although the DDD-based stratification was exploratory, the generally increasing DIP risk across exposure levels offers qualitative support for a dose-response pattern consistent with prior pharmacological understanding of $D_2$R blockade [18,40]. This pattern was most apparent for metric 4, which showed a broadly similar ranking across dose strata. However, the reduced explanatory strength within strata suggests that dose-based subgrouping introduces analytic instability, likely reflecting loss of covariate balance and reduced variability after stratification. These observations indicate that, while dose may influence the in vitro–clinical relationship, larger datasets with broader dosing distributions and more detailed exposure metrics, such as treatment duration and receptor occupancy, will be required to more robustly characterize dose-dependent effects.

Aripiprazole deviated from the general correlation pattern, presenting a lower HR than that expected from metric 4 ($D_2$R $pK_r$ × BBB penetration rate), with similar discrepancies across other metrics. This divergence is most likely attributable to the unique pharmacodynamic profile of aripiprazole as a partial $D_2$R agonist [35]. Unlike full antagonists, aripiprazole displays intrinsic activity at the $D_2$Rs, enabling it to maintain a degree of dopaminergic signaling even at high receptor occupancy. A number of positron emission tomography studies have demonstrated that therapeutic doses of aripiprazole achieve high $D_2$R occupancy without producing corresponding extrapyramidal adverse effects, indicating that occupancy does not translate directly into functional blockade for partial agonists [53-55]. Additionally, aripiprazole exhibits functional selectivity and stabilizes $D_2$R signaling rather than fully suppressing it, which reduces the likelihood of inducing movement disorders despite strong binding [35]. Such pharmacological nuances highlight that future extensions of this framework may require incorporating measures of functional efficacy, such as intrinsic activity, partial agonist efficacy, or occupancy-response weighting, to more accurately model APDs whose clinical effects diverge from antagonist-based predictions.

Another key finding of this study was that $K_r$ better reflects the DIP risks observed in clinical settings than $K_i$. This observation aligns with that made in a previous study by Sykes et al [14], which highlighted the importance of rebinding kinetics in DIP. Our study extends these findings by integrating BBB penetration rate, which improved the strength of the correlation across all metrics. Among the models tested, the combination of $D_2$R $pK_r$ and BBB penetration rate (metric 4) showed the strongest correlation with clinical DIP risk. Notably, the correlation coefficient increased from 0.28 ($pK_r$ alone) to 0.95 ($pK_r$ × BBB penetration rate), indicating that accounting for CNS exposure meaningfully shifted the strength of the association. Conversely, the metrics that incorporated $D_2$R $K_i$ did not sufficiently reflect the variations in real-world DIP risk. Taken together, these findings suggest that CNS accessibility and rebinding kinetics capture important mechanistic features underlying observed differences among APDs.

Several studies have illustrated the relevance of incorporating BBB penetration rate into risk models. Amisulpride and risperidone, both of which have BBB penetration rate values below 1 (0.55 and 0.81, respectively), appeared below the trend line in unadjusted models, indicating a lower-than-expected DIP risk despite high in vitro receptor affinity (Figures 4A and 4C). This discrepancy is likely due to the limited BBB penetration. When BBB penetration rate–adjusted metrics were applied (Figures 4B and 4D), both drugs aligned closer to the trend line. A similar trend was observed for olanzapine and clozapine, which showed comparable HRs in the clinical data. Although olanzapine exhibited a 46% higher $pK_r$ value than clozapine, this difference was reduced to 20% after adjusting for BBB penetration rate, suggesting that the superior BBB penetration of clozapine may compensate for its lower binding

XSL•FO
RenderX

affinity, highlighting the importance of accounting for BBB permeability in DIP risk prediction.

### Limitations

Our study had several limitations. First, the in vitro indicators presented herein are aggregate estimates that are not intended for individual patient prediction. Future research could develop individualized risk prediction models that incorporate these indicators. Second, because most patients in the cohort were treated with relatively low APD doses (≤1.0 the DDD), dose-response characterization was inherently limited, and the relationship between the in vitro metrics and clinical risk across the full dosing spectrum remains unvalidated. Future studies encompassing a wider dosing distribution will be needed to more fully delineate dose-dependent patterns. Third, while the metrics demonstrated correlation with real-world DIP risk among $D_2R$ antagonists, the analysis could not cover all APDs owing to insufficient prescribing frequency, and the current framework does not incorporate intrinsic efficacy, limiting its applicability to partial agonists such as aripiprazole. Therefore, expansion to additional APDs and methodological extensions that account for intrinsic efficacy will be essential for assessing generalizability. Finally, this study used a single-institution CDM database; prescribing patterns and clinical characteristics outside this setting were not captured, and residual confounding inherent to the observational nature may remain despite rigorous propensity score matching. In addition, the identification of DIP onset, even with an enhanced operational definition, may still allow for potential misclassification. Multicenter studies will be valuable to further evaluate the generalizability of the proposed framework. Given these constraints, the findings should be interpreted as exploratory associations rather than definitive causal inferences.

### Conclusions

In conclusion, this study demonstrated that combining receptor-binding kinetics with BBB penetration provides robust in vitro metrics that strongly correlate with the real-world clinical risk of DIP. These findings underscore the importance of integrating receptor kinetics and neuropharmacokinetics with real-world evidence, offering a conceptual foundation that may support more mechanistically informed approaches to future pharmacovigilance and adverse event predictions. Ultimately, such integrative methodologies may help refine early safety assessment and improve decision-making across the drug development continuum, potentially reducing the cost and duration of clinical trials.

## Funding

This study was supported by a National Research Foundation of Korea grant funded by the Korean government (RS-2023-00280552).

## Data Availability

The data generated or analyzed during this study are not publicly available due to institutional restrictions but are available from the corresponding author upon reasonable request and with permission from Seoul National University Hospital.

## Authors' Contributions

HYJ and YMY conceptualized, supervised the study, and served as corresponding authors. HYJ, YMY, HWL, and WTL contributed to data acquisition, analysis, and interpretation. All authors participated in drafting and critically revising the manuscript. All authors have approved the final version of the manuscript.

## Abstract

**Background:** A growing body of research supports the efficacy of text messaging programs to help tobacco users quit, but texting as a strategy for recruiting tobacco users into other evidence-based cessation services, such as quitline coaching, is less well understood. Texting to offer treatment could increase use of cessation resources, an important consideration for health systems trying to improve their quality metric performance on tobacco assessment and counseling.

**Objective:** The aim of this study is to compare the effects of text messages offering free quitline coaching or free nicotine patches on engagement with quitline services by patients identified in electronic health records as unassisted tobacco users.

**Methods:** Participants (N=4171) were adult patients of Los Angeles County Department of Health Services who had had a clinical visit in the past 12 months, were willing to receive text messages, and were identified as unassisted tobacco users (ie, those with no documented advice or assistance to quit in the past 24 months). They included 3139 English speakers and 1032 Spanish speakers. Participants were stratified by language, then randomly assigned to one of two groups. Group 1 received a text offering free quitline coaching. Group 2 received a text offering free nicotine patches. The texts were sent in April and May 2022. Outcome measures were the proportions calling the quitline and receiving evidence-based cessation treatments. Data were analyzed in 2025.

**Results:** Overall, 1.5% (61/4171) of participants called the quitline, including 1.3% (28/2086) in Group 1 and 1.6% (33/2085) in Group 2, and 0.5% (21/4171) received treatment, including 0.4% (8/2086) in Group 1 and 0.6% (13/2085) in Group 2. There was no significant difference either in calls ($P$=.52) or receiving treatment ($P$=.29). However, Spanish speakers were significantly more likely to call than English speakers, 2.3% (24/1032) vs 1.2% (37/3139), respectively ($P$=.008), and engaged in treatment at approximately twice the rate of English speakers, 0.9% (9/1032) vs 0.4% (12/3139), although the latter difference was nonsignificant ($P$=.07).

**Conclusions:** A single text was effective in connecting unassisted tobacco users with evidence-based quitline services for both English and Spanish speakers, but especially the latter. A population health approach of reaching out to tobacco-using patients outside clinical visits can meaningfully supplement provider referral. Research is needed on ways to increase the population health impact of this strategy.

## Introduction

The US Preventive Services Task Force urges health systems to support clinicians in treating tobacco use and calls on them to promote quitline utilization [1]. Quitlines are widely available and provide evidence-based cessation counseling [2]. Most partner with health systems to encourage clinicians to ask their patients if they use tobacco, advise those who do to quit, and connect them to quitlines via electronic referral (e-referral) [3,4]. Some quitlines provide additional services, including nicotine replacement therapy (NRT) and mobile health (mHealth) interventions [5].

mHealth interventions such as mobile apps and text messaging programs have received increasing attention due to their potential to expand the reach of tobacco cessation services. The approach is promising, given how widespread cell phone ownership is. In the United States, 98% of adults have a cell phone, including the same high percentage of White, Black, Latino, and English-speaking Asian adults [6]. In 2024, Americans exchanged nearly 2.2 trillion text messages [7]. Moreover, there is evidence that texting can improve the use of health care services. For example, sending appointment reminders via text increases attendance [8]. Text messages offering cessation treatment could potentially increase use of such services, an important consideration for health systems trying to improve their quality metric performance on tobacco assessment and counseling [9].

While there is growing evidence that text messaging programs can help tobacco users quit [10-12], less research has been done on texting as a way to recruit tobacco users into other evidence-based cessation services [13,14]. Researchers in the United Kingdom found that calls plus texts drove more recruitment for a text messaging trial than calls alone [15] and that sending a reminder about the trial plus a text drove more recruitment than the reminder alone [16]. A New York study reported that multimodal outreach including interactive voice response calls, emails, postcards, and texts led to a 6-fold increase in quitline reengagement [17]. Another New York study found that sending smokers identified in the electronic health record (EHR) 5‐7 texts resulted in 10.0% accepting quitline referral [13]. Researchers in Washington, DC, found that sending emergency department patients screened for tobacco use and willingness to receive up to 4 texts promoting a cessation program led 63.8% to opt in [14]. Illinois researchers reported that sending safety net health center patients identified as smokers in the EHR a letter plus 5 texts outperformed e-referral in driving quitline utilization [18]. Researchers in Vietnam found that frequent texting significantly increased quitline utilization [19]. All of these studies involved multiple text messages, additional modalities, or both.

This study, a pragmatic randomized control trial, implemented a text message campaign in a safety net health system promoting cessation in patients identified as unassisted tobacco users in the EHR. We compared two treatment offers and their uptake by English- and Spanish-speaking patients. The hypotheses were that texting would be a feasible means of recruiting unassisted tobacco users into quitline services, that offering free NRT would attract more enrollees than offering free coaching, and that recruiting by text would work equally well for English and Spanish speakers.

## Methods

### Study Participants and Intervention

Participants were patients of the Los Angeles County Department of Health Services (LADHS), the second largest municipal health system in the United States [20]. LADHS serves about 750,000 unique patients annually [20] and participates in a state Medicaid value-based care program to improve quality metric performance, including on “Tobacco Assessment and Counseling” [9]. Eligible patients were identified by the LADHS population health team using data extraction from the EHR for quality metric reporting. Eligibility criteria were being ≥18 years old, having had a clinical visit in the past 12 months, being willing to receive text messages, and being an unassisted tobacco user (ie, one with no documented advice or assistance to quit in the past 24 months). Of 4171 patients meeting these criteria, 3139 were English speakers and 1032 were Spanish speakers.

Participants were stratified by language, then randomly assigned to one of two groups. Randomization blocks were generated by the quitline, Kick It California, while participants were assigned and text messages were sent by LADHS. The messages were in English or Spanish according to the participant’s language preference. English speakers in Group 1 received a text reading, “Hello [first name], Kick It California works with your provider to help you quit smoking at no cost. A Quit Coach can double your chances of quitting. For more info call [toll-free phone number].” English speakers in Group 2 received a text reading, “Hello [first name], Kick It California works with your provider to help you quit smoking at no cost. You may be able to get nicotine patches mailed to your home at no cost. For more info call [toll-free phone number].” Spanish speakers in each group received a translated version of the message for that group. Four dedicated toll-free phone numbers were used, each of which was only available to members of a single group who spoke either English or Spanish. These steps were taken to enable tracking of incoming calls and to provide callers with linguistically appropriate services. The texts were sent in April and May 2022.

Staff of the quitline who handled incoming calls were blind to the allocation of participants and offered coaching to all who enrolled. Coaching followed a structured, multicall protocol previously proven effective [21,22] and described elsewhere [23]. Quitline staff also offered a free 2-week supply of nicotine patches to all who enrolled unless NRT was contraindicated, regardless of which text message they received. The patches were mailed directly to participants’ homes. To ensure equitable access, a second text message offering free patches was sent to all participants in June 2022.

### Measures

Demographic information obtained from the EHR included age, sex, race/ethnicity, and language. The outcome measures were the proportions of participants calling the quitline and receiving

XSL•FO
RenderX

evidence-based cessation treatments, which could include NRT, quitline coaching, or both. Calls to the quitline and treatments received were attributed to the initial text message only if they took place prior to when the second text message was sent. For those who received coaching, the number of follow-up sessions was also tracked.

### Analysis

Descriptive statistics were used to describe patient characteristics by treatment condition. The proportions of participants calling the quitline and receiving treatment (NRT, coaching, or both) were calculated for each treatment and language group. Differences between treatment groups were assessed using $\chi^2$ tests for categorical variables or the Fisher exact test in the event of small cell sizes. Analyses were conducted in 2025 using SAS (version 9.4; SAS Institute Inc).

### Ethical Considerations

The study was approved as exempt from human subjects review by the University of California Davis institutional review board (application number 1301241 - 6) and the LADHS institutional review board (application number 2018-12-785). Because the institutional review board determination was that the study was not research, informed consent was not required. Data were deidentified to safeguard participant information. Participants were not offered compensation. The trial was registered on ClinicalTrials.gov (NCT07102290).

## Results

Table 1 shows the demographic characteristics, by treatment group, of LADHS patients identified as unassisted tobacco users in the EHR who were randomized into the study. There were no significant differences between groups with regard to age, sex, race/ethnicity, or language, suggesting that the groups were equivalent at baseline.

**Table .** Characteristics of text message recipients in the Los Angeles County Department of Health Services system by randomized condition (N=4171).

| | Group 1, free coaching (n=2086), % | Group 2, free nicotine replacement therapy (n=2085), % | *P* value[a] |
|---|---|---|---|
| Age (years) | | | |
| 18-24 | 2.2 | 2.3 | .49 |
| 25-44 | 31.5 | 30.4 | |
| 45-64 | 52.9 | 52.2 | |
| >64 | 13.5 | 15.1 | |
| Sex | | | |
| Male | 63.1 | 60.4 | .13 |
| Female | 36.9 | 39.6 | |
| Other | 0.05 | 0.05 | |
| Race/ethnicity | | | |
| American Indian/Alaska Native | 0.34 | 0.58 | .25 |
| Asian | 2.5 | 3.0 | |
| Black | 25.9 | 25.1 | |
| White | 6.5 | 7.1 | |

| English | 75.3 | 75.3 | .99 |
| Spanish | 24.7 | 24.8 | |

[a]*P* value from $\chi^2$ test for all variables except sex, which used the Fisher exact test because of cell sizes <5.

[b]Non-Hispanic other includes Pacific Islander, other race, and multiple races.

Figure 1 summarizes the flow of participants through the study. Of 4171 LADHS patients identified in the EHR as unassisted tobacco users, half (n=2086) were randomly assigned to Group 1 and received a text message offering free quitline coaching. The other half (n=2085) were randomly assigned to Group 2 and received a text message offering free NRT. A total of 61 participants responded to the text they received by calling the quitline, including 28 in Group 1 (1.1%) and 33 in Group 2 (1.6%). Of these, 21 participants engaged in treatment, including 8 in Group 1 (0.4%) and 13 in Group 2 (0.6%). Most of these (n=19) received NRT, including 6 in Group 1 (0.3%) and 13 in Group 2 (0.6%), while 11 received a coaching session to help

XSL•FO
RenderX

them prepare to quit, including 5 in Group 1 (0.2%) and 6 in Group 2 (0.3%). Eight participants also completed at least one follow-up session to help them stay on track with quitting, completing 2.1 follow-up sessions on average (not shown in figure).

**Figure 1.** Flow of Los Angeles County Department of Health Services text message recipients through the study.

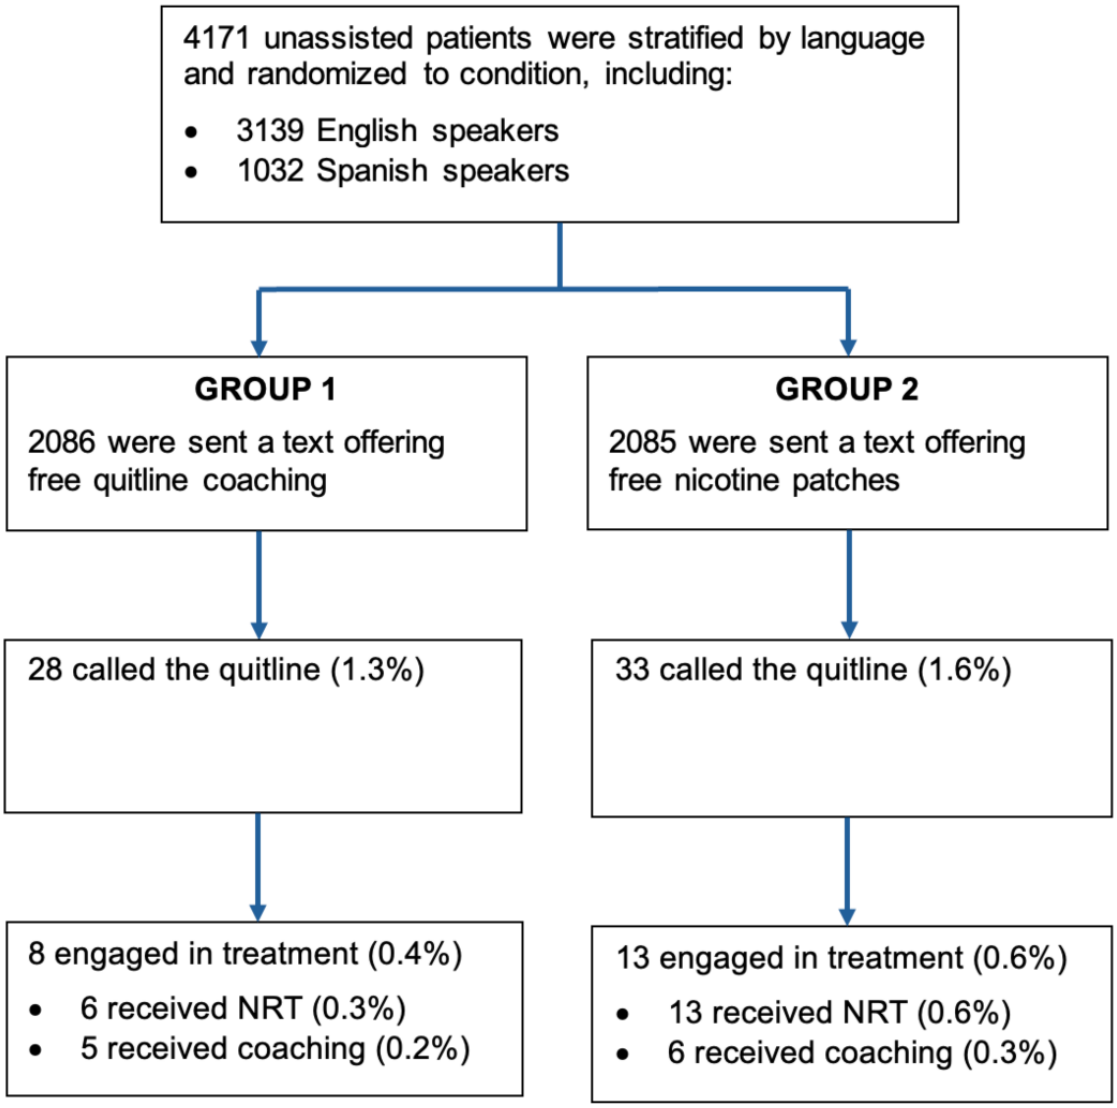

Table 2 shows in more detail the effects of the intervention on calls to the quitline by treatment condition and language. There was no significant difference by treatment condition, with 1.3% (28/2086) of Group 1 participants and 1.6% (33/2085) of Group 2 participants calling the quitline (*P*=.52), nor were there between-group differences within languages. Among English speakers, 1.1% (17/1570) in Group 1 called the quitline vs 1.3% (20/1569) in Group 2 (*P*=.62), and among Spanish speakers, 2.1% (11/516) in Group 1 called the quitline vs 2.5% (13/516) in Group 2 (*P*=.68). However, when examined by the stratification variable, language, there was a significant difference, with Spanish speakers twice as likely as English speakers to call the quitline, 2.3% (24/1032) versus 1.2% (37/3139), respectively (*P*=.008).

**Table .** Calls to the quitline by Los Angeles County Department of Health Services text message recipients by randomized condition and language.

| Language | Group 1, free coaching (n=2086), % (n/N) | Group 2, free nicotine replacement therapy (n=2085), % (n/N) | *P* value[a] | Total (N=4171), % (n/N) | *P* value[b] |
|---|---|---|---|---|---|
| English | 1.1 (17/1570) | 1.3 (20/1569) | .62 | 1.2 (37/3139) | .008 |
| Spanish | 2.1 (11/516) | 2.5 (13/516) | .68 | 2.3 (24/1032) | |
| Total | 1.3 (28/2086) | 1.6 (33/2085) | .52 | 1.5 (61/4171) | |

[a]*P* value from $\chi^2$ test comparing Group 1 to Group 2 for each language category.

[b]*P* value from $\chi^2$ test comparing English to Spanish.

XSL•FO
RenderX

Table 3 shows the effects of the intervention on treatments received. Overall, 21 of 4171 or 0.5% of participants received evidence-based treatment, including 0.4% (8/2086) in Group 1 and 0.6% (13/2085) in Group 2. As with calls to the quitline, there was no significant difference by treatment condition in this outcome (*P*=.29), nor were there between-group differences within languages. Among English speakers, 0.3% (5/1570) in Group 1 engaged in treatment versus 0.4% (7/1569) in Group 2 (*P*=.58), and among Spanish speakers, 0.6% (3/516) in Group 1 engaged in treatment versus 1.2% (6/516) in Group 2 (*P*=.51). Spanish speakers engaged in treatment at approximately twice the rate of English speakers, but the difference was nonsignificant, 0.9% (9/1032) versus 0.4% (12/3139), respectively (*P*=.07).

**Table .** Los Angeles County Department of Health Services text message recipients' receipt of tobacco cessation treatment by randomized condition and language.

| Language | Group 1, free coaching (n=2086), % (n/N) | Group 2, free nicotine replacement therapy (n=2085), % (n/N) | *P* value[a] | Total (N=4171), % (n/N) | *P* value[b] |
|---|---|---|---|---|---|
| English | 0.3 (5/1570) | 0.4 (7/1569) | .58 | 0.4 (12/3139) | .07 |
| Spanish | 0.6 (3/516) | 1.2 (6/516) | .51 | 0.9 (9/1032) | |
| Total | 0.4 (8/2086) | 0.6 (13/2085) | .29 | 0.5 (21/4171) | |

## Discussion

### Principal Findings

This pragmatic trial tested a strategy of sending unassisted tobacco users in a safety net health system a text message promoting quitline services: either free coaching or free NRT. Prior to the trial, clinicians in the system could e-refer patients to the quitline, but use of this mechanism tends to be low [24,25]. The trial offered an opportunity to test a population health strategy of reaching out to tobacco users outside clinical visits, targeting those who had not recently received help to quit. The intervention resulted in 1.5% of identified tobacco users calling the quitline and 0.5% receiving one or more evidence-based treatments. The latter rate is comparable to the treatment reach rate of US quitlines, which is less than 1% annually [5]. Moreover, it resulted from a low-intensity outreach effort—a single text.

The offers of free coaching and free NRT were equally effective at driving enrollment. This result was unexpected, as previous research found that mailers sent to Medicaid households were much more effective at driving quitline utilization when they offered free NRT than when they offered more generic help [26]. By targeting unassisted tobacco users, the texts may have reached an audience more concerned with obtaining any help to quit than a particular kind of help. The texts may also have done a better job "selling" the coaching than the NRT, as the coaching offer included the message, "a Quit Coach can double your chances of quitting." The NRT offer, in contrast, made no explicit attempt to boost positive expectancy. In any case, there was no discernible difference in the two offers' ability to motivate enrollment.

In contrast, there was a notable difference by language: Spanish speakers called the quitline and engaged in treatment at twice the rates of English speakers. These are encouraging results, given that Latino tobacco users are less likely to receive clinical advice to quit than non-Latino White tobacco users [27]. Latinos and Spanish speakers often lack knowledge about available cessation resources, hold misconceptions about cessation treatment, and may view tobacco use as a personal weakness, rather than as a condition to be treated [28-30]. Moreover, there is evidence that while Spanish speakers face barriers accessing digital health information, such as through patient portals, text messaging actually facilitates their access [31]. This may help explain why receiving a language-concordant text from their health system appears to have increased engagement with the quitline among Spanish-speaking patients. Regardless, the result suggests that population health strategies like the one tested in this study could help address disparities in the receipt of clinical advice.

The study adds to previous research on the use of texting to recruit patients into cessation treatment. Several studies have examined texting either alone [13,14,19] or as part of a multimodal outreach approach [15-18]. All studies in the former category involved multiple texts. Taken together, these studies have shown that texting can be effective in recruiting tobacco users into cessation service in the context of multitext or multimodal campaigns. This study adds to this body of research by confirming that recruiting tobacco users via text is feasible and showing that even a single text can increase recruitment.

The lesson we draw from this finding is not that organizations using multiple text messages to recruit tobacco users into evidence-based cessation treatment or using text messages in combination with other modalities should consider downgrading to a single-text format, but rather that this low-cost, almost universally available outreach tool is robust enough to measurably increase recruitment even with a single dose. It speaks to the value of quitlines partnering with health systems on text messaging campaigns to reach tobacco-using patients outside of clinical visits to offer help with quitting. Such population health strategies have the potential to meaningfully supplement direct health care provider treatment and referral [32] and to improve quality metric performance for safety net health systems in a state Medicaid value-based care program without additional staffing costs or burden [9]. Complementary strategies may further increase the effectiveness of text

XSL•FO
RenderX

messaging as a recruitment tool, including using it to reach out to additional groups of patients, using opt-out approaches [33], increasing the number and variety of messages sent [13], using dynamic tailoring [34], offering incentives [26], and offering other mHealth services [14].

The public health significance of this low-cost approach is that other health systems can quickly and widely adopt it to improve population-based tobacco quality metrics, which would have the additive effect of increasing the treatment reach of evidence-based resources such as quitlines. Starting in 2026, community cancer centers accredited by the American College of Surgeons Commission on Cancer, which care for 70% of the nation's patients with cancer, have a new standard to screen every patient newly diagnosed with cancer for smoking and to offer a referral within 30 days [35]. Also in 2026, health plans have a new population-based metric for "Tobacco Use Screening and Cessation Intervention" [36]. Low-cost proactive outreach strategies like the one described in this study can help cancer centers, health plans, provider networks, and other health care entities reach beyond clinical encounters to offer tobacco treatment to their members and patients who may need it.

To our knowledge, this study is the first to show that texting may be a more effective recruitment tool among Spanish-speaking tobacco users than among English-speaking tobacco users. This also speaks to the value of quitlines and health systems partnering to reach underserved patients [27]. All state quitlines in the United States serve both English and Spanish speakers; therefore, all health systems could potentially partner with their quitline on bilingual text messaging campaigns to reduce disparities in access to evidence-based cessation services [37].

### Limitations

This study had limitations. First, only unassisted tobacco users were included in the study; the response and engagement rates may have differed if assisted tobacco users were included. Second, there was no means to identify patients with incorrect phone numbers in the participant list, and there was no way to know whether text messages were received unless patients contacted the quitline. Third, it is unknown whether participants enrolling in the quitline benefited from the service, as the trial was not powered or designed to assess quitting outcomes. Fourth, the study included only one safety net health system, limiting generalizability. Finally, the trial was conducted a little more than two years into the COVID-19 pandemic, and it is unknown to what extent COVID-19–related stressors such as social, economic, and psychosocial distress may have affected patients' willingness to respond to a text message offering help to quit.

### Conclusion

This study showed that a single text message can effectively connect unassisted tobacco users to evidence-based cessation services for both English and Spanish speakers, but especially the latter. It showed that a population health approach of reaching out to tobacco-using patients outside clinical visits can meaningfully supplement provider referral. This population health strategy is being disseminated to and adapted by other safety net health systems and state Medicaid managed care plans in a statewide learning collaborative [38,39]. Future research should examine ways of increasing the population health impact of the strategy.

## Abstract

**Background:** Highly pathogenic avian influenza (HPAI) A(H5N1) clade 2.3.4.4b, a globally predominant strain, was introduced into poultry in the United States in 2022 via spillover from wild birds, and has since been regularly reported, posing ongoing risks to animal and human health. In 2024, the United States reported the first known HPAI A(H5N1) clade 2.3.4.4b infection in dairy cattle, rapidly evolving into a multispecies outbreak among cattle and poultry, with spillover into humans. Publicly available data remained siloed and fragmented, hindering timely response. Innovative multimodal surveillance methods can enhance situational awareness through comprehensive, standardized data collection, integration, and visualization.

**Objective:** This study aimed to describe observations from the application of enhanced surveillance methods that collect, integrate, and visualize multimodal data for real-time tracking of the 2024 - 2025 HPAI A(H5) outbreak in the United States as an innovative, transparent, repeatable, and scalable approach for open-source public health surveillance.

**Methods:** Global.health conducted real-time, multimodal surveillance of the United States 2024 - 2025 HPAI A(H5) outbreak using publicly available data for human cases (Centers for Disease Control and Prevention), animal outbreaks (United States Department of Agriculture), wastewater monitoring (WastewaterSCAN), genomic data (public genomic databases), research updates (scholarly communication), and policy changes and response measures (media and government) for the study period from February 1, 2024 through February 28, 2025. This digital data stream was used to create outbreak resources—an epidemiological linelist, event timeline, and interactive map—using a One Health framework to track emerging hotspots.

**Results:** Global.health curated 70 confirmed human HPAI A(H5) cases across 13 states in a linelist, with exposure for nearly all (n = 65, 92.9%) cases associated with commercial agriculture and related operations. We curated 682 timeline entries across 6 distinct categories: human, cattle, response (eg, research, policy changes, and public health guidance), birds, genome, wastewater, and mammals. The map integrated human cases (n=70) and animal outbreaks (commercial cattle: n=977 and commercial poultry: n=325) into a single view. California was identified as the outbreak epicenter with high numbers of human cases (n=38, 54.3%), commercial cattle outbreaks (n=748, 76.6%), and commercial poultry outbreaks (n=66, 20.3%) during the study period. Wastewater surveillance detected the virus in California, with an unknown source at least 81 days before the first confirmed commercial dairy cattle case.

XSL•FO
RenderX

**Conclusions:** Global.health's approach for integrating traditional and nontraditional public health surveillance data within a One Health framework enhanced early situational awareness during the United States 2024‐2025 HPAI A(H5) outbreak, creating open access to resources that improve contextual understanding of the scope and evolution of this emerging zoonotic event. Further research should seek to understand the full potential of multimodal data in outbreak surveillance.

## Introduction

### Background

The global spread of the highly pathogenic avian influenza (HPAI) virus (A/goose/Guangdong/96-lineage virus of the A(H5) subtype) has resulted in many different clades and genotypes due to genetic mutations, drift, and reassortment [1,2]. The H5Nx goose/Guangdong lineage in clade 2.3.4.4, circulating since 2013, has evolved into 8 different clade variants (2.3.4.4a-h), with clade 2.3.4.4b emerging as a notably fit virus with expanding geographic and host range and becoming widespread globally [3-5]. In early 2022, HPAI A(H5) clade 2.3.4.4b virus was detected in the United States poultry via spillover from wild birds and has since been regularly reported on US poultry farms, continuing to pose a threat to human and animal health [1,6-8].

Early in 2024, farmers in the United States began to report the emergence of a mysterious illness among their cattle herds. This cluster of symptoms was later linked to HPAI A(H5N1) clade 2.3.4.4b virus infection [9]. HPAI is better known for infecting wild and domesticated bird populations, with occasional spillovers into mammals and humans [10]. This appears to be the first time that HPAI (H5N1) has been identified in dairy cattle, aside from controlled infection experiments conducted in 2006 by the Centers for Disease Control and Prevention (CDC) [11-15]. On April 1, 2024, the Texas Department of State Health Services announced the first human case of HPAI A(H5N1). This was the first human case identified since the country's first and only previous confirmed human case of HPAI A(H5N1) in 2022 [16-18]. The individual was a dairy farm worker who had come in contact with infected cattle while at work. Genomic testing of the virus provided strong evidence that the farm worker had been infected via a spillover from dairy cattle and is believed to be the first mammal-to-human transmission of the HPAI H5N1 virus [14,17]. This spillover into humans marked the start of a multistate zoonotic outbreak affecting humans, cattle, poultry, and other mammals [19].

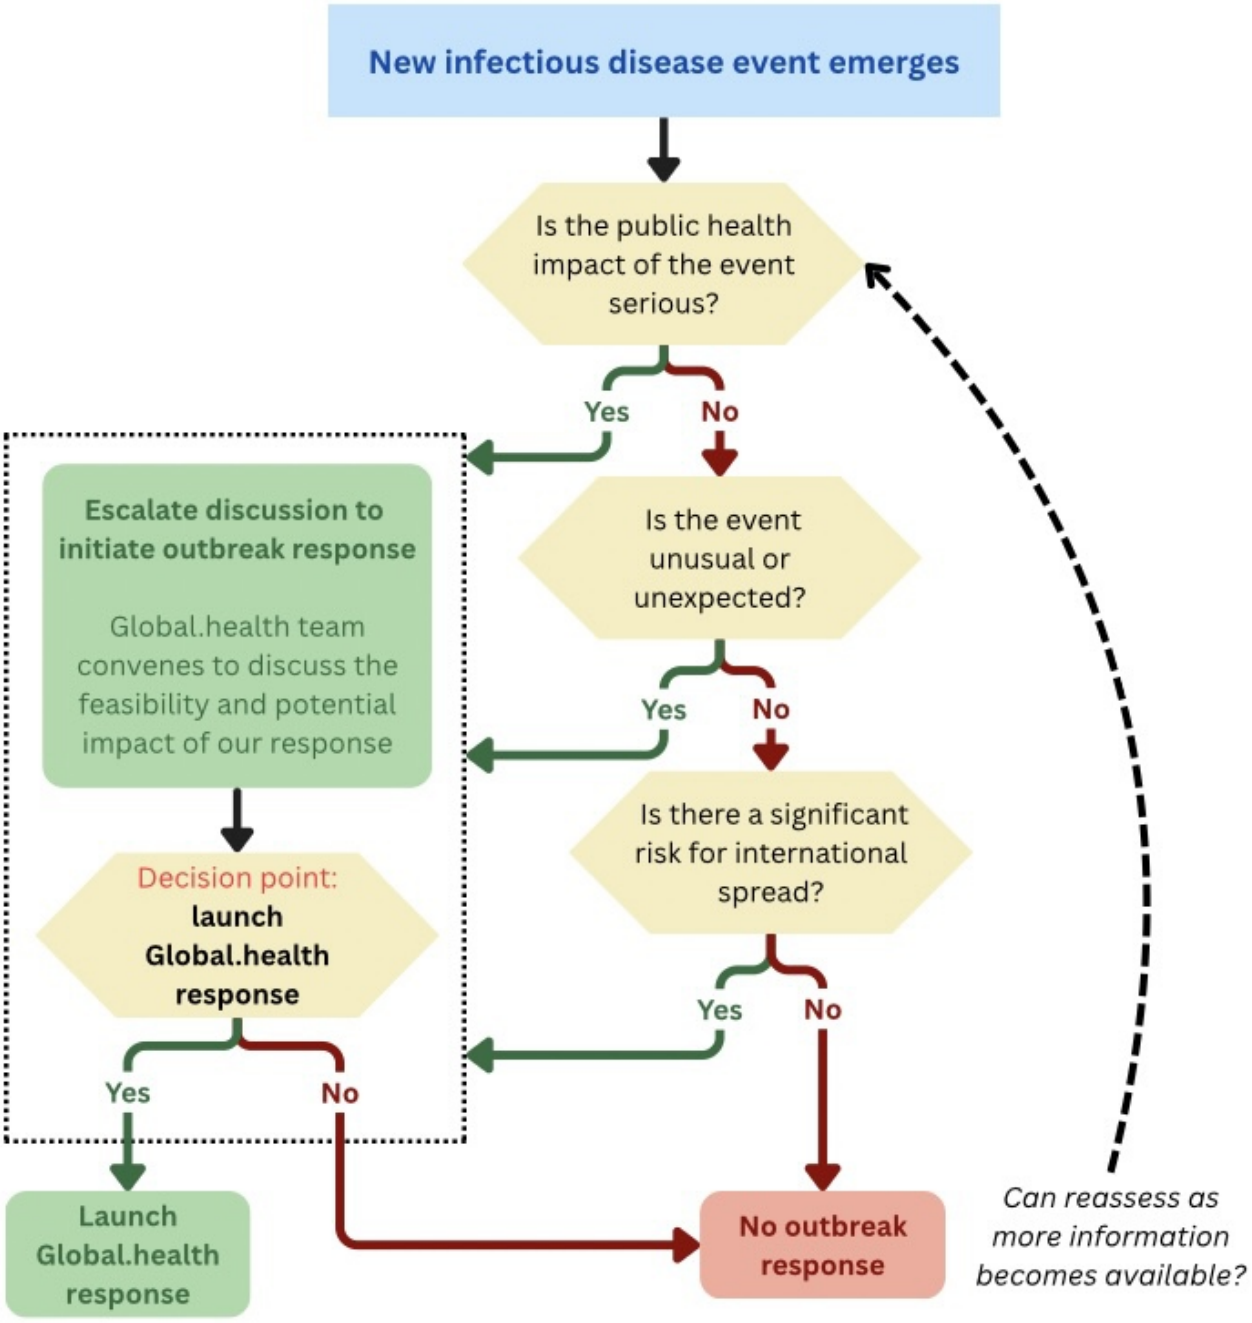
The emergence of a public health threat, such as a zoonotic outbreak, initiates a series of mitigation efforts. Within the United States, multiple local, state, and federal agencies are responsible for protecting and monitoring human, environmental, and animal health [20-22]. This often results in a complex and fragmented response and surveillance system for monitoring multispecies diseases such as HPAI. A key challenge arising from this surveillance landscape is that data collected by responding agencies are often siloed, which in turn can hamper timely analysis and response [23]. Barriers to implementing One Health surveillance systems—including data privacy, quality, and resource capacity—mirror longstanding challenges in the evolution of public health surveillance, highlighting the need for innovative methods to improve monitoring of zoonotic diseases [24,25].

Global.health was formed during the early stages of the SARS-CoV-2 pandemic in 2020 to address the challenge of integrating fragmented data during multiagency, multijurisdictional outbreak responses [23,26-28]. The technology powering Global.health is an open-source, scalable, and accessible platform for the rapid curation, analysis, and visualization of early outbreak data using a common data language for standardized database entry at a global scale [29]. The platform has been deployed in response to mpox, Ebola, and Marburg outbreaks, evolving to address the specific needs presented by each event [30-32]. Metadata associated with individual epidemiological cases can be of great importance to understand early disease dynamics, including origins, transmission dynamics, and key epidemiological parameters.

### Study Objectives

To increase access to data and support One Health analysis of the 2024‐2025 HPAI A(H5) outbreak in the United States, Global.health launched a data collection effort integrating human cases, animal outbreaks, wastewater surveillance, genomic data, research, response efforts, and policy actions. Accompanying this effort was the creation of enhanced data visualizations to improve outbreak insights. In this study, we examine Global.health's multimodal data collection, integration, and visualization efforts. Subsequently, we discuss observations regarding the spread of HPAI A(H5) in the United States during 2024 and 2025. Using information collected between February 2024 and February 2025, this paper highlights the value of integrating disparate datasets into infectious disease surveillance systems to improve situational awareness.

## Methods



### Outbreak Initiation

A set of established protocols are used to analyze emerging public health events and determine if they require the launch of Global.health outbreak response [29]. Early in 2024, the Global.health team initiated an outbreak response to the 2024‐2025 HPAI A(H5) outbreak in the United States. The launch of an outbreak response triggers a cascade of planning and preparatory measures outlined in Figures 1 and 2.

XSL•FO
RenderX

**Figure 1.** Global.health decision instrument for the assessment of an emerging infectious disease event.

XSL•FO
RenderX

**Figure 2.** Outbreak response workflow. AWS: Amazon Web Services; CSV: comma-separated values.

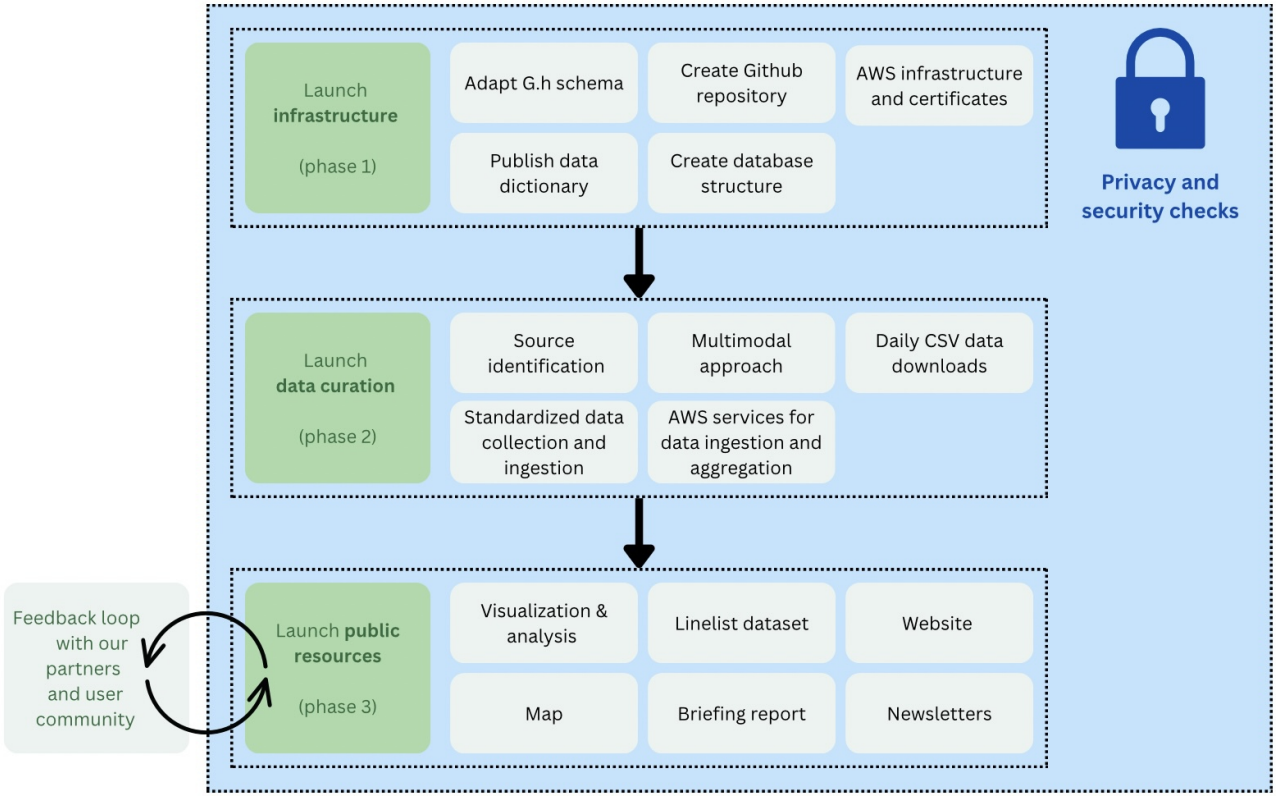


Figure 1 modeled after the World Health Organization's International Health Regulations (2005) Third Edition Annex 2, a cascade of yes or no binary questions are used to support informed decision-making [33]. A "yes" response to these questions will escalate internal discussion around the feasibility and potential impact of our work, considering timing, team resources, publicly available information, and current event coverage. This assessment is used to determine whether or not a new infectious disease event warrants the activation of a Global.health outbreak response. The outcome of this discussion reaches a decision point (yes or no) to launch the Global.health outbreak response. A "yes" decision will move forward with the launch of a Global.health outbreak response outlined in Figure 2. A "no" decision can be reassessed at any time as more information becomes available. Serious public health events include those with high case-fatality rates, limited access to effective prophylaxis or treatment, challenges in detecting the pathogen, spread in community and health care settings, and the need for an enhanced response at multiple levels. A subset of pathogens that Global.health considers as likely triggers for serious public health events are listed by the United Kingdom Health Security Agency as high-consequence infectious diseases [34]. Global.health may respond to other high-consequence infectious diseases such as mpox and measles, as well as vector-borne diseases such as dengue, chikungunya, and yellow fever.

Decision to launch a Global.health response triggers a triphased series of actions that first sets up the infrastructure (phase 1), then launches data curation efforts (phase 2), and later provides public resources to our global user community (phase 3). Examples of the types of activities or products created to support each phase are listed in the relevant section. A feedback loop is built into the model to support a transparent, crowdsourced approach to sharing outbreak information and to enable meaningful collaboration and fact checks through our platform. We consider relevant data privacy laws and regulations and use robust data protection measures and mitigation strategies, including deidentification, data validation, data quality checks, and access control.

## Data Collection: Outbreak Linelist, Human Data

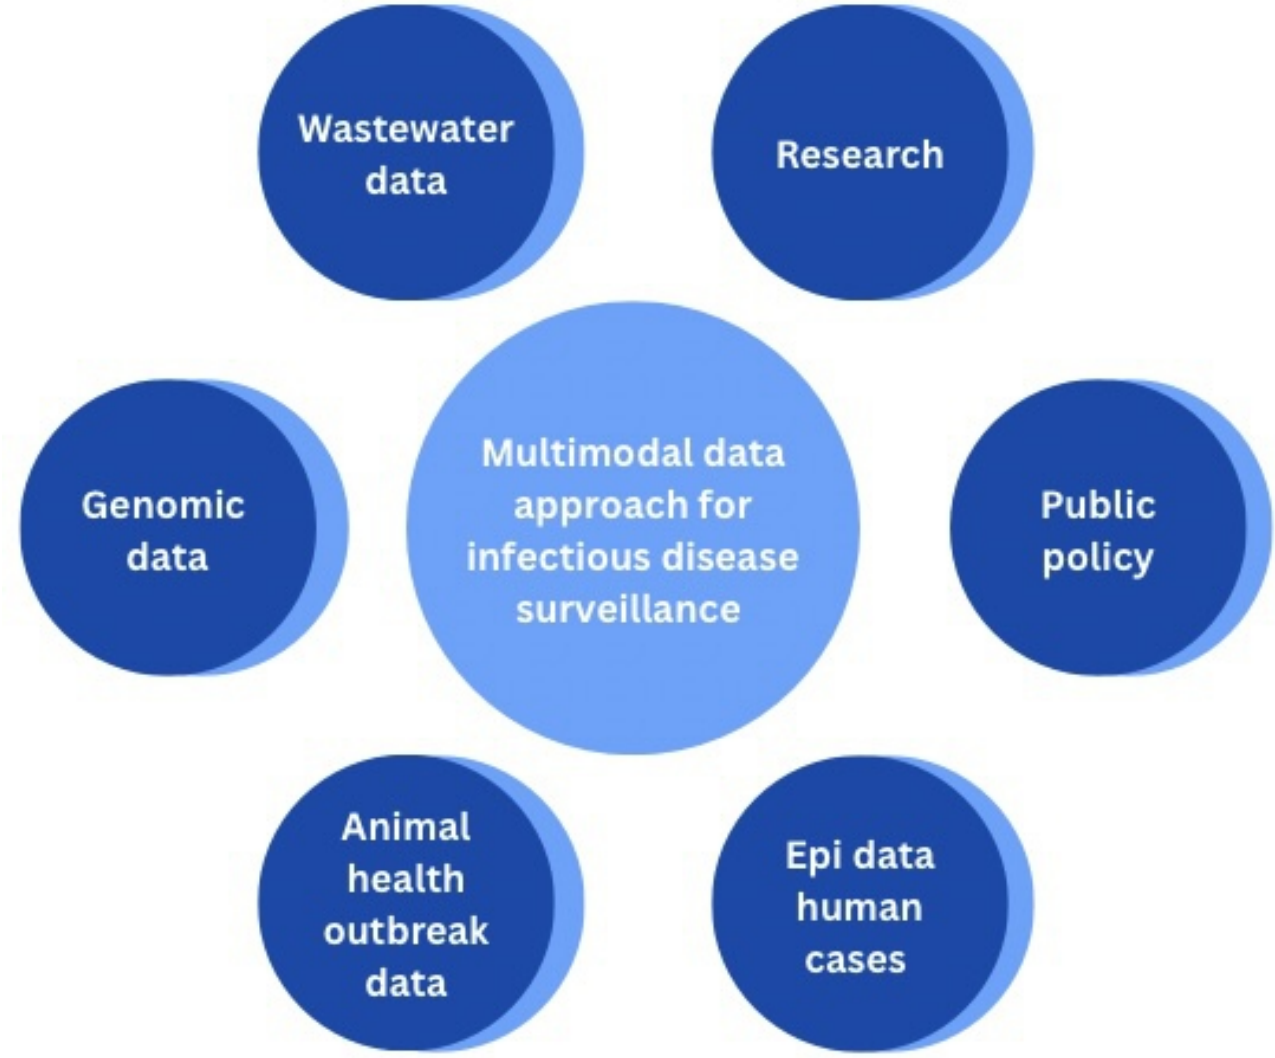
Global.health developed and maintains a common data schema used to structure infectious disease data. During a response, the Global.health outbreak schema is applied and may be adapted for novel data streams or pathogens to create the outbreak linelist that records granular epidemiological data pertaining to human cases in a standardized manner, building on lessons learned from COVID-19 data curation [35,36]. The outbreak schema is used for every outbreak (Multimedia Appendix 1) and can be modified to add new fields of interest. The schema format standardizes key epidemiological outbreak data that are deidentified. The availability of each data element varies by pathogen, location, and source, among other factors. For the 2024 - 2025 HPAI A(H5) outbreak, the Pathogen_name field was expanded to capture subtype detail for HPAI; Pathogen_subtype1 and Pathogen_subtype2 capture data for hemagglutinin and neuraminidase proteins, respectively. The genomics field was expanded to capture distinct information for sequence, clade, and genotype when that information was publicly available. The study period captures and reviews outbreak data in the United States between February 1, 2024, and February 28, 2025. Systematic data collection started in April 2024 and retrospectively added earlier events of significance. Research and data collection were conducted using

XSL•FO
RenderX

secondary data from publicly available, deidentified sources and did not involve human participants. This study followed the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) reporting guideline. Data collection is conducted by a team of curators who undergo extensive training for data collection and standardization. Curators accessed the same publicly available data directly from source websites. No restricted databases were used. Each entry is reviewed and validated by at least one additional curator before posting. Data cleaning included standardization of variable names, removal of duplicate entries, and reconciliation of conflicting reports across sources. No imputation of missing data was performed.

The outbreak linelist includes both confirmed and probable human cases of HPAI in the United States, but only confirmed cases are analyzed in this study. Confirmed cases are defined by the Council of State and Territorial Epidemiologists as those that have tested positive for H5 at a public health laboratory and have been confirmed by testing at the CDC [19,37]. Global.health's primary source for human case data was the CDC in addition to reports from local or state health departments.

Exposure source information reflects what was publicly reported by the CDC and was not defined by the researchers. The exposure source can be one of four categories: dairy herds, poultry farms and culling operations, other animal exposure, and exposure source unknown [19]. For dairy herds and poultry farms, the exposure was associated with commercial agriculture and related operations [19]. For other animal exposure, the exposure was related to other animals such as backyard flocks, wild birds, or other mammals [19]. When the exposure source is unknown, it means the exposure source was unable to be identified following public health investigations [19].



### Data Collection: Outbreak Timeline, Multimodal Data

Complementing the outbreak linelist and to help place the events in context, an outbreak timeline was created [38]. Because the outbreak linelist is exclusive to human cases, an outbreak timeline was developed that used multimodal data to enhance outbreak surveillance methods and weaved together publicly available, diverse data sources (outlined in Figure 3) into a single, integrated chronology that adopted a One Health approach, highlighting the interconnectedness of humans, animals, and our shared environment for this zoonotic outbreak [39]. The outbreak timeline includes entries related to the 2024 - 2025 HPAI A(H5) outbreak during the study period, February 1, 2024 through February 28, 2025. Systematic data collection started in April 2024 and retrospectively added earlier events of significance. Data collection for this event also extended beyond the study period but is not evaluated in this study.

XSL•FO
RenderX

**Figure 3.** A multimodal data approach for integrated infectious disease surveillance.

This figure outlines the types of sources collected to track the emerging H5 HPAI outbreak in the United States. Disparate data sources included human epidemiologic data, commercial cattle and poultry outbreak reports, wastewater detections, genomic sequences, research updates, response measures, and policy actions. The integrated view supports early situational awareness for zoonotic events.

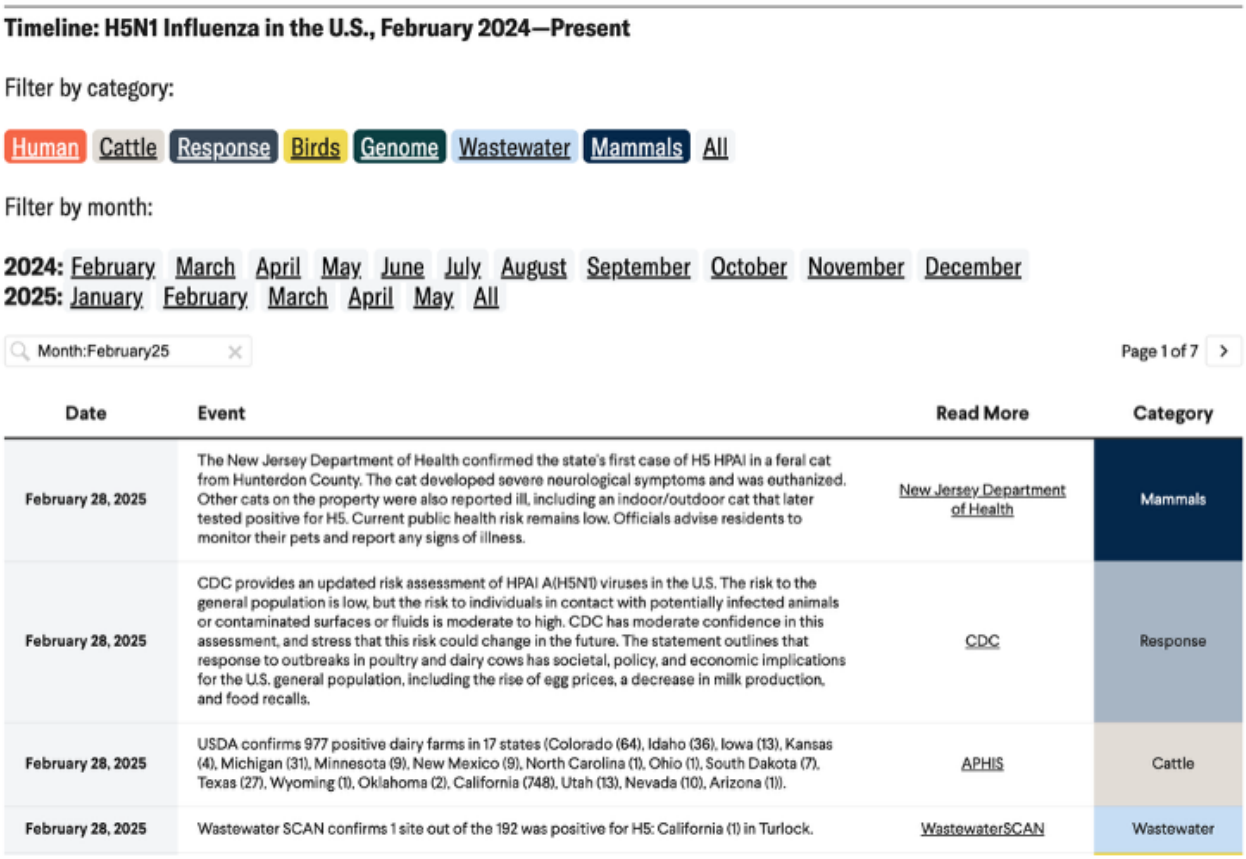
Outbreak timeline entries were organized under four variables: date, event, read more (source link), and category. Each entry was tagged under one of the following categories for easy filtering and organization: human, cattle, response, birds, wastewater, genome, and mammals.

The “human” category included information related to HPAI infections in humans, including case counts and research updates. Our primary sources for human data were press releases and reports from the CDC and local and state health departments.

The primary source used to identify animal outbreaks was the United States Department of Agriculture (USDA) [40]. The USDA website reports HPAI in commercial and backyard flocks, wild birds, mammals, and livestock. For poultry outbreaks included in the “birds” category, using the USDA website, curators were able to ascertain the confirmation date, state and county location, production type, control area release, and the number of birds affected [8]. Only poultry or birds classified under commercial production, including the World Organization for Animal Health (WOAH) poultry category, were included in the descriptive analyses for this study. For livestock outbreaks in the “cattle” category, curators used the USDA website to ascertain confirmation date, state location, production type, and species [41]. Outbreaks among “cattle” species and “dairy milking cows” as the production type were included in these analyses. The “mammals” category provides updates on HPAI in other mammals besides cattle and humans.

For the collection of wastewater data, curators manually reviewed publicly available WastewaterSCAN reports from 192 wastewater testing sites across the United States [42]. WastewaterSCAN is an academic partner of the CDC’s National Wastewater Surveillance System (NWSS), and system data are collected and reported to the CDC [43]. WastewaterSCAN provided early, open-access to routinely tested wastewater surveillance data for the H5 subtype with results displayed on a public dashboard, updated daily, starting in May 2024 [42,44]. Filters were selected for pathogen (influenza), view by location, subtype (H5), locations (national, all wastewater sites, n=192).

XSL•FO
RenderX



Data are available from WastewaterSCAN as of May 7, 2024, and are available for the remainder of the study period. Positive detections should be interpreted with consideration of the complexities of H5 in wastewater, primarily noting the inability to distinguish between human and animal sources (both domesticated and wild), as discussed in this research.

For the collection of genomic data, including clade and genotype information, sequence name, and accession number, the curation team gathered details from research and technical updates and information submitted to the Global Initiative on Sharing All Influenza Data virus genomic database or to GenBank, the genetic sequence database run by the US National Institutes of Health [45,46]. Data collection and reconciliation efforts for HPAI are ongoing.

The "response" category highlights response efforts, including policy mandates and changes to recommendations and guidelines as the outbreak evolved. This category also encompasses new research related to the response to the outbreak, such as the development of diagnostics and animal vaccines. Sources for "response" entries include news outlets, government agencies, preprint servers, and research journals.

Curators performed daily source checks, and all timeline entries were reviewed by at least one additional curator before posting to help ensure accuracy and consistency in reporting. Global.health collaborated with Think Global Health to publish a weekly version of the outbreak timeline (Figure 4) [38].

**Figure 4.** Outbreak timeline.

### Visualizing Multimodal Data

The outbreak visualization map was created to accompany the outbreak linelist and multimodal outbreak timeline as publicly available resources [47]. Based on our development experience with maps from COVID-19, mpox (2022 and 2024), Ebola (Uganda 2022), and Marburg (Equatorial Guinea 2023), we used the Mapbox Boundaries and Mapbox GL JS library to create a state-level human HPAI map and later added new data overlays for county-level animal outbreaks in commercial cattle and poultry. Further visualization methods are described in Multimedia Appendix 2 [48].

### Ethical Considerations

No institutional review board approval was applied for. Research was conducted using secondary data from publicly available sources that are deidentified. The research monitored public health signals without involving human participants and was designed to provide timely situational awareness and contribute to generalizable knowledge.

## Results

### Outbreak Linelist, Human Data

As of February 28, 2025, there were a total of 70 confirmed human cases of HPAI A(H5N1) reported in 13 states across the United States [5,19]. Only one confirmed human case of HPAI A(H5N1) had ever been documented in the United States before this outbreak, underscoring a sharp rise in incidence [10,17,49]. Included cases were publicly reported (eg, confirmed human HPAI cases meeting source-defined criteria for our setting and

XSL•FO
RenderX

study period). Data availability varied across sources. due to public reporting practices; no data linkage was performed. Nearly all confirmed human cases (92.9%) were from exposure associated with commercial agriculture and related operations. Among the confirmed human cases, 58.6% (n=41) occurred after exposure to infected commercial dairy herds. Additionally, 34.3% (n=24) resulted from exposure to infected commercial poultry farms and culling operations. Two human cases were exposed to other animals (such as backyard flocks, wild birds, or other mammals). For 3 cases, 1 Missouri resident and 2 Californian children, the source of exposure was unknown [19].

H5N1 was the only pathogen subtype that had been identified among these human cases. The sequencing of specimens showed that clade 2.3.4.4b of H5N1 was responsible for these infections, which was the same clade reportedly causing the outbreaks in cattle, poultry, and wild birds [5,50-52]. During the study period, of these sequenced human specimens where data were publicly available, 3 genotypes of clade 2.3.4.4b had been identified: B3.13, D1.1, and D1.3 [10,52,53]. There was no evidence of human-to-human transmission of the virus as of February 28, 2025 [19]. All confirmed human cases during the study period with a known exposure source had resulted from zoonotic, animal-to-human transmission. As of February 28, 2025, there had been only one death reported within the United States [19]. The case fatality rate for the US outbreak was 1.4%. Sixty-one confirmed human cases reported some kind of symptom associated with HPAI as of February 28, 2025. When specific symptoms were noted (Table 1), the 3 most common symptoms reported were fever, conjunctivitis or eye discomfort or watery discharge, and cough. Global.health findings align with those reported in publications in the *New England Journal of Medicine* and *Nature Medicine*, whose researchers analyzed the symptomatology of individuals with confirmed HPAI infections [54,55].

**Table .** Symptom variables and their respective definitions used in our clinical analysis of confirmed human HPAI cases. Definitions include alternate terms for variables, which were grouped to avoid duplicates. These variables were extracted from the human case line list dataset. These symptoms were reported among the 61 individuals with confirmed HPAI infections in the United States between February 1, 2024, and February 28, 2025.

| Variable | Definition |
|---|---|
| pink_eye_conjunctivitis | “pink eye” “conjunctivitis” “eye discomfort” “eye redness” |
| watery_eyes | “watery discharge” “eye tearing” “drainage” “discharge” |
| subconjunctival_hemorrhage | “subconjunctival hemorrhage” |
| upper_respiratory_tract | “upper respiratory tract symptoms” “mild upper respiratory symptoms” |
| respiratory_symptoms | “common respiratory infection symptoms” “severe respiratory illness” “respiratory symptoms” |
| sore_throat | “sore throat” |
| runny_nose | “runny nose” |
| chest_pain | “chest pain” |
| nausea | “nausea” |
| weakness | “weakness” |
| vomiting | “vomiting” |
| diarrhea | “diarrhea” |
| nasal_congestion | “nasal congestion” |
| fatigue | “fatigue” |
| fever | “fever” |
| cough | “cough” |

Table 1 outlines the symptom variables and their respective definitions used in our clinical analysis of confirmed human HPAI cases. Definitions include alternate terms for variables, which were grouped to avoid duplicates. These variables were extracted from the human case linelist dataset. These symptoms were reported among the 61 individuals with confirmed HPAI infections in the United States between February 1, 2024, and February 28, 2025.

## Outbreak Timeline, Multimodal Data

Early in the outbreak, the Global.health team partnered with Think Global Health, a digital publication by the Council on Foreign Relations supported by Bloomberg Philanthropies. Think Global Health is an online bulletin that examines the ways in which changes in health are reshaping economies, societies, and the everyday lives of people around the globe. Think Global Health published data curated by the Global.health team, creating the outbreak timeline (Figure 4) [38]. During the study period, the outbreak timeline was the 16th most viewed story on the Think Global Health website and recorded over 5800 page views from its publication through February 28, 2025. It also experienced periodic surges in traffic such as when it was first published in June 2024, with additional spikes in October 2024 and January 2025. The outbreak Timeline is accessible directly through the Global.health website, GitHub, and ThinkGlobalHealth.org [26,38,56].

XSL•FO
RenderX

Figure 4 outlines the outbreak timeline published on the Think Global Health website, which presents events related to HPAI in the United States between February 1, 2024, and February 28, 2024 [38]. The timeline allows readers to sort entries by category or month. Each entry provides the date, a brief description of the event, a source link for more details, and the assigned category.

As of February 28, 2025, the outbreak timeline data consisted of a total of 682 entries across all categories. Sixty entries in the "human" category included information related to HPAI infections in humans (eg, case counts and research updates). As case counts rapidly increased in the fall of 2024, some timeline entries reported multiple newly confirmed human infections on the same day, which is why the number of human infections exceeds the number of entries tagged in the "human" category. However, summing the case reports included in our 60 "human" entries provides the total number of confirmed cases reported in the United States. For animal outbreak data, there were 116 entries in the "birds" category, with the latest timeline entry capturing a total of 325 positive detections at commercial poultry farms across 37 states and 1 US territory (Figure 5). There were 191 entries under the "cattle" category, with the latest timeline entry capturing a total of 977 positive detections at commercial dairy farms across 17 states (Figure 5).

**Figure 5.** Highly pathogenic avian influenza (HPAI) detections at commercial poultry and cattle farms per state, 2024 - 2025.

Figure 5 outlines HPAI detections among humans, commercial poultry farms, and commercial cattle farms by state in the United States between February 1, 2024, and February 28, 2025. These charts depict the number of human cases (blue), commercial poultry farms with positive detections (green), and commercial cattle farms with positive detections (red) per state collected through a multimodal data approach. The state sums correspond to the total case reports collected in the timeline, human cases (n=70), commercial poultry farm outbreaks (n=325), and commercial cattle farm outbreaks (n=977). Shading indicates the number of outbreaks per state, where the shading gets darker for states with more detections.

A total of 189 entries in the "wastewater" category displayed wastewater detections across the country. The "wastewater" category displayed results from our observation of positive H5 detections using WastewaterSCAN's public dashboard in Michigan, Idaho, Texas, Minnesota, Iowa, California, South Dakota, Colorado, Arkansas, Florida, Nevada, Tennessee, Utah, Maine, Delaware, New Jersey, Illinois, Kansas, Connecticut, and Massachusetts as of February 28, 2025 [42].

The timeline also incorporated 31 entries in the "genome" category detailing genomic information about the outbreak and research related to the avian influenza genome. There were 29 entries in the "mammals" category that provided updates on HPAI detections in other mammals besides cattle and humans, such as domestic and feral cats, black rats, pigs, zoo animals (eg, harbor seals), house mice, deer mice, prairie voles, and desert cottontails. Sixty-six entries in the "response" category highlighted response efforts, including policy mandates, and changes to recommendations and guidelines as the outbreak evolved.

## Visualizing Multimodal Data

The outbreak visualization map allows users to explore human cases and animal outbreaks in a single view, supporting a One Health approach to outbreak surveillance [47].

Figure 6 shows the spatial distribution of reported cases of HPAI in humans, commercial poultry, and commercial cattle outbreaks as of February 28, 2025 (confirmation dates were used to pinpoint cases in time). During the study period, there were 13 states with confirmed human cases, 17 states with infected commercial cattle, and 37 states plus 1 US territory with infected commercial poultry. Of the confirmed human cases, 41 were the result of exposure to commercial dairy herds (cattle), 24 were the result of exposure to commercial poultry farms and culling operations, 2 resulted from exposure to other animals (ie, other noncommercial birds, including backyard poultry), and 3 had an unknown exposure source. California emerged as a hotspot during the study period, reporting the highest numbers of human cases and commercial cattle outbreaks in the United States. Overall, 54.3% (n=38) of all human cases in the United States were reported in California, including 36 human cases associated with cattle exposure and 2 cases with an unknown exposure source [19].

**Figure 6.** Outbreak visualization map.

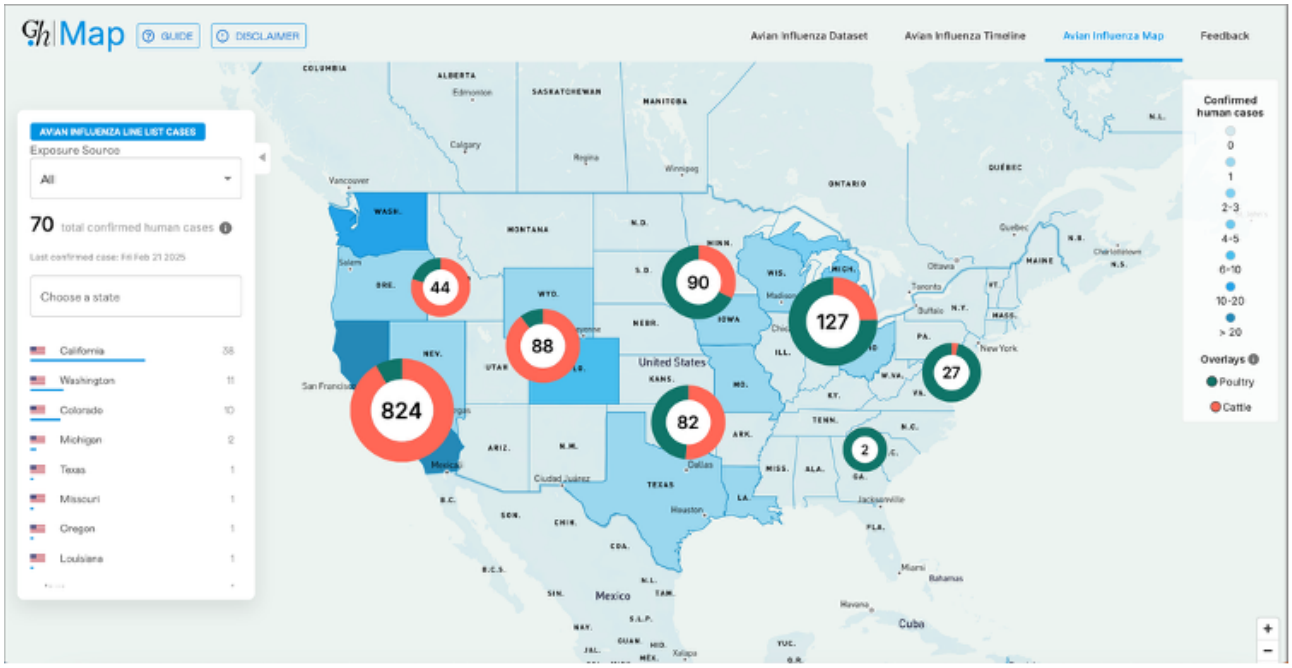

Figure 6 displays the outbreak visualization map with human and animal surveillance data compiled between February 1, 2024, and February 28, 2025. The map shows the geographic distribution of confirmed human cases and overlays corresponding poultry and cattle outbreak data in a single view to show emerging hotspots. Circle markers indicate regional- or state-level outbreak totals for each species, with the ability to filter and zoom for spatial granularity. A further description of the methods is described in Multimedia Appendix 2.

## Case Study: California

This case study focuses on the temporal progression of HPAI A(H5) detections in public health surveillance data. We examined human health, animal outbreak (commercial cattle and commercial poultry), and wastewater surveillance data

XSL•FO
RenderX

reported during the study period from February 1, 2024 through February 28, 2025, filtered to events occurring in California. During the study period, we also recorded response actions, policy changes, and research updates in our outbreak timeline; however, these activities are not the focus of this case study and are acknowledged only for contextual completeness.

In April 2024, WastewaterSCAN developed and evaluated a test targeting the H5 hemagglutinin gene of influenza A for use in wastewater surveillance [44]. Routine H5 testing was implemented at sites nationwide in May 2024, with results publicly reported beginning in June [42,44]. On June 10, 2024, WastewaterSCAN reported the first positive H5 detection at a wastewater treatment site in California [42]. Additional positive wastewater detections were observed in July and September, representing early signals of viral presence in the state before confirmed infections in animals or humans [42], but notably not before the detection of HPAI in wild birds. Although the interpretation of wastewater detections is complex and does not allow attribution to a specific host, wastewater surveillance is recognized as a useful early-warning component of outbreak monitoring [44,57,58].

Eighty-one days after the first positive wastewater detection, on August 30, 2024, the California Department of Food and Agriculture confirmed the state's first HPAI detection in commercial dairy cattle in Sacramento County within the Central Valley [59].

Before the 2024‐2025 HPAI A(H5) outbreak, the USDA reported HPAI infections among commercial poultry in Fresno County, California, in August 2022 (outbreak reference: Fresno 01). From 2022 to 2024, periods of active detection were interspersed with intervals without reported cases, alongside ongoing efforts by poultry producers to strengthen biosecurity measures to protect flocks and prevent disease spread [8]. The state was subsequently self-declared free of HPAI in poultry on June 28, 2024, following completion of required response actions and surveillance [60]. On September 18, 2024, 100 days after the initial wastewater detection, the USDA confirmed a new HPAI outbreak in commercial poultry in Merced County (outbreak reference: Merced 12), marking the first detection since the state's HPAI-free declaration and resulting in the loss of that status [60].

On October 3, 2024, the California Department of Public Health announced the state's first confirmed human cases of HPAI A(H5) in 2 adult dairy farm workers with occupational exposure to infected cattle, occurring 115 days after the first wastewater detection [61]. No epidemiological link between the 2 individuals was identified, and there was no evidence of human-to-human transmission [61].

Positive H5 detections in wastewater continued throughout the remainder of the study period, with an increasing trend observed beginning in October 2024 and peaking between November 2024 and January 2025 [42]. Human infections among individuals with occupational exposure followed a similar temporal pattern, with confirmed cases peaking in October (n=16), November (n=12), and December (n=8) of 2024 [19]. Viral genome sequencing findings supported spillover from dairy cattle as the source of infection among affected farm workers, consistent with observations in other states [62]. However, in most cases, the definitive source of H5 detections in wastewater has not been determined.

By the end of the study period, California had reported 748 positive detections among commercial dairy farms and 66 positive detections among commercial poultry farms, illustrating rapid expansion of the outbreak within animal populations [8,41]. These trends are displayed in Figure 7.

XSL•FO
RenderX

**Figure 7.** Graph of key data surveillance events in the California outbreak of highly pathogenic avian influenza (HPAI) A(H5) (February 1, 2024, to February 28, 2025).

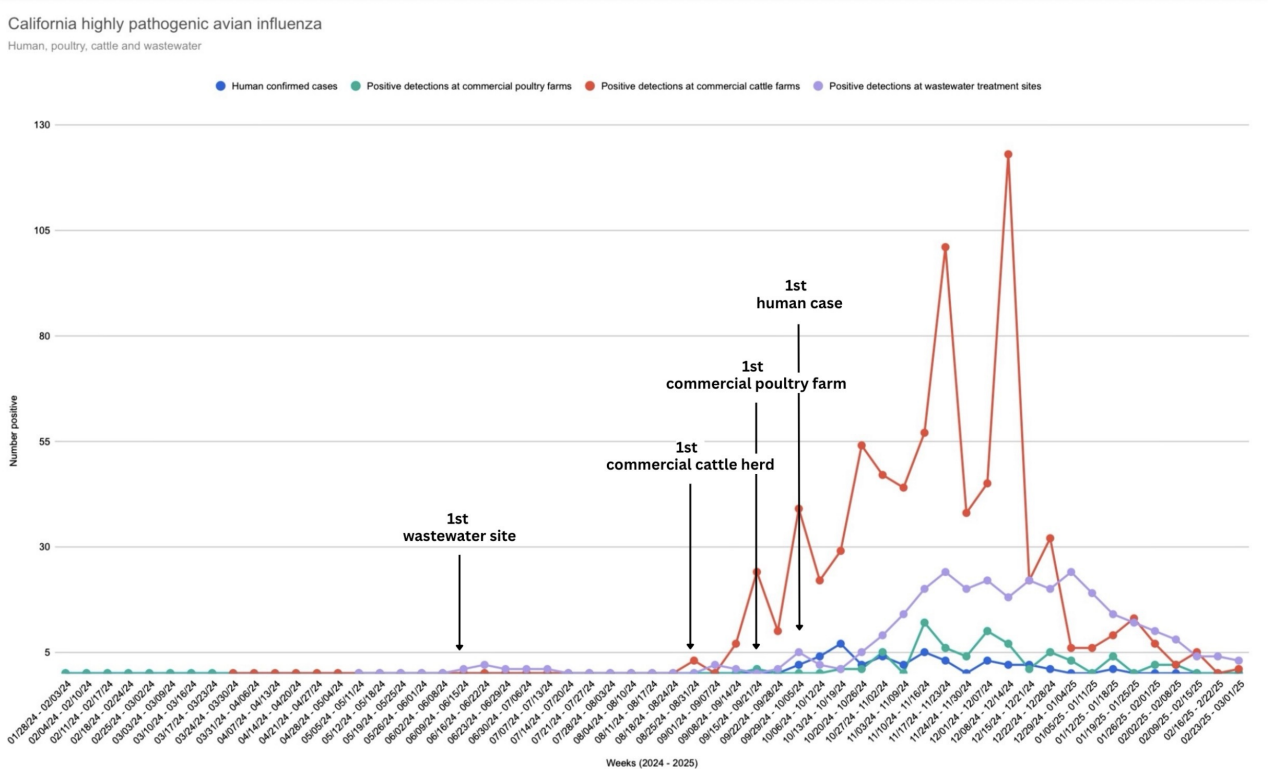

Figure 7 displays the time-series analysis used to track HPAI A(H5) activity across multiple data modalities in California. The dataset includes the number of positive human cases, detections at commercial poultry farms, detections at commercial dairy cattle farms, and wastewater treatment site detections. The study period is from February 1, 2024, through February 28, 2025, and dates were matched to CDC epidemiological weeks, ranging from January 28, 2024 (week 5, 2024) through March 1, 2025 (week 9, 2025). Data from WastewaterSCAN were not available before May 7, 2024. Cattle data from the USDA were not available before March 25, 2024. The USDA reports historical poultry outbreak data dating back to the introduction of HPAI in California in 2022. The first positive detection of H5 at a wastewater site in California occurred on June 10, 2024, followed by the first positive detection at a commercial cattle farm on August 30, 2024. There was also a positive detection at a commercial poultry farm on September 18, 2024, the first detection of HPAI in poultry since California was declared HPAI-free in June 2024. The first human cases of HPAI in California were announced on October 3, 2024, 115 days after the first positive detection at a wastewater site.

## Discussion

### Principal Findings

In this study, we examined Global.health's multimodal data collection, integration, and visualization efforts in response to the 2024 - 2025 HPAI A(H5) outbreak using data collected in the United States between February 2024 and February 2025. The data collection efforts resulted in the development of publicly accessible resources to improve contextual understanding and track the outbreak, including the outbreak linelist dataset (human) and outbreak timeline (multimodal data collection: human, animal, wastewater, genomic, research, response, and policy). The data collected were also used to produce an outbreak visualization map (human and animal), which overlaid instances among humans, cattle, and poultry for enhanced data visualization and insight capabilities.

When disparate data points were examined holistically, in real-time—tracking human, animal, and wastewater data together—this approach helped identify emerging hotspots, highlighted outbreak trends, and improved situational awareness. California is examined in this study as an outbreak hotspot that quickly became an epicenter. Wastewater was an early indication of the virus in the state, with positive A(H5) detection of unknown source origin in June 2024 [42].

In the context of the 2024 - 2025 HPAI A(H5) outbreak, the time between initial detection in wastewater and cases in animals and humans highlights an important window of opportunity for early response. Monitoring of wastewater data coupled with trend analysis, taking into account events such as annual bird migration, can provide insight into changes in trends that can point to emerging outbreaks. Monitoring of these trends within the context of contributing sources is important for the identification of zoonotic diseases with pandemic potential, such as HPAI [63]. Further, a coordinated and collaborative One Health approach to better understand the source could guide public health actions to hone methods and protocols for future respiratory illness seasons or outbreaks (eg, a positive H5 detection in wastewater may prompt further monitoring or testing in animals, milk, or humans; or identify the need for

XSL•FO
RenderX

deployment of wastewater testing to high-priority locations to focus on areas with a higher risk of disease transmission) [58].

This outbreak demonstrated key challenges and complexities with wastewater surveillance of HPAI noted in prior literature: an inability to distinguish between human and animal sources [64]; nonhuman and noncattle animal inputs, including wild and migratory birds [64,65]; industrial and agricultural inputs into wastewater [63]; stormwater contributions [64-66]; timely data integration to address knowledge gaps [58]; unknown thresholds for sensitivity in testing and positive detection [58]; current testing is not specific for H5N1 and may also detect low-pathogenic H5 influenza viruses [67]; and differences in laboratory approaches and reporting practices may complicate interpretation [58].

Although waste processing from industrial dairy farms in the United States is highly regulated and, as a result, most farms have internal systems such that waste is not designed to be dumped into municipal sewage systems, research has demonstrated that animal inputs have been responsible for some wastewater detections [44,63,68]. Dairy processing discharge into sewage systems has been studied with evidence to support the hypothesis of dairy industry contributions and the likelihood of multiple sources feeding into wastewater treatment plants [63]. Retrospective testing in other affected areas (Texas and North Carolina) has also shown that H5 was detectable in wastewater before the state identified H5-infected cattle, providing early warning for outbreaks that may contribute to the sewershed [63].

Further, the A(H5) virus is enzootic in wild birds, and animal sources should be considered when interpreting influenza subtype detections in wastewater [64]. Wild birds can be asymptomatic carriers of HPAI [6,69], and the movement and congregation of birds during migration, among all 4 US migratory flyways [70], and on a broader intercontinental scale, where birds may live or stop in different habitats [71], have been shown to be important factors in the geographic spread and ongoing circulation and phylogenetic changes of avian influenza viruses [52,72-77]. California is in the Pacific Flyway, a major migratory route for more than a billion visiting birds each year [78], creating risk for spillover events and point-source transmissions [72], where previous studies have aimed to model high-risk areas in the state [79,80]. The USDA conducts wild bird surveillance for avian influenza viruses of concern and reports positive detections of HPAI in wild birds and poultry in California before and during our study period [8,69]. However, wild bird surveillance data were not collected as part of this study. Wild bird detections are discussed in this context as a potential source contributing to the sewershed and subsequent positive detection in wastewater surveillance data [65]. Further research is needed to assess the geographic representativeness of site detections in California, including associations with migratory bird activity, seasonality of positive detections [81], historical avian influenza detections, and proximity to commercial agriculture.

While the interpretation of the virus in wastewater is complex, it is recognized as an important tool in the surveillance of emerging pathogens and has the potential to improve our understanding of outbreak dynamics and strengthen ongoing avian influenza surveillance efforts, with implications for animal and human health [44,64]. Wastewater data can complement traditional epidemiological data and existing health-monitoring systems [58,82], as demonstrated by Global.health's multimodal data approach to comprehensive disease surveillance.

Future work should focus on determining the origin of H5 in US municipal wastewater systems and include efforts to sequence viral genome fragments present in wastewater samples. Further, there is a critical need for clear communication to explain the meaning and interpretation of detection for influenza A virus and subtypes in wastewater.

The study demonstrates how the compilation of open-source multimodal data can provide early situational awareness and a more complete view of emerging zoonotic outbreaks. Open-source tools that are able to adapt and scale in real time as an outbreak evolves and presents new challenges, integrating new data sources for enhanced surveillance, are in line with broader calls to modernize pandemic intelligence by leveraging cross-sectoral and nontraditional data streams [83]. Global.health was able to quickly adapt the outbreak schema for the standardized collection of key information pertinent to this pathogen. In this study, we highlighted observations gained from the integration of data from official and nonofficial media sources. Our open-source format supports a transparent approach to information sharing, especially in the early days when there may be delays in official reporting, siloed and fragmented data, and data vacuums. This integration and methodology presents an innovative, valuable, and repeatable approach for open-source public health surveillance for zoonotic or other emerging or reemerging pathogens.

## Limitations

Global.health strives to ensure that the data collated and shared on our platform are timely and accurate. In addition to the limitations associated with interpretation discussed in the Discussion section, (eg, the source of H5 signals in wastewater), there are important limitations associated with the data collected by Global.health during the 2024 - 2025 HPAI A(H5) outbreak. As part of quality assurance, data requires continuous reconciliation and validation across local, state, national, and international datasets to ensure alignment and to track changes. All Global.health data collection relies on publicly available data that are deidentified. Further research is needed to realize the full potential of open-source, multimodal data integration to support outbreak response and the impact it can have on public health as a whole.

Curators faced many challenges while building an emerging infectious disease dataset in real time, including delays in reporting for human cases, animal outbreaks, and wastewater detections; delays in confirmatory testing; limited data standardization within and across government organizations; lack of precision of virus nomenclature and terminology (eg, avian influenza, bird flu, AI, HPAI, HPAI A(H5), HPAI A(H5N1), HPAIV, H5, H5Nx, H5N1, and H5-type being used inconsistently and interchangeably in media sources and scientific literature); presentation of aggregated case data; limited case metadata; and retroactive removal and addition of

XSL•FO
RenderX

impacted herds, flocks, and wastewater sites. USDA reports confirmed outbreak events by date and location using outbreak reference numbers (also referred to as special IDs). Global.health conducted regular data reconciliation efforts to mitigate retroactive, unannounced, and unexplained changes and data discrepancies between Global.health and our primary sources (WastewaterSCAN and USDA). The average look-back period was 1 week for Global.health to check and update data and was limited by time and available resources. USDA published the total number of cattle outbreaks on their website, and we were able to align counts on a daily basis. However, cumulative numbers were not available from USDA (Poultry) or WastewaterSCAN. Therefore, publicly available data from these sources may differ from the results of this study. These challenges reflect longstanding gaps in US surveillance systems; however, advanced tools and approaches create opportunities to integrate data not traditionally accessible to public health [84]. Innovative methods, such as artificial intelligence and automated quality control tools, may also help enhance data quality in real time [85,86]. To ensure data transparency, all outbreak resources are publicly accessible and point back to the original sources of information.

Primary sources for multimodal data collection are listed for this research. Additional relevant sources may be available, but were not included in this study.

## Conclusions

As outbreaks and the public health landscape evolve, so too must surveillance methods; how data are gathered, analyzed, and visualized matters. Further, the 2024 - 2025 HPAI A(H5) outbreak in the United States again highlighted the importance of a One Health approach as the pandemic potential of zoonotic outbreaks grows [87]. Focusing on the interplay of humans, animals, and the shared environment will assist researchers, public health teams, and communities in better understanding the origins, evolution, and scope of emerging zoonotic events. Our data collection efforts and research showed both the value and the challenges of integrating disparate sources to modernize surveillance methods and create public resources that enhance early situational awareness. The potential for wastewater surveillance, and other emerging data modalities, to provide an early indication of disease in a community calls for increased research into how to interpret positive detections in the context of multimodal datasets. Accurate, accessible, real-time data are the cornerstone of prudent outbreak response. Early, open access to data and visualization tools, such as those put forward by Global.health, can demonstrate value in a public health response approach that is adaptable and resilient in the face of emerging threats.

## Funding

This work was supported by the Rockefeller Foundation (grant PC-2022-POP-005) and the Wellcome Trust (grant 228186/Z/23/Z). The funding sources had no involvement in the study design, data collection, data analysis, data interpretation, writing of the report, or submission decisions.

## Data Availability

Data collected for this study will be made available upon publication. Our data products include the linelist dataset (human cases), data dictionary, interactive map, and event timeline. No additional related documents will be available. Data can be accessed through the Global.health website. Global.health commits to releasing code and software tools under the MIT License and data, where possible, under the CC BY 4.0 license. Both the University of Oxford and Boston Children's Hospital serve as data controllers. If you choose to access, download, or use Global.health data, we ask that you adhere to our terms of use, privacy policy, and citation guidelines provided on the Global.health website.

## Abstract

**Background:** Tuberculosis (TB) remains one of the leading causes of death from a single infectious disease worldwide. In Thailand, persistent gaps in early detection and access to TB care remain important public health challenges, particularly among populations in rural and remote areas.

**Objective:** This study aimed to develop and evaluate predictive models for TB outcomes using routine surveillance data to support risk stratification, thereby informing public health decision-making in Chiang Mai Province, Thailand.

**Methods:** A retrospective cohort study was conducted using data from 5557 TB cases registered in the National Tuberculosis Information Program in Chiang Mai Province from 2020 to 2024. Models were developed to predict treatment success, mortality, and time to treatment initiation. We evaluated model performance using the area under the receiver operating characteristic curve, the Harrell Concordance Index, and error-based metrics for time-to-treatment prediction. Scenario analyses were conducted under predefined assumptions to assess projected changes in detection-related indicators, treatment coverage, and mortality relative to provincial baseline indicators.

**Results:** The models demonstrated good predictive performance. Mortality was associated with HIV co-infection (hazard ratio 5.80) and was highest among older adults with HIV co-infection (hazard ratio 12.30). Treatment delays were longer among individuals living in rural or remote areas and among those without health insurance, with mean delays ranging from 8 to 18 days. These findings suggest distinct patterns in TB outcomes, with mortality more closely related to clinical vulnerability and treatment delay more closely related to health care access factors. Under modeled scenarios, the models projected that detection-related indicators would increase by 25%, treatment coverage would increase by 15%, and mortality would decrease by 20% relative to provincial baseline conditions.

**Conclusions:** Predictive modeling using routine TB surveillance data may support risk stratification and provide insights into treatment outcomes and delays. The findings highlight the combined roles of clinical vulnerability and health care access factors in TB outcomes and support further evaluation of data-driven approaches to inform targeted TB interventions in resource-limited settings.

## Introduction

Tuberculosis (TB) remains one of the leading causes of death from a single infectious disease worldwide. The World Health Organization (WHO) estimates that 10.7 million people developed TB globally in 2024, of whom 8.3 million were diagnosed and notified, highlighting persistent gaps in case detection and reporting. Although global health efforts have made progress in TB diagnosis and treatment, global TB incidence declined by approximately 12% between 2015 and 2024, remaining well below the End TB Strategy target of a 50% reduction by 2025 [1].

Thailand is classified as a high-burden country for TB and TB/HIV by the WHO. Thailand has an estimated 113,000 new TB cases annually, corresponding to an incidence of 157 per 100,000 population. Of these, HIV co-infection accounts for 9,400 cases, and 13,000 deaths are attributed to TB each year [2]. Reported treatment coverage is approximately 71%,

XSL•FO
RenderX

indicating persistent gaps in access to diagnosis and care. Previous studies have shown that TB does not distribute evenly across Thailand but rather clusters in several areas, particularly along international border regions [3]. These geographic and health-system disparities highlight the need for analytical approaches that integrate epidemiological, clinical, and health service data to support more precise and equitable TB control.

Mathematical models, particularly compartmental models such as the SEIR (susceptible-exposed-infectious-recovered) framework, have been widely used to study TB epidemiology. Unlike the classical SIR model, the SEIR framework explicitly includes an exposed compartment representing individuals who are infected but not yet infectious, thereby accounting for the latent stage before progression to active TB disease [4,5]. However, classical SEIR-based approaches often rely on simplifying assumptions, such as homogeneous mixing and fixed transition rates between compartments. These approaches may have limited ability to capture individual-level heterogeneity in clinical risk, health care access, and treatment outcomes.

Researchers are increasingly applying machine learning (ML) methods to TB-related predictive tasks, such as incidence prediction, diagnosis, and treatment outcome prediction [6,7]. These approaches can exploit high-dimensional, heterogeneous data and demonstrate strong predictive performance for specific TB-related outcomes. ML-based approaches have also been incorporated into clinical decision support systems to assist with diagnostic and treatment decision-making [8,9]. However, most existing studies focus on isolated prediction tasks and do not explicitly link individual-level risk estimation with broader epidemiological disease-stage structures.

The strengths of SEIR-based epidemiological models and ML approaches are complementary. SEIR-based frameworks [10] provide a structured way to conceptualize disease progression at the population level, whereas ML approaches enable data-driven prediction of observable individual-level outcomes from clinical and surveillance data. However, there remains limited evidence on how routine TB surveillance data can be organized within an epidemiologically informed framework to generate practical predictions of treatment outcomes, mortality, and treatment delays. This gap is particularly important in settings where surveillance systems contain rich programmatic data, but practitioners do not routinely use them for risk stratification or decision support.

TB control in Thailand is primarily implemented through health care facility–based diagnosis, registration, and treatment reporting. In contrast, routine programmatic reporting remains centered on surveillance and treatment monitoring rather than risk-prediction tools. Ongoing programmatic work includes surveillance and focused interventions for key high-risk or vulnerable populations, such as people living with HIV, prisoners, migrants, older adults, and non-Thai populations [11,12]. Thailand has established the National Tuberculosis Information Program (NTIP) as a national online TB reporting system. However, there are gaps in translating surveillance data into analytical tools that can support decision-making at different levels of the health care system.

NTIP is Thailand's national TB reporting system that collects data on diagnoses, treatment registrations, and outcomes from health care facilities [13]. While NTIP provides a standardized national dataset, it reflects diagnosed and registered TB cases and does not capture unobserved infection or transmission processes. These characteristics make NTIP suitable for developing predictive models focused on routinely observed clinical and programmatic outcomes. Integration of NTIP data with analytical models that combine an epidemiologically informed structure and predictive modeling may support more systematic use of surveillance data for risk stratification and policy planning.

Therefore, this study aimed to develop and evaluate a TB surveillance framework based on an SEIR-informed conceptual structure and predictive models using NTIP data from Chiang Mai Province. Specifically, the study aimed to assess whether routinely collected surveillance data could support risk prediction, risk stratification, and public health decision-making for TB outcomes in a resource-limited setting.

## Methods

### Study Design

This retrospective cohort study used routine surveillance data to develop a TB surveillance framework that combines an SEIR-informed conceptual structure with individual-level predictive models. We used the SEIR framework [10,14] to guide the conceptual organization of TB disease stages. Empirical modeling focused on clinical and programmatic outcomes recorded in NTIP, including treatment success, mortality, and time to treatment initiation.

Within this framework, NTIP provided data on diagnosed and registered TB cases, treatment outcomes, deaths, and treatment initiation dates. Registered TB cases represented the observed infectious state among patients captured by the surveillance system. We operationalized recovery-related outcomes as treatment success, and we used recorded deaths to represent mortality. NTIP did not directly capture susceptible and exposed populations; therefore, we retained them as conceptual components of the SEIR-informed framework. Table 1 summarizes the observability and operationalization of SEIR-D (susceptible-exposed-infectious-recovered-death) components in NTIP data.

The study, therefore, linked an epidemiologically informed disease-stage framework with predictive modeling of observed outcomes among patients diagnosed with and registered for TB.

XSL•FO
RenderX

**Table .** Summarizes the observability and operationalization of SEIR-D (susceptible-exposed-infectious-recovered-death) components in the National Tuberculosis Information Program (NTIP) data[a].

| Component | Epidemiological meaning | NTIP observability | Operationalization in this study |
|---|---|---|---|
| Susceptible | Population at risk of TB[b] infection | Not directly observed | Conceptual component of the SEIR-informed framework |
| Exposed | Individuals with TB infection before registered active TB disease | Not directly observed | Conceptual component of the SEIR-informed framework |
| Infectious | Diagnosed active TB cases | Observed among registered cases | Registered TB cases recorded in NTIP |
| Recovered | Successful treatment outcome | Observed | Treatment success recorded in NTIP |
| Death | Death during treatment or follow-up | Observed | Death recorded in NTIP treatment outcome data |
| Treatment delay | Interval from diagnosis to treatment initiation | Observed | Days between diagnosis and treatment initiation |

[a]SEIR-D components were defined within an SEIR-informed conceptual framework and operationalized according to the structure of the NTIP surveillance dataset. Susceptible and exposed populations were not directly observed in NTIP and were retained as conceptual components. Empirical analyses focused on registered TB cases, treatment success, death, and time to treatment initiation. Treatment delay was considered a programmatic interval rather than a disease-state compartment.

[b]TB: tuberculosis.

## Study Area and Data Sources

Data were obtained from the NTIP, including records of patients with TB registered in Chiang Mai Province between October 2020 and September 2024. The NTIP database provided individual-level data on diagnosis, treatment registration, comorbidities, and treatment outcomes.

## Inclusion and Exclusion Criteria

The study population consisted of patients registered for TB treatment in NTIP during the study period. We excluded patients with missing values for key variables required for model development, including age, sex, district of residence, treatment initiation date, or treatment outcome. These variables were required to define the analytical cohort, predictor structure, and primary outcomes. The analytical dataset comprised 5557 cases after data cleaning and eligibility screening based on variable completeness. Records were excluded only when missingness involved variables essential for defining the analytical cohort, primary outcomes, or model structure; we addressed missing values in nonessential variables separately using multiple imputation.

## Data Management and Preparation

The key variables in the analytical dataset were age, sex, district of residence, date of treatment initiation, and treatment outcome. Records with missing values in key analytical variables were excluded. Missing values were imputed for nonessential variables, such as selected comorbidities and health care system indicators, using multiple imputation by chained equations, which generated 20 imputed datasets to account for the uncertainty of the imputed values and to reduce potential bias associated with complete-case analysis [14-16]. The imputation model included observed demographic, clinical, and health system variables and assumed a missing-at-random mechanism conditional on these observed variables. This approach is consistent with established recommendations for handling incomplete observational data when missingness is assumed to be conditional on observed variables [14,16].

BMI, comorbidities, HIV status, insurance status, and other predictor variables were recorded at TB registration or initial clinical assessment and used as baseline predictors for subsequent recorded outcomes. A BMI of less than 18.5 kg/m$^2$ was defined using the BMI value recorded at registration or initial assessment. We used the Tukey fences and the isolation forest algorithm [17] to identify outliers. We set the contamination parameter of the isolation forest algorithm to 0.05, and we checked model outputs for clinical plausibility. Residence categories were defined using geographic accessibility to TB services, including the distance from residence to treatment facilities. Urban residence, representing the most accessible category, was used as the reference group for residence variables. All eligible records were retained for model development and assessed using train-test splitting and internal cross-validation.

## Development of Predictive Models

We conducted predictive modeling using observable outcomes from the final analytic NTIP dataset of 5557 TB cases. We selected models according to the structure of the recorded outcomes and the statistical requirements of each prediction task. We applied logistic regression for binary treatment success [17,18], the Cox proportional hazards model for time-to-event mortality with censoring [19,20], and the log-normal accelerated failure time model for time to treatment initiation [20]. This approach allowed each model to correspond to the scale, timing, and censoring structure of each outcome under analysis. Because NTIP records diagnosed and registered TB cases rather than the full susceptible or exposed population, model construction focused on clinical and programmatic outcomes available among registered patients. The SEIR framework was used to organize disease-stage concepts, consistent with compartmental modeling approaches that distinguish susceptible, exposed, infectious, and recovered states [10,21].

XSL•FO
RenderX

A multivariable logistic regression model was used to predict treatment success as a binary outcome, selected for its interpretability and suitability for clinical decision-making [17,18]. A Cox proportional hazards model [19,20] was used to estimate the hazard of death with time-to-event data, accounting for censoring. We tested the proportional hazards assumption using Schoenfeld residuals. We fitted an accelerated failure time model with a log-normal distribution to estimate delays between diagnosis and treatment initiation; this approach estimates the effect of covariates on event time rather than on the hazard function [20].

Together, these models estimated binary outcomes, time-to-event risks, and delays within a unified analytical framework based on recorded clinical and programmatic end points, including treatment success, mortality, and diagnosis-to-treatment delay. We specified the predictive models for recorded outcomes rather than for latent or unobserved transmission states. Model performance was assessed using discrimination and calibration metrics, including the area under the receiver operating characteristic curve (AUC) for classification models [22] and concordance-based measures for survival models [23].

### Model Training and Validation

We assessed model performance using a train-test split (train: 4446/5557, 80%; test: 1111/5557, 20%) and performed internal validation using 10-fold stratified cross-validation on the training set. For classification models, the AUC was used as a performance metric [22]. For survival models, the Harrell Concordance Index was used as a performance metric [23]. We assessed prediction error for the time-to-treatment model using root mean squared error and mean absolute error. Additionally, we assessed the goodness-of-fit of the logistic regression model using the Hosmer-Lemeshow test [17]. We assessed discrimination, calibration, and prediction error across outcome types and model specifications.

### Management of Conflicting Outcomes

We analyzed mortality and treatment success as separate outcome-specific end points. We modeled mortality using time-to-event methods, whereas we modeled treatment success as a binary outcome. We applied this outcome-specific modeling strategy to support risk stratification across different stages of the TB care pathway. We interpreted estimates as predictive associations rather than causal effects.

### Analysis of Scenarios

We performed scenario analyses to assess projected changes in detection-related indicators, treatment coverage, and mortality under predefined modeled assumptions. The baseline scenario represented the observed provincial TB program conditions prior to applying the modeled changes. Baseline values included the provincial detection-related indicator, treatment coverage, and mortality rate, which were derived from Chiang Mai provincial TB program indicators. We derived the time to treatment initiation from recorded diagnosis and treatment initiation dates in NTIP and modeled it separately using a log-normal accelerated failure time model.

We represented screening as a programmatic process related to case detection rather than as a disease-state compartment. We specified detection-related changes as proportional changes relative to provincial TB program baseline indicators. We represented changes in treatment processes using predefined relative changes in treatment coverage and mortality, which were applied to provincial baseline indicators.

In the baseline scenario, the detection-related indicator was 87.08%, treatment coverage was 71.90%, and mortality was 11.90% [12]. The scenario parameters for detection-related improvement, treatment coverage improvement, and mortality reduction were predefined assumptions rather than estimates from an observed intervention. We, therefore, interpreted scenario outcomes as model-based projections rather than observed intervention effects, consistent with the use of modeling approaches to inform public health decision-making in the absence of direct population-level evidence [24].

### Statistical Analysis and Software

We conducted all analyses using R (version 4.1.2; R Foundation for Statistical Computing) and Python (version 3.11; Python Software Foundation). We defined statistical significance as $P<.05$, and we reported all estimates with 95% CI. As NTIP represents a registry of reported TB cases rather than a sampled survey dataset, we therefore did not apply survey weighting. Given the analysis's predictive and exploratory focus, we instead emphasized effect estimates, CI, and model performance metrics rather than confirmatory hypothesis testing.

### Ethical Considerations

The research ethics committee of the Faculty of Public Health, Chiang Mai University (approval: ET030/2025) and the Chiang Mai Provincial Public Health Office approved the study protocol. We anonymized all data prior to analysis and retained no identifiable personal information. Data were stored in secure, encrypted systems in accordance with applicable data protection regulations.

## Results

### Demographic, Clinical, and Health Care Access Characteristics of the Study Participants

This study analyzed 5557 TB cases recorded in the NTIP in Chiang Mai Province between 2020 and 2024. Most participants were male (3756, 67.6% cases), and the mean age was 45.3 (SD 14.8) years. HIV co-infection was present in 556 (10.0% cases), 1000 (18.0%) cases had diabetes mellitus, and 1223 (22.0%) cases had a BMI <18.5 kg/m$^2$. Health care access characteristics included absence of health insurance in 445 (8.0%) cases, rural residence in 1556 (28.0%) cases, and remote residence in 445 (8.0%) cases (Table 2).

XSL•FO
RenderX

**Table .** Baseline demographic, clinical, and health care access characteristics of the study population (N=5557)[a].

| Characteristic | Values |
|---|---|
| Male sex, n (%) | 3756 (67.6) |
| Age (y), mean (SD) | 45.3 (14.8) |
| HIV-positive, n (%) | 556 (10.0) |
| Diabetes mellitus, n (%) | 1000 (18.0) |
| BMI (<18.5 kg/m$^2$), n (%) | 1223 (22.0) |
| No health insurance, n (%) | 445 (8.0) |
| Rural residence, n (%) | 1556 (28.0) |
| Remote residence, n (%) | 445 (8.0) |

[a]Baseline demographic, clinical, and health care access characteristics of National Tuberculosis Information Program–registered patients with tuberculosis in Chiang Mai Province, Thailand, 2020 - 2024. Data are presented as n (%) or mean (SD).

## Predictive Model Performance

Predictive models demonstrated good performance across recorded TB outcomes. The AUC for the treatment success model was 0.88 (95% CI 0.86 - 0.90), indicating good discrimination. The mortality model showed the Harrell Concordance Index of 0.86 (95% CI 0.84 - 0.88), indicating good concordance between predicted and observed survival outcomes. We summarized prediction error for time to treatment initiation using root mean squared error and mean absolute error, with values of 8.2 days and 5.7 days, respectively. The logistic regression model was adequately calibrated, with no evidence of poor fit based on the Hosmer-Lemeshow test ($P$>.05; Table 3).

**Table .** Performance of predictive models for tuberculosis outcomes[a].

| Outcome | Model | Performance metric |
|---|---|---|
| Treatment success | Logistic regression | AUC[b]=0.88 (95% CI 0.86 - 0.90) |
| Mortality | Cox proportional hazards model | Harrell Concordance Index=0.86 (95% CI 0.84 - 0.88) |
| Time to treatment initiation | Log-normal AFT[c] model | RMSE[d]=8.2 days; MAE[e]=5.7 days[f] |

[a]Performance metrics of predictive models for tuberculosis outcomes in a retrospective cohort of National Tuberculosis Information Program–registered patients in Chiang Mai Province, Thailand, 2020 - 2024.

[b]AUC: area under the receiver operating characteristic curve.

[c]AFT: accelerated failure time.

[d]RMSE: root mean squared error.

[e]MAE: mean absolute error.

[f]RMSE and MAE represent prediction errors for the time to treatment initiation, expressed in days.

## Treatment Success as a Recovery-Related Outcome

We modeled treatment success as the recovery-related outcome recorded in NTIP. The logistic regression model for treatment success demonstrated good discrimination, with an AUC of 0.88 (95% CI 0.86 - 0.90), indicating that routinely recorded clinical and programmatic variables are informative for classifying treatment success among registered patients with TB.

## Factors Associated With Mortality

HIV infection was associated with higher mortality among patients with TB (HR 5.80; 95% CI 4.20 - 7.90; $P$<.001). Patients aged older than 65 years with HIV co-infection had the highest estimated mortality risk (HR 12.30; 95% CI 8.90 - 16.40; $P$<.001). Higher mortality was also associated with diabetes mellitus (HR 3.10; 95% CI 2.30 - 4.40; $P$<.001) and a BMI of less than 18.5 kg/m$^2$ (HR 2.30; 95% CI 1.70 - 3.10; $P$<.001; Table 4). We present these estimates as outcome-specific associations from the mortality model.

XSL•FO
RenderX

**Table .** Factors associated with mortality[a].

| Factor | HR[b] (95% CI) | *P* value |
|---|---|---|
| HIV-positive | 5.80 (4.20 - 7.90) | <.001 |
| Age (>65 y with HIV co-infection) | 12.30 (8.90 - 16.40) | <.001 |
| Diabetes mellitus | 3.10 (2.30 - 4.40) | <.001 |
| BMI (<18.5 kg/m$^2$) | 2.30 (1.70 - 3.10) | <.001 |

[a]Factors associated with mortality among patients with tuberculosis in Chiang Mai Province, Thailand, from 2020 to 2024. Hazard ratios were estimated using Cox proportional hazards models.

[b]HR: hazard ratio.

### Factors Associated With Treatment Delay

Treatment delays were longer among individuals living in rural and remote areas than among those living in urban areas. Rural residence was associated with an average delay of 12 (95% CI 9 - 15) days, remote residence with 18 (95% CI 14 - 22) days, lack of health insurance with 8 (95% CI 6 - 10) days, and age >70 years with 6 (95% CI 4 - 9) days (Table 5). We present treatment-delay estimates as mean differences with 95% CI.

**Table .** Factors associated with treatment delays[a].

| Factor | Days, mean difference (95% CI) |
|---|---|
| Rural residence | 12 (9 - 15) |
| Remote residence | 18 (14 - 22) |
| No health insurance | 8 (6 - 10) |
| Age (>70 y) | 6 (4 - 9) |

[a]Factors associated with treatment delay among patients with tuberculosis in Chiang Mai Province, Thailand, 2020 - 2024. Estimates represent differences in the expected time to treatment initiation derived from the accelerated failure time model. Urban residence, the most accessible residence category, was used as the reference group for rural and remote residence estimates.

### Simulation Results of Modeled Scenarios

We derived baseline values for scenario comparisons from Chiang Mai provincial TB program indicators. The scenario analysis did not model the redistribution of specific resources between geographic risk areas. Instead, it represented potential programmatic improvements in detection-related indicators, treatment coverage, and mortality under predefined assumptions. Under these modeled scenarios, the models projected detection-related indicators to increase by 25% (95% CI 22 - 28), treatment coverage by 15% (95% CI 12 - 18), and mortality to decrease by 20% (95% CI 16 - 24) relative to baseline conditions (Table 6). Readers should interpret these projections as scenario-based estimates rather than as observed effects of resource reallocation or implemented program changes.

**Table .** Projected outcomes under modeled scenarios relative to provincial baseline indicators[a].

| Outcome | Provincial baseline (%) | Projected change (%) | 95% CI (%) |
|---|---|---|---|
| Detection-related indicators | 87.08 | +25 | 22 - 28 |
| Treatment coverage | 71.90 | +15 | 12 - 18 |
| Mortality | 11.90 | –20 | 16 - 24 |

[a]Projected outcomes under modeled scenarios are relative to provincial baseline indicators in Chiang Mai Province, Thailand. Estimates represent model-based projections under predefined assumptions and do not reflect observed intervention effects or implemented program changes. Baseline values were obtained from provincial tuberculosis program indicators.

## Discussion

### Principal Findings

This study examined TB outcomes using routinely collected surveillance data and applied predictive modeling to identify factors associated with mortality and treatment delay. The findings suggest distinct patterns in TB outcomes, where mortality was more strongly associated with clinical vulnerability, while treatment delay was more closely related to health care access factors. By examining these outcomes within a unified surveillance-based analytical framework, this study highlights the importance of distinguishing between clinical risk factors and health care access barriers when designing TB control strategies, as these domains reflect distinct yet interacting pathways that influence patient outcomes.

The SEIR-informed framework provided a structure for organizing disease-stage concepts, and the predictive models focused on recorded clinical and programmatic outcomes in NTIP, including treatment success, mortality, and time to

XSL•FO
RenderX

treatment initiation. This approach linked an epidemiological disease-stage perspective with practical risk stratification using routinely collected surveillance data.

### Comparison With Previous Studies

The association between HIV co-infection and higher mortality observed in this study (HR=5.80) is consistent with prior survival analyses showing reduced survival among patients with TB or HIV coinfection [25] and cohort evidence identifying HIV positivity as a predictor of mortality among patients with TB [26]. The relatively high magnitude of association observed in this study may, therefore, reflect not only HIV-related clinical vulnerability and the increased complexity of clinical management in patients with coinfection, but also contextual factors such as diagnostic timing and health system access, which previous studies have identified as contributors to diagnostic delays and poorer TB outcomes [27].

In addition to HIV co-infection, baseline metabolic and nutritional factors also appear relevant to TB outcomes. The associations observed for diabetes are consistent with data from prospective cohorts, indicating that diabetes and prediabetes are associated with adverse TB treatment outcomes [28]. Moreover, prior research has linked dysglycemia to more severe disease presentation, including higher radiographic severity and increased bacillary load, as well as increased TB lethality among patients with diabetes [29]. Low BMI may indicate nutritional vulnerability and should be interpreted in the context of a broader clinical risk profile rather than as an independent predictor, consistent with survival analyses demonstrating the significance of baseline clinical characteristics in shaping TB mortality risk [26].

In addition to these clinical risk factors, health system and access-related barriers also contributed to differences in TB outcomes. Regarding treatment delay, the finding that rural and remote populations experienced longer delays is consistent with systematic review evidence indicating that delays in diagnosis and treatment of TB continue to be important barriers to TB control [27]. One suggested approach to reduce these access gaps is active case-finding, particularly through community-based approaches [30] and screening in general or at-risk populations [31]. However, these approaches are likely to be most effective when implemented with appropriate coverage and linked to timely diagnosis and treatment initiation. These findings suggest that geographic variation in treatment delay may reflect underlying disparities in health care access and care pathways rather than solely spatial disease patterns.

### Interpretation and Implications

From a methodological perspective, the results are consistent with a broader pattern in the TB modeling literature, in which different modeling approaches capture different aspects of the disease process. Researchers have applied ML methods to address several TB-related predictive tasks, including diagnostic classification with high-dimensional serological data [32], incidence prediction using meteorological and air pollution data [6], and treatment outcome prediction using routinely available clinical indicators [33]. Recent work has also examined the use of ML for TB incidence forecasting within broader epidemiological modeling frameworks [34]. Such approaches are often designed to optimize predictive accuracy; however, they may have limited interpretability regarding underlying disease mechanisms, particularly when the observed data include only diagnosed and reported cases rather than the full spectrum of transmission dynamics.

Mechanistic models, particularly SEIR-based approaches, provide a structured framework for conceptualizing disease progression and population-level disease dynamics [35] and have been extended to examine TB dynamics under different modeling assumptions [36]. Nevertheless, such models often rely on simplifying assumptions and may not fully capture real-world heterogeneity or individual-level risk. In this study, we used the SEIR framework conceptually to organize disease stages, while applying predictive models to recorded outcomes in routine surveillance data. The analysis, therefore, focused on recorded clinical and programmatic outcomes rather than population-level transmission dynamics. This approach supports alignment between theoretical disease-stage concepts and the structure of routinely available surveillance data.

Recent advances in hybrid TB modeling suggest that integrating mechanistic models with ML may provide a more balanced framework that supports predictive performance while maintaining epidemiological interpretability [37]. In this study, this integration was applied at a conceptual level, reflecting the structure and constraints of routine surveillance data. The study demonstrates a practical approach to organizing surveillance data within an epidemiologically informed framework to support the prediction of recorded TB outcomes and risk stratification.

The literature has well established that TB epidemiology exhibits spatial heterogeneity, with geographic variation observed across spatial and socioeconomic contexts [3,38]. More recently, work using satellite imagery and urban density measures has shown that spatial proxies may help identify areas for targeted active case-finding, while highlighting the need for cautious interpretation of geographic risk patterns [39]. The observed association between geographic residence and treatment delay suggests that spatial disparities in TB outcomes are attributable to differences in health care access and service availability. However, spatial clustering does not necessarily reflect transmission dynamics, and geographic variation may also be due to differences in health care access, reporting systems, population structure, and socioeconomic conditions. This distinction is important because outcomes may vary geographically due to both epidemiological and health-system factors.

From a programmatic perspective, the findings suggest that interventions targeting both early case detection and reduction of structural barriers to health care access may be needed to improve TB outcomes, rather than applying a uniform strategy across all populations. This distinction has implications for intervention design, as strategies to address clinical risk (eg, comorbidity management) may differ substantially from those intended to address access barriers (eg, service decentralization or active case-finding). This interpretation is consistent with the scenario analyses presented in this study, which show that improvements in detection and treatment processes could be

XSL•FO
RenderX

associated with changes in projected outcomes under modeled assumptions. These projections provide scenario-based estimates of possible implications for programs, and readers should interpret them in the context of the assumptions and baseline indicators used in the analysis.

Targeted case-finding strategies may help improve access to diagnosis, especially in high-risk populations. However, delays in TB care are multifactorial and influenced by both patient- and health system–level factors [27,30]. The effectiveness of these approaches may, therefore, depend on both expanded access and integration into routine care pathways. In practical terms, predictive outputs may help TB programs prioritize active follow-up, outreach screening, referral support, patient navigation, and closer monitoring for clinically vulnerable patients or those living in underserved areas. Further implementation research is needed to determine whether these outputs should guide additional resources, the redistribution of existing resources, or both. Digital health technologies and clinical decision support systems may facilitate implementation [8,40], but future studies should evaluate their practical impact in real-world clinical and public health settings.

### Strengths

This study used a large dataset derived from a routine TB surveillance system, supporting the relevance of the findings to real-world programmatic settings. The analysis considered multiple outcomes, including treatment success, mortality, and time to treatment initiation, allowing for a broader assessment of the TB care pathway. In addition, the use of established statistical approaches supported risk stratification and the identification of high-risk subgroups using routinely available data. These strengths may enhance the applicability of the findings to TB control programs, although readers should interpret the results within the context of surveillance-based data.

A further strength of the study is the alignment between the analytical methods and the structure of the available surveillance data. By focusing on recorded outcomes, the framework supports practical interpretation for routine programmatic settings while retaining an epidemiologically informed structure for organizing disease-stage concepts.

### Limitations

This study has several important limitations. First, the use of routinely collected surveillance data may be subject to missing data, misclassification, and variability in data quality across reporting sites. Important variables, including socioeconomic status, income, education, migrant status, health care-seeking behavior, timing of symptom onset, and distance to health care facilities, may not have been consistently recorded. Their absence may have introduced residual confounding, particularly in the analysis of treatment delay, as unmeasured social and structural barriers may partly explain the observed associations between rural or remote residence and delayed treatment initiation. The study period also overlapped with the COVID-19 pandemic, which may have affected health care-seeking behavior, TB screening activities, diagnostic access, reporting completeness, and time to treatment initiation [41].

Second, the study was based on registered TB cases in NTIP and may not capture undiagnosed cases, unreported cases, or individuals who did not access care. Readers should therefore interpret the findings as reflecting patterns among registered patients rather than the full burden and heterogeneity of TB in the underlying population. Because NTIP includes diagnosed and registered patients with TB, it cannot directly estimate the population-level effect of increased screening on undiagnosed or unreported cases. Readers should therefore interpret the assumed increase in screening or detection-related indicators in the scenario analysis as a programmatic assumption applied to provincial baseline indicators rather than as an effect estimated from the NTIP cohort itself.

Third, although we used the SEIR framework to guide the conceptual organization of disease stages, the available surveillance data did not directly observe susceptible or exposed populations, and we did not empirically estimate or validate SEIR transition parameters. Accordingly, readers should interpret the framework as SEIR-informed rather than as a fully parameterized transmission model. The observational design also limits causal inference; readers should interpret observed associations as predictive or outcome-specific rather than causal. In addition, combining an epidemiologically informed disease-stage framework with individual-level predictive models requires cautious interpretation; researchers should not directly infer population-level concepts from individual-level associations.

Finally, although we performed internal validation using train-test splitting and cross-validation, we did not conduct external validation using independent datasets. The models may perform differently in settings with varying epidemiological profiles, health care access patterns, population characteristics, reporting completeness, or data quality. The use of multiple predictors and outcome-specific models may also increase the risk of overfitting, particularly in subgroups or lower-frequency outcomes. We based the scenario analysis on predefined assumptions and provincial baseline indicators rather than observed intervention data; therefore, readers should interpret projected changes as illustrative programmatic projections. Future studies should compare performance with simpler baseline models, validate calibration and discrimination in independent datasets, examine sensitivity to scenario assumptions, and evaluate feasibility and implementation in routine TB control.

## Conclusions

TB outcomes in Chiang Mai Province reflected the combined influence of clinical vulnerability and health care access barriers. Mortality was more strongly associated with clinical factors, including HIV co-infection, older age, diabetes, and low BMI. In contrast, treatment delay was more closely related to rural or remote residence and lack of health insurance. These findings suggest that TB control strategies should combine intensified clinical monitoring for high-risk patients with improved access to timely diagnosis and treatment for underserved populations.

An SEIR-informed predictive framework using routine surveillance data may support risk stratification and program planning by identifying high-risk groups and access-related

XSL•FO
RenderX

delays in the TB care pathway. The findings support practical actions such as active follow-up for patients with HIV co-infection or other clinical vulnerabilities, strengthened outreach and referral pathways in rural and remote areas, improved linkage to care for uninsured patients, and targeted prioritization of follow-up, outreach, and linkage-to-care activities.

Model-based scenario results suggest that improvements in detection-related indicators and treatment coverage could contribute to better TB outcomes under predefined assumptions. However, readers should interpret these projections cautiously because they are based on modeled scenarios rather than observed intervention effects. Before wider implementation, future studies should externally validate the predictive framework in independent datasets and evaluate it prospectively in routine TB control settings to assess feasibility, calibration, clinical usefulness, and impact on decision-making.

## Acknowledgments

The authors thank the staff of the Chiang Mai Provincial Tuberculosis Control Network and the public health personnel at all levels of the health system for their cooperation in data preparation and verification. The authors declare the use of generative AI during manuscript revision. ChatGPT by OpenAI was used under full human supervision to support text generation for revised wording, proofreading and editing, and reformatting. Generative AI was not used to generate original data, conduct statistical analyses, create or modify figures, select references independently, or make independent scientific interpretations. All AI-assisted content was reviewed, edited, verified, and approved by the authors. Responsibility for the accuracy, integrity, and final content of the manuscript lies entirely with the authors. Generative AI tools are not listed as authors and do not bear responsibility for the final outcomes.

## Funding

This research was supported by Chiang Mai University.

## Authors' Contributions

PS conceptualized the study, performed the investigation, collected data, and drafted the original manuscript.
EB contributed to data analysis, curation, and editing.
AT conducted formal analysis and data curation, and contributed to writing and review. SM contributed to methodology development and critical review. SC was responsible for validation and manuscript review. WB supervised the overall study, provided resources, and served as the corresponding author. All authors read and approved the final version of this manuscript.

## Conflicts of Interest

## Abstract

**Background:** Hypertension, a leading cause of cardiovascular disease, is a significant public health challenge, with urban India reporting prevalence rates up to 40%. Excessive salt intake, averaging 8 to 11 g/day in India, far exceeds the World Health Organization–recommended limit of 5 g/day and is a key modifiable risk factor. While 24-hour urine collection is the gold standard for measuring 24-hour urinary excreted salt levels, its practicality in large-scale studies is limited, necessitating alternative methods such as spot urine sampling and dietary recall.

**Objective:** This study aimed to address current knowledge gaps by evaluating 24-hour urinary excretory salt levels across age groups and comparing the gold standard of 24-hour urinary salt excretion with estimates from spot urine samples and 24-hour dietary recalls among adolescents and their parents in Chandigarh, India.

**Methods:** A cross-sectional survey was conducted among 462 adolescents and 395 parents from public schools in Chandigarh, part of a cluster randomized controlled trial focused on reducing chronic disease risk factors. Twenty-four–hour urinary excreted salt levels were measured via 24-hour urine collection, spot urine samples were analyzed with the Kawasaki, Tanaka, and INTERSALT equations, and 2 nonconsecutive 24-hour dietary recalls using a correction factor of 0.9. Bland-Altman plots were used to assess agreement between methods.

**Results:** The mean 24-hour urinary excreted salt levels measured via 24-hour urine samples were 6.95 g/day (SD 0.24; 95% CI 6.48 - 7.42) for adolescents and 7.73 g/day (SD 0.3; 95% CI 7.18 - 8.28) for parents. Spot urine estimates showed variability, with the INTERSALT equation with potassium yielding the closest results to 24-hour measurements for parents (mean 8.12, SD 0.4 g/d; 95% CI 7.36 - 8.95) and adolescents (mean 7.97, SD 0.4 g/day; 95% CI 7.16 - 8.77). Dietary recall underestimated 24-hour urinary excreted salt levels for both groups (mean 4.15, SD 0.08 g/day for adolescents and mean 3.62, SD 0.08 g/day for parents).

**Conclusions:** Spot urine sampling, particularly the INTERSALT with potassium equation, offers a feasible alternative to 24-hour urine collection for estimating population-level 24-hour urinary excreted salt levels among adolescents and adults in resource-limited settings. Dietary recall alone significantly underestimates intake and should be supplemented with objective measures. These findings support the use of tailored estimation methods based on age for improved hypertension management strategies in India.

## Introduction

Hypertension is a major global health issue, significantly contributing to the burden of cardiovascular disease, which remains the leading cause of death worldwide [1]. In India, the prevalence of hypertension is high, with 40% of urban adults living with hypertension, compared with 17% in rural areas [2]. In Chandigarh, a union territory, the issue is particularly pronounced, affecting 45% of women and 58% of men [2].

Excessive salt intake is one of the most impactful yet modifiable risk factors for hypertension [3-5]. Globally, average salt consumption is nearly twice the maximum daily intake of 5 g/day recommended by the World Health Organization (WHO) [6]. In India, estimates indicate that people consume an average of 11 g/day, while recent national data report a mean intake of 8 g/day among adults aged 18 to 69 years [2,6]. Similar trends are seen in other countries; for instance, a study from Iran found that adolescents aged 10 to 15 years consume about 9.7 g/day, reflecting a widespread pattern of high salt intake across age groups [7]. The latest 2024 report suggests that nearly 1.4 billion people worldwide are hypertensive, underscoring the need for effective preventive and management strategies [1,8]. Studies from India and other low- and middle-income countries have shown that high salt consumption during adolescence is a risk factor for hypertension later in life [5,9].

To create effective management strategies, it is important to have clear criteria for evaluating the impact of different approaches. While the health risks linked to high salt intake are well known, accurately measuring salt consumption in the population is limited by several challenges. These difficulties make it hard to obtain reliable data on salt intake patterns, which in turn affects the development and implementation of targeted public health programs aimed at reducing health risks [10]. While the 24-hour urine collection method is the most accurate for estimating 24-hour urinary excretory salt levels, it is often impractical for large population studies due to logistical demands. Spot urine sampling provides a more feasible alternative, using formulas such as INTERSALT, Kawasaki, and Tanaka to estimate 24-hour urinary salt excretion from single urine samples or through 24-hour dietary recall [10,11]. However, the applicability and accuracy of these methods within the Indian context are not well studied, and few investigations have compared these estimates to the benchmark 24-hour urine collection [12]. Moreover, in India, previous studies on urinary salt excretion have focused exclusively on adults. To our knowledge, no study has objectively examined this important factor among adolescents using urine samples, although several studies have assessed dietary salt intake in this age group. Thus, this is the first study, to our knowledge, to objectively estimate urinary salt excretion among adolescents in the Indian context [13,14].

This study aimed to address current knowledge gaps by evaluating the 24-hour urinary excretory salt levels across age groups and comparing the gold standard of 24-hour urinary salt excretion with estimates from spot urine samples and 24-hour dietary recalls among adolescents and their parents in Chandigarh.

## Methods

This study was based on a cross-sectional survey carried out as part of a cluster randomized controlled trial to assess the impact of a school-based health promotion intervention package in reducing the behavioral risk factors associated with chronic diseases [15]. The survey was conducted among adolescents studying in public schools and one of their parents in the Union Territory of Chandigarh, India, from May 2018 to September 2019.

### Study Setting

The study was conducted in public schools as the Director of Public Instruction did not allow enrollment of private schools in the study. Data collected from the Department of School Education, Chandigarh, revealed that 106 public schools had eighth-grade classes, and on average, 10,790 adolescents studied in eighth grade in these schools. Most schools had 4 to 5 sections in the eighth-grade class. Each section of the class had about 30 adolescents.

### Participants

On the basis of the knowledge that behaviors contributing to chronic diseases, such as a preference for salty foods, often emerge during early adolescence, this study selected assenting eighth-grade adolescents and one of their parents based on their mutual preference [16]. Inclusion criteria required that participants planned to remain in the city for at least 1 year following recruitment and that the selected parent was younger than 65 years.

### Sample Size and Sampling

Details on the sample size calculation are described in the protocol paper of the broader cluster randomized controlled trial [17]. Broadly, calculations considered expected means or proportions for the control group, estimated intervention effects, and coefficient of variation values derived from adolescent data from previous studies [18-21]. To ensure sufficient power across all risk factors, the maximum calculated cluster size (n=12) was selected. Consequently, 12 clusters (schools), each with 30 adolescents, yielded an estimated total sample size of 360 adolescents and 360 parents.

### Data Collection Tools

Several tools were used for data collection after receiving assent from adolescents (Multimedia Appendix 1) and consent from parents (Multimedia Appendix 2). These tools included the interview schedule for recording sociodemographic information, behavioral risk factors, and anthropometric, physiological, and biochemical measures (Multimedia Appendix 3).

A 24-hour dietary recall questionnaire was used to assess the 24-hour dietary urinary excreted salt levels. Evidence suggests that a single 24-hour dietary recall is unable to provide the usual consumption pattern of the participants. To overcome this drawback, two 24-hour dietary recalls were collected for all participants on nonconsecutive days [22].

Twenty-four–hour urine and morning second-spot urine samples were collected to estimate the level of urinary salt excretion

XSL•FO
RenderX

(g/day). To assess BMI, height was measured with a United Nations Children's Fund standardized anthropometer to the nearest 0.1 cm, and weight was measured with a portable electronic weighing scale to the nearest 0.1 kg. Blood pressure (BP) was recorded for all participants using a digital sphygmomanometer (Omron Healthcare Co Ltd).

### Data Collection Methods

SK collected the dietary, anthropometric, and physiological data. Additionally, a team of 3 members, including SK and 2 field investigators, collected urine samples. The field investigators were qualified up to the graduation level, and they had received training for data collection related to urine samples.

Neither the investigator nor the data collectors were blinded to the intervention. Standard operating procedures were developed to maintain uniformity and standardization in sample collection and analysis (Multimedia Appendix 4)

After obtaining the study participants' written informed consent, SK provided questionnaires to adolescents to record their responses in the classroom setting for recording sociodemographic characteristics and 24-hour dietary recall. SK was present in the classroom and explained each question to all the adolescents before they recorded their responses. Any query raised by the adolescents was answered.

To record the two 24-hour dietary recalls, all the adolescents in the same cluster filled out their forms themselves (self-administration). In comparison, in-person interviews were carried out with parents. The first 24-hour dietary recall was recorded during the first interaction with all the participants in the schools. The second 24-hour dietary recall was collected a week later. The data collection of the 24-hour dietary recall was manually recorded using the Multiple-Pass Method [22]. After collecting sociodemographic data and dietary recalls, participants' anthropometric and BP measurements were obtained in a separate room one by one. An average of 3 readings was used for each participants' BP measurement, with a resting period of at least 5 minutes between each reading. Finally, instructions for the collection of urine samples were provided. Specific days were fixed for collecting urine samples from the home setting. The details of BMI, BP, and 24-hour and second-spot urine samples collection are provided in Multimedia Appendices 4 and 5.

During Saturday home visits, participants received instructions regarding the process of 24-hour urine collection on Sundays and second-spot urine collection on Monday morning. Urine collection containers were provided to them. They were instructed to discard the first void of the morning and then start collecting the subsequent voids for the next 24 hours (Multimedia Appendix 6). Second-spot urine samples are preferred over first morning samples because they are less influenced by overnight concentration and better reflect daytime sodium excretion. This improves the accuracy of estimating 24-hour urinary sodium compared with first morning samples [23].

Participants were advised to write the time of their voids and whether they had collected each void in the collection container or not for 24 hours using a structured proforma (Multimedia Appendix 7). The urine samples were collected on Monday mornings and analyzed for urinary salt levels on the same day.

### Data Management and Analysis

The 24-hour dietary data were entered in a Microsoft Excel sheet. For the estimation of sodium intake, the Prospective Urban Rural Epidemiology study computer software was used [24]. This tool was developed explicitly for assessing the intake of Indian foods and has been previously validated in Indian settings [24]. The details of the estimation of 24-hour urinary excreted salt levels using this tool have been provided in Multimedia Appendix 8. Twenty-four–hour dietary urinary excreted salt levels from the 2 recalls of every participant were calculated separately and then averaged and multiplied by a correction factor of 0.9 to estimate their usual 24-hour urinary excreted salt levels.

For BMI categorization of adolescents into severe thinness, thinness, normal weight, overweight, and obese categories, WHO growth reference percentiles that were age and sex specific for the 5- to 19-year age group were used [25]. For parents, WHO Asia-specific BMI cutoffs were used to categorize them into underweight, normal weight, overweight, and obese categories [26].

For BP assessment among adolescents, percentiles for systolic BP and diastolic BP were assessed based on each adolescent's height, age, and sex (normal: <90th percentile; borderline-elevated BP: systolic BP or diastolic BP ≥90th percentile but <95th percentile; elevated BP: systolic BP or diastolic BP ≥95th percentile). Recent 2025 American College of Cardiology and American Heart Association guidelines were used to categorize adult participants into normal, elevated, stage 1, and stage 2 hypertension [27].

Urinary excreted salt levels were estimated from spot urine samples using a series of established estimation equations. The equations used were Tanaka, Kawasaki, and INTERSALT with potassium [28] (Multimedia Appendix 9). Twenty-four–hour urinary excreted salt levels values that were greater than 3 SDs above or below the mean were excluded from all analyses. Twenty-four–hour urinary salt excretion was estimated from 24-hour urine samples using the formula mentioned in Multimedia Appendix 9. As both 24-hour urine collections (gold standard) and spot urine–based equations estimate 24-hour urinary salt excretion, the salt intake derived from 24-hour dietary recall was adjusted using a 0.9 correction factor to approximate urinary excreted salt. This adjustment is based on the established physiological evidence that approximately 90% of ingested salt is excreted in urine under steady-state conditions [29]. Paired samples 2-tailed *t* tests were used to compare mean population 24-hour urinary excreted salt levels estimated by the 24-hour urine collections, spot urine equation-based methods, and 24-hour dietary recalls. To determine the agreement between individual-level 24-hour urinary excreted salt levels estimated from 24-hour collections and methods based on spot urine collections and dietary recall, Bland-Altman plots were used. The difference between the methods was plotted against the mean of the 2 methods. Data are presented as mean (95% CI) unless otherwise specified. Statistical analyses were conducted using R (version 4.3.0; R Foundation for Statistical Computing).

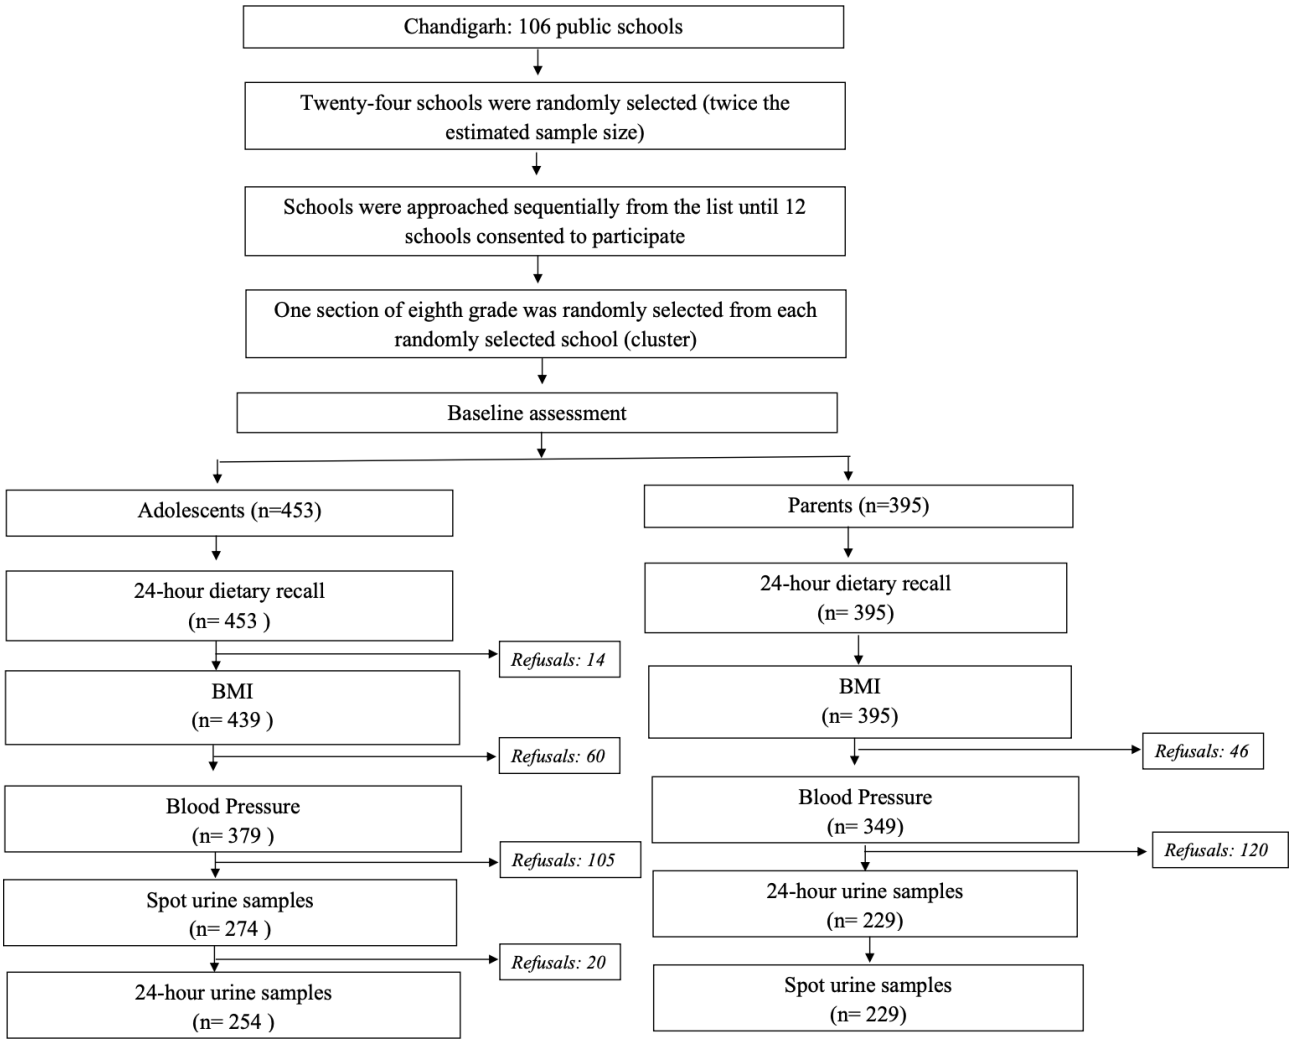
### Ethical Considerations

Ethics approval was obtained from the institutional ethics committee of the Post-Graduate Institute of Medical Education and Research, Chandigarh (INT/IEC/2018/000082; January 22, 2019). Permission to conduct the study in schools was granted by the Department of Education, Chandigarh, with letter number 1296-DSE-UT-S5-11(65)11-II. As this study was part of a cluster randomized controlled trial, the study was registered in Clinical Trials Registry-India (CTRI/2019/09/021452).



Written assent of adolescents and written consent from their parents were obtained after informing them about the study purpose, data to be collected, estimated time for data collection, the confidentiality of the data, and risks involved before their enrollment in the study (Multimedia Appendices 1 and 2).

## Results

### Participants

Of the 462 eligible adolescents, 453 (98.1%) consented to be part of the study (Figure 1). One parent was supposed to be enrolled in the study for each adolescent. However, 395 consenting parents enrolled in the study.

**Figure 1.** Sampling strategy and participation rates for various indicators among all study participants.

The mean age was 13 (SD 0.4) years for adolescents and 37 (SD 0.3) years for parents (Table 1). Of all participating adolescents, 46.1% (209/453) were girls, and of all parents, 61% (241/395) were mothers. Nearly a quarter (105/439, 23.9%) of the participating adolescents were underweight, whereas half (197/395, 49.9%) of the parents were either overweight or obese (Table 1). Among adolescents, 3.4% (13/379) had stage 2 hypertension compared with 25.5% (89/349) of parents. There were differential participation rates for each of the indicators used in this study, as shown in Figure 1.

**Table .** Study participants' characteristics.

| Participant characteristics | Adolescents | Parents |
|---|---|---|
| Age (y), mean (SD; 95% CI) | 13.12 (0.4; 13.05-13.19) | 37.1 (0.3; 36.54-37.67) |
| Female, n (%) | 209/453 (46.1) | 241/395 (61.0) |
| Weight (kg), mean (SD; 95% CI) | 39.4 (0.45; 38.6-40.3) | 61.95 (0.63; 60.71-63.19) |
| BMI (kg/m$^2$), mean (SD; 95% CI) | 17.4 (0.17; 17.1-17.8) | 25.11 (0.22; 24.67-25.55) |
| BMI classification[a,b], n (%) | | |
| Underweight | 105/439 (23.9) | 27/395 (6.8) |
| Overweight and obese | 46/439 (10.5) | 197/395 (49.9) |
| Blood pressure[c,d], n (%) | | |
| Normal | 346/379 (91.3) | 204/349 (53.7) |
| Hypertension stage 1 | 17/379 (4.5) | 56/349 (14.7) |
| Hypertension stage 2 | 13/379 (3.4) | 89/349 (23.4) |

[a]Adolescent BMI categories were based on World Health Organization growth reference percentiles age and sex specific for 5-19 y (2007): ≤−2 SD, severe thinness; >−2 SD to ≤−1 SD, thinness; >−1 SD to ≤+1 SD, normal weight; >+1 SD to ≤+2 SD, overweight; and >+2 SD, obesity.

[b]Parent BMI categories were defined as follows: underweight, <18.5 kg/m$^2$; normal weight, 18.5-24.9 kg/m$^2$; overweight, 25.0-29.9 kg/m$^2$; and obese, ≥30.0 kg/m$^2$.

[c]Adolescent blood pressure (BP) categories were based on age-, height-, and sex-specific percentiles: normal, <90th percentile; borderline-elevated BP, systolic BP or diastolic BP ≥90th percentile but <95th percentile; elevated BP, systolic BP or diastolic BP ≥95th percentile.

[d]Parent BP categories were defined as follows: normal, systolic BP <120 mm Hg and diastolic BP <80 mm Hg; elevated BP, systolic BP 120-129 mm Hg and diastolic BP <80 mm Hg; stage 1 hypertension, systolic BP 130-139 mm Hg or diastolic BP 80-89 mm Hg; and stage 2 hypertension, systolic BP ≥140 mm Hg or diastolic BP ≥90 mm Hg.

## Urinary Excreted Salt Levels

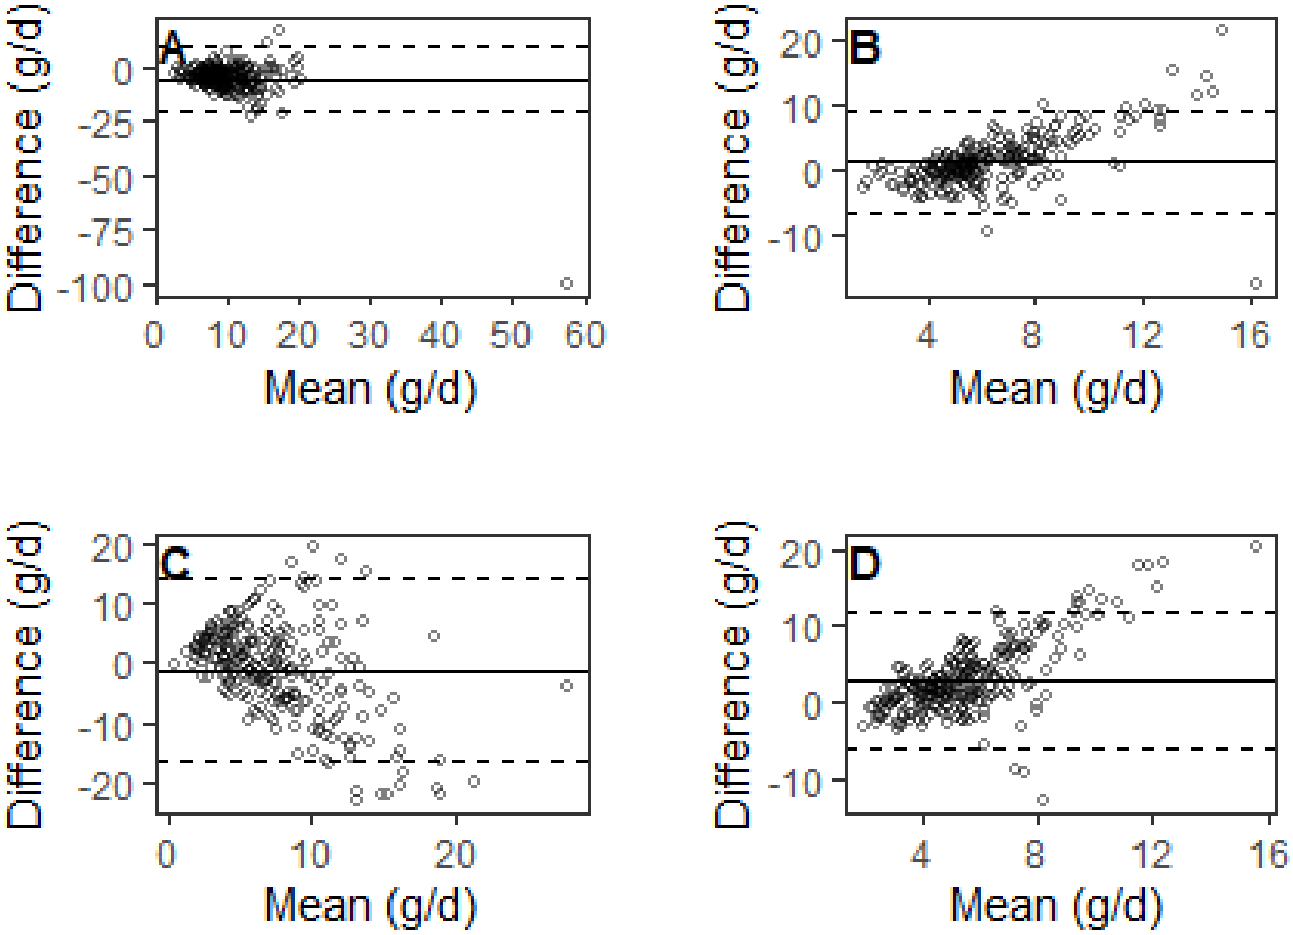
Based on the 24-hour urine samples, the measured 24-hour urinary excreted salt level among adolescents was 6.95 g/day (SD 0.24; 95% CI 6.48-7.42), and for their parents it was 7.73 g/day (SD 0.3; 95% CI 7.18-8.28). These measured estimates were compared with estimated 24-hour urinary excreted salt levels derived from various urine equations by using spot urine samples and 24-hour dietary recall. (Multimedia Appendix 9).

Twenty-four–hour dietary recall estimates of 24-hour urinary excreted salt levels were the lowest for both adolescents (mean 4.15, SD 0.08 g/day; 95% CI 3.99-4.31) and parents (mean 3.62, SD 0.08 g/day; 95% CI 3.47, 3.77; Table 2).

**Table .** Population-level estimates of 24-hour urinary excreted salt among adolescents and their parents[a].

| | Adolescents (g/day), mean (SD; 95% CI) | Parents (g/day), mean (SD; 95% CI) |
|---|---|---|
| Measured 24-hour urinary salt | 6.95 (0.24; 6.48-7.42) | 7.73 (0.3; 7.18-8.28) |
| Estimated 24-hour dietary salt | 4.15 (0.08; 3.99-4.31) | 3.62 (0.08; 3.47-3.77) |
| Estimated Kawasaki equation | 12.83 (0.5; 11.92-13.74) | 12.72 (0.3; 12.17-13.28) |
| Estimated Tanaka equation | 5.79 (0.13; 5.55-6.04) | 6.89 (0.12; 6.65-7.13) |
| Estimated INTERSALT equation with potassium | 7.97 (0.4; 7.16-8.77) | 8.12 (0.4; 7.36-8.95) |

[a]Sample sizes varied by indicator and are presented in Figure 1. Equations used to estimate urinary salt excretion are provided in Multimedia Appendix 9.

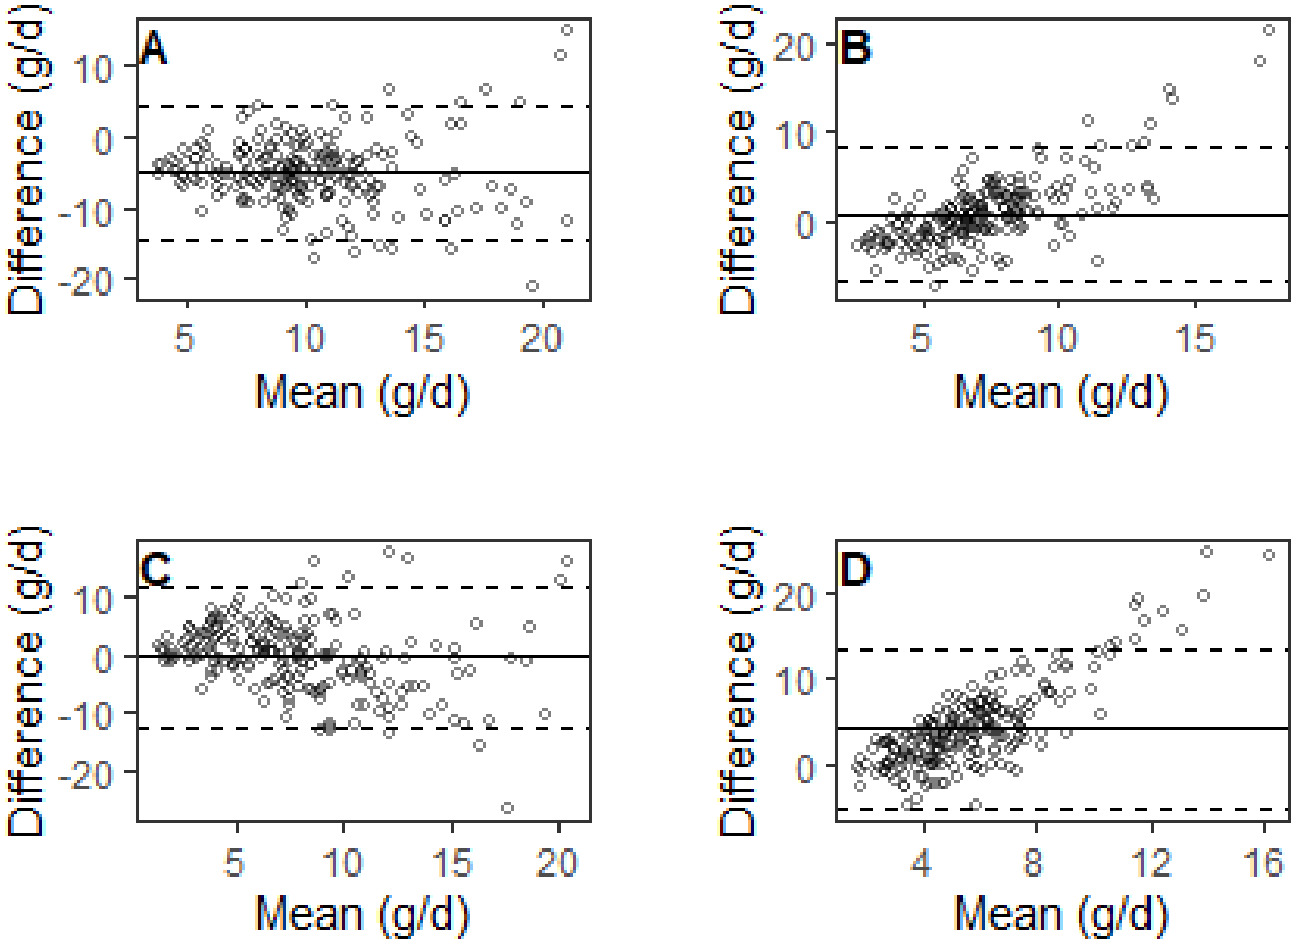


## Agreement Between Methods of Estimating 24-Hour Urinary Excreted Salt Levels

For population-level 24-hour urinary excreted salt level estimation, comparisons among methods revealed that among adolescents there were no significant differences between the estimates derived from 24-hour urine collections and those obtained using the Kawasaki ($P$<0.001) and Tanaka equations ($P$=0.008), as well as 24-hour dietary recall ($P$<0.001). The INTERSALT equation with potassium slightly underestimated the 24-hour salt levels (mean −1.16 g/day; 95% limits of agreement −16.3 to 13.99 g/day; $P$=.02; Figure 2).

XSL•FO
RenderX

**Figure 2.** Bland-Altman plots comparing 24-hour urinary excretory salt estimates from 24-hour urine, spot urine samples, and 24-hour dietary recall in adolescents. Bias and 95% limits of agreement (LoA) in comparing 24-hour urinary salt excretion assessed through 24-hour urine samples (gold standard) with (A) Kawasaki (bias −5.78, LoA −21.13 to 9.57), (B) Tanaka (bias 1.29, LoA −6.52 to 9.10), (C) INTERSALT with potassium (bias −1.16, LoA −16.30 to 13.99), and (D) 24-hour dietary recall (bias 2.92, LoA −6.00 to 11.85).



Among parents, there were no significant differences between the estimates derived from 24-hour urine collections and those obtained using the Kawasaki and INTERSALT equations, as well as 24-hour dietary recall. Tanaka slightly overestimated the 24-hour salt levels (mean 0.71 g/day; 95% limits of agreement −6.82 to 8.24 g/day; *P*=.008; Figure 3).

XSL•FO
RenderX

**Figure 3.** Bland-Altman plots comparing 24-hour urinary excretory salt estimates from 24-hour urine samples, spot urine samples, and 24-hour dietary recall in parents. The graphs show bias and 95% limits of agreement (LoA) in assessing 24-hour urinary salt excretion through 24-hour urine samples (the gold standard) with (A) Kawasaki (bias −5.16, LoA −14.42 to 4.10), (B) Tanaka (bias 0.71, LoA −6.82 to 8.24), (C) INTERSALT with potassium (bias −0.23, LoA −12.22 to 11.75), and (D) 24-hour dietary recall (bias 4.18, LoA −5.25 to 13.60) methods.

## Discussion

### Key Findings

This study suggests that spot urine samples can be practical alternatives to 24-hour collections for estimating population-level 24-hour urinary excreted salt levels in Indian populations, with INTERSALT with potassium being the most suitable method. The INTERSALT with potassium equation showed closer agreement with the gold standard, 24-hour urine samples, at the population level; in contrast, the 24-hour dietary recall method tended to underestimate the urinary excreted salt levels. Adolescence is a period of significant physiological change with distinct nutritional requirements; therefore, 24-hour urine samples remain the gold standard for assessing 24-hour urinary excreted salt levels in this age group. However, understanding 24-hour urinary excreted salt levels in this group is crucial, as studies suggest that high salt consumption in early years is a major risk factor for hypertension later in life. Importantly, this is a modifiable behavior that can be addressed during early adolescence through appropriate interventions [5,9].

The mean population intake estimated in the study is comparable to the earlier studies; for instance, standard 24-hour urinary salt excretion, widely regarded as the gold standard, was measured at 7 g/day among adolescents and 8 g/day among their parents [13,30]. These findings align closely with previous studies, such as one conducted in China, where the average 24-hour urinary salt excretion for adolescents was 8.2 g/day using 24-hour urine samples [31]. Additionally, an Indian study estimated the weighted mean 24-hour urinary excreted salt levels from 24-hour urine samples to be 8.59 g/day in Delhi and 9.46 g/day in Andhra Pradesh, further supporting the validity of our findings [30]. In this study, the mean 24-hour urinary salt excretion estimated through the INTERSALT equation with potassium, based on spot urine samples, was 8.0 g/day for adolescents and 8.12 g/day for their parents. These values are consistent with Dong et al [31], where adolescent 24-hour urinary salt excretion was reported as 8.4 g/day using the same equation. Another Indian study using the INTERSALT equation with potassium yielded comparable results, with estimates of 8.13 g/day in Delhi and 8.81 g/day in Andhra Pradesh [30]. Together, these findings suggest that the INTERSALT equation with potassium can yield population-level estimates closely aligned with those obtained from 24-hour urine collections for adults, making spot urine samples a feasible option in settings where 24-hour collections are challenging.

The biochemical assessment of 24-hour urinary excreted salt levels, based on urinary measures, proves to be more accurate than dietary recall methods. In this study, dietary recalls on 2 nonconsecutive days estimated 24-hour urinary excreted salt

XSL•FO
RenderX

levels between 4 and 4.5 g/day for participants across all age groups. This underestimation is supported by the literature; for example, McLean et al [32] conducted a meta-analysis of 28 studies and confirmed that dietary recall methods consistently underestimate 24-hour urinary excreted salt levels when compared with 24-hour urine collections.

Among the various methods for estimating 24-hour urinary excreted salt levels, the INTERSALT equation with potassium applied to spot urine samples produced no statistical difference from the gold standard of 24-hour urine collection, with differences of 0.23 g/day among parents. Previous studies indicate that among urine equations, including Kawasaki, Tanaka, and INTERSALT, the INTERSALT method demonstrates the most reliable performance in estimating mean population sodium intake, minimizing bias effectively [31,33]. However, there was a significant difference between 24-hour salt levels assessed through INTERSALT with potassium for adolescents. This variation may be attributed to differences in urinary potassium levels between adolescents and adults, influenced by growth-related physiological changes, dietary habits, and hormonal fluctuations during adolescence, all of which can affect potassium excretion [34].

### Strengths and Limitations

This study has several strengths and limitations. Pilot testing was conducted prior to data collection to assess feasibility and refine research instruments, helping to address potential challenges. A key strength is the use of validated tools in the Indian context, along with standardized equipment and protocols for BP assessment.

The 24-hour dietary recall is a reliable method for assessing population-level intake compared with tools such as the Food Frequency Questionnaire. Although it may not fully capture usual intake, we used recalls on 2 nonconsecutive days to improve reliability. The study was adequately powered, and the findings can inform sample size calculations for future research.

A limitation is the exclusion of private schools, which may affect representation across socioeconomic groups. However, as a large proportion of the Indian population belongs to low- and middle-income groups, the findings remain reasonably generalizable to the Indian settings.

Overall, this study supports the utility of spot urine samples, specifically with equations such as the INTERSALT equation with potassium, for accurately estimating population-level 24-hour urinary excreted salt levels in adults.

## Conclusions

In settings where 24-hour urine collections are impractical, spot urine equations such as INTERSALT with potassium offer effective alternatives for estimating 24-hour urinary sodium excretion in adult populations in the Indian context. However, 24-hour dietary recall methods often underestimate 24-hour urinary excreted salt levels, and their accuracy can be significantly improved when combined with objective measurements. This combined approach is especially valuable for designing and implementing effective salt reduction interventions. As part of a larger cluster randomized controlled trial, the findings can support objective assessment of urinary salt excretion in resource-limited settings. Future interventional studies may also adopt the tools used in this study to monitor changes in behavioral risk factors, including dietary behaviors assessed through 24-hour recall.

## Acknowledgments

No generative artificial intelligence tools were used in the writing, analysis, or preparation of this manuscript.

The authors would also take this opportunity to extend their special thanks to the George Institute of Global Health, Hyderabad, for providing them with the funds to conduct laboratory testing of the urine samples collected as part of this study.

## Funding

MK received funding from the George Institute for Global Health, Hyderabad (project ID 5562), to support laboratory testing of the urine samples collected as part of this study. The funder had no role in the conceptualization of the study, study conduct, data analysis, interpretation of findings, or dissemination of the results.

## Data Availability

The fully anonymized dataset supporting the findings of this study is available in a public repository [35].

## Authors' Contributions

SK contributed to conceptualization, investigation, data curation, and writing the original draft. RK and MK contributed to conceptualization, methodology, supervision, validation, and provision of resources. ASC contributed to formal analysis. All authors contributed to writing, review, and editing of the manuscript and approved the final version for publication.

## Abstract

**Background:** Bacterial gastroenteritis remains a substantial public health burden. South Korea has operated an electronic sentinel surveillance system (SSS) since 2000; in 2023, a total of 211 sentinel hospitals conducted surveillance for 11 notifiable types of bacterial gastroenteritis. The system has not undergone a comprehensive evaluation.

**Objective:** This study evaluated the SSS's operational performance and reporting completeness, assessed the population-based geographic allocation of sentinel sites, and explored concordance between SSS reports and National Health Insurance (NHI) claim records.

**Methods:** We conducted a mixed methods evaluation using a 2024 survey of staff at the 211 sentinel hospitals, an interview with the Korea Disease Control and Prevention Agency (KDCA) operator, KDCA operational reporting records, nationwide NHI claim records, and regional population statistics. The primary evaluation year was 2023; 2021 was a nonconsecutive descriptive comparator because these were the 2 complete annual extracts available in the analytic dataset. We calculated delayed reporting, submission completeness, and on-time completeness. Exploratory Pearson correlations compared paired weekly all-pathogen totals (52 weeks per year), annual surveillance target, and diagnosis code category counts within each age group (11 paired categories), and actual vs population-proportional sentinel allocations across 17 regions.

**Results:** Of 211 sentinel hospitals, 180 (85.3%) responded. In total, 90% (162/180) rated reporting as simple or adequate; responses on goal awareness and overall satisfaction were predominantly neutral. The delayed reporting proportion was 2.4% (255/10,652) in 2021 and 1.1% (122/10,972) in 2023; submission completeness was 99.9% (10,652/10,660) and 100% (10,972/10,972), respectively; and on-time completeness was 97.5% (10,397/10,660) and 98.9% (10,850/10,972), respectively. The exploratory weekly SSS-NHI correlation was 0.899 in 2021 and 0.937 in 2023. Age-stratified annual cross-category correlations ranged from 0.665 to 0.969 in 2021 and from 0.939 to 0.983 in 2023. Correlations between actual and population-proportional sentinel allocations were 0.946 in 2021 and 0.951 in 2023.

**Conclusions:** The SSS demonstrated favorable operational performance, with low reporting delay and near-complete submission. The claim comparison showed strong ecological comovement but cannot establish sensitivity or diagnostic equivalence because the data sources use different case definitions and counting units. Priorities are clearer communication of operational goals, standardized operator training, and future validation using patient- or episode-level data linked to laboratory results.

## Introduction

Gastroenteritis is caused by a wide range of pathogens, including bacteria, viruses, and parasites, that infect the gastrointestinal tract [1]. The causal pathogen is often not identified or reported [2], yet bacterial enteric pathogens are responsible for a large share of the burden, accounting for an estimated 20% to 40% of diarrhea cases worldwide [3,4]. The downstream consequences are striking: enteric infectious diseases caused an estimated 1.27 million deaths worldwide in 2023, with diarrheal disease accounting for most of these deaths (1.11 million) [5], whereas in high-income settings, acute gastroenteritis drives substantial outpatient and inpatient costs [6,7].

XSL•FO
RenderX

South Korea is no exception to this burden. Health insurance claims for 18 foodborne pathogens recorded more than 300,000 cases annually between 2008 and 2012 [8]. Among Korean children between 2004 and 2019, bacterial pathogens were responsible for 3% to 20% of acute gastroenteritis cases, with *Escherichia coli* and *Salmonella* spp. predominating [9]. By 2023, bacterial gastroenteritis accounted for half of all gastroenteritis cases reported to the Korea Disease Control and Prevention Agency (KDCA); *Salmonella* spp., *Campylobacter* spp., and enteropathogenic *E. coli* were the most frequently notified pathogens [10]. The case for close monitoring is likely to intensify: South Korea's summers are growing warmer and longer, which favors bacterial transmission [11], and rising international travel has made surveillance of previously unreported pathogen genotypes increasingly important [9].

South Korea introduced a sentinel surveillance and electronic reporting system in 2000 [12] targeting infectious diseases with high incidence but low severity [13]. By 2023, a total of 11 types of bacterial gastroenteritis were classified as group 4 notifiable diseases and had to be reported to the health authority within 7 days of diagnosis through the sentinel surveillance system (SSS) [13]. Today, 211 sentinel hospitals submit weekly case reports to the KDCA through this nationwide network. Surveillance systems for gastrointestinal diseases vary widely worldwide in design and data source, ranging from laboratory-based and sentinel-clinician networks to syndromic and administrative claim–based approaches; a recent systematic review found such systems to be validated for routine use in at least 10 countries [14]. A previous evaluation looked at the SSS for hand, foot, and mouth disease [15], but to our knowledge, no comprehensive evaluation has yet examined the SSS specifically for bacterial gastroenteritis. Closing this gap matters: routine surveillance for this disease group needs to be assessed on its own terms, and concrete strategies for improvement need to be identified.

To address this gap, we conducted a mixed methods evaluation of South Korea's electronic SSS for bacterial gastroenteritis with 2023 as the primary evaluation year and 2021 as a nonconsecutive descriptive comparator. The objectives were to (1) assess simplicity, acceptability, timeliness, submission completeness, and on-time completeness; (2) examine whether sentinel site allocation across 17 regions was proportional to population size; and (3) explore whether weekly all-pathogen totals and annual age-stratified surveillance target or diagnosis code category patterns in SSS reports were concordant with National Health Insurance (NHI) claim records.

# Methods

## Study Design

This mixed methods surveillance system evaluation combined a cross-sectional survey and structured operator interview with retrospective analysis of operational reporting records, NHI claim records, and regional population statistics. The primary evaluation year was 2023, with 2021 used only as a nonconsecutive descriptive comparator. The operational and external comparison components were analyzed separately so that claim data were not treated as a reference standard for laboratory-confirmed SSS cases.

## Data Sources

### *Overview*

From July 29, 2024, to August 30, 2024, we emailed a semistructured questionnaire to the staff member responsible for case notification at each of the 211 sentinel hospitals. Items covered the perceived simplicity of reporting, awareness of SSS operational goals, overall satisfaction, and mean weekly reporting time. From these 211 hospitals, we received 180 (85.3%) completed questionnaires.

We conducted a structured interview with the KDCA operator responsible for routine SSS operation. Topics included reporting compliance, ease of data collection and dissemination, recurrent data quality problems, operator workload, and whether formal training or standardized operating materials were provided. Separately, KDCA operational extracts supplied the number of designated sentinel sites, facilities with no laboratory-confirmed case notifications for more than 6 months (an indicator distinct from missing scheduled weekly submissions), and weekly on-time and delayed submission counts for 2021 and 2023.

Nationwide NHI claim records were obtained from the Health Insurance Review and Assessment Service for January 2021 to December 2021 and January 2023 to December 2023. Variables included *International Classification of Diseases, 10th Revision* (*ICD-10*), diagnosis code and position; outpatient or inpatient status; age group; treating institution region; service date; and billed laboratory test procedures. Official resident registration population counts for the 17 administrative regions in the corresponding years were obtained from the Korean Statistical Information Service and were used only to calculate population-proportional expected numbers of sentinel sites [16].

Table 1 lists the 11 types of gastroenteritis that are notifiable through the SSS, with their causative pathogens and diagnostic criteria [17].

XSL•FO
RenderX

**Table .** Laboratory-confirmed types of bacterial gastroenteritis included in South Korea's electronic sentinel surveillance system (SSS) and national SSS case counts in 2023.

| Diseases | Causative pathogen | Diagnostic criteria | KDCA[a]-reported cases in 2023, n |
|---|---|---|---|
| Salmonellosis | Nontyphoidal *Salmonella* spp. | Isolation and identification of nontyphoidal *Salmonella* spp. from specimens (stool and rectal swabs) | 3540 |
| *Vibrio parahaemolyticus* gastroenteritis | *V parahaemolyticus* | Isolation and identification of *V parahaemolyticus* from specimens (stool and rectal swabs) | 101 |
| ETEC[b] | ETEC | Isolation and identification of *Escherichia coli* possessing heat-labile toxin genes (*LT*) or heat-stable toxin genes (*ST*) from specimens (stool and rectal swabs) | 481 |
| EIEC[c] | EIEC | Isolation and identification of *E. coli* possessing the invasive factor gene (*ipaH*) from specimens (stool and rectal swabs) | 55 |
| EPEC[d] | EPEC | Isolation and identification of *E. coli* possessing adherence factor genes (*eaeA* and *bfpA*) from specimens (stool and rectal swabs) | 1963 |
| Campylobacteriosis | *Campylobacter jejuni* and *Campylobacter coli* | Isolation and identification of *Campylobacter* spp. from specimens (stool, rectal swabs, and vomitus) | 3167 |
| *Clostridium perfringens* enteritis | *C. perfringens* | Detection of *C. perfringens* at levels of $\geq 10^6$ CFU[e] per gram in specimens (stool and vomitus) or isolation and identification of *C. perfringens* possessing enterotoxin-specific genes (*cpa* and *cpe*) from specimens (stool, rectal swabs, and vomitus) | 423 |
| *Staphylococcus aureus* intoxication | *S. aureus* | Isolation and identification of *S. aureus* possessing enterotoxin genes from specimens (stool, rectal swabs, and vomitus) | 160 |
| *Bacillus cereus* gastroenteritis | *B. cereus* | Isolation and identification of *B. cereus* possessing toxin genes (*hblC*, *nheA*, *entFM*, *cytK2*, *becT*, and *CER*) from specimens (stool, rectal swabs, and vomitus) | 42 |
| Yersiniosis | *Yersinia enterocolitica* | Isolation and identification of *Y. enterocolitica* from specimens (stool, rectal swabs, and vomitus) | 169 |
| Listeriosis | *Listeria monocytogenes* | Isolation and identification of *L. monocytogenes* from specimens (stool and rectal swabs) | 10 |

[b]ETEC: enterotoxigenic *E. coli*.

[c]EIEC: enteroinvasive *E. coli*.

[d]EPEC: enteropathogenic *E. coli*.

[e]CFU: colony-forming unit.

### *Case Identification in NHI Claim Data*

To identify NHI claim records corresponding to the 11 SSS targets, we used *ICD-10* codes A02, A04, A05, and A32 and their pathogen-specific subcodes where available. These diagnosis code categories correspond to salmonellosis, other bacterial intestinal diseases, bacterial foodborne intoxications, and listeriosis. They do not establish microbiological identification of the causative pathogen. Some parent codes encompass more than one organism; therefore, category-level analyses compared SSS surveillance targets with corresponding

XSL•FO
RenderX

diagnosis code categories and should not be interpreted as one-to-one pathogen matching.

Counts were extracted at the claim record level rather than at the unique patient or episode level; repeated outpatient or inpatient claims for the same person could therefore be included. To increase coding specificity, we retained primary or secondary diagnosis records accompanied by a billed laboratory test procedure and excluded follow-up records without an active diagnosis code. A billed test indicates only that testing was ordered or claimed; the result is not available in NHI data. Consequently, the algorithm may include empirically treated or miscoded records and is not equivalent to the laboratory-confirmed SSS case definition. We did not use these data to calculate incidence, case count ratios, capture fractions, or diagnostic accuracy. Throughout the manuscript, "claim records" denotes NHI observations, and "cases" denotes SSS reports.

## Study Period

The primary evaluation year was 2023 because it was the most recent complete year in the project dataset and was closest to the 2024 survey and operator interview. The analytic dataset also contained a complete 2021 extract, which was retained as a nonconsecutive historical comparator; 2022 was not included in the extract available to this study. We did not treat 2021 as an unaffected prepandemic baseline. Comparisons between 2021 and 2023 are descriptive snapshots, and no continuous temporal trend or causal effect of the COVID-19 pandemic was inferred.

## Evaluation Framework

### *Overview*

Our evaluation used the KDCA guidelines [18], which adapt the US Centers for Disease Control and Prevention framework for evaluating public health surveillance systems [19]. The framework had previously been applied to another South Korean SSS [15]. We assessed operational performance (simplicity, acceptability, and timeliness), reporting completeness (submission completeness and on-time completeness), and geographic allocation. Because sensitivity requires a valid denominator or reference standard and NHI claims do not provide one, sensitivity was not estimated. Weekly and age-stratified claim comparisons were analyzed as a separate exploratory external concordance component. Table 2 shows the operational definitions and data sources.

XSL•FO
RenderX

**Table .** Operational definitions and data sources for the mixed methods evaluation of South Korea's electronic bacterial gastroenteritis sentinel surveillance system (SSS) using 2021 and 2023 operational and claim data and a 2024 survey and operator interview.

| Domains | Attribute | Operational definition | Source |
|---|---|---|---|
| Performance | Simplicity | Percentage of surveyed sentinel staff rating the reporting process as simple or adequate | 2024 sentinel hospital survey |
| Performance | No case notifications for >6 mo | Percentage of designated sentinel hospitals with no laboratory-confirmed bacterial gastroenteritis case notifications for >6 mo; distinct from missing scheduled weekly submissions | KDCA[a] operational data |
| Performance | Acceptability | Distribution of responses on awareness of SSS operational goals | 2024 sentinel hospital survey |
| Performance | Acceptability | Distribution of responses on overall satisfaction with SSS operation | 2024 sentinel hospital survey |
| Performance | Timeliness | Delayed reports divided by all submitted reports; B/(A + B) | KDCA operational data |
| Reporting completeness | Submission completeness | All submitted reports divided by expected reports; (A + B)/C | KDCA operational data |
| Reporting completeness | On-time completeness | Reports submitted within 7 d divided by expected reports; A/C | KDCA operational data |
| Exploratory external comparison | Weekly temporal concordance | Pearson correlation between weekly all-pathogen SSS cases and NHI[b] claim records (n=52 wk per y); not a sensitivity measure | KDCA and NHI claims |
| Exploratory external comparison | Age-stratified cross-category concordance | Pearson correlation between annual counts across 11 SSS surveillance targets or corresponding diagnosis code categories within each age group; not one-to-one pathogen validation | KDCA and NHI claims |
| Network allocation | Geographic allocation | Pearson correlation between population-proportional expected and actual sentinel site counts across 17 regions | KDCA and KOSIS[c] population data |

[a]KDCA: Korea Disease Control and Prevention Agency.

[b]NHI: National Health Insurance.

[c]KOSIS: Korean Statistical Information Service.

### *Simplicity*

Simplicity captures the ease of structuring and operating the surveillance system [18]. We checked it in 3 aspects: case reporting, data collection, and dissemination of analytic results. Sentinel hospital personnel rated the simplicity of the case reporting process. The KDCA operator was asked about ease of data collection and result dissemination. Each item used a 3-point scale: simple, adequate, or complex.

### *Acceptability*

Acceptability reflects how willing stakeholders are to take part in operations, reporting, and data use [18]. We measured it in 3 ways. The first was the proportion of sentinel hospitals with no laboratory-confirmed bacterial gastroenteritis case notifications for 6 months or longer in a year divided by the total number of sentinel hospitals multiplied by 100. This indicator concerned the absence of notified cases and was distinct from scheduled weekly report submission; a zero-case weekly submission counted toward completeness. The second was awareness of operational goals, asked as follows: "Are you aware of the operational goals of the surveillance system?" (responses: "yes," "neutral," or "no"). The third was overall satisfaction, asked as follows: "What is your overall satisfaction with the operation of the surveillance system?" (responses: "good," "neutral," or "poor").

### *Timeliness*

The KDCA expects sentinel hospitals to report cases within 7 days of diagnosis [13]. Broadly, timeliness refers to the time needed for reporting, analysis, and feedback within the SSS [18]. We measured it as the delayed reporting proportion: reports submitted after the 7-day window divided by the total number of reports submitted (the sum of on-time and delayed reports).

XSL•FO
RenderX

### *Completeness*

If A denotes scheduled weekly submissions received within 7 days, B denotes delayed scheduled weekly submissions, C denotes the expected number of scheduled weekly submissions (number of designated sentinel hospitals multiplied by 52 weeks), and weekly submissions could report one or more cases or zero cases, we calculated submission completeness as (A + B)/C and on-time completeness as A/C. The delayed reporting proportion, our timeliness measure, was B/(A + B). These indicators were not arithmetic complements: timeliness was conditional on submissions that were received, whereas completeness used all expected submissions as the denominator. Reporting both forms of completeness separated failure to submit from delay among submitted weekly reports.

### Exploratory External Concordance

For exploratory external comparison, we aggregated SSS cases and NHI claim records across all 11 target categories by epidemiologic week and calculated a Pearson correlation using 52 paired weekly totals within each year. This ecological correlation asks whether the 2 data streams comove over weeks; it does not determine whether they identify the same patients or diagnoses. In a separate age-stratified analysis, we compared annual counts across 11 SSS surveillance target or corresponding diagnosis code categories within each age group (n=11 paired categories per panel). Because these correlations are sensitive to the highest-incidence categories, some parent *ICD-10* codes encompass more than one organism, and the claim definition is not laboratory confirmed, they were interpreted descriptively rather than as validation metrics.

### Geographic Allocation

For each of South Korea's 17 administrative regions, the population-proportional expected number of sentinel hospitals was calculated as the total number of sentinel sites multiplied by the region's share of the national resident population. Pearson correlation coefficients compared expected and actual site counts across regions for 2021 and 2023. This indicator assessed whether the network's allocation followed population distribution; it did not evaluate regional disease incidence, regional reporting completeness, or geographic representativeness of reported cases.

### Statistical Analysis

Survey and operational data were summarized using frequencies, proportions, and means. Pearson correlation coefficients were calculated separately for weekly external concordance (52 paired weeks per year), age-stratified annual cross-category concordance (11 paired categories per age group and year), and geographic allocation (17 paired regions per year). Weekly coefficients were treated as descriptive because consecutive observations may be temporally autocorrelated and shared seasonality was not modeled. *P* values are reported descriptively and were not used to classify system performance; no adjustment for multiple exploratory correlations was applied. Analyses were conducted in SAS (version 9.4; SAS Institute).

### Reporting Guideline

We used the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) checklist for cross-sectional studies as a reporting aid for the survey and observational claim components [20]. A completed checklist is provided as Checklist 1. Because this study also included surveillance operational records and a single-operator interview, the STROBE checklist does not cover every component of the mixed methods evaluation.

### Ethical Considerations

The institutional review board of Kongju National University approved this study (approval number KNU_IRB_2024-072). Because we used deidentified, aggregated sentinel hospital data; an institutional interview with the KDCA operator; and anonymized NHI claim data, individual informed consent was waived. All data handling complied with the relevant Korean regulations on personal information and statistical data.

## Results

### Survey Results From Sentinel Hospitals

Of the 180 responding sentinel hospitals, 18 (10%) rated the reporting process as simple, 144 (80%) rated it as adequate, and 18 (10%) rated it as complex. Thus, 90% (162/180) rated reporting as simple or adequate (Table 3).

Responses on operational goal awareness and satisfaction were predominantly neutral. For awareness, of the 180 respondents, 55 (30.6%) answered "yes," 97 (53.9%) were neutral, and 28 (15.6%) answered "no." For overall satisfaction, 4.4% (n=8) rated the system as good, 79.4% (n=143) rated it as neutral, and 16.1% (n=29) rated it as poor (Table 3). These marginal distributions were analyzed separately; no within-respondent association among the 3 survey items was tested.

**Table .** Responses to the 2024 survey of staff responsible for bacterial gastroenteritis notification at 85.3% (180/211) of the sentinel hospitals in South Korea (n=180)[a].

| Items | Positive response, n (%) | Neutral or "adequate" response, n (%) | Negative response, n (%) |
|---|---|---|---|
| Rating of the reporting process | Simple: 18 (10) | Adequate: 144 (80) | Complex: 18 (10) |
| Awareness of the goals of the SSS[b] | Yes: 55 (30.6) | Neutral: 97 (53.9) | No: 28 (15.6) |
| Overall satisfaction with the SSS | Good: 8 (4.4) | Neutral: 143 (79.4) | Poor: 29 (16.1) |

[a]Mean time taken to report cases per week 30.6 (SD 92.7) minutes.

### KDCA Operational Data

In 2023, a total of 2.8% (6/211) of the sentinel hospitals reported no laboratory-confirmed bacterial gastroenteritis cases for more than 6 months. This did not indicate missing scheduled weekly submissions; zero-case weekly submissions were counted in the completeness measures. The KDCA operator also reported that no formal standardized training program was provided for the role in 2023.

The delayed reporting proportion was 2.4% (255/10,652) of submitted weekly reports in 2021 and 1.1% (122/10,972) in 2023. Submission completeness was 99.9% (10,652/10,660) of expected weekly submissions in 2021 and 100% (10,972/10,972) in 2023. On-time completeness was 97.5% (10,397/10,660) and 98.9% (10,850/10,972) submissions in 2021 and 2023, respectively (Table 4).

**Table .** Operational reporting indicators, sentinel-reported cases, and National Health Insurance (NHI) claim record counts for 11 bacterial gastroenteritis diagnosis categories in South Korea (2021 and 2023)[a].

| Indicators | 2021 | 2023 |
|---|---|---|
| Sentinels in the surveillance system, n | 205 | 211 |
| Facilities with no laboratory-confirmed case notifications for >6 mo, n/N (%) | 3/205 (1.5) | 6/211 (2.8) |
| On-time scheduled weekly submissions received within 7 d (denoted as A), n | 10,397 | 10,850 |
| Delayed scheduled weekly submissions (denoted as B), n | 255 | 122 |
| Delayed reporting proportion (calculated as B/[A + B]), % | 2.4 | 1.1 |
| Expected scheduled weekly submissions (denoted as C [calculated as sentinel sites × 52 wk]), n | 10,660 | 10,972 |
| Submission completeness ([A + B]/C), % | 99.9 | 100 |
| On-time completeness (A/C), % | 97.5 | 98.9 |
| Total NHI claim records for the 11 bacterial gastroenteritis diagnosis categories, n | 36,572 | 39,376 |
| Health care facilities with NHI claim records for the 11 diagnosis categories, n | 1030 | 1183 |
| NHI claim records for patients aged 0 - 6 y, n | 8045 | 6307 |
| Sentinel-reported cases for patients aged 0 - 6 y, n | 1333 | 1370 |

[a]Weekly submissions may include zero-case reports. The >6 month indicator denotes no laboratory-confirmed case notifications and is distinct from missing weekly submissions. NHI values are claim record counts and are not deduplicated by patient or episode; they must not be interpreted as incidence or directly compared with sentinel surveillance system case counts as if the counting units were equivalent.

### Exploratory External Concordance and Geographic Allocation

Using 52 paired weekly all-pathogen totals per year, the exploratory Pearson correlation between SSS-reported cases and NHI claim records was 0.899 in 2021 and 0.937 in 2023 (Figure 1). These coefficients describe ecological weekly comovement and do not measure diagnostic agreement or surveillance sensitivity.

In the annual age-stratified cross-category analyses, each coefficient was based on 11 paired surveillance target or diagnosis code categories. The coefficients ranged from 0.665 to 0.969 in 2021 and from 0.939 to 0.983 in 2023. For children aged 0 to 6 years, the coefficients were 0.969 in 2021 and 0.982 in 2023; the largest 2023 coefficient was 0.983 in the group aged 7 to 12 years. The coefficients differed numerically between the 2 years, particularly in older age groups, but the nonconsecutive years and small number of category-level observations do not support a trend or causal interpretation. Full panels are shown in Multimedia Appendices 1 and 2.

The correlation between population-proportional expected and actual sentinel site counts across South Korea's 17 administrative regions was 0.946 in 2021 and 0.951 in 2023 ($P$<.001 in both cases; Table 5), indicating close alignment of site allocation with population distribution.

RenderX

**Figure 1.** Weekly temporal concordance between total National Health Insurance (NHI) claim records carrying 1 of 11 bacterial gastroenteritis diagnosis codes and laboratory-confirmed cases reported through South Korea's sentinel surveillance system shown separately for 2021 (A) and 2023 (B). Each point represents 1 epidemiologic week (n=52 per year); the line is the fitted linear relationship, and the shaded area is its 95% CI. The correlation is ecological and descriptive; shared seasonality and serial autocorrelation were not modeled, and the coefficient does not indicate diagnostic agreement or sensitivity. KDCA: Korea Disease Control and Prevention Agency.

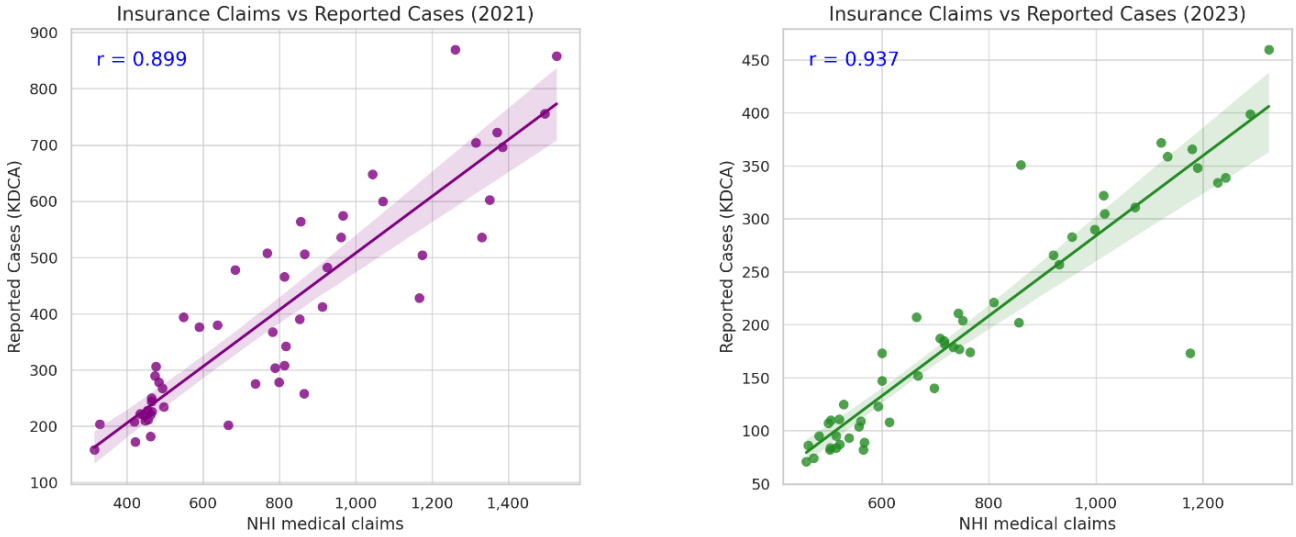

**Table .** Summary of operational performance reporting completeness, exploratory external concordance, and geographic allocation for South Korea's electronic bacterial gastroenteritis sentinel surveillance system (2021 and 2023)[a].

| Domains | Attribute | 2021 | 2023 | Interpretation |
|---|---|---|---|---|
| Performance | Reporting process rated as simple or adequate | —[b] | 90% (162/180) | Predominantly simple or adequate |
| Performance | Awareness of operational goals; response distribution | — | Yes: 30.6% (55/180); neutral: 53.9% (97/180); no: 15.6% (28/180) | Predominantly neutral |
| Performance | Overall satisfaction; response distribution | — | Good: 4.4% (8/180); neutral: 79.4% (143/180); poor: 16.1% (29/180) | Predominantly neutral |
| Performance | Delayed reporting proportion | 2.4% (255/10,652) | 1.1% (122/10,972) | Low |
| Reporting completeness | Submission completeness | 99.9% (10,652/10,660) | 100% (10,972/10,972) | Near complete |
| Reporting completeness | On-time completeness | 97.5% (10,397/10,660) | 98.9% (10,850/10,972) | High |
| Exploratory external comparison | Weekly SSS[c]-NHI[d] concordance (Pearson *r*; n=52 wk) | 0.899 | 0.937 | Strong descriptive ecological correlation |
| Exploratory external comparison | Age-stratified cross-category concordance (Pearson *r* for age of 0 - 6 y; n=11 categories) | 0.969 | 0.982 | Strong exploratory correlation |
| Network allocation | Population-proportional vs actual sentinel site allocation (Pearson *r*; n=17 regions) | 0.946 | 0.951 | Strong alignment |

[a]Neutral survey responses are reported separately and were not combined with positive responses. Correlation coefficients are descriptive. The sentinel surveillance system–National Health Insurance coefficients do not establish sensitivity, diagnostic agreement, one-to-one pathogen matching, or equivalence of counting units; the geographic coefficient assesses population-based site allocation only.

[b]No corresponding survey data were available for 2021; the survey was conducted in 2024 to evaluate the 2023 surveillance system.

## Discussion

### Principal Findings

Relative to the study objectives, the electronic SSS showed favorable operational performance. In 2023, a total of 90% (162/180) of respondents rated reporting as simple or adequate, 1.1% (122/10,972) of submitted weekly reports were delayed, submission completeness was 100% (10,972/10,972), and on-time completeness was 98.9% (10,850/10,972). Actual sentinel site allocation also closely followed population-proportional allocation across 17 regions. The exploratory external comparisons showed strong weekly ecological comovement between SSS cases and NHI claim records and generally strong annual cross-category correlations within age groups.

Acceptability findings were less favorable and more difficult to interpret. Only 30.6% (55/180) of respondents clearly reported awareness of the SSS's operational goals, whereas 53.9% (97/180) selected "neutral" and 15.6% (28/180) selected "no." Overall satisfaction was also mostly neutral (143/180, 79.4%), with 4.4% (8/180) rating it as good and 16.1% (29/180) rating it as poor. Because the awareness item did not state the operational goals, neutral or negative responses may reflect either limited awareness or ambiguity in the question. Nevertheless, clearer communication and routine onboarding are warranted. The absence of a standardized training program for the KDCA operator further supports the need for role-specific training and written operating procedures.

### Comparison With Prior Work

Systematic evaluation of surveillance systems can identify operational gaps and improve the information available to public health agencies. Although established frameworks exist, evaluations differ in the attributes assessed, data sources used, and analytic methods applied [19,21,22]. Our approach combined the US Centers for Disease Control and Prevention framework [19] with the KDCA-adapted framework [18], as in a previous evaluation of South Korea's hand, foot, and mouth disease SSS [15]. Electronic notification systems have also been evaluated in other settings [23]. The present system likewise performed favorably for reporting simplicity, timeliness, and completeness while also revealing opportunities to improve stakeholder engagement and operator training.

Timeliness is a central surveillance attribute because delayed notification can reduce the usefulness of information for public health action [22]. NHI claims are not a substitute for real-time reporting because billing and data access processes introduce delay. The SSS, in contrast, requires notification within 7 days of diagnosis [13]. The 1.1% (122/10,972) delayed reporting proportion in 2023, therefore, indicates strong adherence to the specified reporting window. This metric does not measure onset-to-detection delay or outbreak detection speed, and its interpretation depends on the common 7-day threshold rather than pathogen-specific urgency [22,24]. Automated outbreak detection systems use different end points and require separate evaluation [25].

The external comparison requires more cautious interpretation. Surveillance sensitivity is the proportion of true community cases captured, which cannot be estimated without a credible denominator or reference standard. Other studies have compared gastroenteritis surveillance with web-based symptom reports or medication sales [26,27], and Korean claim data have been used to complement passive surveillance [28]. In our study, the weekly correlation used 52 ecological observations per year and indicates comovement of aggregate counts only. Consecutive weeks may be temporally autocorrelated, and shared seasonal patterns were not modeled; the coefficient should therefore be interpreted as descriptive comovement rather than an independent observation validation estimate. The age-stratified panels used 11 annual category-level observations and are particularly sensitive to leverage from high-incidence categories. Some *ICD-10* parent codes encompass more than one organism, further limiting pathogen-specific interpretation. Moreover, NHI claim records are not laboratory confirmed and were not deduplicated by patient or episode. Differences between the 2021 and 2023 coefficients, therefore, should not be interpreted as evidence that sensitivity changed. Validation of capture and diagnostic accuracy would require patient- or episode-level linkage to laboratory results or another microbiologically confirmed reference source. Geographic allocation should also be distinguished from case representativeness: our regional analysis assessed where sentinel hospitals were located relative to population, not whether reported disease incidence was representative.

The results support the operational value of a nationally coordinated electronic reporting platform, but they do not establish early outbreak detection performance, which was not evaluated. Potentially transferable design features include population-informed sentinel site allocation, standardized laboratory case definitions, and centralized electronic reporting. Site placement can influence outbreak detection and access to surveillance facilities [29,30]. Periodic comparison with administrative data may be useful as a quality assurance signal when interpreted as ecological consistency rather than as validation of cases or estimation of underreporting.

### Public Health and Informatics Implications

Electronic sentinel reports and administrative claims serve different functions. The SSS provides the timely, laboratory-based notifications required for routine surveillance. Claim data become available later and reflect reimbursement coding rather than confirmed infection. Their appropriate role in this context is retrospective quality assurance: marked divergence in weekly or category-specific patterns could prompt targeted review of coding, laboratory practice, or reporting workflows. Claim data alone cannot identify which source is correct, quantify underreporting, or replace laboratory-based surveillance.

Three practical improvements follow from the evaluation. First, routine feedback to sentinel hospitals could display reporting completeness and carefully labeled ecological concordance indicators, with alerts used to trigger review rather than grade performance automatically. Second, concise digital onboarding and standardized training materials should be provided to both

XSL•FO
RenderX

sentinel personnel and KDCA operators. Third, future evaluations should obtain patient- or episode-level claims and link them, where legally and technically feasible, to laboratory-confirmed surveillance records. Such validation would directly address the case definition and duplicate use limitations identified in this study.

### Limitations

The principal limitation concerns the external comparator. NHI claims record diagnosis codes and billed procedures, not laboratory results, whereas SSS cases require laboratory confirmation. Claims may therefore include false-positive coding, empiric treatment, or unconfirmed testing. Accordingly, the correlations are interpreted only as exploratory ecological comparisons and not as a proxy for sensitivity.

Claims were counted at the record level and were not deduplicated by patient or clinical episode. Repeated use could alter weekly or category-specific patterns, particularly if revisit frequency varies by pathogen, age, or year. We did not compare absolute count levels, calculate incidence, or estimate capture fractions. Patient- or episode-level analysis is required before claims can be used for those purposes.

The survey response rate was 85.3% (180/211), but the characteristics of respondents were not formally compared with those of nonrespondents. Simplicity and acceptability estimates may therefore be affected by nonresponse and social desirability bias. We also did not test within-respondent associations among reporting simplicity, goal awareness, and satisfaction; the 3 marginal distributions should be interpreted separately. The operator interview involved 1 person, so it was used as contextual evidence rather than as a basis for generalizable quantitative inference.

The correlation analyses also have scope limitations. Weekly concordance was assessed in only 2 nonconsecutive years, so no continuous trend or pandemic effect can be inferred. Consecutive weekly observations may be temporally autocorrelated, and high coefficients may partly reflect shared seasonal patterns; seasonality and serial correlation were not modeled. Each age-stratified panel contained 11 category-level observations, several clustered near zero, and Pearson correlations were sensitive to high-incidence categories; multiple exploratory correlations were not adjusted for multiplicity. Some *ICD-10* parent codes encompass more than one organism, so the category-level comparisons do not imply one-to-one pathogen matching. The geographic analysis compared population-proportional and actual site allocation across 17 regions but did not compare regional disease incidence patterns.

Finally, our timeliness metric used a common 7-day threshold and did not measure the interval from symptom onset to detection or public health action. We did not evaluate outbreak detection algorithms, detection delay, flexibility, positive predictive value, stability, or cost-effectiveness [31,32]. These attributes require additional data and should be addressed in future evaluations.

### Conclusions

South Korea's electronic SSS for bacterial gastroenteritis demonstrated favorable operational performance, including low reporting delay, near-complete submission, and population-aligned sentinel site allocation. Exploratory correlations with NHI claim records showed ecological comovement. Clearer communication of system goals, standardized operator training, and validation using deduplicated patient- or episode-level data linked to laboratory results are the most important next steps. These distinctions are relevant to other jurisdictions considering administrative data as a supplement to rather than a replacement for laboratory-based electronic surveillance.

### Acknowledgments

The authors thank the staff of the participating sentinel hospitals and the Korea Disease Control and Prevention Agency personnel who contributed survey and operational information. During revision, the authors used ChatGPT (OpenAI) for language editing, structural organization, and internal consistency checks. The tool was not used to generate or analyze study data. All outputs were critically reviewed, verified, and revised by the authors, who take full responsibility for the manuscript.

### Funding

This work was supported by the research program funded by the Korea Disease Control and Prevention Agency (grant 2024-04-019). The funder had no involvement in the study design; data collection, analysis, and interpretation; manuscript preparation; or decision to submit the work for publication.

### Data Availability

The aggregated survey and Korea Disease Control and Prevention Agency–reported data supporting the findings of this study are presented within the article and its multimedia appendices. The National Health Insurance medical claims data are not publicly available because of restrictions imposed by the Health Insurance Review and Assessment Service (HIRA) of the Republic of Korea, but they can be requested from the HIRA through a formal application process for legitimate research purposes.

## Abstract

**Background:** Prior studies involving music festivals (including on-site surveys, drug checking, and wastewater-based analyses) suggest that recreational substance use is common among festivalgoers, though preferred substances and usage may be region- and event-specific. However, multiyear, event-specific wastewater surveillance data in the United States are limited.

**Objective:** This study aimed to characterize concentrations of high-risk substances (HRS) and their metabolites in wastewater surrounding an annual electronic dance music (EDM) festival in Las Vegas, Nevada, USA. Using a progressive sampling approach over 3 consecutive years (2023 - 2025), we assessed trends and examined comparisons by sample type, day, and location to inform situational awareness and future public health surveillance efforts and risk mitigation strategies.

**Methods:** Wastewater samples were collected from utility access points at the festival site (2024 - 2025), off-site in the surrounding community (2023 - 2024), and at the downstream wastewater treatment plant (WWTP; 2023 - 2025) during the festival week and weekend. For comparison, samples from a nonfestival weekend were collected off-site and at the WWTP in 2023. Target analytes consisted of 24 parent compounds and metabolites, including stimulants, opioids, and sedatives, which were analyzed by liquid chromatography–tandem mass spectrometry (LC-MS/MS) with isotope dilution. Analyte selection prioritized substances associated with overdose risk and with prior festival-related surveillance.

**Results:** Cocaine (and 3 of 4 measured metabolites), methamphetamine, amphetamine, 11-nor-9-carboxy-Δ-9-tetrahydrocannabinol (THC-COOH), and tramadol were detected in 100% of festival weekend samples; 3,4-methylenedioxymethamphetamine (MDMA; ecstasy) was detected (at concentrations of up to nearly 2 mg/L) in all but 1 festival site sample collected prior to the start of the event in 2025. Festival-associated signals were most pronounced for stimulant-related analytes, which were also detected in WWTP and off-site samples during the festival. Compared with nonfestival weeks, MDMA concentrations were approximately 10 to 30 times higher at off-site locations and nearly 100 times higher at the downstream WWTP during the festival. Opioid-related concentrations were comparable at the WWTP and the festival site, although there were notable detections of norfentanyl and relatively high concentrations of tramadol in some festival site samples. MDMA- and cocaine-related analyte concentrations peaked during the final festival days in 2024 and 2025; the 2023 samples highlighted the presence of HRS in local wastewater during nonfestival weekends.

**Conclusions:** Event-focused, multiyear wastewater surveillance detected stimulants and psychoactive substances, opioids, and Δ-9-tetrahydrocannabinol (THC) associated with an annual EDM festival weekend. Findings are consistent with previous wastewater-based studies of music and dance festivals, with MDMA concentrations among the highest reported in similar

XSL•FO
RenderX

surveillance efforts. Codetection of opioid- and stimulant-related analytes suggests varied usage preferences, polysubstance use, and/or unintentional adulteration (eg, lacing). These findings demonstrate the value of wastewater monitoring as a complementary, population-level tool to support public health preparedness, harm-reduction strategies, and attendee safety during large-scale events. These data also inform wastewater utilities about expected influent composition during special events, with relevance for treatment operations and water reuse applications.

## Introduction

Large events, including music festivals, can present unique public health and safety challenges, particularly if attendees choose to engage in high-risk health behaviors such as recreational substance use. Surveys suggest that substance use is common among festivalgoers [1,2], with 24% of respondents in one study reporting an intention to use drugs at music festivals [3]. Researchers have previously investigated underlying reasons for adverse outcomes associated with festival-specific substance use behaviors, identifying a complex blend of factors such as first-time use among inexperienced attendees, new or unfamiliar drug sources (ie, drugs purchased from strangers), crowding, heat, exhaustion, and more [4]. The presence of adulterated or counterfeit drugs in this setting further exacerbates potential health risks among festivalgoers; a review of 6 studies involving voluntary drug-checking stations at festival sites found adulterants in 11% to 55% of tested samples [5]. These data sources may still underestimate the scope of this problem, as most event-related surveys, interviews, and drug-checking studies rely on voluntary participation and self-reporting of stigmatized (and often illicit) substance use behaviors.

In the search for a complementary, noninvasive tool for characterizing event-related recreational substance use, researchers have explored wastewater monitoring and wastewater-based epidemiology (WBE) of high-risk substances (HRS) at music festivals. Wastewater results from festivals in Australia [6,7], Brazil [8], and 6 European countries [9] suggest event- and region-specific differences in the types and amounts of drugs present. Lai et al [6] noted consistency in per capita consumption estimates for conventional and emerging illicit drugs (based on daily, on-site, and composite wastewater samples) across 2 years of a recurring summer music festival in Australia, suggesting that attendees may exhibit consistent year-over-year substance use patterns surrounding an event.

Las Vegas, Nevada, USA, is an international entertainment destination with multiple large annual events. Year-round activities draw tourists and locals alike, but one of the largest annual events is an electronic dance music (EDM) festival that has attracted more than 520,000 annual attendees in recent years [10]. During the festival weekend in 2022, surface water in the Las Vegas Wash, which primarily conveys discharged effluent from local wastewater treatment plants (WWTPs), was analyzed for the presence of pharmaceuticals and recreational drugs that had persisted through wastewater treatment, as a means of assessing ecological and environmental risks [11]. That study identified a unique fingerprint of community substance use associated with the festival weekend, including 3,4-methylenedioxymethamphetamine (MDMA; ecstasy), methamphetamine, cocaine, and ketamine. In fact, the median MDMA concentration in the Las Vegas Wash during the festival was 46 times higher than the study control (ie, nonfestival period) [11]. Elevated concentrations of drugs and their metabolites have important implications for Las Vegas Wash ecology and for understanding substance use in the local community during the event. However, due to the efficacy of wastewater treatment in attenuating concentrations of some trace organics [12,13], including HRS [14], direct monitoring of untreated wastewater (rather than effluent-impacted surface water) is preferable for WBE efforts.

Building on these local findings [11], this study characterizes HRS occurrence in site-specific and community-level raw wastewater surrounding the festival weekend over 3 consecutive years (2023, 2024, and 2025). Specifically, this study examines wastewater-based assessments of HRS over time and across sampling locations, festival days, and sample types (grab vs composite). This work further characterizes the wastewater-based HRS profile of the festival weekend for both the corresponding wastewater utility (to understand event-related changes in influent wastewater composition and to potentially inform wastewater treatment and reuse operations) and public health and safety personnel (to inform future event-related public health surveillance activities, responses, and resource allocations).

## Methods

### Festival Information

During each year of the study period (2023 - 2025), the festival was held over a single mid-May weekend at a large outdoor venue within the same sewershed as the casino-resort corridor known as the Las Vegas Strip. Off-site promotional events catering to attendees began as early as the preceding Tuesday, but the on-site campground opened on Thursday. The on-site festival was then held nightly on Friday, Saturday, and Sunday, closing at 5:30 AM each morning. The festival concluded on Monday morning, with the campground closing later that day.

### Wastewater Sampling

#### *Sampling Locations and Sample Handling*

Festival-related wastewater sampling expanded each year of the study, from pilot sampling in 2023 to more comprehensive

XSL•FO
RenderX

sampling before, during, and after the festival weekend in 2024 and 2025. Similar sampling schemes (pre-event, during, and postevent) have been described in previous event-based wastewater monitoring studies [15]. Sample locations and types by year and collection day are shown in Table 1. An aliquot (80 mL) of each collected sample was transferred to two 40-mL amber glass vials (containing 50 mg/L of ascorbic acid for oxidant quenching and 1 g/L of sodium azide for biological preservation) and then stored at 4°C until processing and analysis. A map of these sampling locations in the context of Las Vegas area sewersheds is shown in Figure 1. Although the site-specific sampling efforts required mapping of wastewater flows originating from contributing buildings, sites, or complexes, it was not possible to determine each sample's specific points of origin *within* those contributing buildings, sites, or complexes, thereby maintaining individual privacy.

**Table .** Wastewater sampling locations by day and year during the festival week and weekend. Samples were composite unless otherwise noted[a].

**Figure 1.** Map of the Las Vegas area sewersheds and wastewater sampling locations. mgd: million gallons per day; WWTP: wastewater treatment plant.

### *WWTP Sampling*

Raw influent wastewater samples were collected each year from the WWTP downstream of the event venue by collaborating utility partners. This WWTP treats approximately 110 million gallons per day (mgd) and serves the casino-resort corridor of the Las Vegas Strip (with an average weekly visitor volume of approximately 800,000 throughout the year), in addition to the international airport, a large university, and a residential population of approximately 1 million. In 2023, 1 grab sample was collected at the WWTP after the final night of the festival (on Monday morning, May 22, 2023), and again 5 and 7 weeks later (nonfestival Mondays of June 26 and July 10, 2023, respectively). In 2024, 24-hour volume-proportional (flow-paced) influent composite samples were collected each morning during the festival (starting Friday and ending Monday, with collections representing the preceding 24 h), with a corresponding grab sample collected for comparison on Monday morning (as in 2023). Finally, the 2025 WWTP sampling expanded the 2024 sampling scheme to include composite sampling on Thursday (prefestival) and Tuesday mornings

XSL•FO
RenderX

(postfestival), with another grab sample collected for comparison on Tuesday.

### *Community (Off-Site) Sampling*

Time-proportional composite samples were collected using an autosampler (AS950, Hach) from utility access points (ie, manholes) receiving wastewater from the international airport, the casino-resort corridor of the Las Vegas Strip, and a cluster of bars and nightclubs near the Strip. Sampling details associated with these "off-site" manhole locations were described previously [16], and the days of the week represented by these samples are detailed in Table 1 and Multimedia Appendix 1. In 2023, samples from the airport, the Las Vegas Strip, and bars were collected during the festival weekend (in May) and the 2 nonfestival comparison weekends (in late June and early July). Similar sentinel-site sampling was performed in 2024 but not in 2025. Previous event-based HRS wastewater studies similarly included samples from the surrounding community [6] and nonfestival weekends [9] for comparison. No flow data were available for these sampling locations.

### *Festival-Site Sampling*

In response to preliminary community-scale results from 2023, festival site-specific sampling was initiated in 2024 and repeated in 2025. Wastewater was collected by the collaborating wastewater utility from a manhole receiving wastewater only from the festival venue and campground (ie, mobile showers and restrooms discharging to the sewer collection system); these flows ultimately travel to the downstream WWTP. In 2024, a field-deployable autosampler was not yet available for use by the collaborating utility, so grab samples were collected daily from Friday to Monday morning (n=4) to complement the samples collected at the downstream WWTP. In 2025, the sampling period was extended from Thursday (prefestival) to Tuesday (postfestival), and, in lieu of grab samples (except for a supplemental Tuesday grab), 24-hour time-proportional composite samples were collected using an autosampler (CA101, C.E.C. Analytics). Therefore, sample type is a potential confounding variable for direct comparisons between 2024 and 2025 concentrations. The festival attracted more than 520,000 attendees each year, but no corresponding wastewater flow data were available for the festival-site sampling.

### Sample Analysis

Target analytes in this study included 24 parent compounds and metabolites (Table S1 in Multimedia Appendix 2). As in our concurrent campus-based wastewater monitoring campaign [17], nonopioid substances included cocaine and its metabolites (benzoylecgonine [BZE], ecgonine methyl ester [EME], ecgonine, and norcocaine), methamphetamine (and amphetamine), MDMA (and 3,4-methylenedioxyamphetamine [MDA]), Δ-9-tetrahydrocannabinol (THC; also 11-hydroxy-Δ-9-tetrahydrocannabinol [THC-OH] and 11-nor-9-carboxy-Δ-9-tetrahydrocannabinol [THC-COOH]), and the tranquilizer xylazine. Natural (heroin, morphine, and codeine), semisynthetic (hydrocodone and oxycodone), and synthetic (fentanyl, methadone, and tramadol) opioid targets were also included. Relevant opioid metabolites included 6-acetylmorphine for heroin, norfentanyl for fentanyl, and 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP) for methadone. Fentanyl and xylazine were added to the analyte panel in 2025.

Analyses involved direct injection of aqueous samples after a 10-fold dilution to reduce matrix interference; samples were diluted further if concentrations fell outside the calibration range. All compounds were analyzed by liquid chromatography–tandem mass spectrometry (LC-MS/MS) with isotope dilution quantification according to previously published methods [18,19]. Analyses used a CTC Autosampler (CTC Analytics) and a 1260 LC Binary Pump (Agilent). Target compounds and their isotopically labeled analogs were then analyzed using positive electrospray ionization (ESI) in multiple reaction monitoring (MRM) mode on a 6500 QTRAP mass spectrometer (SCIEX). Additional analytical details for all target compounds, including method reporting limits (MRLs) and MRM transitions, are included in Text S1 in Multimedia Appendix 2. Field and analytical blanks (consisting of Milli-Q water treated as samples) were negative for all target compounds.

### Statistical Analysis

Wilcoxon signed-rank tests were conducted in R using RStudio. The first analysis compared site-specific analyte concentrations between 2024 and 2025 (ie, festival 2024 vs festival 2025 and WWTP 2024 vs WWTP 2025), and data were limited to sampling days that overlapped in both years. Note that the festival comparison was potentially confounded by the difference in sample type (grab in 2024 and composite in 2025). The second analysis compared same-day concentrations at the festival site and the WWTP across both 2024 and 2025. Any concentrations below the MRL were omitted from the statistical analyses, along with their paired samples.

### Ethical Considerations

The University of Nevada, Las Vegas Institutional Review Board reviewed this project and determined it to be exempt from human participant research regulations and from the requirement for informed consent, according to federal regulations and university policy.

## Results

### Detection Frequencies and Analyte Concentrations by Year and Sampling Location

### *Principal Findings*

Analyte detection frequencies and corresponding concentrations were shared electronically with the collaborating wastewater utility and the local health authority as soon as the data were finalized. Detection frequencies for each analyte by year and sampling location during the festival weekend are shown in Table 2, with the airport, bars, and Las Vegas Strip sampling sites combined as "off-site" locations.

Cocaine (and 3 of 4 metabolites), methamphetamine, amphetamine, THC-COOH, and tramadol were detected (above the MRL) in 100% of samples across all years and all locations during the festival week and weekend (excluding the 2023

XSL•FO
RenderX

nonfestival comparison weeks). This finding is consistent with previous wastewater surveillance studies in Southern Nevada; for example, methamphetamine and THC typically exhibit some of the highest per capita consumption rates based on Southern Nevada's community-scale wastewater concentrations [19]. Additionally, amphetamine has been one of the most frequently detected compounds in the sewer collection system of a local university campus [17]. In 2010, elevated cocaine consumption was linked to a major sporting event weekend based on wastewater samples collected from the same Southern Nevada WWTP in this study [14]—a finding also observed in 2023 [19]. Here, norcocaine—the one exception among the cocaine metabolites—was detected in only a subset of the samples collected upstream of the WWTP, specifically in all 3 samples from the bars in 2023 (festival and nonfestival weekends) and in 1 sample from the festival site in 2025 (grab sample only). Neither heroin, THC, nor xylazine (analyzed only in 2025) was detected above the MRL in any samples in this study, and the major heroin metabolite acetylmorphine was not detected at all in 2025 or at the WWTP in 2024.

MDMA was detected in all festival-impacted samples (including off-site, festival site, and WWTP samples), except for a 2025 festival site composite collected *before* the campground was officially opened for the weekend. In the previous community-scale study, MDMA occurrence was rare in neighboring Southern Nevada sewersheds (20%±8% detection frequencies in the previous study), compared to the WWTP in this study (92% detection frequency previously) [19]. MDMA occurrence in influent wastewater at this WWTP is presumably driven primarily by contributions from the Las Vegas Strip, but the high MDMA detection frequency across all festival weekend samples (including those from the airport) highlights the impact of the event across the city. Although detected in 100% of festival weekend off-site samples, MDMA was below the MRL in both airport samples and in one of the Las Vegas Strip samples during nonfestival weeks in 2023, and it was also below the MRL in all samples collected at a local university campus in 2025 [17]. Similarly, MDA (a major metabolite of MDMA) is rarely observed in local wastewater samples; for example, the only detection of MDA in the previous sewershed-level wastewater study in Southern Nevada was associated with an unrelated music festival in September 2022 [19]. Thus, the MDA detection frequencies in this study, primarily associated with the bars and festival samples, are notable.

Although stimulant-related analytes were most frequently detected, several opioid-related analytes (eg, tramadol, codeine, hydrocodone, oxycodone, norfentanyl, and morphine) were present in more than 50% of samples across the study years and locations. Some detection frequencies varied by location; for example, codeine, hydrocodone, and norfentanyl detection frequencies were lower at the festival site compared with off-site (2024) and the WWTP (2024 and 2025). Both festival and off-site samples yielded fewer detections of EDDP compared to the WWTP samples. The co-occurrence of opioids and stimulants may reflect a variety of substance use behaviors, preferences, polysubstance use, and/or unintentional adulteration (ie, lacing).

Analyte concentrations by year and sample location during the festival week and weekend are shown in Multimedia Appendix 2 (Figure S1), and concentrations are listed in Multimedia Appendix 1. Within each site, and despite the difference in sample type at the festival site (ie, grab in 2024 and composite in 2025), concentrations of each analyte were not significantly different between 2024 and 2025 (all Wilcoxon signed-rank $P>.05$). Notably, several stimulant-related (cocaine metabolites, amphetamine, methamphetamine, MDA, and MDMA) and THC-related (THC-COOH and THC-OH) concentrations observed in the festival site wastewater exceeded those in samples from the WWTP or off-site locations by more than an order of magnitude (Figure S1, Multimedia Appendix 2). In fact, stimulant-related analytes had some of the highest observed wastewater concentrations, with BZE reaching as high as 587,000 ng/L at the festival site. This was exceeded only by MDMA in festival site samples, which reached 1,280,000 ng/L in 2024 and 1,860,000 ng/L in 2025; these concentrations are among the highest festival-related wastewater MDMA concentrations reported in the literature.

[n]THC-COOH: 11-nor-9-carboxy-Δ-9-tetrahydrocannabinol.

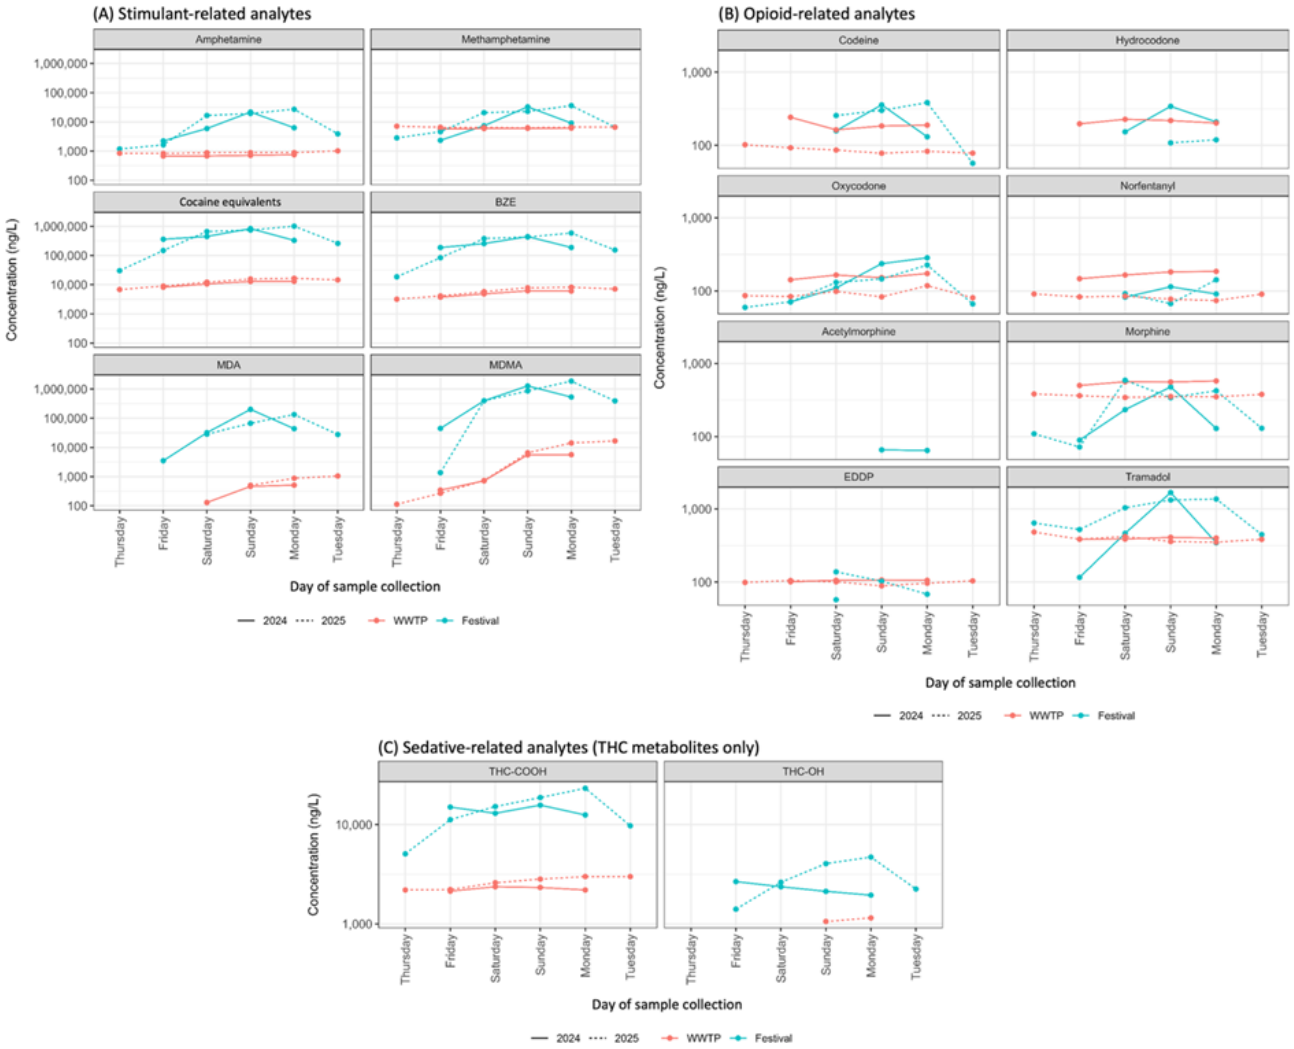
### *2023 Pilot Year: Festival vs Nonfestival Weeks*

Analyte concentrations in the 2023 samples are shown in Multimedia Appendix 2 (Figure S2) by sample location and collection event (festival weekend in May vs nonfestival weekends in June and July). Although no 2023 sampling occurred at the festival site, MDMA and MDA concentrations were notably higher in the festival weekend samples across all sites (bars, the Las Vegas Strip, the airport, and the WWTP). In fact, the airport-related detections of MDMA and MDA occurred only during the festival weekend, highlighting potential contributions from visitors traveling to Las Vegas for festival-related activities. MDMA concentrations at the bars and the Las Vegas Strip were approximately 10 and 30 times higher, respectively, during the festival compared with nonfestival sampling events, and nearly 100 times higher at the WWTP (treating relatively consistent community flows of ~110 mgd). Along with the approximate 10-fold change in wastewater MDMA concentration at the bars, the norfentanyl concentration was nearly 2 times higher during the festival week, highlighting potential risks of fentanyl use, adulteration, or contamination [20], and the need for increased awareness of these possibilities [21].

Concentrations of other substances (eg, methamphetamine, amphetamine, and THC metabolites) were similar or even higher on nonfestival weekends; a similar observation for methamphetamine was observed for a baseline (higher concentration) vs special event weekend (lower concentration) in an earlier study conducted in Las Vegas [14]. Regardless of the week, wastewater concentrations at the bars were consistently higher than those at the Las Vegas Strip, the airport, and the WWTP for cocaine (and multiple metabolites) and methamphetamine. Importantly, these results highlight the widespread consumption of HRS across Southern Nevada during festival and nonfestival weekends.

### *2024-2025: Day of Festival Week*

Analyte concentrations by year and day of wastewater sample collection (Friday-Monday in 2024; Thursday-Tuesday in 2025) and sample location (festival vs WWTP) are shown in Figure 2; analytes not detected at these sites in either year (heroin, THC, and xylazine) and analytes with singular detections (fentanyl, methadone, and norcocaine) are not shown. Gerrity et al [19] previously documented the instability of cocaine-related compounds in wastewater but demonstrated that the overall mass balance of cocaine and its metabolites was conserved over 60 days of hold time. Thus, the cocaine-related compounds are aggregated in Figure 2 as “cocaine equivalents” (after accounting for differences in molecular weight), with BZE also shown for comparison.

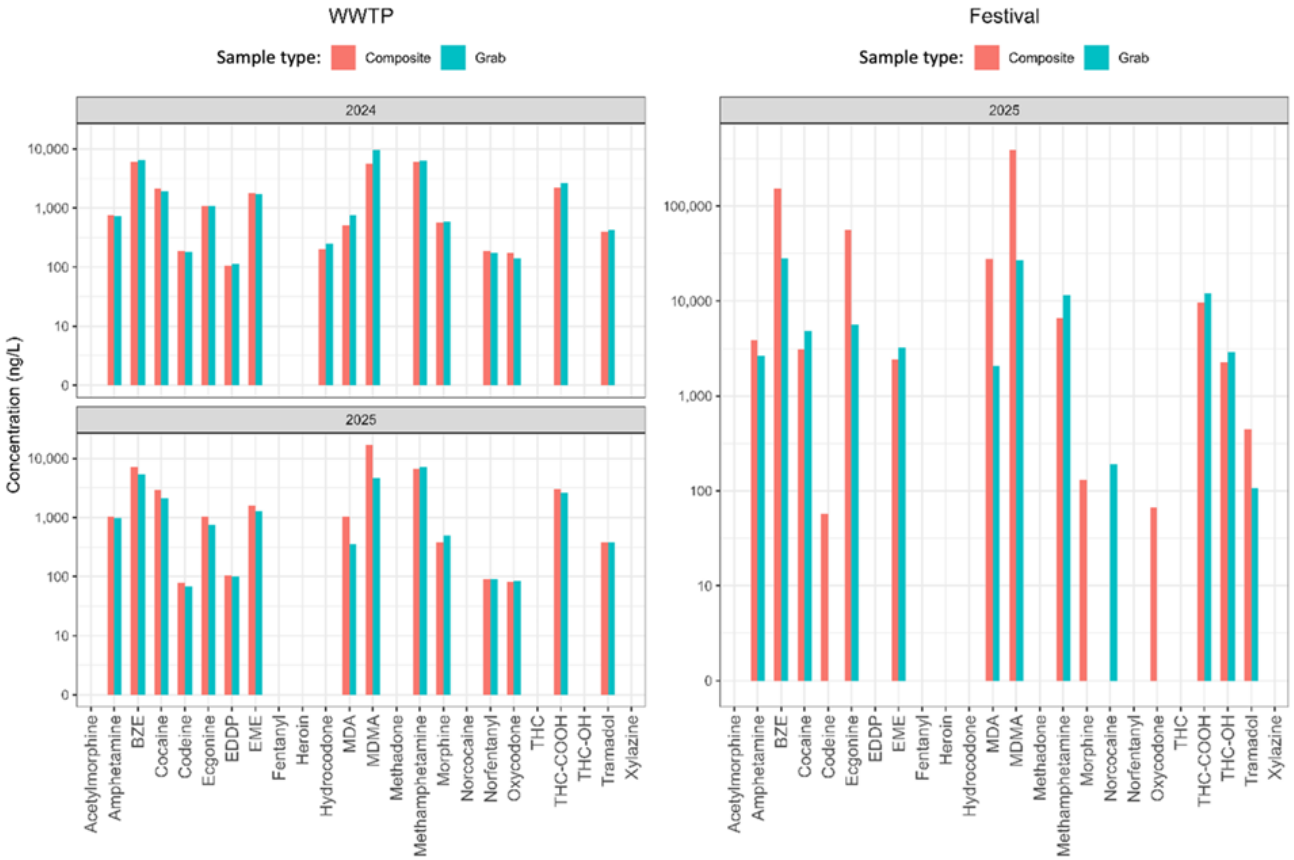


For the analytes detected at least twice, concentrations tended to peak in samples collected on either Sunday or Monday, surrounding the culmination of the festival. Increasing concentrations of stimulants (including amphetamine, methamphetamine, MDMA, MDA, BZE, and cocaine equivalents in Figure 2A) were particularly evident over the main festival days at both sites. In 2025, festival-site MDMA concentrations increased rapidly from below the MRL before the campground was opened to 1370 ng/L after the first full day of the festival, and ultimately peaked at 1,860,000 ng/L at the end of the weekend (in the Sunday-Monday sample); residual high concentrations persisted through the Tuesday sample collections.

Although each analyte’s concentration within the sampling sites did not differ significantly between 2024 and 2025, concentrations across both years were significantly different between the festival site and the WWTP for amphetamine, cocaine equivalents, BZE, ecgonine, MDMA, and THC-COOH (all Wilcoxon signed-rank $P$=.008). As expected due to significant dilution from municipal wastewater flows, stimulant concentrations were often lower at the WWTP relative to the festival site. That being said, BZE more than doubled, and MDMA increased more than 100-fold at the WWTP during the 2025 festival week. THC-COOH and THC-OH were also higher in the festival samples compared to the WWTP samples (Figure 2C). Although there were some day-to-day variations, opioid-related concentrations were generally more similar or even higher at the WWTP relative to the festival (Figure 2B), but some opioids (eg, oxycodone, morphine, and tramadol) exhibited increasing trends at the festival site over the first few days of the festival.

XSL•FO
RenderX

**Figure 2.** Concentrations in wastewater from the festival site (blue) and WWTP (red) by day of collection in 2024 (solid line) and 2025 (dashed line) for (A) stimulants, (B) opioids, and (C) sedatives (THC-COOH and THC-OH only). Note: 2024 festival samples are grab samples; others are composite. Analytes not detected in either year (heroin, THC, and xylazine) and analytes with singular detections (fentanyl, methadone, and norcocaine) are not shown. BZE: benzoylecgonine; EDDP: 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine; MDA: 3,4-methylenedioxyamphetamine; MDMA: 3,4-methylenedioxy-methamphetamine; THC: tetrahydrocannabinol; THC-COOH: 11-nor-9-carboxy-Δ-9-tetrahydrocannabinol; WWTP: wastewater treatment plant.



### *2024-2025: Grab vs Composite Sampling*

As shown in Figure 3, concentrations were similar between grab and composite samples collected at the WWTP in 2024. In 2025, WWTP composite sample concentrations were higher than the corresponding grab samples for the analytes expected to be impacted by the festival, including some cocaine-related compounds, MDA, and MDMA. These differences between 2024 (Monday collections) and 2025 (Tuesday collections) may have been driven by the day of the week, with the Tuesday grab likely to be less affected by the festival weekend. Similarly, the 2025 festival composite sample (Monday-Tuesday) yielded higher concentrations of BZE (5.5-fold), ecgonine (9.9-fold), MDA (13.4-fold), MDMA (14.6-fold), and tramadol (4.2-fold) compared to the corresponding Tuesday grab sample. Notably, codeine, morphine, and oxycodone were detected in the composite but not in the corresponding grab sample, while only norcocaine was detected in the grab sample and not in the corresponding composite sample.

XSL•FO
RenderX

**Figure 3.** Comparison of analyte concentrations in corresponding composite (red) and grab (blue) samples for the WWTP (2024 and 2025; left) and the festival site (2025 only; right). BZE: benzoylecgonine; EDDP: 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine; EME: ecgonine methyl ester; MDA: 3,4-methylenedioxyamphetamine; MDMA: 3,4-methylenedioxy-methamphetamine; THC: tetrahydrocannabinol; WWTP: wastewater treatment plant.

## Discussion

### Principal Findings

This multiyear surveillance study analyzed wastewater from multiple locations to characterize the presence and concentration of substances (and their metabolites) surrounding an annual EDM festival. The findings in 2023 reaffirmed the presence of HRS in raw community wastewater during festival and nonfestival time points, with notable differences by weekends and sample locations. The findings from 2024 to 2025 further illustrated the prevalence of stimulants (cocaine, methamphetamine, and notably MDMA) in festival-site wastewater, although opioid-related analytes were also detected there and in the community. Detections related to THC were not unexpected, given the legality of recreational marijuana products in the state of Nevada and prior literature indicating its frequency in festival-related WBE studies [22].

The study festival (with more than 520,000 annual attendees) is large in comparison to other events included in prior wastewater-based studies of substance use. The 2010 to 2011 Australian festival described by Lai et al [6], for example, had daily attendees between 12,100 and 19,700; Bijlsma et al [9] sampled from 6 European music festivals with a total combined attendance of 465,000. A recent systematic review [22] included 23 WBE studies on HRS, with 6200 to 600,000 attendees; only 2 studies reported attendance in excess of 500,000 people.

Although this study included just 3 sequential years, the results offer a preliminary wastewater-based profile of substances and metabolites present at the festival site, namely stimulants (eg, MDMA, cocaine, and methamphetamine), as well as select opioids. Lai et al [6] similarly noted consistency in festival attendance and wastewater-based HRS profiles each year, in line with findings that event-related WBE findings may vary by attendee characteristics and time of year [23]. Elsewhere, researchers have documented wastewater-based concentrations rising to a peak during the event [23], a pattern also observed here on the final days of the festival and potentially reflecting accumulation and/or intentional discarding at the end of the event [8]. Multiple WBE studies have highlighted wastewater-based profiles of substance use surrounding holidays [23-25], during weekends compared to weekdays [24], and among nightclub, music event, and festival attendees in general [26-28], with some variation by region and music genre [22]. Several results in this study indicated concurrent detections of select analytes (eg, MDMA and norfentanyl at the bars), highlighting another potential opportunity for multifaceted public health responses to address intentional (or unintentional) polydrug use [29] amid the recent wave of polysubstance use and related deaths in the US overdose crisis [30].

### MDMA and Other Stimulants

Across analytical approaches, geographic locations, and event types, MDMA was the most consistently detected substance in the Cainamisir et al [22] review of 23 wastewater studies of

XSL•FO
RenderX

psychoactive substances at music festivals. The maximum MDMA concentrations in this study (1,280,000 ng/L and 1,860,000 ng/L), however, exceeded concentrations reported previously [22], including those from a neighboring Southern Nevada sewershed during a separate music festival in the fall of 2022 (1100 ng/L) [19] and from a festival in Thailand (1267 ng/L) [31]. An analysis of pooled wastewater from a festival in Belgium, however, reported a higher concentration (7580 ng/mL=7,580,000 ng/L) [32]. The accumulation of MDMA over a festival weekend (with a blood half-life of 8 h; 95% clearance within 40 h [33]) may help explain the concentrations in this study. Importantly, prior work has observed that MDMA concentrations tend to be higher on weekends, even in the absence of a large event or festival [34,35]. Recent wastewater findings in Europe also emphasized higher MDMA loads during weekends compared to weekdays (occurring in more than 75% of cities studied), though overall MDMA wastewater loads in European cities decreased by nearly 16% from 2024 to 2025 [36].

Methamphetamine and cocaine (and its metabolites) were consistently present over the festival weekends (with 100% detection frequencies), but the 2023 nonfestival weekend concentrations suggest community use independent of the event. A separate local wastewater surveillance study conducted in 2022 to 2023 [19] similarly concluded that methamphetamine and cocaine were among the highest per capita consumption estimates across all Las Vegas sewersheds. Wastewater detections of cocaine (the parent compound) have been reported in similar festival-based studies [22], albeit with slightly lower concentrations (eg, a maximum of 8914 ng/L in Brazil [8] vs 10,000 ng/L in this study). Here, we used a mass-balance approach to visualize total cocaine equivalents, but focusing on one of the more abundant cocaine metabolites, specifically BZE, may be sufficient for public health and event-related wastewater monitoring of cocaine use (Figure 2). Cainamisir et al [22] highlighted geographic variability in wastewater-based indicators of methamphetamine presence and consumption at festivals elsewhere, though the methamphetamine detections in this study align with the established presence of the substance in Southern Nevada [37].

## Opioid HRS Targets

Although stimulants were detected most frequently in this study, several opioids were also present during the festival week and weekend, both on-site and in the broader community. Norfentanyl, for example, was detected in both festival and WWTP wastewater, though more consistently at the WWTP; this aligns with the prior local findings [19] and could reflect some medical use. Other festival-related WBE studies have reported detections of norfentanyl, though it was not the most common analyte; in one study, norfentanyl was detected at only 2 of 6 festivals sampled [7]. Generally, festival-related opioid concentrations in this study mirrored those at the downstream WWTP, suggesting a less-pronounced event-associated use compared with the stimulants discussed earlier. However, the co-occurrence of some opioids and stimulants in site-specific wastewater samples may reflect intentional or unintentional polysubstance use (ie, through lacing) [29], although this cannot be confirmed with wastewater alone.

The absence of heroin (the parent compound) detections was not unexpected, given previous work suggesting its potential instability in the presence of the quenching agent, ascorbic acid, used here [19]. Heroin and its metabolite acetylmorphine are known to be subject to rapid degradation in wastewater [38], though acetylmorphine has been detected during previous hold-time experiments [19], in other local studies [17], and here in 2023 (n=4 off-site samples and 2 WWTP samples) and in 2024 (n=2 off-site samples and 2 festival-site samples).

## Limitations

Several elements of this study may limit and/or confound the interpretation of results and their broader contextualization in the fields of WBE and public health. First, due to practical and logistical limitations, the wastewater sampling framework varied each year of the study, complicating year-over-year comparisons. Multiday sampling in 2024 and 2025 offered more granular detail about the festival week and weekend, and the limited comparisons between grab and composite samples highlighted the potential effect of sample type on analyte detections (eg, codeine, morphine, oxycodone, and norcocaine) and on concentrations (eg, MDMA). Generally, composite samples are preferred over grab samples in the WBE literature, given concerns about potentially nonrepresentative slugs of wastewater that may underestimate or overestimate the presence of a target analyte in wastewater [39]. However, the results of this study show that even limited grab sampling offers valuable information about HRS presence and use surrounding an event.

Analyte source, consumption, metabolism, excretion, stability, and dilution in wastewater are also key factors that affect interpretation of wastewater results. Others have addressed metabolism with correction factors to back-calculate consumption estimates [19,40]. This would be a valuable addition to future festival-specific WBE studies for HRS, although corresponding flow measurements would be needed to calculate mass loadings. Wastewater analyses also do not distinguish between the various individuals present at a festival, potentially including attendees, artists, vendors, staff, and volunteers. Supplemental analyses to distinguish between licit and illicit consumption of select substances (eg, methamphetamine) have been established [41], but were not performed here. This means, for example, that a portion of the amphetamine and methamphetamine concentrations observed here may be due to medically prescribed use, rather than illicit use. Furthermore, these wastewater detections may partially reflect intentional discarding (ie, dumping) of substances in festival restrooms and subsequent in-sewer degradation during and/or at the end of the event, as has been noted previously [8]. Although wastewater monitoring does not identify specific sources (eg, original user or lacing vs polysubstance use vs intentional discarding), these findings still complement existing public health surveillance activities and indicate the presence of these substances on-site and in the community surrounding the event.

Results were not normalized to wastewater flow rate, a fecal indicator, or another analyte (eg, caffeine or sucralose). As described earlier, normalization would have facilitated consumption calculations and/or captured differences in human

XSL•FO
RenderX

urine or fecal load within these samples [19]. Site-specific consumption estimates could be calculated with site-level flow data and corrections for metabolism or excretion or molecular weight equivalence [19,40]. Importantly, upstream flows may be highly variable throughout the day and across the event.

This study included a selection of conventional prescription and recreational substances of public health significance, but a variety of other targets could be included in future work. Several published event-focused studies have used wastewater to characterize the presence of less-regulated novel psychoactive substances (NPS) [7,9]. Wastewater may be particularly valuable in tracking the emergence of new substance use trends, including NPS and misuse of existing substances (eg, xylazine), in tandem with other sources such as online discussion forums [42]. Future wastewater-based efforts might also include medetomidine, naloxone (despite potential instability in wastewater [43]), and ketamine, which may be increasingly common [26] and co-occurring with fentanyl [44]. Others have previously characterized the community wastewater-based occurrence of ketamine in Europe [24]; ketamine was also found in the Las Vegas Wash during the 2022 festival weekend [11].

At least one similar WBE study endeavored to relate wastewater HRS results to clinical outcomes or other datasets, although these analyses were beyond the scope of this study. This previous festival-based work measured wastewater HRS concentrations along with self-reported substance use behaviors [7], but links between festival HRS wastewater data and health outcomes associated with substance use (eg, overdoses, health care encounters, and deaths) are less clear in the literature. This does not, however, diminish the serious health outcomes that have been reported among festivalgoers [4,45], including critical care admissions at a tertiary care hospital in Las Vegas associated with the festival weekend [46,47]. In a 2023 case series of intensive care unit (ICU) admissions, substances reportedly used included MDMA (6/6 patients), cocaine (n=2), fentanyl (n=1), lysergic acid diethylamide (LSD; n=1), THC (n=1), and/or alcohol [1,46]. A recent local retrospective cohort study also found that drug or alcohol overdose patients related to the festival in this study were younger and more likely to be admitted to the ICU than nonfestival-related drug or alcohol overdose patients, although the 2 groups did not differ significantly in other characteristics, drug use patterns, or ultimate health outcomes [47]. In 2025, the Clark County coroner's office reported that MDMA contributed to 2 deaths in the Las Vegas area during the festival weekend [48].

## Implications for Public Health Response

These results offer valuable insights for public health and clinical situational awareness [22] of substance use during the festival week or weekend, complementing other surveillance activities, emergency responses, and the ultimate reporting of health care use and serious clinical outcomes. Selected results, such as the relatively few heroin-related detections in this study, may reflect an evolving landscape of substance use behaviors among attendees. Palamar et al [26] described changes in substances of choice in New York City nightlife and dance club settings from 2017 to 2022, with survey responses indicating decreased use of heroin, nonmedical prescription opioids, and cocaine (among other stimulants) in the post–COVID-19 era, accompanied by increased use of ketamine, psilocybin, poppers, and other NPS. Together with ongoing surveys, online forum monitoring [42], drug checking, and traditional public health or clinical surveillance, event-based wastewater surveillance may inform continued investment in prevention and future responses or interventions, both on-site and in the community, to support successful events while prioritizing attendee and community health and safety. Text S2 in Multimedia Appendix 2 provides additional discussion and recommendations on how event-based wastewater surveillance can inform on-site and community-level public health activities, including activities that have been implemented specifically for the music festival in question.

## Implications for Utilities

Event-related wastewater monitoring also offers insight into expected changes in the composition of influent wastewater flows surrounding the event. Although in-sewer mixing, dilution, and degradation likely explain the lower analyte concentrations in the WWTP samples compared with the festival site, the WWTP still experienced significant increases (10- to 100-fold) in influent concentrations of select analytes (eg, MDMA and MDA) over the event weekend. In addition to changes in flow driven by large influxes of people associated with special events, these compositional changes have implications for wastewater treatment processes, water reuse, and downstream environmental surface water quality [11,22,49], highlighting how wastewater monitoring can be informative and mutually beneficial for utilities and public health entities.

## Conclusions

Event-related wastewater monitoring is an evolving subtopic in the field of WBE. Several studies have already explored targeted wastewater monitoring for pathogens such as SARS-CoV-2 at the Olympics [50] and other mass gatherings [15], but WBE has also been applied to substance use at music festivals in countries like Australia and Thailand. In Las Vegas, this approach has now been extended to characterize the use of HRS at the community level and in treated wastewater effluent surrounding events and festivals, as has been done elsewhere [11,14,17,19]. Here, wastewater surveillance surrounding a large EDM festival in 3 sequential years at on-site and off-site locations further explored WBE as a complementary tool for public health monitoring of substance use or misuse. Stimulant concentrations were notably elevated during event weekends, with high peak concentrations of MDMA and cocaine-related analytes, but opioid-related detections were also observed. These findings may inform both public health surveillance and response activities and wastewater utility operations.

Wastewater monitoring should complement, not replace, existing public health surveillance and response structures. Multifaceted public health surveillance systems can integrate wastewater surveillance for both pathogens and HRS to expand event-related preparedness, including interventions to prioritize the health and safety of attendees on-site and in the community. Future research may explore additional HRS targets, other non-EDM festivals and events, trends over time, and alignment with other data sources (including health outcomes). Local public health

XSL•FO
RenderX

agencies, community stakeholders (eg, health care systems, nonprofit organizations, and local government), and other tourism and event destinations similarly stand to benefit from data-driven understanding of the public health implications of events and mass gatherings.

## Acknowledgments

We thank the Clark County Water Reclamation District (CCWRD) for its contributions to this study. Specifically, we thank Carlton Utter, Adrian Romero, Alycia Ybarra, and LaToya Blanche of CCWRD for helping collect representative samples. The authors attest that there was no use of generative AI technology in the generation of text, figures, or other informational content of the manuscript.

## Funding

This project was supported in part by the Fund for a Resilient Nevada (FRN), which is administered by the Nevada Department of Human Services (DHS) to address the impacts, risks, and harms of opioid use in the State of Nevada. The funder had no involvement in the study design, data collection, analysis, interpretation, or writing of the manuscript. These findings are solely the responsibility of the authors and do not necessarily represent the official views of FRN or Nevada DHS.

## Abstract

**Background:** The COVID-19 pandemic has triggered major global challenges, highlighting the need for timely surveillance and accurate forecasting to curb disease transmission and reduce the health burden. Traditional modeling approaches usually rely on aggregated data on confirmed cases. However, testing data can be unreliable due to low availability and uptake, as well as registration delays. In Sweden, the 1177 health care helpline provides valuable syndromic surveillance data that can capture early signals of infection prior to confirmation through testing.

**Objective:** This study aims to evaluate the effect of integrating syndromic surveillance data on short-term COVID-19 forecast accuracy.

**Methods:** We developed a novel epidemiological model named $SI_sI_cHRD$ (susceptible-infected$_{suspected}$-infected$_{confirmed}$-hospitalized-recovered-deceased), incorporating data from the 1177 health care helpline cross-linked with national registers on COVID-19 testing, hospitalizations, and deaths. In the novel model, the population with infection is divided into suspected infections ($I_s$; those reporting symptoms to 1177) and confirmed infections ($I_c$; those who tested positive). Accuracy metrics of this model are compared to a model without data from the 1177 health care helpline. To evaluate model performance across different pandemic phases between March 2 and December 31, 2020, we used a daily rolling-window approach with a 60-day fitting period to predict confirmed infections, hospitalizations, and deaths over the subsequent 30 days. Prediction performance was evaluated using mean absolute error and mean absolute percentage error (MAPE).

**Results:** The proposed $SI_sI_cHRD$ model successfully captured the temporal dynamics of confirmed, hospitalized, and death cases. The model achieved a median mean MAPE of 61.6% (IQR 37.6%-79.6%) for confirmed cases, 37.5% (IQR 18.9%-57.5%) for hospitalizations and for deaths, the model achieved a median MAPE of 0.65% (IQR 0.3%-1.9%), indicating substantially higher predictive accuracy for severe outcomes compared to confirmed infections and hospital admissions. Compared to the model without syndromic surveillance data, short-term forecasting performance of the $SI_sI_cHRD$ model reduced MAPE by an average of 15.7 percentage points for confirmed cases, 8.17 percentage points for hospitalizations, and 1.99 percentage points for deaths. Overall, the results demonstrate predictive stability for severe outcomes during the early phase of the pandemic.

**Conclusions:** The proposed model demonstrated predictive performance by integrating individual-level data with health care helpline syndromic data on testing and severe disease outcomes, capturing early signals from symptomatic individuals and distinguishing suspected cases from subsequently confirmed infections, leading to better forecasts of severe outcomes such as hospitalizations and deaths. This framework can support public health decision-making in future outbreaks.

## Introduction

Pandemics have repeatedly caused significant loss of life and triggered severe economic crises worldwide [1]. In 2019, the world encountered one of the deadliest pandemics in modern history, the SARS-CoV-2, also known as COVID-19, which resulted in approximately 18.2 million deaths worldwide from January 1, 2020, to December 31, 2021 [2]. SARS-CoV-2 belongs to the coronavirus family and is primarily transmitted from human to human. Among coronaviruses, it is considered the most contagious [3]. Due to its rapid global spread, the World Health Organization officially declared it a global pandemic on March 11, 2020 [4]. In Sweden, the first COVID-19 case was reported on January 31, 2020, involving a traveler who had arrived from Wuhan, China [5]. By mid-March 2020, the virus had spread across all regions of Sweden, posing significant challenges for public health surveillance and health care systems [6,7]

Effective monitoring of community-level disease transmission is crucial for public health and health care systems [8]. To predict and monitor disease transmission, evaluate the course of the pandemic, and assess the impact of public health intervention policies, epidemiological mathematical models are often used [9]. Such models have proven to be valuable tools for policymakers, enabling data-driven decision-making by exploring different scenarios and their potential outcomes in a controlled manner [10,11]. Among these, the susceptible-infected-recovered (SIR) model is widely regarded as one of the most fundamental and influential frameworks for describing the transmission dynamics of infectious diseases [12]. Over time, several extensions of the SIR model, including susceptible-infected-recovered-susceptible, susceptible-exposed-infected-recovered, and susceptible-infected-susceptible, have been developed to improve short-term infection forecasting [13-15].

While various approaches exist, much of the focus has traditionally been on confirmed cases identified through widespread testing programs. However, traditional case counts are often insufficient for early detection of novel infectious diseases due to limitations in testing capacity and laboratory resources [6]. Syndromic surveillance offers an effective alternative, providing a more comprehensive view of disease dynamics [16-18]. For instance, in the United States, researchers developed a smartphone-based syndromic surveillance system and identified loss of taste and smell as strong predictors of COVID-19 infection [16]. Similarly, app-based self-reported symptoms data have been used to predict COVID-19 cases in Sweden, England, and the United Kingdom [19-23]. Recent studies have indicated that integrating data-driven and epidemiological models, when combined with syndromic and digital data sources, can improve the rapid detection and prediction of infectious diseases. Mathematical and computational models have not only guided immediate responses but also informed medium- and long-term strategies, playing a crucial role in policy planning, public health interventions, and global coordination during the pandemic [24]. Similarly, in a study conducted in 2021, the authors used time series of online search query frequencies to gain insights into COVID-19 prevalence across multiple countries [25]. In these studies [26,27], the authors extended classical compartmental models by incorporating media coverage as a behavioral and informational factor influencing disease transmission dynamics. Drew et al [28] introduced a COVID-19 Symptom Study app in 2020 to collect large-scale, real-time data on symptoms, risk factors, and outcomes, which was subsequently used for scalable epidemiological analysis and modeling to inform public health response.

To respond effectively to outbreak events, policymakers must be well-prepared, relying on real-time and historical data collected from epidemiological, health care, and social processes [29-32]. In Sweden, syndromic surveillance has become a valuable complement to traditional public health monitoring, offering real-time insights into the spread of COVID-19 and other infectious diseases [19]. One important source of syndromic data is Sweden's National Telehealth Service, the 1177 health care helpline, which often serves as a first point of contact with the health care system for patients. While data are captured for administrative purposes, they have been used in several epidemiological studies for early detection of water-borne disease outbreaks and during the COVID-19 pandemic [33-35]. For example, Spreco et al [34] used aggregated 1177 data as an early signal to estimate potential health care demands in the upcoming weeks. Moreover, a study conducted in 2024 found that calls to Sweden's 1177 health care helpline reporting COVID-19–related symptoms were important predictors of hospitalizations during the early phase of the pandemic [35].

While previous studies highlight the potential of syndromic surveillance data for disease monitoring, their added value when linked to comprehensive individual-level health register information for improving model accuracy remains poorly understood. In contrast to previous approaches based primarily on aggregated syndromic surveillance data, our study integrates individual-level 1177 symptom data with linked health register information within a compartmental transmission model, allowing individuals to be followed from symptom reporting through subsequent testing and severe disease outcomes. Therefore, in this paper, we extend traditional mathematical models to incorporate a compartment for suspected infection based on individual-level syndromic surveillance data linked with health register data. This approach enables the model to capture early symptomatic signals at the individual level and connect them with subsequent testing outcomes and severe disease progression. The aim of this study is to assess the effect of this integration on the accuracy of short-term infectious disease predictions using a model without syndromic surveillance data as a benchmark.

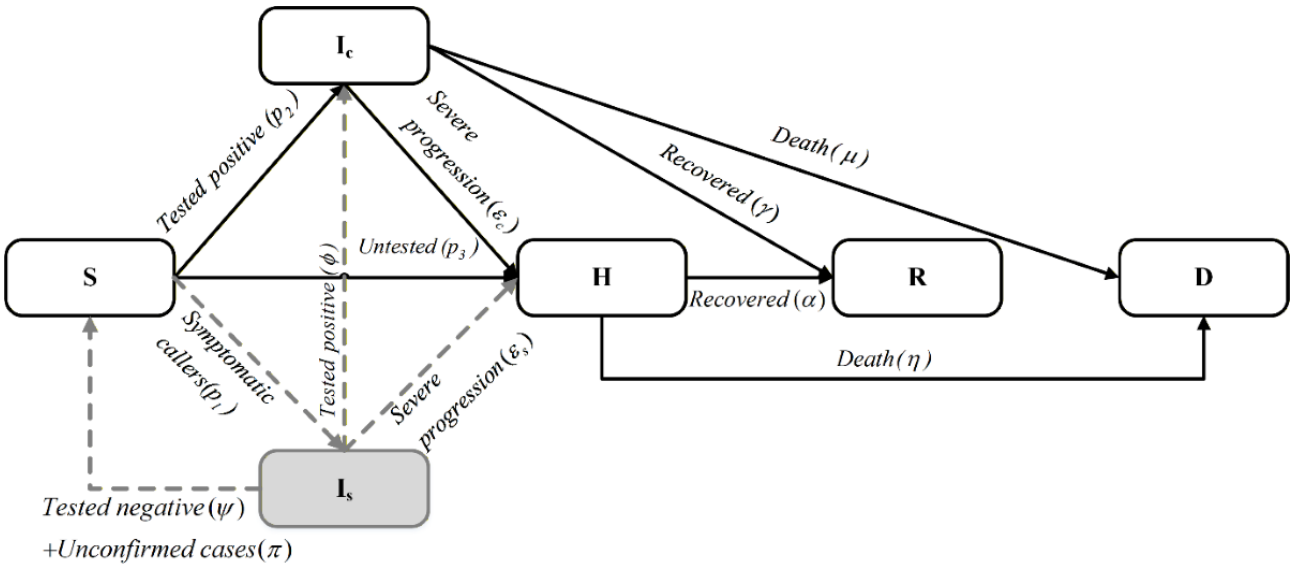
## Methods

### Overview

The study population consists of all individuals registered in Sweden on December 31, 2019. The first year of the COVID-19 pandemic was analyzed, covering the period from March 2 to December 31, 2020. Daily confirmed infections, hospitalizations, and deaths were incorporated to capture the temporal dynamics of the disease. This section outlines the data sources, model formulation, and discusses the process for tracing the flow of individuals through the different model compartments using individual-level data.



### Data Sources

Information on key symptoms, including fever, cough, and shortness of breath, was extracted from 1177 records and used as the basis for defining suspected infections in the modeling framework. Telehealth call data were obtained from the Swedish 1177 health care advice helpline. During the COVID-19 outbreak in 2020, the number of people calling the helpline for advice on COVID-19–related symptoms spiked, providing valuable syndromic surveillance information [33]. Individual-level demographic data were retrieved from the Swedish Total Population Register. Information on laboratory-confirmed cases was obtained from the national register on notifiable diseases, SMINet, maintained by the Public Health Agency of Sweden. Data on hospital admissions for COVID-19 were extracted from the National Patient Register, while dates of death were obtained from the Swedish Tax Authority. Individual-level data from the 1177 health care helpline were linked with multiple national register-based data sources using the personal identification number assigned to all Swedish residents at birth or immigration. This linkage enables tracking of individuals from symptom reporting to testing outcomes, hospitalization, death, or recovery.

### Epidemiological Model

In this study, we developed 2 epidemiological models. The first is a baseline model, referred to as the $SI_cHRD$ (susceptible-infected$_{confirmed}$-hospitalized-recovered-deceased) model. The second is an extended version of this framework that integrates data from the 1177 health care helpline, termed the $SI_sI_cHRD$ (susceptible-infected$_{suspected}$-infected$_{confirmed}$-hospitalized-recovered-deceased) model. The only difference between the models is the addition of the $I_s$ compartment that integrates the 1177 symptom data, while all other compartments and transitions remain unchanged in Figure 1. No births or natural deaths were included in the model due to the relatively short study period.

**Figure 1.** Block diagram of the $SI_sI_cHRD$ (susceptible [S]-infectedsuspected [Is]-infectedconfirmed [Ic]-hospitalized [H]-recovered [R]-deceased [D]) model.

### $SI_cHRD$ Model

This baseline model divides the population into 5 compartments: susceptible (S), infected$_{confirmed}$ ($I_c$), hospitalized (H), recovered (R), and deceased (D). The corresponding system of differential equations governing the dynamics of each compartment is given below. The model parameters along with their descriptions are summarized in Table 1.

Here, β denotes the transmission rate, $p_2$ represents the probability of an individual becoming infected, and $\varepsilon_c$ corresponds to the proportion of individuals who develop severe symptoms requiring hospitalization. γ is the recovery rate for individuals with infection, while $\mu$ denotes the rate of death among nonhospitalized cases. $p_3$ represents the probability that an individual is directly admitted to the hospital without prior testing, α is the recovery rate for hospitalized patients, and η indicates the rate of death within the hospital.

XSL•FO
RenderX

**Table 1.** Model parameters and their descriptions.

| Symbols | Description |
|---|---|
| $\beta_S$ & $\beta_C$ | Transmission rate of $I_s$ & $I_c$ compartments |
| $p_1$ | Probability that a susceptible individual calls and reports COVID-19–related symptoms to the 1177 health care helpline. |
| $p_2$ | Probability that an individual with infection tested positive without calling 1177 |
| $p_3$ | Probability that an individual with infection is directly hospitalized |
| $\psi$ | Individuals who report COVID-19–like symptoms to the 1177 health care helpline but are subsequently tested negative for COVID-19. |
| $\pi$ | Return to S (if not in $I_c$ or H within 14 days) |
| $\varphi$ | Transition of individuals who reported symptoms and tested positive |
| $\varepsilon_s$ | Rate of severe progression from $I_s$ to H compartment |
| $\varepsilon_c$ | Rate of severe progression from $I_c$ to H compartment |
| $\gamma$, $\alpha$ | Recovery rates from $I_c$ & H compartments |
| $\mu$, $\eta$ | COVID-19–related death rates in $I_c$ & H compartments |

## $SI_sI_cHRD$ Model

To incorporate early symptom reporting and detect untested cases, the $SI_cHRD$ model extends by including individual-level 1177 health care helpline data. In the proposed model, the infected compartment is divided into 2 subgroups, $I_s$ and $I_c$, resulting in the $SI_sI_cHRD$ model.

Individuals in the susceptible compartment may become infected upon contact with infectious individuals, who can be either $I_c$ or $I_s$. The transmission rates differ for these 2 categories, as some suspected cases may not be infected. $\beta_c$ denotes the transmission rate from confirmed individuals, while $\beta_s$ represents the transmission rate from suspected individuals. The rate of change of the susceptible compartment over time is given by:

The $I_s$ compartment represents individuals who reported their symptoms to the 1177 health care helpline. The probability $p_1$ represents the fraction of individuals with infection who call and report COVID-19 symptoms before any positive test or hospital admission enters the $I_s$ compartment. Individuals remain in this compartment for 14 days and return to S at a rate $\pi$ unless they are tested positive (transition to $I_c$ at a rate $\varphi$), are hospitalized (transition to H at a rate $\varepsilon_s$), or are tested negative (return to S at a rate $\psi$). The rate of change of the $I_s$ compartment over time is given by:

The dynamics of the $I_c$ individuals change over time as some newly people with infection test positive for COVID-19. This includes 2 groups: individuals who tested positive without contacting the 1177 health care helpline (at a rate of $p_2$), and those who reported their symptoms to the 1177 health care helpline and subsequently tested positive within 14 days (at a rate of $\varphi$). Individuals leave compartment $I_c$ at the same rates as in the $SI_cHRD$ model. The rate of change of the $I_c$ compartment over time can be expressed as follows:

The number of hospitalized individuals increases as severe cases arise from the $I_s$ and $I_c$ compartments at rates $\varepsilon_s$ and $\varepsilon_c$, respectively. Additionally, $p_3$ represents the probability that the fraction of individuals with infection neither called the 1177 health care helpline nor tested positive and directly required hospitalization. Hospitalized patients leave this compartment either by recovering at a rate $\alpha$ or by dying due to COVID-19 at a rate $\eta$, consistent with the $SI_cHRD$ model assumptions. The rate of change of the hospitalized compartment over time can be expressed as follows:

The number of recovered individuals increases at the same rate as in the $SI_cHRD$ model. The rate at which the recovered compartment changes over time can be expressed as follows:

The number of deceased individuals increases as people die due to COVID-19 from the $I_c$ compartment at rates $\mu$, as well as from the hospitalized compartment at rate $\eta$. The rate of change of the deceased compartment can be expressed as follows:

## Parameters Estimation and Model Calibration

To evaluate model performance, the first step involves optimizing model parameters. A total of 14 unknown parameters were estimated using individual-level data, that is, . The study population could be directly assigned to their respective compartment at any given time point. Hence, the initial conditions of all compartments were directly extracted from the

XSL•FO
RenderX

individual-level data. The stepwise fitting and prediction procedure is described as follows:

A short-term fitting and rolling calibration framework was applied in this study, consistent with the use of moving or sliding-window approaches in previous short-term forecasting studies [34,36]. These studies have used different fitting, evaluation, and prediction periods and step sizes. In this study, a 60-day moving fitting window with a 1-day step size was used. At each prediction date, the model parameters were estimated using the preceding 60 days of observations and subsequently used to generate predictions for the following 30 days. The 60-day fitting window was selected to provide sufficient observations for reliable parameter estimation while maintaining the ability to capture temporal variations in transmission patterns. Random values between 0 and 1 were used as initial parameter values. The parameters were then optimized by solving the system of model equations numerically using MATLAB's ode15s solver, suitable for stiff equations, while minimizing the objective function that quantifies the discrepancy between observed (actual) $y_i^{obs}$ and model predicted values $y_i^{pred}$ at each time point $i$, where $n$ denotes the total number of days:

### Model Prediction and Evaluation

The fitted parameters were subsequently used to generate model predictions. After parameter estimation, the model was simulated for the following 30 days, and the predicted values were compared with the observed data for validation. Model performance was assessed using the error metrics mean absolute error (MAE) and mean absolute percentage error (MAPE).

Here, $y_i^{obs}$ denotes the observed (actual) number of cases (eg, confirmed infected, hospitalized, and number of deaths actual cases) at time point $i$, and $y_i^{pred}$ represents the corresponding model-predicted value. The index $i = 1,2,...,n$ refers to the total number of observed time points (days). To further evaluate predictive performance, both the baseline model and the extended model incorporating 1177 syndromic surveillance data were fitted using a 60-day rolling window. These fitted models were then used to generate 30-day-ahead predictions for confirmed cases, hospitalizations, and deaths. The study period spans from March 2, 2020, to December 1, 2020. Model calibration and forecasting were performed using a rolling-window approach, with a 60-day fitting window followed by a 30-day prediction window. The fitting window was shifted forward by 1 day for each subsequent calibration. A total of 216 daily error values were analyzed for each compartment over the evaluation period (May 1, 2020, to December 1, 2020). For further analysis, the evaluation period was divided into 3 distinct periods. Period 1 covers (May 1, 2020, to June 10, 2020), period 2 spans (June 11, 2020, to August 31, 2020), and period 3 includes (September 1, 2020, to December 1, 2020).

### Ethical Considerations

This study was reviewed and approved by the Swedish Ethical Review Authority, with original permit number 2020-06492 and subsequent amendments 2021-01115, 2022-01355-02, 2022-06118-02, and 2024-02342-02.

## Results

The number of callers reporting each symptom, together with the corresponding counts of confirmed infections ($I_c$), hospitalized, and no confirmed infection, was summarized in Table 2. A substantial number of individuals reporting symptoms were later classified as having no confirmed infection (unconfirmed symptomatic callers with respect to COVID-19). In particular, 312,784 (94.78%) individuals reported breathing difficulties, 468,379 (94.41%) reporting fever, and 326,623 (95.43%) reporting cough were identified as having no confirmed infection. This group includes individuals who tested negative as well as those who were not tested and were not subsequently observed in any other compartment within a 14-day follow-up period. This high number of unconfirmed symptomatic callers may reflect heightened public concern, stress, and anxiety during the pandemic, particularly during the initial phase in March-April 2020 when 1177 call volumes increased sharply. In addition, the limited availability of COVID-19 testing during this early phase may have resulted in symptomatic individuals remaining unconfirmed despite potentially having an infection.

**Table 2.** Frequency of COVID-19–related symptoms reported to the 1177 health care helpline during the study period March-December 2020 and transitions to downstream compartments. Confirmed infections (Ic) include individuals who tested positive within 14 days after symptom reporting. Hospitalized individuals are those who are directly admitted for COVID-19 after symptom reporting without prior testing. Individuals who were not tested positive, hospitalized, or died within 14 days were considered to have no confirmed infection.

| Symptoms | Suspected infections ($I_s$) | Confirmed infections ($I_c$), n (%) | Hospitalized (H), n (%) | No confirmed infection, n (%) |
|---|---|---|---|---|
| Breathing difficulties | 330,066 | 13,407 (4.06) | 3875 (1.17) | 312,784 (94.78) |
| Fever | 496,087 | 23,497 (4.74) | 4211 (0.85) | 468,379 (94.41) |
| Cough | 342,248 | 13,749 (4.01) | 1876 (0.55) | 326,623 (95.43) |

The MAE and MAPE of infected confirmed cases ($I_c$) for the models with and without 1177 data, along with their difference over time, are presented in Figure 2 (panels A and B). The time series analysis shows clear temporal variation in model performance. Early in period 1, the model incorporating 1177 data generally exhibits lower prediction errors compared to the model without 1177. However, during the summer starting period (period 2), both models show increased error, with

XSL•FO
RenderX

relatively higher variability in the model with 1177. Late in period 3 (November-December), the model with 1177 again demonstrates improved performance, with lower error compared to the model without 1177. Specifically, the median MAPE difference was 5.26% (IQR –4.80% to 25.25%) in period 1, –0.07% (IQR –22.96% to 46.22%) in period 2, and 0.0008% (IQR –1.75% to 0.07%) in period 3.

Furthermore, box plot analysis (Figure 2, panels C and D) compares the distribution of MAE and MAPE for both models across the 3 periods. In period 1, the model incorporating 1177 shows a median MAPE of 31.37% (IQR 20.03%-39.96%), compared to 33.33% (IQR 25.73%-58.86%) for the model without 1177. In period 2, the model with 1177 yields a median MAPE of 82.90% (IQR 74.51%-160.5%), compared to 98.13% (IQR 63.82%-168.5%) without 1177. In period 3, the model with 1177 reports a median MAPE of 59.35% (IQR 35.72%-64.11%), whereas the model without 1177 shows a median MAPE of 56.94% (IQR 49.35%-64.12%).

Finally, Figure 2 (panel E) illustrates the fitting and prediction performance of both models. The model incorporating 1177 data achieves a MAE of 488.58, whereas the model without 1177 data shows a substantially higher MAE of 16901.38, indicating poor predictive performance in the absence of helpline data.

**Figure 2.** Performance comparison of the $SI_cHRD$ (susceptible-infected$_{confirmed}$-hospitalized-recovered-deceased; without 1177) and $SI_sI_cHRD$ (susceptible-infected$_{suspected}$-infected$_{confirmed}$-hospitalized-recovered-Deceased; with 1177) models for InfectedConfirmed cases. (A-B) The temporal variation of the mean absolute error (MAE) and mean absolute percentage error (MAPE), respectively, for the models with and without 1177 health care helpline data. The blue line represents the $SI_cHRD$ model (without 1177 data), whereas the red line represents the $SI_sI_cHRD$ (with 1177 data). The orange line indicates the difference in error values between the 2 models, highlighting periods where the inclusion of 1177 data improves (positive values) or reduces (negative values) predictive performance. The gray histogram in the background represents the daily number of observed confirmed cases. (C-D) The box plot distributions of MAE and MAPE, respectively, for both models across the 3 evaluation periods. (E) The short-term fitting and 30-day-ahead prediction performance. Black lines represent the observed COVID-19 data in Sweden, blue lines indicate the fitting and prediction results of the $SI_cHRD$ (without 1177) model, and red lines indicate the results of the $SI_sI_cHRD$ (with 1177). The purple dashed line marks the transition between the fitting and prediction periods. The corresponding MAPE values are displayed using the same color as each model curve, enabling direct comparison of predictive performance.

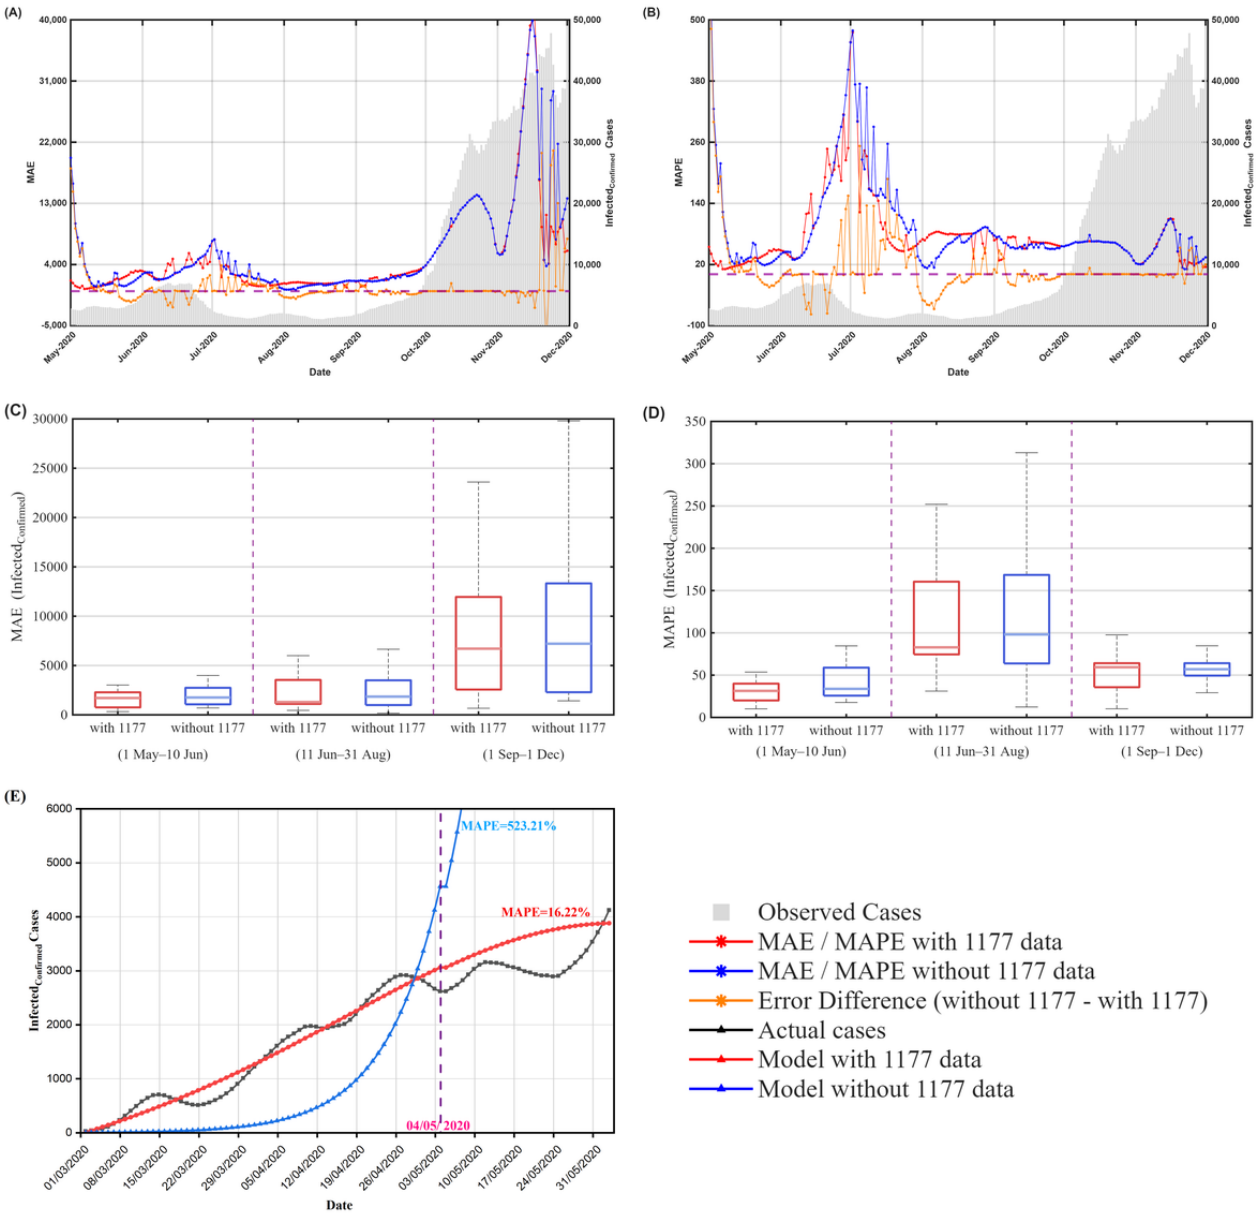

Figure 3 (panels A and B) presents the MAE and MAPE of hospitalized cases (H) for the models with and without 1177 data, along with their temporal difference. The time-series analysis reveals clear variations in model performance across different epidemic periods. Early in period 1, the model incorporating 1177 data generally performs better. However, during the summer period (period 2), both models exhibit poorer performance, with slightly higher errors observed in the model with 1177. In the subsequent period 3, the relative performance alternates, with the model with 1177 showing improved accuracy at certain time points, while the model without 1177 performs better at others. Specifically, the median MAPE difference was 0.0097% (IQR –2.69% to 8.57%) in period 1, 0.42% (IQR –9.38% to 42.24%) in period 2, and –1.27% (IQR –9.08% to 1.19%) in period 3.

XSL•FO
RenderX

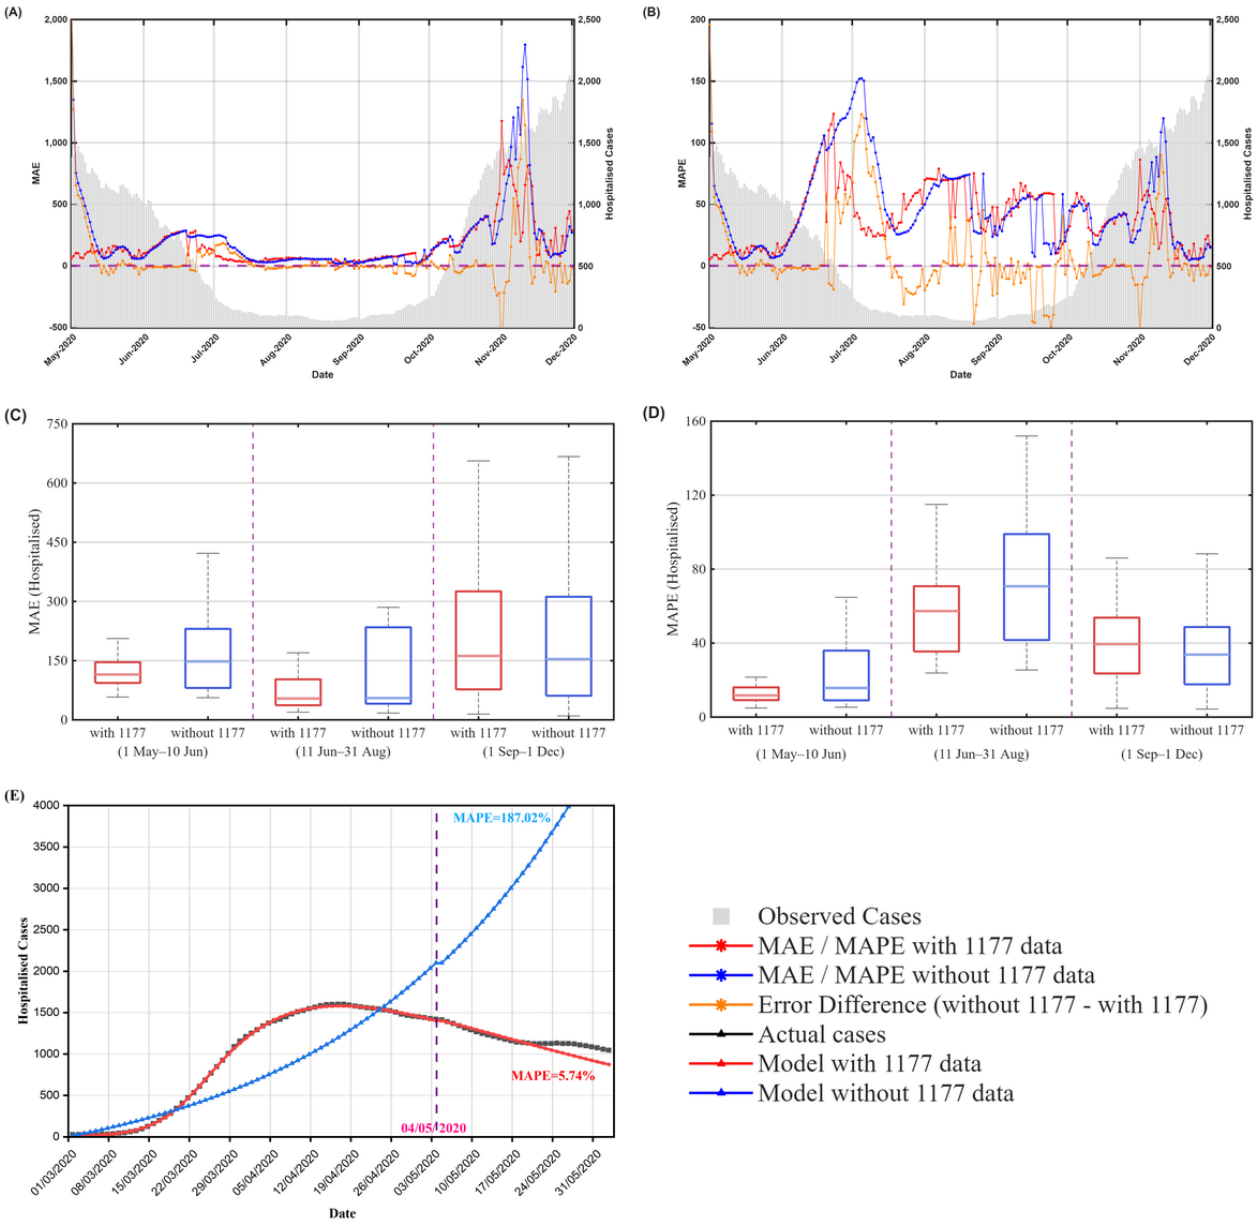
Panels C and D in Figure 3 present box plots of MAE and MAPE for both models, enabling a period -wise comparison. In period 1, the model incorporating 1177 achieves a median MAPE of 11.72% (IQR 9.17%-16.05%), compared to 15.73% (IQR 9.06%-35.95%) for the model without 1177. In period 2, the model with 1177 yields a median MAPE of 57.33% (IQR 35.47%-70.77%), which is lower than the 70.73% (IQR 41.68%-98.95%) observed for the model without 1177. In period 3, the model with 1177 reports a median MAPE of 39.44% (IQR 23.60%-53.76%), whereas the model without 1177 shows a slightly lower median MAPE of 33.80% (IQR 17.69%-48.70%).

Finally, panel E in Figure 3 illustrates the fitting and prediction performance for hospitalized cases. The model incorporating 1177 data achieves a MAE of 63.86, compared to 2128.59 for the model without 1177 data, demonstrating that inclusion of 1177 data substantially improves the model's ability to capture hospital burden, particularly during the early stages of the pandemic.

Figure 4 (panels A and B) presents the MAE and MAPE of deaths (D) for the models with and without 1177 data, along with their temporal differences. The time-series analysis indicates that both models perform well throughout the evaluation period, with the model incorporating 1177 data showing improved performance during period 1. Overall, the difference in MAPE between the 2 models remained small, with the median MAPE difference remaining below 1.20% across the entire evaluation period, suggesting comparable predictive performance for mortality estimation.

Panels C and D in Figure 4 present box plots of MAE and MAPE distributions across the 3 evaluation periods. In period 1, the model incorporating 1177 data achieves a median MAPE of 1.71% (IQR 1.01%-3.93%), compared to 2.93% (IQR 1.48%-22.50%) for the model without 1177 data, indicating improved accuracy when incorporating symptom-reporting information. In period 2, both models demonstrate similar performance, with the model including 1177 data yielding a slightly lower median MAPE of 0.36% (IQR 0.17%-0.69%) compared with 0.38% (IQR 0.07%-0.74%) for the model without 1177 data. In period 3, the model without 1177 data performs marginally better, with a median MAPE of 0.94% (IQR 0.04%-3.07%) compared with 1.06% (IQR 0.28%-3.30%) for the model incorporating 1177 data.

Finally, panel E in Figure 4 illustrates the fitting and prediction performance for deaths. The model incorporating 1177 data achieves a substantially lower MAE of 177.78 compared with 4184.68 for the model without 1177 data, highlighting the benefit of incorporating 1177 information for improving mortality prediction.



Overall, incorporating 1177 health care helpline data improved forecasting performance across all outcomes, including confirmed cases, hospitalizations, and deaths during period 1 of the pandemic. In period 2, the model incorporating 1177 data continued to show slightly better forecasting performance compared with the model without 1177 data, although the overall performance of both models was less favorable than in period 1. In contrast, during period 3, the model without 1177 data performed better than the model incorporating 1177 data, particularly for confirmed cases and hospitalizations. These findings indicate that the forecasting benefit of incorporating 1177 data was most evident in Period 1, remained present but weaker in period 2, and was not consistently observed during period 3.

To provide a comprehensive assessment of model performance, both median errors and average reductions were evaluated over the evaluation period (May 1, 2020, to December 1, 2020). Median MAPE values showed marginal differences between models with and without 1177 data across all outcomes, being 61.6% (IQR 37.6%-79.6%) and 61.4% (IQR 40.6%-91.1%) for confirmed cases, 37.5% (IQR 18.9%-57.5%) and 41.0% (IQR 19.1%-66.0%) for hospitalizations, and 0.65% (IQR 0.3%-1.9%) and 0.74% (IQR 0.3%-2.2%) for deaths. In contrast, the average reductions in MAPE were 15.7, 8.17, and 1.99 percentage points, while the corresponding average reductions in MAE were 685, 53.40, and 101 for confirmed cases, hospitalizations, and deaths, respectively, indicating the greatest improvement for case predictions and confirming overall improved predictive performance following incorporation of 1177 health care helpline data.

The purple dashed line marks the transition between the fitting and prediction periods. The corresponding MAPE values are displayed using the same color as each model curve, enabling direct comparison of predictive performance.

## Discussion

In this study, 2 epidemiological models were developed and evaluated: a baseline $SI_cHRD$ model without 1177 data and an extended $SI_sI_cHRD$ model integrating individual-level syndromic surveillance data from the Swedish 1177 health care helpline. The aim was to assess the contribution of health care helpline data to predicting COVID-19 infections. To contextualize model performance, the calling volume data were divided into 3 temporal periods: period 1 (March 2 to June 10, 2020), during which call volumes increased from 19,785 to 48,869; period 2 (June 11 to August 31, 2020), where call volumes gradually decreased from 48,555 to 22,440; and period 3 (September 1 to December 31, 2020), during which call volumes further declined, ranging from 22,515 to approximately

XSL•FO
RenderX

6000. It was observed that higher call volumes during period 1 coincided with lower prediction errors and more stable model performance. The relatively poorer performance observed during period 2 may be partly attributable to the decline in call volume, which reduced the amount of syndromic information available to the model. In addition, changes in health care-seeking behavior during the summer period, including increased travel and social gatherings, may have altered symptom-reporting patterns. The increased availability of COVID-19 testing services may also have reduced the need for individuals to report their symptoms through the 1177 helpline. During period 3, model performance was less favorable, coinciding with a substantial decline in call volume, as fewer individuals reported COVID-19–related symptoms through the 1177 helpline. In addition, the increasing availability of self-testing toward the end of 2020 and greater public awareness of COVID-19 symptoms may have influenced individuals' decisions to test and seek health care. Overall, the reduced call volume, together with changes in health care-seeking behavior, testing practices, and epidemic dynamics, may have contributed to the reduced forecasting performance observed during periods 2 and 3. Thus, although 1177 data were associated with improved model performance during the earlier periods of the pandemic, their additional predictive value was less evident toward the end of 2020.

Furthermore, the relatively high median MAPE of 61.6% for confirmed cases indicates substantial error in the point forecasts and limits their interpretation as precise estimates of the absolute number of confirmed cases. Several previous studies have reported substantial variation in forecasting accuracy across models, epidemic phases, and forecasting horizons [37,38]. Therefore, the median MAPE observed in our study should be interpreted in the context of the forecasting horizon and the temporal variation in COVID-19 epidemic dynamics.

Incorporating syndromic surveillance data from the 1177 health care helpline improved short-term forecasting performance, reducing MAPE on average by 15.7 percentage points for confirmed cases, 8.2 percentage points for hospitalizations, and 2.0 percentage points for death cases compared to the model without 1177 data. The model effectively captured early infection dynamics during period 1 and maintained reasonable predictive performance during period 2, whereas its performance declined during period 3. These findings highlight the importance of syndromic surveillance data, particularly during the initial phase of a pandemic.

Syndromic surveillance has previously been used in various contexts, including online search trends, symptom-reporting platforms, and mobile health applications, to support early outbreak detection [28,35]. A study conducted in 2025 found that anomalies detected in 1177 health care helpline calls occurred 7 days before confirmed COVID-19 cases, 13 days before hospitalizations, and 22 days before deaths in Sweden [33]. These findings further support the role of helpline-based syndromic data as an early warning signal for emerging outbreaks. In another study, the authors reviewed syndromic surveillance approaches by examining 4 main data streams: emergency department and hospital records, pharmacy and over-the-counter sales, citizen-generated participatory data, and hybrid multisource systems [39]. Their analysis demonstrated that syndromic indicators could detect outbreaks 2-14 days earlier than conventional laboratory reporting, highlighting their potential for timely epidemic detection.

Previous studies have demonstrated the importance of telehealth-based syndromic data for monitoring infectious disease dynamics. In particular, Spreco et al [34] showed that aggregated 1177 health care helpline symptom data could be used for nowcasting COVID-19 trends. They reported satisfactory nowcasting performance for COVID-19 hospitalizations based on reported adult cough symptoms during the high transmission period (April 5-April 25, 2020), with MAPE ranging from 3%-9%, whereas fever-based nowcasting showed substantially higher errors (14%-52%) during the same period. Their approach relied on analyzing temporal trends in aggregated symptom data. In contrast, our study integrates individual-level 1177 symptom to trace individuals across disease states, enabling direct observation of their trajectories through the different compartments. This allows us to assess what happens following symptom reporting, specifically, whether individuals are subsequently confirmed by testing positive, thereby providing real-world evidence on the predictive value of syndromic data. Notably, during period 1 (May 1 to June 10, 2020), the model incorporating 1177 data achieved a median MAPE of 31.37% for confirmed cases. For hospitalizations, the median MAPE was 11.72%, indicating improved predictive performance compared to confirmed cases. For deaths, the model performed best, with a median MAPE of 1.71% over the same period.

A key strength of our study is that the proposed model can predict confirmed COVID-19 cases, hospitalizations, and deaths during the early stage of the pandemic, when call volumes to the 1177 health care helpline were exceptionally high due to heightened public concern and anxiety. The baseline $SI_cHRD$ model (without 1177 data) showed relatively poor performance during the initial period of the pandemic, likely due to limited testing capacity and reporting delays, which emphasizes the importance of complementary syndromic surveillance data during emerging outbreaks. Incorporating individual-level 1177 symptom data allowed the model to distinguish between laboratory-confirmed cases, unconfirmed symptomatic callers, and hospital cases, thereby reducing predictive errors. These findings highlight that the relative performance of compartmental models and complementary surveillance approaches may vary across different phases of an epidemic or pandemic. During the early phase of an emerging outbreak, when transmission patterns, testing practices, and health care-seeking behavior may change rapidly, syndromic surveillance data may provide useful complementary information when routine surveillance systems are still developing. As the epidemic progresses and surveillance and testing systems become more established, conventional compartmental models may provide useful forecasting information, while the additional contribution of syndromic surveillance may become less evident.

The limitations of this study include reliance on 1177 symptom data, which does not capture individuals who did not contact

XSL•FO
RenderX

the service and may therefore miss a substantial number of infections. Although we could follow individuals after symptom reporting using register data, we could not distinguish between untested positive cases and calls related to non-COVID-19–related health issues. Another limitation of this study is that 13 parameters were estimated simultaneously from 3 observed time series. Structural and practical identifiability of the estimated parameters were not formally assessed [40]. Therefore, the uniqueness of the parameter estimates and their reliability under the available data cannot be formally established from the current analysis. Additional factors likely contributing to higher errors include testing delays and underreporting, as well as changes in social behaviors in light of public health recommendations that abruptly altered transmission patterns. Additionally, the use of a daily rolling window may introduce inaccuracies during weekends and holidays. The visualized error trends further highlight the advantage of integrating syndromic surveillance data into infectious disease modeling. Although the baseline $SI_cHRD$ model performed reasonably well during stable transmission periods, its simplified formulation limited its ability to capture complex epidemic dynamics, particularly during periods of rapid trend changes or multiple waves. The fitted curves often followed smooth exponential-like patterns, reflecting the absence of early symptomatic signals and reduced structural flexibility, which made the model less stable during abrupt shifts in transmission.

Future work could focus on expanding the model by integrating additional data streams, such as mobility patterns, demographic characteristics, vaccination information, wastewater surveillance, and internet search trends, to further improve forecasting accuracy while also accounting for time lags and reporting delays [41-43]. In addition, sensitivity analysis and formal assessments of the structural and practical identifiability of the estimated parameters should be conducted to evaluate the robustness and reliability of the model parameter estimates.

Overall, integrating individual-level syndromic data from the 1177 health care helpline improved short-term COVID-19 forecasting performance during the early stage of the pandemic. The extended model captured early changes in transmission and provided more accurate predictions of confirmed cases, hospitalizations, and deaths during this period. These findings highlight the value of incorporating high-resolution syndromic surveillance data into epidemiological modeling frameworks, while emphasizing the need to account for reporting structures and context-specific data limitations. Although this study uses the Swedish 1177 health care helpline, the proposed framework could be adapted to other health care systems with accessible telehealth or syndromic surveillance data. However, its effectiveness and generalizability may depend on differences in health care-seeking behavior, reporting practices, data availability, and telehealth infrastructure across settings.

## Abstract

**Background:** Synthetic population and persona datasets can provide artificial individual-level records without exposing personal data. However, for surveillance use, they must preserve the joint profiles that define vulnerable groups, not only marginal distributions.

**Objective:** This study evaluated whether a public statistics–based Korean synthetic persona dataset is consistent with Korea Community Health Survey (CHS) and Korean Statistical Information Service (KOSIS) benchmarks for auxiliary small-area public health surveillance.

**Methods:** We compared 1,000,000 synthetic persona rows with 1,156,122 adult respondents from the 2021-2025 CHS and selected KOSIS municipal indicators. Core variables were age group, sex, marital status, living-alone status, and education; province or municipal area replaced marital status in the regional profiles. Economic activity and occupation were treated as sensitivity domains. We compared marginal and joint distributions using percentage-point differences and total variation distance (TVD) and quantified CHS sampling uncertainty using 500-replicate stratified cluster percentile bootstrap intervals and compared high-dimensional TVD with CHS split-half references. Sparse-cell, KOSIS correlation, and regional composition-standardized analyses assessed robustness and potential downstream use.

**Results:** Persona rows were close to CHS for sex (TVD<0.001, 95% bootstrap percentile interval 0.000-0.001), province (TVD 0.006, bootstrap percentile interval 0.005-0.006), living-alone status (TVD 0.008, bootstrap percentile interval 0.007-0.009), and age group (TVD 0.013, bootstrap percentile interval 0.012-0.014). Differences were larger for marital status (TVD 0.039, bootstrap percentile interval 0.038-0.040) and education (TVD 0.059, bootstrap percentile interval 0.058-0.061). The national core profile had a TVD of 0.106 (bootstrap percentile interval 0.105-0.107), compared with a CHS split-half median of 0.009 (2.5th-97.5th percentile 0.008-0.011). The municipal profile had an observed TVD of 0.117, a bootstrap mean of 0.122 (95% bootstrap percentile interval 0.120-0.123), and a split-half median of 0.082 (2.5th-97.5th percentile 0.080-0.084). After restriction to CHS cells with n≥100, the municipal TVD decreased to 0.091. At the municipal level, CHS- and persona-composition standardized unmet health care rates differed by a mean of 0.109 percentage points (Pearson $r$=0.567), but standardization with national profile-specific probabilities did not reproduce observed local CHS rates (Pearson $r$=0.004 for persona composition). The conditional KOSIS living-alone comparison was modest (Pearson $r$=0.547).

**Conclusions:** The synthetic persona data showed close agreement for several basic demographic margins but less consistent agreement for high-dimensional sociodemographic profiles. They may support composition-based scenario development and dashboard prototyping but should not be used as stand-alone sources for local surveillance or health-outcome inference without additional calibration and validation.

## Introduction

Effective small-area public health surveillance requires more than estimating average health indicators by region [1,2]. Decision-makers also need to know which groups are vulnerable, where they live, and how demographic and socioeconomic characteristics cluster within local populations [1,3]. These profiles are difficult to observe reliably at small-area levels because survey data become sparse after stratification, whereas public statistics–based systems commonly provide marginal distributions or selected cross-tabulations rather than flexible individual-level structures [3,4].

Synthetic population and persona datasets are therefore attractive for public health informatics because they can provide artificial individual-level records for scenario analysis, vulnerability profiling, dashboard development, and data-system testing without exposing real personal records [5-8]. Their value for surveillance, however, depends on whether they preserve the joint profiles that define vulnerability, not simply whether they look plausible at the margin [9-13]. Prior work on synthetic patients, synthetic microdata, and population synthesis has emphasized that resemblance, utility, privacy, and intended-use validity are distinct evaluation dimensions, and that fitting marginal totals may still distort multivariable dependence structures [6-14].

This issue has become timely in Korea because Nemotron-Personas-Korea, a public statistics–based Korean synthetic persona dataset, is now available for reuse in digital population health workflows. The dataset was released by NVIDIA under a Creative Commons Attribution (CC-BY) 4.0 license and includes 1 million rows covering 17 provinces and 252 districts, with demographic, household, educational, occupational, and regional attributes [15]. The dataset documentation describes seed sources including Korean Statistical Information Service (KOSIS) census and public statistics data; Supreme Court data on name, birth year, and sex; National Health Insurance Service health checkup information; Korea Rural Economic Institute food consumption behavior survey materials; and NAVER Cloud seed data and domain expertise [15]. However, public availability and broad demographic coverage do not establish fitness for surveillance use.

The Korean setting provides a useful benchmark structure. The Korea Community Health Survey (CHS) produces observed small-area health indicators for local health planning and monitoring at the city, county, and district levels [16,17]. Synthetic personas should therefore not be presented as substitutes for CHS municipal-level estimates. A more appropriate question is whether they can serve as an auxiliary analytic layer for scenario analysis, vulnerability profiling, dashboard prototyping, and calibration. CHS individual records provide a complex-sample survey benchmark for observed combinations of individual characteristics [16,17], whereas KOSIS provides seed-source–informed public statistics benchmarks for selected regional characteristics [18].

This study evaluates whether a public statistics–based Korean synthetic persona dataset is consistent with CHS and KOSIS benchmarks in ways that matter for auxiliary small-area public health surveillance. We use a layered validation approach that moves from basic margins to joint distributions, high-dimensional profiles, policy-relevant vulnerable profiles, sparse-cell sensitivity, CHS temporal stability, KOSIS regional ranking consistency, split-half noise references, independence baselines, and downstream composition-standardized sensitivity. The purpose is to distinguish where synthetic personas can responsibly support descriptive planning or scenario-oriented work and where additional calibration is needed before subgroup or small-area inference [9,12,13].

## Methods

### Study Design

We performed a benchmark consistency study of a synthetic persona dataset intended for auxiliary public health informatics and surveillance planning [12,13]. The primary aim was not to predict CHS municipal-level unmet health care rates, but to assess whether synthetic persona rows reproduced sociodemographic distributions observed in CHS [16,17]. We compared persona distributions with CHS complex-survey benchmarks and selected KOSIS aggregate indicators that also informed persona generation [18]. Table 1 summarizes the benchmark comparison layers, data sources, analytic metrics, and intended interpretation.

XSL•FO
RenderX

**Table 1.** Validation layers, benchmark sources, metrics, and interpretation[a].

| Validation layer | Benchmark source | Main metrics | Surveillance interpretation | Main limitation |
|---|---|---|---|---|
| Marginal distributions | CHS[b] | TVD[c], JS[d] divergence, and percentage-point difference | Basic sociodemographic structure check | Does not assess whether characteristics co-occur correctly |
| Joint and high-dimensional profiles | CHS | TVD, percentile bootstrap interval, CHS split-half TVD, and independence baseline TVD | Evaluates whether profile structure exceeds margin-only agreement | Sparse cells and municipal instability limit direct subgroup inference |
| Policy-relevant vulnerable profiles | CHS | Weighted percentage, difference in percentage points, and CHS 95% CI | Interpretable profile-level consistency for planning scenarios | Profile consistency does not validate persona-based health outcomes |
| KOSIS[e] public-statistics benchmarks | KOSIS | Pearson and Spearman correlations and exact-match sensitivity | Seed-source–informed aggregate consistency check | Not fully independent; denominators and source years differ |
| Sensitivity domains | CHS and KOSIS | Economic activity, occupation, KOSIS exact-match, and sparse-cell diagnostics | Assesses robustness to harmonization and sparse-cell decisions | Exploratory; not used as core evidence |

[a]Each layer evaluates a different aspect of benchmark consistency rather than replacing official CHS or KOSIS estimates.

[b]CHS: Korea Community Health Survey.

[c]TVD: total variation distance.

[d]JS Divergence: Jensen-Shannon divergence.

[e]KOSIS: Korean Statistical Information Service.

## Data Sources and Benchmark Roles

The synthetic persona dataset was treated as the validation target. We used NVIDIA Nemotron-Personas-Korea, an open-source Korean-language synthetic persona dataset released under a CC-BY 4.0 license [15]. Version 1.0 was released on April 20, 2026. The dataset card published by NVIDIA on Hugging Face describes 1 million rows, with structured fields including sex, age, marital status, family type, education level, occupation, district, province, and country, as well as 7 narrative persona text fields [15]. The analytic unit in this study was the row-level structured demographic record, not the narrative text fields. The dataset card identifies the following sources: KOSIS census tables covering sex, province, industry, occupation, travel, and leisure; Supreme Court data on names, birth year, and sex; National Health Insurance Service Health Checkup Information as of December 31, 2024; materials from the Korea Rural Economic Institute's 2024 Food Consumption Behavior Survey; and seed data and domain expertise contributed by NAVER Cloud during dataset design [15]. It does not provide a common reference year for every source. Consistent with synthetic data evaluation guidance, the dataset was evaluated as a potential auxiliary analytic layer, not as a record-level representation of real individuals or an official population estimate [12,13].

The CHS 2021-2025 was used as the main survey benchmark because CHS is designed to produce local community health statistics using a complex survey design [16,17]. The final 2025 CHS microdata were officially released on February 25, 2026 [17]. We included all 1,156,122 adult respondents with positive person weights and valid design identifiers: 229,242 in 2021, 231,785 in 2022, 231,752 in 2023, 231,728 in 2024, and 231,615 in 2025. CHS person weights were used to estimate weighted benchmark distributions [19]. The pooled design comprised 28,309 analytic strata and 112,299 analytic primary sampling units (PSUs). Survey year was appended to the CHS stratum and cluster identifiers. The unmet health care denominator was used only for analyses of the unmet health care indicator.

KOSIS public statistics–based indicators were used as seed-source–informed aggregate benchmarks because KOSIS provides official Korean statistical indicators across population and regional domains [18]. This analysis used 2 municipal-level indicators that were directly relevant to vulnerable-profile surveillance and available in the local analysis files: aged population share and older-adult living-alone household share. In this study, municipal-level areas correspond to Korean si/gun/gu units, including cities, counties, districts, and wards. The aged population indicator used 2025 KOSIS counts of persons aged 65 years or older divided by the total population. The older-adult living-alone indicator used the KOSIS older-adult one-person-household percentage; the local KOSIS export available for this indicator was 2024 and was carried forward into the 2025 comparison table. The KOSIS-persona comparison used 252 matched municipal-level areas: 216 exact si/gun/gu matches, 35 parent-city values repeated across administrative-gu rows where KOSIS reported a parent city, and one Sejong province-city match. Indicator definitions and linkage notes are provided in Table S2 in Multimedia Appendix 1. Because KOSIS denominators differ from persona adult rows and because KOSIS/public statistics were among the persona seed sources, KOSIS comparisons were interpreted as seed-source–informed regional ranking checks rather than fully independent absolute-level validation.

## Variable Harmonization

Common core variables were harmonized across CHS and persona records: current province code, current municipal-level area code, age group, sex, marital status, living-alone status, and coarse education. These variables were selected because they are available in both the persona dataset and CHS and

XSL•FO
RenderX

correspond to common demographic and socioeconomic stratifiers used in health inequality monitoring [3,15-17]. Age was grouped into the following 5 categories: 19 to 29 years, 30 to 44 years, 45 to 64 years, 65 to 74 years, and 75 years or older. Education was classified into low, middle, and high categories. Economic activity and occupation were retained as sensitivity variables rather than core variables.

Economic activity and occupation required special handling. Persona economic activity was derived from generated occupation text, and persona occupation was a generated detailed job-title string, whereas CHS uses survey-coded economic activity and occupation variables [15-17]. We therefore excluded both economic activity and occupation from the core manuscript analysis and treated them as sensitivity variables. A separate occupation recoding quality assurance compared the original keyword mapping with an expanded sensitivity mapping.

Detailed variable mapping is provided in Table S1 in Multimedia Appendix 1. Briefly, region was harmonized to current province and municipal-level area codes, with historical code changes and renamed or reorganized administrative areas mapped to current codes through a reviewed crosswalk, age was grouped using identical cutoff points, sex and marital status were mapped to shared categories, and education was classified into 3 analytically comparable levels. CHS living-alone status was derived from household variables, and persona living-alone status was derived using a prespecified exact-match rule for the Korean-language family-type label denoting living alone. All 39 distinct family-type labels were audited, and the only ambiguous label was evaluated using alternative recoding rules. Missing or unmapped values were excluded only from comparisons involving the affected variable, and each distribution was normalized over its comparison-specific denominator. All 1 million persona rows were aged 19 to 99 years, so the adult restriction excluded no persona rows.

### Benchmark Consistency Measures

For each benchmark comparison, we computed CHS weighted percentages and persona row percentages. Distributional consistency was summarized using percentage-point differences, standardized differences, total variation distance (TVD), and Jensen-Shannon divergence [20,21]. TVD was used as the main scalar summary because it quantifies the total amount of distributional mass that would need to be shifted for the 2 distributions to match [20]. For example, a TVD of 0.05 indicates that 5% of the distributional mass would need to be reassigned across categories for the CHS and persona distributions to match [20]. Prior synthetic data evaluation work has used TVD across univariate, bivariate, and 3-way empirical marginal distributions as a model-free measure of synthetic data fidelity, with holdout data used as a reference for sampling noise rather than a fixed universal cutoff [9,12,13]. Accordingly, we interpreted TVD descriptively and comparatively, focusing on whether discrepancies increased from marginal distributions to higher-dimensional profiles and whether they persisted after sparse-cell restrictions. We did not apply a universal TVD threshold to declare 2 empirical distributions as equivalent or nonequivalent [9,12,13].

CHS cell-level sampling uncertainty was estimated using a Taylor-linearized ratio estimator where the number of cells was computationally tractable, consistent with design-based analysis of complex health surveys [19]. For each benchmark cell, the weighted cell proportion was estimated as the ratio of the cell-specific weighted total to the total weighted denominator. The linearized residual for each analytic primary sampling unit was calculated as the cluster cell weight total minus the estimated cell proportion multiplied by the cluster total weight; stratum-level variance contributions were then summed across analytic strata and divided by the squared total weight. As a prespecified analytic handling rule, singleton strata were assigned the average variance contribution from nonsingleton strata for the same cell when needed. CIs were calculated on the percentage scale using the 95% normal critical value and truncated to the 0% to 100% range. Cell-level uncertainty estimates were not generated for very high-dimensional comparisons when the number of cell-by-stratum combinations exceeded the prespecified computational threshold of 8,000,000. Sparse cells were interpreted as diagnostic signals rather than definitive population truths.

To quantify sampling uncertainty in scalar distributional measures, we additionally used a 500-replicate stratified cluster bootstrap for the TVD and Jensen-Shannon divergence estimates reported in Tables 2 and 3 [22]. CHS analytic PSUs were resampled with replacement within analytic strata defined by survey year and kstrata; persona distributions were treated as fixed. The cell universe was fixed to the observed union of CHS and persona cells. We report the observed plug-in estimate, bootstrap mean, and 2.5th to 97.5th percentile interval separately. In sparse high-dimensional universes, resampled CHS data occupy fewer cells than the full sample, which can produce positive plug-in TVD bias. We did not replace the observed estimate with a bootstrap bias–corrected estimate because such corrections can overcorrect under sparse multinomial support; the observed full-sample TVD was retained as the descriptive point estimate. For the CHS split-half reference, PSUs were randomly divided into 2 approximately equal groups within each design stratum. Weighted distributions were estimated in each half and their TVD was calculated over 100 random splits; the median values and 2.5th to 97.5th percentiles were reported. Because each half used half the survey sample, this reference is a conservative upper bound for full-sample sampling noise.

**Table 2.** Marginal sociodemographic benchmark consistency between Korea Community Health Survey estimates and synthetic persona rows[a].

| Variables | K[b] | TVD[c] (95% bootstrap percentile interval) | JS[d] divergence (95% bootstrap percentile interval) | Maximum absolute difference (percentage points) | Mean absolute difference (percentage points) |
|---|---|---|---|---|---|
| Age group | 5 | 0.013 (0.012-0.014) | 0.000 (0.000-0.000) | 0.99 | 0.52 |
| Sex | 2 | 0.000 (0.000-0.001) | 0.000 (0.000-0.000) | 0.02 | 0.02 |
| Province | 17 | 0.006 (0.005-0.006) | 0.000 (0.000-0.000) | 0.27 | 0.07 |
| Living-alone status | 2 | 0.008 (0.007-0.009) | 0.000 (0.000-0.000) | 0.82 | 0.82 |
| Education | 3 | 0.059 (0.058-0.061) | 0.002 (0.002-0.002) | 5.94 | 3.96 |
| Marital status | 4 | 0.039 (0.038-0.040) | 0.001 (0.001-0.001) | 3.89 | 1.94 |

[a]Intervals are fixed-cell-universe percentile bootstrap intervals from 500 stratified cluster bootstrap replicates of Korea Community Health Survey analytic primary sampling units; persona distributions were treated as fixed. Economic activity and occupation were moved to sensitivity analyses. Values displayed as 0.000 are positive values that round off to 0.000 at the reported precision rather than exact zeros.

[b]K: number of union cells.

[c]TVD: total variation distance.

[d]JS: Jensen-Shannon.

**Table 3.** Core joint and high-dimensional sociodemographic benchmark consistency between Korea Community Health Survey and synthetic personas, excluding economic activity and occupation[a].

| Combination | K[b] | Observed TVD[c] | Bootstrap mean[d] (95% bootstrap percentile interval) | CHS[e] split-half TVD[f] | Independence baseline TVD[g] |
|---|---|---|---|---|---|
| Age×sex | 10 | 0.015 | 0.015 (0.014-0.016) | 0.003 (0.002-0.005) | 0.019 |
| Age×living-alone status | 10 | 0.020 | 0.021 (0.019-0.022) | 0.003 (0.002-0.005) | 0.037 |
| Age×sex×living-alone status | 20 | 0.023 | 0.023 (0.022-0.024) | 0.004 (0.003-0.006) | 0.044 |
| Age×sex×education | 30 | 0.063 | 0.063 (0.062-0.064) | 0.005 (0.003-0.007) | 0.258 |
| Province×age×sex×living-alone status×education | 1015 | 0.080 | 0.080 (0.079-0.081) | 0.025 (0.023-0.028) | 0.272 |
| Municipal area×age×sex×living-alone status×education[h] | 14,550 | 0.117 | 0.122 (0.120-0.123) | 0.082 (0.080-0.084) | 0.295 |
| National core high-dimensional profile[i] | 238 | 0.106 | 0.106 (0.105-0.107) | 0.009 (0.008-0.011) | 0.451 |

[a]Economic activity and occupation were moved to sensitivity analyses because these variables had greater harmonization uncertainty.

[b]K: number of union cells.

[c]TVD: total variation distance.

[d]The bootstrap column reports the replicate mean followed by the 2.5th-97.5th percentile interval.

[e]CHS: Korea Community Health Survey.

[f]The Korea Community Health Survey split-half total variation distance is the median with its 2.5th-97.5th percentile interval across 100 within-stratum random primary sampling unit splits.

[g]The independence baseline was constructed by multiplying Korea Community Health Survey marginal distributions.

[h]For the municipal profile, the bootstrap interval is above the observed total variation distance because bootstrap resampling increased sparsity; this comparison should be interpreted alongside the number of union cells and the Korea Community Health Survey split-half reference.

[i]The national core high-dimensional profile combines age group, sex, marital status, living-alone status, and education.

## Analytic Strategy

We conducted 8 analyses. First, we compared marginal distributions for core harmonized variables. Second, we compared low-dimensional joint distributions, including age by sex, age by living-alone status, age by sex by living-alone status, and age by sex by education. Third, we evaluated core national, provincial, and municipal high-dimensional profiles excluding economic activity and occupation. Fourth, we compared policy-relevant vulnerable profiles that did not depend on economic activity or occupation recoding. Fifth, we performed sensitivity analyses for economic activity, occupation, occupation recoding, living-alone recoding, and economic activity–based vulnerable profiles. Sixth, we performed sparse-cell sensitivity analyses by restricting comparisons to cells with CHS sample sizes of at least 30, 50, or 100. Seventh, we compared persona regional profiles with KOSIS public statistics benchmarks using Pearson and Spearman correlations, including exact-match and conditional living-alone sensitivity

XSL•FO
RenderX

analyses [18]. Eighth, we conducted additional uncertainty and robustness analyses using CHS temporal-stability diagnostics; within-stratum PSU split-half TVD references; product-of-CHS-margins independence baselines; and national, provincial, and municipal composition-standardized unmet health care analyses. These analyses were used as descriptive references for benchmark variability and fitness for use, not as formal equivalence tests.

We interpreted these analyses in terms of practical surveillance readiness using evidence triangulation rather than fixed TVD cutoffs. A persona layer was interpreted as more suitable for descriptive planning when discrepancies were small in absolute percentage-point terms: TVD was low relative to lower-dimensional benchmark comparisons, persona-versus-pooled-CHS TVD did not exceed relevant CHS variability references, and KOSIS correlations supported regional ranking consistency. Policy-relevant vulnerable profiles were considered usable for scenario generation or dashboard prototyping only when benchmark differences and uncertainty diagnostics were displayed alongside persona estimates. A profile was interpreted as requiring calibration before inferential surveillance use when discrepancies increased with dimensionality, exceeded CHS variability references, or depended on variables with substantial harmonization uncertainty. Independence baselines were interpreted in relation to the strength of the underlying CHS dependence. Profiles whose discrepancy narrowed toward the CHS split-half reference after sparse-cell restriction were interpreted as weaker evidence of residual discrepancy than profiles that remained far above it.

### Analysis Software and Reproducibility

All data processing and statistical analyses were conducted in Python (Python Software Foundation) using scripted workflows. CHS weighted percentages were calculated from person weights within each comparison-specific denominator, whereas persona percentages were calculated from synthetic row counts [19]. For aligned distributions, TVD and Jensen-Shannon divergence were calculated from normalized proportions, bootstrap intervals resampled CHS analytic PSUs within strata, sparse-cell restrictions used unweighted CHS cell counts, and KOSIS comparisons used Pearson and Spearman correlations across matched municipal-level units [18]. The analysis scripts are publicly archived on Zenodo [23].

### Ethical Considerations

The Institutional Review Board of Sunchon National University (1040173-202606-HR-032-02) approved this study for an exemption from review. This study used deidentified CHS benchmark estimates obtained through official data-use procedures, public KOSIS aggregate indicators, and synthetic persona rows [15-18]. The analysis did not involve participant recruitment, intervention, direct contact with individuals, or identifiable private information. The synthetic persona records do not represent observed individuals, although synthetic data still require explicit evaluation of utility, privacy, and intended-use fitness before downstream use [8,12,13]. Informed consent was not applicable to this secondary analysis of deidentified, aggregate, and synthetic data.

## Results

### Data Sources and Harmonized Variables

The persona dataset, CHS, and KOSIS played distinct benchmark roles (Table 4). Personas were evaluated as synthetic individual rows. CHS provided the main weighted survey benchmark. KOSIS provided seed-source–informed public statistics benchmarks for regional aging-related vulnerability.

**Table 4.** Data sources, benchmark roles, analytic units, and key variables.

| Data source | Role | Unit | Key variables | Benchmark interpretation |
|---|---|---|---|---|
| Nemotron-Personas-Korea | Synthetic persona dataset | Synthetic individual row (n=1,000,000; age 19-99 years) | Region, age, sex, marital status, and family type used to derive living-alone status, education, occupation | Validation target; not observed surveillance data |
| CHS[a] 2021-2025 | Survey benchmark | Weighted adult survey respondent (n=1,156,122; 28,309 strata; 112,299 PSUs[b]) | Common sociodemographic variables, survey weights and design variables; unmet health care need for downstream sensitivity analysis | Complex-sample survey benchmark, comparison-specific valid denominators, and not a population gold standard |
| KOSIS[c,d] public statistics | Aggregate benchmark | Municipal-level aggregate indicator | Aged-population share and older living-alone household share | Seed-source–informed consistency benchmark and denominators differ from persona rows |

[a]CHS: Korea Community Health Survey.

[b]PSU: primary sampling unit.

[c]KOSIS: Korean Statistical Information Service.

[d]KOSIS was treated as a seed-source–informed public statistics benchmark rather than an independent validation source because KOSIS/public statistics were among the persona seed sources.

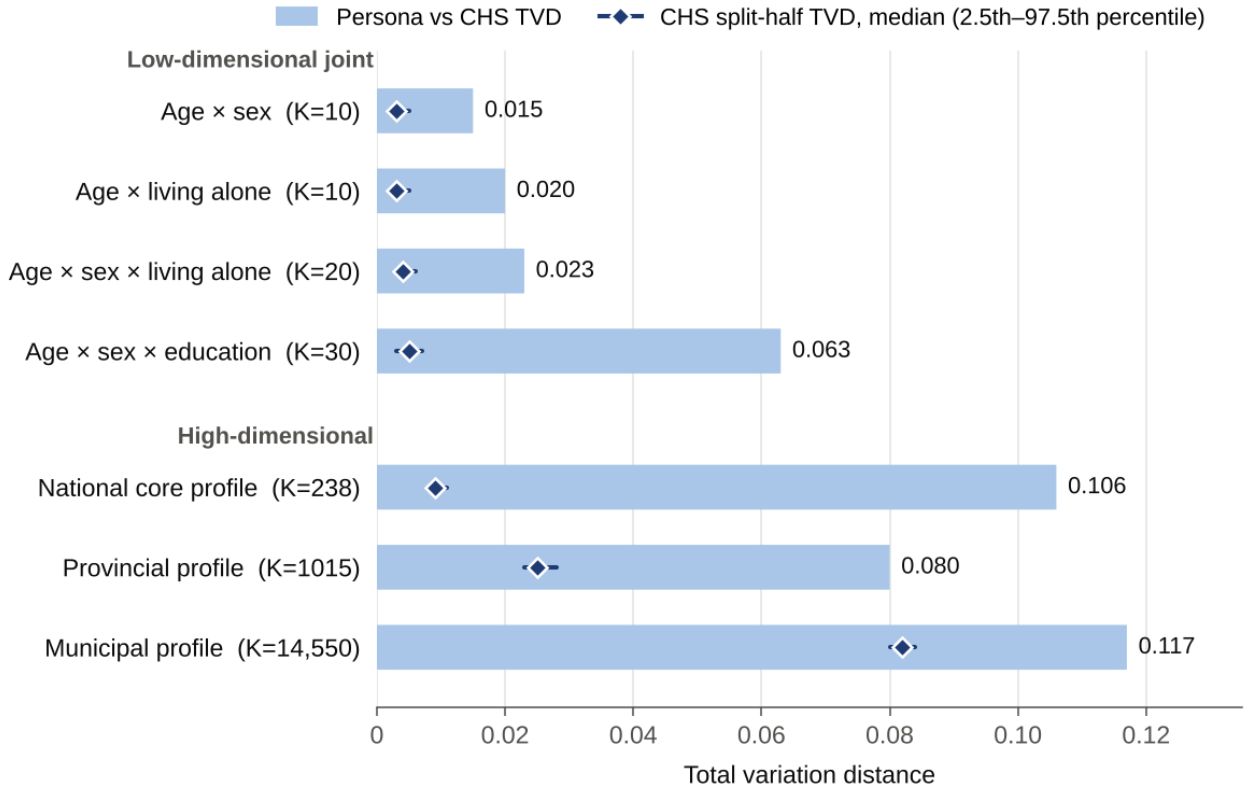
### Marginal Benchmark Consistency

Basic demographic margins showed close agreement between persona rows and CHS survey benchmarks (Table 2). TVD was <0.001 (bootstrap percentile interval 0.000-0.001) for sex, 0.006 (bootstrap percentile interval 0.005-0.006) for province, 0.008 (0.007-0.009) for living-alone status, and 0.013 (bootstrap percentile interval 0.012-0.014) for age group. Larger differences were observed for marital status (TVD 0.039,

XSL•FO
RenderX

bootstrap percentile interval 0.038-0.040) and education (TVD 0.059, bootstrap percentile interval 0.058-0.061).

Economic activity and occupation were excluded from the core marginal table because both required interpretation of generated occupation text; their results are reported as sensitivity analyses in Table S5 in Multimedia Appendix 1.



## Joint Benchmark Consistency Excluding Occupation

Joint-distribution discrepancies increased with profile dimensionality (Table 3). TVD was 0.015 (bootstrap percentile interval 0.014-0.016) for age by sex, 0.020 (bootstrap percentile interval 0.019-0.022) for age by living-alone status, 0.023 (bootstrap percentile interval 0.022-0.024) for age by sex by living-alone status, and 0.063 (bootstrap percentile interval 0.062-0.064) for age by sex by education.

The largest core discrepancies appeared in higher-dimensional profiles. The provincial 5-way profile had observed TVD 0.080, a bootstrap mean of 0.080 (0.079-0.081), and a CHS split-half median of 0.025 (2.5th-97.5th percentile 0.023-0.028). The national 5-way profile had TVD 0.106 (bootstrap mean 0.106; 0.105-0.107), substantially above its split-half median of 0.009 (2.5th-97.5th percentile 0.008-0.011). The municipal 5-way profile had observed TVD 0.117, a bootstrap mean of 0.122 (0.120-0.123), and a split-half median of 0.082 (2.5th-97.5th percentile 0.080-0.084). The municipal bootstrap distribution lay above the full-sample estimate because resampling increased sparsity in the 14,550-cell universe. Relative to independence baselines, the gain was small for age by sex (0.015 vs 0.019), where CHS dependence was weak, but large for age by sex by education (0.063 vs 0.258), where dependence was stronger. Thus, the national discrepancy was clear, whereas the municipal comparison required interpretation alongside its sparse-cell and split-half diagnostics.

In Figure 1, the multiplication sign "x" denotes cross-classified joint distributions. The municipal-level profile comprises municipal area, age, sex, living-alone status, and education. The provincial profile comprises province, age, sex, living-alone status, and education. The national high-dimensional profile comprises age, sex, marital status, living-alone status, and education. Economic activity and occupation are excluded from this core figure and evaluated in sensitivity analyses. Bars show persona-versus-CHS TVD; diamonds and horizontal lines show the CHS split-half median and 2.5th to 97.5th percentile range across 100 within-stratum primary sampling unit splits. "K" denotes the number of union cells. Municipal-level areas correspond to Korean si/gun/gu units, including cities, counties, districts, and wards.

**Figure 1.** Total variation distance between the synthetic persona data and CHS benchmark across progressively richer sociodemographic profiles, with CHS split-half references.

## Policy-Relevant Vulnerable Profiles

Policy-relevant vulnerable profiles showed moderate national-level agreement (Table 5). Adults aged 65 years or older who were widowed women represented 5.10% of the CHS weighted benchmark and 6.02% of persona rows, a difference of 0.93 percentage points. Adults aged 65 years or older with low education and living alone represented 3.59% of CHS and 3.30% of persona rows, a difference of –0.29 percentage points. Differences were –0.13 percentage points for women aged 75

XSL•FO
RenderX

years or older living alone and 0.01 percentage points for adults aged 19 to 29 years living alone. Economic activity–based vulnerable profiles were not treated as core findings and are reported separately in Table S6 in Multimedia Appendix 1.

In Table 5, profiles are cross-classified sociodemographic groups selected for public health surveillance relevance, including older adults, women, living-alone status, and low education. Economic activity–based vulnerable profiles are reported in Table S6 in Multimedia Appendix 1. Differences were calculated from unrounded percentages.

**Table 5.** Policy-relevant vulnerable profile consistency between CHS[a] and synthetic personas.

| Vulnerable profile | CHS weighted %, survey benchmark | Persona %, synthetic rows | Difference, pp[b] | CHS 95% CI |
|---|---|---|---|---|
| Age 65+ years, widowed female | 5.10 | 6.02 | 0.93 | 5.05-5.15 |
| Age 65+ years, low education, living alone | 3.59 | 3.30 | –0.29 | 3.55-3.63 |
| Female, 75+ years, living alone | 2.07 | 1.94 | –0.13 | 2.04-2.10 |
| Age 19-29 years, living alone | 2.68 | 2.69 | 0.01 | 2.63-2.74 |

[a]CHS: Korea Community Health Survey.

[b]pp: percentage point.

## Occupation and Living-Alone Harmonization Sensitivity

Economic activity and occupation harmonization were evaluated in Table S5 in Multimedia Appendix 1, and vulnerable profiles depending on economic activity were reported in Table S6 in Multimedia Appendix 1. Economic activity had marginal TVD 0.017 (95% bootstrap percentile interval 0.016-0.018), and the profile adding economic activity had TVD 0.137 (95% bootstrap percentile interval 0.136-0.138). Occupation had marginal TVD 0.271 (95% bootstrap percentile interval 0.271-0.272), which decreased to 0.149 under the expanded keyword mapping; the occupation-containing high-dimensional profile had TVD 0.368 (95% bootstrap percentile interval 0.367-0.369). Economic activity and occupation were therefore retained as sensitivity evidence rather than core benchmark domains. Living-alone recoding sensitivity was evaluated separately in Table S9 in Multimedia Appendix 1. The living-alone results were robust to alternative treatment of the single ambiguous family-type label: marginal TVD ranged from 0.008 to 0.014, national core TVD from 0.105 to 0.106, and municipal core TVD was 0.117 under all 3 rules.

As a regional downstream compositional sensitivity analysis, we applied national CHS profile–specific medical-need and unmet-need probabilities to CHS and persona profile distributions (Table S7 in Multimedia Appendix 1). Using a primary minimum cell count of 30, the mean absolute difference between CHS- and persona-composition standardized rates was 0.076 percentage points across 17 provinces and 0.109 percentage points across 252 municipalities. Municipal standardized rates had Pearson $r$=0.567 and Spearman ρ=0.683 across the 2 compositions. However, composition-standardized rates did not reproduce observed municipal CHS unmet-need rates (persona composition: mean absolute difference 1.635 percentage points; Pearson $r$=0.004). Because CHS- and persona-composition rates differed by only 0.109 percentage points on average, CHS-composition rates also departed from observed municipal rates by at least 1.5 percentage points on average. Therefore, the lack of agreement with observed local rates reflects the limits of standardization with national profile-specific probabilities rather than persona composition alone. This analysis evaluated compositional sensitivity, not health outcome prediction.

## Sparse-Cell and Sampling-Uncertainty Findings

Sparse-cell sensitivity differed materially between national and municipal profiles (Table S8 in Multimedia Appendix 1). The national core TVD remained 0.105 after restriction to CHS cells with n≥100, far above its split-half median of 0.009 (2.5th-97.5th percentile 0.008-0.011). In contrast, municipal TVD decreased from 0.117 across all cells to 0.105 at n≥30 and 0.091 at n≥100, with 73.0% of CHS mass and 69.2% of persona mass retained at n≥100. The all-cell municipal TVD exceeded its split-half median of 0.082 (2.5th-97.5th percentile 0.080-0.084), which is itself a conservative upper bound for full-sample sampling noise. Because the split-half reference was estimated across all cells rather than within each restricted cell universe, the restricted TVD values are not directly comparable with it. The municipal discrepancy was therefore smaller and less clearly separated from CHS sampling noise than the national discrepancy, but it was not explained by sparse cells alone. For the occupation-containing sensitivity profile, TVD decreased from 0.368 to 0.232 at n≥100; this restriction retained 96.9% of CHS mass but only 70.2% of persona mass, indicating that 29.8% of persona rows occupied combinations that were rare or absent in CHS.

## CHS Temporal Stability and CI Diagnostics

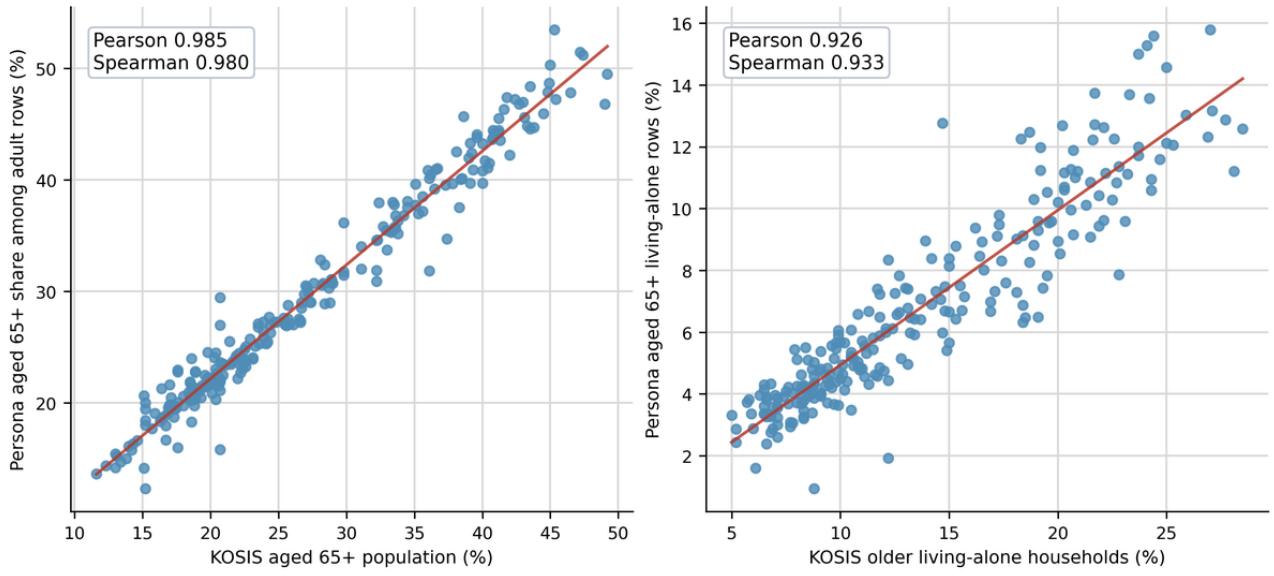
The temporal-stability analysis compared persona-versus-pooled-CHS TVD with year-specific CHS-versus-pooled-CHS TVD for the same benchmark layers. For age group, the persona TVD was 0.013, below the maximum CHS year-versus-pooled TVD of 0.020. For living-alone status, the persona TVD was 0.008, also below the maximum CHS yearly TVD of 0.012. These results support the interpretation that the age and living-alone margins were close relative to ordinary CHS year-to-year variation.

In contrast, discrepancies for education and higher-dimensional profiles exceeded the CHS temporal-stability reference (Table S4 in Multimedia Appendix 1). Education had

XSL•FO
RenderX

persona-versus-pooled CHS TVD 0.059 compared with maximum CHS year-versus-pooled TVD 0.016. Age by sex by education had persona TVD 0.063 compared with maximum yearly TVD 0.037. The national core profile had persona TVD 0.106 compared with maximum yearly TVD 0.045. The municipal profile had persona TVD 0.117 compared with maximum yearly TVD 0.091; this smaller difference should be interpreted with the municipal split-half and sparse-cell results.

CHS 95% CI diagnostics were intentionally interpreted cautiously because the pooled CHS benchmark included more than 1 million observations and therefore produced narrow CIs. For several margins and vulnerable profiles, persona percentages fell outside the pooled CHS 95% CIs despite absolute differences of less than 1 percentage point. For example, the maximum age-group difference was 0.99 percentage points. These diagnostics show that statistical distinguishability from a large survey benchmark does not by itself imply public health invalidity; substantive interpretation should consider absolute percentage-point differences, TVD, temporal CHS stability, sparse cells, and intended surveillance use.



## KOSIS Public Statistics Benchmark Consistency

KOSIS public statistics comparisons showed strong regional ranking consistency for age structure but weaker consistency for the stricter conditional living-alone comparison (Figure 2 and Table S3 in Multimedia Appendix 1). Across 252 regions, the correlation between KOSIS aged-population share and persona aged-adult-row share was 0.985 by Pearson correlation and 0.980 by Spearman correlation. The composite proxy comparing KOSIS older-adult living-alone household share with persona aged-65-plus living-alone adult-row share was Pearson correlation of 0.926 and Spearman correlation of 0.933. However, the stricter conditional comparison of persona living-alone share among rows aged 65 years or older with the KOSIS older-adult living-alone household indicator was weaker (Pearson $r$=0.547; Spearman ρ=0.576). Exact municipal-match sensitivity produced similar conclusions: aged-population ranking remained strong (Pearson $r$=0.989; Spearman ρ=0.991), whereas conditional older-adult living-alone consistency remained modest (Pearson $r$=0.530; Spearman ρ=0.550).

Because KOSIS indicators used total population or household denominators while personas represented adult synthetic rows, absolute-level differences were not interpreted as direct validation. The KOSIS results indicate that the persona data captured regional age-structure rankings well, but they provide weaker support for living-arrangement structure among older adults after conditioning on age.

In Figure 2, points represent matched municipal-level areas, corresponding to Korean si/gun/gu units; fitted lines show linear trends. The left panel compares the KOSIS percentage of residents aged 65 years or older with the corresponding persona share among adult rows. The right panel compares the KOSIS older-adult one-person-household percentage with the corresponding persona share of rows that were both aged 65 years or older and living alone among all adult rows. Because these KOSIS indicators differ from persona row denominators and because KOSIS was among the public statistical sources used to construct the persona data, this figure is interpreted as a seed-source–informed public statistics benchmark check rather than independent validation; exact-match and conditional living-alone sensitivity results are reported in Table S3 in Multimedia Appendix 1.

**Figure 2.** Municipal-level regional consistency between KOSIS public-statistics indicators and corresponding synthetic persona profiles. KOSIS: Korean Statistical Information Service.

## Summary of Surveillance Readiness

The validation layers support a tiered interpretation for surveillance use. The persona data appear suitable for descriptive surveillance planning when the use case depends on basic demographic margins and regional age-structure rankings. Policy-relevant vulnerable profiles may be useful for scenario generation and dashboard prototyping if benchmark differences and uncertainty diagnostics are reported alongside persona estimates. The national high-dimensional discrepancy indicates a need for calibration. At the municipal level, the discrepancy

XSL•FO
RenderX

exceeded the all-cell CHS split-half reference but narrowed after sparse-cell restriction, so its separation from CHS sampling noise was less clear. Detailed local profiles should therefore be used as calibration diagnostics rather than direct evidence for resource allocation, subgroup inference, or local health outcomes.

## Discussion

In this benchmark-consistency study, public statistics–based synthetic personas reproduced basic demographic margins and regional aging-related rankings but did not fully reproduce higher-dimensional individual profiles. Agreement was strongest for age, sex, province, and living-alone status; discrepancies became more apparent for education and profiles combining several sociodemographic characteristics. The national core profile remained clearly different from its CHS split-half reference after sparse-cell restriction, whereas the municipal profile exceeded its all-cell split-half reference by a smaller margin and its discrepancy narrowed after the sparsest cells were excluded. The study's main contribution is a practical distinction between row-level plausibility and readiness for surveillance use, consistent with synthetic data evaluation frameworks that distinguish resemblance, utility, privacy, and intended-use validity [9,12,13].

The observed pattern is plausible given how public statistics–based personas are constructed. Variables such as age, sex, and region were among the generator's public statistics inputs and can therefore be represented with relatively high fidelity [15]. Their agreement should be interpreted as consistency with design inputs rather than independent external validation. Regional aging-related indicators also have clear aggregate counterparts in KOSIS, which helps explain the strong regional ranking consistency observed in this study [18].

The larger discrepancies in education and high-dimensional profiles point to a different issue: preserving margins does not ensure preservation of dependence structures [10,11]. The independence baseline clarified this distinction. Age by sex showed little improvement over a product of CHS margins because the underlying dependence was weak, whereas age by sex by education was substantially closer to CHS than its independence baseline. Thus, the persona data retained some joint information but did not preserve enough of the joint structure to support uncalibrated subgroup inference.

This distinction is especially important for small-area surveillance. At the municipal level, CHS itself contains sparse high-dimensional cells, and its split-half reference is conservatively high because each half contains only half the sample [16,19,20]. The municipal persona TVD of 0.117 exceeded this conservative reference (median 0.082; 2.5th-97.5th percentile 0.080-0.084) and decreased to 0.091 after restriction to CHS cells with n≥100; because the split-half reference was estimated across all cells, the restricted value should not be read as falling within CHS sampling noise. A discrepancy in a sparse local profile is therefore better read as a signal for calibration or further review, rather than as a precise estimate of how far the persona distribution departs from the local population [12,13,19].

We did not base readiness on a single distributional cutoff. Instead, we combined absolute percentage-point differences, TVD patterns across increasing profile dimensionality, sparse-cell and CHS temporal-stability diagnostics, split-half and independence references, and KOSIS regional ranking consistency. The regional downstream analysis provided a separate fitness-for-use check: substituting persona for CHS demographic composition changed municipal standardized unmet-need rates by about 0.1 percentage points on average, although the municipal ranking of these rates was only moderately preserved (Pearson $r$=0.567). Neither composition reproduced observed municipal CHS rates, because standardization with national profile-specific probabilities does not capture local outcome variation. Composition-only analyses therefore do not establish that synthetic personas can reproduce local health outcomes.

This study extends prior work on synthetic populations by shifting attention from marginal plausibility to surveillance-relevant population structure. Synthea established the value of synthetic health records for public health informatics infrastructure, but its primary contribution was generation of realistic synthetic clinical histories and data standards rather than validation against small-area survey benchmarks [6]. The synthpop literature focused on producing synthetic versions of confidential microdata while balancing data utility and disclosure protection [7], and biomedical synthetic patient studies similarly evaluated synthetic data through utility and privacy lenses [8]. Population synthesis studies have long recognized that fitting target margins is not sufficient when downstream use depends on correlations among attributes. For example, Pritchard and Miller [11] addressed simultaneous fitting to household and person margins, and Jeong et al [10] used copulas to preserve dependence structures in synthetic population generation. Synthetic data fidelity frameworks have further evaluated empirical marginal and joint distributions, often interpreting distributional distances in relation to holdout data or sampling variability rather than universal thresholds [9]. In public health and epidemiologic applications, TVD has been used as a descriptive measure of distributional difference across age, sex, region, and other product spaces [24]. These precedents support TVD as a useful summary measure, but they do not justify a single cutoff for practical equivalence.

These findings show why this distinction matters for surveillance. The persona dataset performed well for several basic margins and for regional rankings of aging-related vulnerability. Departures became clearer when variables were combined into profiles closer to the way public health vulnerability is defined in practice. This pattern is consistent with the methodological concern that a synthetic population can look credible at the margin while losing important dependence structures.
